Because R.W. presented with both edema and ascites, an initial weight loss of up to 2.20 pounds/day (1 kg/day) would be reasonable with slowing to 1.10 pound/day (0.5 kg/day) when the edema resolves. Gradual diuresis avoids diuretic-induced depletion of intravascular fluid volume by permitting ascitic fluid to equilibrate with intravascular fluid. Long-term management of ascites is done in the outpatient setting. Severe cases with respiratory distress or impaired ambulation as well as patients with SBP (see Chapter 70, Intra-Abdominal Infections) require hospitalization. If outpatient therapy is

an option, a weekly evaluation initially would be prudent to prevent overdiuresis and electrolyte disturbances.[38]

Refractory Ascites

Case 25-1, Question 9: Over the next several days, R.W.'s spironolactone dosage was increased to 400 mg/day. Furosemide was simultaneously increased to 80 mg bid without major improvement in diuresis. Laboratory data revealed that R.W.'s SCr had increased to 3.2 mg/dL (estimated creatinine clearance: 26 mL/minute) and his BUN had increased to 45 mg/dL. Serum electrolytes were as follows:

K, 3.1 mEq/L
Na, 130 mEq/L
Cl, 88 mEq/L
Bicarbonate, 32 mEq/L

R.W. became progressively short of breath because of restricted diaphragmatic movement secondary to his significantly enlarged abdomen. What therapeutic measures are appropriate for R.W.'s refractory (diuretic-resistant) ascites?

The AASLD guidelines mention a few treatment options for refractory ascites. Midodrine 7.5 mg given three times daily to increase blood pressure (BP) in patients with hypotension could possibly convert diuretic-resistant patients to diuretic-sensitive ones. In addition, discontinuation of β-blockers is recommended because these drugs are associated with increased mortality in patients with refractory ascites. The guidelines also mention avoiding angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) because of the risk of hypotension.[38]

Because of the increase in SCr and respiratory distress, R.W.'s ascites treatment needs modification. Patients with cirrhosis experiencing respiratory distress despite diuretic therapy, sodium restriction, and appropriate management of hypotension (discontinuation of β-blockers and adding midodrine) may warrant more aggressive second-line treatment, including large-volume paracentesis, shunting procedures, or both.[38] Paracentesis involves

the removal of ascitic fluid from the abdominal cavity with a needle or a catheter. Although paracentesis can remove large amounts of ascitic fluid (eg, 10 L), removal of as little as 1 L of fluid may provide considerable relief from the painful stretching of skin and the respiratory distress that occurs with massive ascites. The ascitic fluid often reaccumulates rapidly after paracentesis. The major complications of overly aggressive, large-volume paracentesis include hypotension, shock, oliguria, encephalopathy, and renal insufficiency. Other potential complications of paracentesis are hemorrhage, perforation of the abdominal viscera, infection, and protein depletion.[38]

ALBUMIN

Case 25-1, Question 10: R.W. continues to reaccumulate ascitic fluid and is exhibiting signs of declining renal function. A 6 L paracentesis coupled with a 50 g albumin infusion is ordered. Why are albumin infusions used in conjunction with paracentesis?

Large-volume (>4 L) paracentesis should be performed for patients with tense ascites, resulting in respiratory distress or impaired ambulation. However, large-volume paracentesis is associated with paracentesis-induced circulatory dysfunction (PICD), which manifests as ascites recurrence, development of HRS, hyponatremia, and decrease in survival.[72,73] Intravenous (IV) albumin infusions are commonly administered to prevent PICD after large-volume paracentesis.[38] Use of albumin in combination with large-volume paracentesis increases circulatory function, prevents the subsequent reactivation of vasoconstrictors, and reduces the incidence of PICD.[73] Although albumin is costly and sometimes in short supply, for some patients it is appropriate with paracentesis.[74] In one study, patients requiring large-volume paracentesis (≥6 L/day) received either concomitant IV albumin (40 g) or saline. The incidence of PICD was significantly higher in the saline than the albumin group (33.3% vs 11.4%, respectively). The prevalence of PICD after paracentesis depends on the volume of ascites removed

such that albumin infusion may not be necessary for a single paracentesis <4 to 5 L.[38,74] For large-volume paracentesis ≥6 L, 6 to 8 g of albumin is typically administered for each liter of ascites removed.[38]

Bernardi et al[73] conducted a meta-analysis of 17 randomized controlled trials (total of 1225 patients) evaluating albumin versus alternative therapies (dextran, gelatin, saline, etc.) in the acute treatment of cirrhotic patients undergoing large-volume paracentesis. The odds of death were lower by 36% in the albumin group (P = .038).[73] In addition, a trial evaluating albumin administered to patients with SBP showed a lower incidence of renal impairment (10% vs 33%; P = .002), lower overall mortality at 3 months (22% vs 41%; P = .03), and lower hospital mortality (10% vs 29%; P = .01) than the group that did not receive albumin.[75] A previous meta-analysis by Wilkes and Navickis[76] evaluating albumin and mortality found no improvement in mortality with albumin administration. However, only part of the analysis focused on ascites (five trials).[76]

DEXTRAN 70 AND OTHER PLASMA EXPANDERS

The use of synthetic plasma expanders with large-volume paracentesis has also been explored in patients with refractory ascites.[77] Ginès et al[78] studied patients with ascites refractory to diuretic therapy, who required paracentesis. More patients treated with dextran 70 (34.4%) or polygeline (37.8%) experienced PICD than those receiving albumin (18.5%).[78] Hydroxyethyl starch, an effective colloid agent for intravascular volume expansion, should not be used in patients with cirrhosis, because repeated administration in this population has been reported to accumulate in the hepatocytes, causing severe portal hypertension and acute liver failure.[79]

R.W. should be given 50 g of 25% albumin administered at a rate of 3 mL/minute, for the 6 L of ascitic fluid removed. Albumin 25% infusion is preferred because 5% solution has fivefold the sodium load and a larger volume to give the same amount of protein.[38] More rapid administration than 3 mL/minute in patients with

hypoproteinemia can cause circulatory overload and pulmonary edema. R.W. should be monitored for anaphylactic reactions (rare), hypotension, hypertension, and signs of pulmonary edema.[80–82]

Alternative Therapy

Case 25-1, Question 11: What alternative treatments are available for the management of refractory ascites? How would these alternatives be applied in R.W.'s case?

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Transjugular intrahepatic portosystemic shunt (TIPS) is another option for patients who are refractory to the pharmacologic interventions described previously. It is a nonsurgical technique for establishing a shunt in patients with portal hypertension (**Fig. 25-2**).[83] The TIPS procedure involves opening a conduit between the hepatic vein and the intrahepatic segment of the portal vein with an expandable metal stent placed during an angiographic procedure. This low-resistance channel allows blood to return to the systemic circulation and reduces portal pressure. In addition, TIPS may improve urinary sodium excretion. The major complications of TIPS include severe encephalopathy and shunt occlusion. HE (see Case 23-5, Question 1) occurs in ~20% of patients after TIPS.[83] Because of poor prognosis, liver transplantation should be considered for appropriate candidates refractory to pharmacologic treatment and/or shunt placement.[38] Selection of surgical shunt procedures may include evaluation of liver transplantation candidacy because some procedures may complicate the feasibility of a future liver transplantation procedure.

Figure 25-2 Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension. (Adapted with permission from Smeltzer SC, Bare BG. *Brunner and Suddarth's Textbook of Medical-Surgical Nursing*. 9th ed. Lippincott Williams & Wilkins; 2000.)

Salerno et al[84] conducted a meta-analysis of cirrhotic patients with refractory ascites and found that transplant-free survival was higher in the TIPS group (38.1% vs 28.7% at 3 years; $P = .035$) and the recurrence of ascites was lower (42% vs 89%; $P < .0001$) than in the large-volume paracentesis group. The average number of HE episodes was significantly higher in the TIPS group ($P = .006$). However, the probability of developing the first episode of HE was similar between the groups ($P = .19$).[84] Bureau et al[85] conducted a randomized controlled trial to determine the effects of TIPS with stents covered with polytetrafluoroethylene in patients with refractory ascites. Covered stents reflect a more current practice as compared

to previous literature that analyzed the outcomes of bare metal stents. Patients were randomly assigned to groups that received covered TIPS (*N* = 29) versus large-volume paracenteses and albumin as necessary (LVP+A; *N* = 33). The results of the study found that a higher proportion of patients in the TIPS group survived without a liver transplant for 1 year as compared to those in the LVP+A group (93% vs 52%; *P* = .03). Patients in the TIPS group also had a lower number of paracenteses (32 vs 320), lower portal hypertension–related bleeding (0% vs 18%; *P* = .01), and lower hospitalization rate (35 vs 17 days; *P* = .04) as compared to the LVP+A group. The 1-year probability of remaining free of encephalopathy was similar for each group (65%).[85]

The AASLD guidelines mention that as experience and technology with TIPS improves, the outcomes associated with TIPS in future trials may also improve.[38] Currently, the AASLD treatment guidelines continue to recommend TIPS for the treatment of refractory ascites in patients for whom paracentesis is contraindicated, deemed ineffective as determined by the frequency of repeated paracentesis (more than three times per month), or intolerant of repeated large-volume paracentesis.[86]

PERITONEOVENOUS SHUNT

A peritoneovenous shunt consists of a surgically implanted valve in the abdominal wall, an intra-abdominal cannula, and an outflow tube tunneled subcutaneously from the valve to a vein that empties directly into the superior vena cava. In this manner, ascitic fluid can be withdrawn from the abdominal cavity and be returned to the vascular space. Multiple contraindications exist to a surgical shunt procedure, and as hepatic function worsens, surgical risks significantly increase in likelihood.[87] The lack of survival benefit, surgical complications, including fibrous adhesions complicating future liver transplantation, and the high risk of shunt occlusion have led to the reserving of peritoneovenous shunt procedures for patients with refractory ascites that are not candidates for paracentesis, liver transplantation, or TIPS.[38]

CLONIDINE

It has been shown that the activation of the sympathetic nervous system leads to renal hypoperfusion and sodium retention. The activated sympathetic nervous system stimulates renal α_1-adrenoreceptors and causes decreases in renal blood flow and glomerular filtration rate. Additionally, norepinephrine increases proximal tubular reabsorption of sodium and enhances renin, aldosterone, and vasopressin secretions.[88–90] Preliminary evidence suggests that clonidine may be of benefit in refractory ascites and an activated sympathetic nervous system. Lenaerts et al[91] conducted a very small study in patients randomly assigned to receive repeated large-volume paracentesis (4–5 L every 48 hours) plus IV albumin (7 g/L ascites) until ascites disappeared, or a combination of clonidine 0.075 mg bid for 8 days and then clonidine 0.075 mg bid with spironolactone 200 to 400 mg daily for 10 days. Both groups were discharged with spironolactone adjusted according to individual response. During the first hospitalization, the mean weight loss in the paracentesis group was higher than in the clonidine group, but the mean hospital stay was shorter in the clonidine group ($P \leq .01$). Clonidine decreased sympathetic activity and increased glomerular filtration rate. During the follow-up, the number of rehospitalizations for ascites was higher and the mean time to the first readmission was shorter in the paracentesis group than in the clonidine group ($P \leq .01$).[91] Yang et al. conducted a study in Chinese patients with refractory ascites. Patients were randomized to receive clonidine 0.075 mg twice daily in addition to spironolactone and furosemide ($N = 135$) versus diuretics alone ($N = 135$) for 3 months. The study found that 55% to 60% of patients in the clonidine group responded to the addition of clonidine. Patients in the clonidine group also had a significantly higher 1-year survival rate ($P = .0001$) compared to patients with diuretics alone. Interestingly, this study also found that a therapeutic response of clonidine can be predicted by certain genetic polymorphisms. The authors stated a possibility of polymorphism analysis to identify patients with cirrhosis that can benefit from the addition of clonidine to diuretics for the treatment of

refractory ascites.[90] The addition of clonidine to diuretic therapy may be an effective therapeutic modality; however, more trial data are needed to establish the role of clonidine in the treatment of ascites. Currently, the use of clonidine is considered experimental by the AASLD guidelines.[38]

In consideration of R.W.'s increasing SCr concentration, rising BUN, and the grave prognosis of HRS, TIPS is a reasonable therapeutic alternative if R.W. cannot tolerate or requires frequent large-volume paracentesis. Patients with a history of SBP and ascites with advanced liver failure or renal impairment appear to benefit from SBP prophylaxis. R.W. would benefit from the addition of SBP prophylaxis because of his history of SBP (see Chapter 70, Intra-Abdominal Infections).

ESOPHAGEAL VARICES

Treatment

CASE 25-2

Question 1: C.V., a 55-year-old, pale-looking female with alcohol- induced cirrhosis, was admitted for hematemesis. C.V. has a history of recurrent upper GI bleeding and documented esophageal varices. She has no other significant medical history. She is not taking any medications and has no known drug allergies. On examination, her BP was 78/40 mm Hg, pulse rate was 110 beats/minute, and respiratory rate was 22 breaths/minute. Her skin was cold; chest and cardiac examinations were within normal limits and abdominal examination revealed ascites and a palpable spleen. Bowel sounds were normal. Laboratory values included the following:

Hgb, 6.8 g/dL
Hct, 22%
Albumin, 3.0 g/dL
AST, 160 IU
ALT, 250 IU
Alkaline phosphatase, 40 IU
Creatinine, 2.0 mg/dL
PT, 18 seconds (INR, 1.5)

Serum electrolytes, all within normal limits
An electrocardiogram revealed sinus tachycardia.

What are the immediate goals of therapy and treatment measures of the highest priority in managing C.V.'s hematemesis?

GOALS OF THERAPY

Most patients with cirrhosis develop portal hypertension, which can progress to bleeding varices (dilated veins in the upper GI tract that protrude into the esophageal or gastric lumens). Of patients with Child–Turcotte–Pugh class A cirrhosis, 40% develop esophageal varices, as compared with 85% of those with Child–Turcotte–Pugh class C cirrhosis.[24,92] Unless varices bleed, they do not cause significant complications or symptoms.

The progression and severity of varices is directly related to the severity of portal hypertension. The major site of concern in portal hypertension is the coronary vein, draining the bottom of the esophagus and upper stomach. The scarring and fibrosis associated with cirrhosis initially lead to an increase in portal vein pressure (PVP), which may eventually rise, causing backflow of blood supply and subsequent increased pressure in the veins coming off the portal vein. Hyperkinetic circulation in the branches of the portal vein raises the esophageal transmural pressure and increases the risk of upper GI bleeding. Because the veins are designed for low-pressure circulation (5–8 mm Hg) and generally cannot tolerate a sustained hyperdynamic circulation, the shunting of high portal pressure blood results in gastric and esophageal varices. When PVP exceeds 12 mm Hg, patients are at increased risk of variceal hemorrhage.[93]

Varices can only be visualized during a diagnostic endoscopy. Esophageal varices are graded as small or large (>5 mm). The presence or absence of red signs (red wale marks or red spots) on varices is also noted.[92]

Despite improvement in the management of portal hypertension, massive bleeding from esophageal or gastric varices is the leading cause of death in patients with cirrhosis.[94] Prevention of variceal bleeding is critical because the mortality rate remains at 32% in

Child–Turcotte–Pugh class C patients.[94] New varices develop at a rate of 5% to 10% per year in patients with cirrhosis. Once varices develop, they enlarge by 4% to 10% each year.[95] Acute variceal bleeding is considered a medical emergency and should be treated immediately. Treatment goals include volume resuscitation, acute treatment of bleeding, and prevention of recurrence of variceal bleeding. Approximately 10% to 20% of patients are refractory to endoscopic and medical intervention and may require life-saving portal decompressive shunt surgery or TIPS.[24]

GENERAL MANAGEMENT

Resuscitation is the first priority in patients with acute bleeding episodes. An indwelling nasogastric tube (NG) should be placed, then saline or tap-water lavage of the stomach, with suctioning of the gastric contents, should be initiated promptly to prevent airway complications such as aspiration pneumonia.[83,96] Obtunded or unconscious patients should be intubated to maintain and protect the airway. Pharmacologic treatment should be initiated immediately to reduce bleeding and the risk of hypotension-induced renal failure. The patient should also be monitored for any abnormal electrolyte and metabolic chemistries (eg, potassium, sodium, bicarbonate), hypoxia (eg, PO_2, pH), SCr, and decreased urinary output.[96]

Rebleeding is most likely to occur within the first 2 to 5 days in patients with large varices and in patients with advanced liver disease (ie, Child–Turcotte–Pugh class C, Table 25-1).[24,97] Factors associated with early rebleeding include age older than 60 years, acute renal failure, and severe initial bleeding defined by Hgb <8 g/dL at presentation. Risk factors for late rebleeding are severe liver failure, continued alcohol abuse, large variceal size, renal failure, and hepatocellular carcinoma.[97]

HYPOVOLEMIA/BLOOD LOSS

Care should be taken when correcting hypovolemia so as not to increase the degree of portal hypertension by overtransfusion, which can increase the risk of further bleeding. Hypovolemia should be

immediately managed to maintain a systolic BP of 90 to 100 mm Hg and the Hgb between 7 and 9 g/dL.[24,98] C.V.'s pallor, cold and clammy skin, rapid pulse, and a systolic BP <80 mm Hg suggest significant hypotension and hypovolemia needing correction with whole blood or packed red cell transfusion and cryoprecipitate.[27,92,97]

Patients with liver disease and elevated bilirubin frequently develop some level of vitamin K deficiency. Prolongation of the PT because of vitamin K deficiency usually improves within 12 hours after a 10-mg parenteral or oral dose of vitamin K. In contrast, a prolonged PT caused by poor liver function is not responsive to the administration of vitamin K. If no improvement is seen in INR after a 1-mg dose of vitamin K, repeated administration is unlikely to have therapeutic benefit.[27] Although vitamin K is often administered in the treatment of acute variceal bleeding, there are no data to support this practice.[99] For rapid correction of INR because of bleeding or a planned invasive procedure, fresh frozen plasma has been used. However, this may lead to increased portal pressure. Cryoprecipitate may be a viable alternative because of lower infusion volume and less impact on portal pressure.[27]

Case 25-2, Question 2: Three units of whole blood and eight units of cryoprecipitate were transfused initially. C.V.'s stomach was lavaged with saline, and the gastric aspirate from the NG tube continued to be strongly positive for blood. Four hours later, her bleeding still persisted. What other pharmacologic interventions can be used to control C.V.'s bleeding esophageal varices?

OCTREOTIDE

Octreotide is a synthetic analog of somatostatin, with similar pharmacologic properties and a slightly longer half-life. Somatostatin is available in Europe, but is substituted with octreotide or vapreotide (orphan drug status) in the United States (**Table 25-2**).[100–103] Octreotide is shown to be effective for controlling acute variceal bleeding and appears comparable in efficacy to vasopressin and balloon tamponade, with fewer side effects. Octreotide is administered as a 50-100 μg bolus followed by an infusion of 50 μg/hour for 2 to 5 days.[92] In one study, complete bleeding control

was achieved in all patients receiving octreotide after 48 hours of therapy compared with 64% of patients who are treated with vasopressin, and 59% in the omeprazole group ($P < .005$). Patients receiving vasopressin also experienced more side effects (abdominal cramps, nausea, tremor, decreased cardiac output, myocardial ischemia, and bronchial constriction) than those receiving octreotide or omeprazole ($P < .01$). In patients with bleeding not controlled within 48 hours in the vasopressin and omeprazole groups, complete bleeding control was subsequently achieved by octreotide.[104] In a meta-analysis assessing the efficacy of vasopressin, octreotide, and somatostatin administered to patients with acute variceal bleeds, studies found that control of acute hemorrhage was significantly greater with octreotide when compared with vasopressin ($N = 2$; risk ratio [RR] 1.31, 95% confidence interval [CI] 1.10–1.56), whereas mortality was not significantly different ($N = 1$; RR 1.00, 95% CI 0.54–1.85). Hemostasis was significantly lower with vasopressin when compared with somatostatin (RR 0.75, CI 0.61–0.92), whereas no significant difference in mortality or rebleeding was detectable.[105] In general, octreotide is fairly well tolerated.[104] Although some centers may still initiate therapy with vasopressin, most will use octreotide as first-line therapy and reserve vasopressin for treatment failures.

Table 25-2
Treatment of Acute Bleeding

Therapy	Mechanism	Side Effects and Risks
Octreotide	Selective and potent vasoconstrictor that reduces portal and collateral blood flow by constricting splanchnic vessels	Diarrhea, hyperglycemia, hypoglycemia, constipation, rectal spasms, abnormal stools, headache, dizziness, fat malabsorption

Therapy	Mechanism	Side Effects and Risks
Vasopressin	Nonspecific vasoconstrictor of all parts of the vascular bed	Abdominal cramping, nausea, tremor, skin blanching, phlebitis, hematoma at the site of the infusion, worsening of hypertension, angina, arrhythmias, myocardial infarction, bowel necrosis, gangrene, dilutional hyponatremia
Endoscopic variceal ligation (EVL)	An elastic band is placed around the mucosa and submucosa of the esophageal area containing the varix, leading to strangulation, fibrosis, and ideally obliteration of the varix.	Moderate bleeding, hypotension, gastrointestinal discomfort, esophageal ulceration, perforation
Sclerotherapy	Injection of 0.5–5 mL of a sclerosing agent (eg, concentrated saline: 11.5% NaCl or ethanolamine oleate) into each varix at points about 0.79 inch (2 cm) apart to induce immediate hemostasis (cessation of bleeding within 2–5 minutes)	Esophageal ulceration, stricture formation, esophageal perforation, retrosternal chest pain, temporary dysphagia
Balloon tamponade	Bleeding is controlled by direct compression of the varices at the gastroesophageal junction or at the bleeding site by a Sengstaken–Blakemore tube or Linton tube (gastric varices only). The tube is passed through the mouth and into the stomach. A balloon is then inflated, which applies direct compression to the varices.	Aspiration (>10% incidence), pressure necrosis, pneumonitis, esophageal ulceration and rupture, bleeding on balloon deflation, chest pain, asphyxia (aspiration may be minimized by endotracheal intubation and continued aspiration of oropharyngeal secretions)

Therapy	Mechanism	Side Effects and Risks
Transjugular intrahepatic portal systemic shunt (TIPS)	A conduit between the hepatic vein and the intrahepatic segment of the portal vein with an expandable metal stent placed during an angiographic procedure. This channel allows blood to return to the systemic circulation and reduces portal pressure.	Bleeding, thrombosis, stenosis, severe encephalopathy, hepatic failure, shunt occlusion, shunt migration

VASOPRESSIN

Vasopressin, a naturally occurring hormone (also known as 8-arginine vasopressin, ADH), is produced by the posterior pituitary and was originally derived for the treatment of diabetes insipidus in persons with pituitary insufficiency.[100,101] Its use to control variceal bleeding is a non–Food and Drug Administration (FDA)-labeled use that takes advantage of its intense smooth muscle vasoconstrictive properties. Vasopressin (Table 25-2) is effective in reducing or terminating bleeding in ~60% of patients with variceal hemorrhage.[100,101] Of concern are reports of patients developing hypertension, angina, arrhythmias, gangrene, and, rarely, myocardial infarction while receiving vasopressin. Vasopressin is given as a continuous IV infusion because of its short half-life. To minimize dose-related adverse effects, the lowest effective dosage should be used. Vasopressin may be administered by peripheral IV infusion, but use of a central vein is preferred because of the risk of tissue necrosis if extravasation occurs. Most commonly, vasopressin is initiated as a continuous IV infusion of 0.2 to 0.4 units/minute, and

increased by 0.2 units/minute every hour until control of bleeding is obtained (maximal dose 0.8 units/minute).[92] Approximately 12 hours after the control of bleeding, the infusion rate can be decreased by half. Higher doses should be avoided because dosages exceeding 1 unit/minute fail to control hemorrhage in patients who are unresponsive to lower dosages.[106] Because of the potential for serious cardiovascular and dermatologic complications caused by nonspecific vasoconstriction, vasopressin should be used only when necessary and for a duration necessary to control bleeding. The duration of infusion should not exceed 24 hours.[92] Interestingly, a meta-analysis of four randomized controlled trials comparing vasopressin for the acute treatment of variceal bleeding with nonactive treatment or placebo found no difference in mortality.[100] Because the efficacy of vasopressin for the treatment of esophageal bleeding is limited and adverse effects (eg, abdominal cramping, arrhythmias, and gangrene) are of great concern (Table 25-2), it has largely been replaced by octreotide. Nonetheless, some clinicians still prescribe vasopressin.

Nitroglycerin can help to minimize the adverse vascular and cardiac effects of vasopressin and enhance the reduction in portal pressure. When given by IV infusion, the nitroglycerin dosage is 40 to 200 µg/minute.[100,102,107] A randomized trial by Gimson et al[108] found a lower rate of complications in the vasopressin and nitroglycerin group compared with vasopressin alone. At the end of the 12-hour study period, variceal hemorrhage was controlled in 68% receiving combined therapy versus 44% in those given vasopressin alone ($P < .05$). Major complications requiring cessation of therapy were less common in those given nitroglycerin with vasopressin compared with those given vasopressin alone ($P < .02$).[108]

TERLIPRESSIN

Terlipressin, a synthetic analog of vasopressin and a prodrug of lypressin (currently not available in the United States), effectively controls acute bleeding from esophageal varices in 80% of patients. Fewer cardiovascular side effects have been associated with

terlipressin than with vasopressin.[109] Octreotide, vapreotide, vasopressin, and terlipressin have been shown to be effective in the control of acute variceal hemorrhage.[110,111] Seo et al[112] conducted a large prospective, multicenter, randomized, noninferiority trial comparing the effects of terlipressin, somatostatin, and octreotide followed by endoscopic treatment in patients with acute variceal bleeding. Similar rates of control of bleeding and reduction in mortality were achieved in all groups (NS). However, terlipressin was used at doses lower than recommended.[92,112]

Pharmacologic therapy for C.V. (somatostatin or its analogs [octreotide or vapreotide] or terlipressin) should be initiated as soon as variceal hemorrhage is suspected and continued for 2 to 5 days after diagnosis is confirmed.[92]

ENDOSCOPIC VARICEAL LIGATION AND BALLOON TAMPONADE

Case 25-2, Question 3: Octreotide and vasopressin are nonspecific vasoconstrictors that require continuous IV infusion and carry a risk of systemic side effects. What place does endoscopic variceal ligation (EVL) have in the management of C.V.'s hemorrhage? What is a balloon tamponade? Are alternative therapies such as TIPS appropriate?

After successful resuscitation, endoscopy should be performed within 12 hours to establish the cause of bleeding.[92] Fiberoptic endoscopy allows direct visualization of the esophagus and location of the bleeding. Those with actively bleeding varices can be treated with EVL or balloon tamponade. Sclerotherapy has also been used in some cases (Table 25-2). EVL is a well-tolerated procedure (Table 25-2).[110,113–117] Villanueva et al,[118] in a randomized controlled trial, found that the use of variceal ligation instead of sclerotherapy had a lower failure rate (4% vs 15%; P = .02) and a lower transfusion requirement (P = .05). No statistically significant differences were found in mortality. Adverse effects (eg, aspiration pneumonia, esophageal bleeding, ulceration, and chest pain) occurred in 28% of patients receiving sclerotherapy and 14% with ligation (RR 1.9, 95%

CI 1.1–3.5; $P = .03$).[118] In another similar but smaller study, Sarin et al[119] found that the rate of rebleeding was lower in the EVL group than in the sclerotherapy group (6.4% vs 20.8%; $P < .05$). EVL is the recommended form of therapy for acute esophageal variceal bleeding, although sclerotherapy has been used in the acute setting if ligation is technically difficult. Endoscopic treatments are best used in combination with pharmacologic therapy, which preferably should be started before endoscopy.[111] The AASLD Practice Guidance on Portal Hypertensive Bleeding in Cirrhosis recommend that for the control and management of acute hemorrhage, the combination of vasoconstrictive pharmacologic therapy and variceal ligation is the preferred approach.[92] Therefore, C.V. should immediately be treated with octreotide for 2 to 5 days, and EVL to control the esophageal variceal bleeding.[24,92]

BALLOON TAMPONADE

Balloon tamponade is used to control bleeding by direct compression to the site of origin in massive hemorrhage cases (Table 25-2). It is important to remember that balloon tamponade is only a temporary measure and can cause pressure necrosis after 48 to 72 hours. Thus, the balloon should be deflated after 12 to 24 hours. Deflation and removal of the tube can result in removal of the fibrin scab at the bleeding site, resulting in rebleeding. Balloon tamponade has been used in rebleeding episodes refractory to vasoconstrictive pharmacologic therapy and EVL. This modality may achieve temporary control of the bleeding and allow time for other measures such as TIPS to be undertaken.[92,110,120,121]

ALTERNATIVE TREATMENT MODALITIES

Transjugular intrahepatic portal systemic shunt

Although the combination of pharmacotherapy (octreotide, terlipressin, or somatostatin) and EVL has been shown to be beneficial in controlling acute bleeding, rebleeding episodes can occur.[92,110] Poor responders to initial therapy may require further intervention to lower portal pressure and control the bleeding.

Henderson et al[122] conducted a prospective, multicenter trial comparing distal splenorenal shunt (DSRS) to TIPS for variceal bleeding refractory to medical treatment with β-blockers and endoscopic therapy. Patients with Child–Turcotte–Pugh class A and class B cirrhosis and refractory variceal bleeding were randomly assigned to DSRS or TIPS. No significant differences were found in survival at 2 and 5 years (DSRS, 81% and 62%; TIPS, 88% and 61%, respectively). Thrombosis, stenosis, and reintervention rates were significantly higher in the TIPS group (DSRS, 11%; TIPS, 82%; $P < .001$). Rebleeding, encephalopathy, ascites, need for transplantation, quality of life, and costs did not significantly differ between groups.[122] TIPS has the advantage of being less invasive and faster than surgical portal systemic shunts. Long-term patency of the TIPS remains problematic (Table 25-2). TIPS can be used as a bridge to liver transplantation and might be an effective option for nonsurgical patients or in recurrent bleeding uncontrolled by pharmacologic and endoscopic therapy.[86,92,110,123,124] "Early" or preemptive TIPS (within 72 hours from endoscopy and EVL) may be considered in those at high risk for rebleeding. High risk may be classified as those with Child–Turcotte–Pugh class B/C with active bleeding on endoscopy despite vasoactive therapy.[92] Patients with successful TIPS do not require specific therapy for portal hypertension or varices.[92] TIPS would be an option for C.V. if EVL and pharmacologic therapy fail.

Surgery

Surgical creation of a portacaval shunt has been effective in reducing portal pressure and in preventing recurrent bleeding. These shunts, however, are associated with a high incidence of HE and may exacerbate hepatic parenchymal dysfunction by shunting blood away from the liver. Mesocaval shunts and DSRSs are also effective in preventing variceal rebleeding and may be associated with a lower incidence of HE.[125]

INFECTION PROPHYLAXIS: SHORT-TERM ANTIBIOTICS

CASE 25-2, QUESTION 4: Should CV receive prophylaxis for bacterial infections?

Variceal hemorrhage is a risk factor for the development of severe bacterial infections, which increase mortality.[92] Short-term administration of antibiotics for the prevention of bacterial infections in patients with variceal hemorrhage has demonstrated favorable results.[126,127] In a prospective, randomized trial comparing norfloxacin 400 mg bid for 7 days (N = 60) with no treatment controls (N = 59), the norfloxacin group had a significantly lower incidence of SBP (3.3% vs 16.9%; $P < .05$), although the decrease in mortality (6.6% vs 11.8%) did not reach statistical significance.[126] Because of the emergence of infections caused by quinolone-resistant bacteria, Fernandez et al[127] compared oral norfloxacin with IV ceftriaxone in the prophylaxis against bacterial infection in cirrhotic patients with GI hemorrhage. Patients were randomly assigned to oral norfloxacin 400 mg bid or IV ceftriaxone 1 g/day for 7 days. Antibiotics were initiated after emergency endoscopy and within 12 hours of hospital admission. The probability of developing proven infections (26% vs 11%; $P < .03$), and bacteremia or SBP (12% vs 2%, $P < .03$) was significantly higher in patients receiving norfloxacin as compared with ceftriaxone. No significant difference was seen between groups in mortality at 10 days.[127] A Cochrane review of 12 trials evaluating the role of antibiotic prophylaxis with placebo or no antibiotic prophylaxis to prevent bacterial infections in cirrhotic patients with upper GI bleeding reported that antibiotic prophylaxis was associated with a significant decrease in mortality from bacterial infections (RR 0.43, 95% CI 0.19–0.97).[128]

The AASLD guidelines recommend 7 days of antibiotic prophylaxis for the prevention of SBP in patients with variceal hemorrhage. Antibiotic recommendations should be based on local antimicrobial susceptibility patterns, with ceftriaxone (1 g/24 hour) being the first choice in patients with advanced cirrhosis, in those with prior quinolone prophylaxis use, and in hospital settings with high

prevalence of quinolone-resistant bacterial infections.[92] C.V. should be treated with ceftriaxone 1 g/day for 7 days to prevent SBP.

PRIMARY PROPHYLAXIS

Case 25-2, Question 5: All variceal hemorrhage interventions up to this point were aimed at terminating the acute bleeding episode. Could drug therapy have helped prevent the first episode of bleeding from C.V.'s esophageal varices?

Preventing the initial occurrence of variceal bleeding is referred to as primary prevention or primary prophylaxis. Pharmacologic prophylaxis is aimed at reducing the HVPG to ≤12 mm Hg, or a decrease from baseline of ≥20%.[129,130] In a small study by Vorobioff et al[129] none of the patients with HVPG ≤12 mm Hg bled from portal hypertension–related causes as compared to 42% in the HVPG >12 mm Hg group. In addition, only one of the six patients with a HVPG <12 mm Hg as compared with 16 (of 24) in the HVPG >12 mm Hg group died during the study period ($P < .06$).[129] In addition, Escorsell et al[130] confirmed that a fall of HVPG by 20% or more from baseline was associated with a decreased risk of variceal bleeding (6% vs 45%; $P = .004$).

β-Blockers

Nonselective β-adrenergic blockers decrease portal pressure through a reduction in portal venous inflow as a result of a decrease in cardiac output (β_1-adrenergic blockade) and splanchnic blood flow (β_2-adrenergic blockade). Only nonselective β-blockers have an adrenergic vasoconstrictive effect on mesenteric arterioles, resulting in a decrease in portal pressure. In addition to nonselective β-adrenergic blockers, carvedilol has additional α_1-antiadrenergic (vasodilator) activity. It decreases portal flow, but also acts as a vasodilator within intrahepatic circulation. It has been shown to be effective in the primary prevention of variceal bleeding compared to EVL for patients with medium/large varices. However, it is limited by its systemic hypotensive effects.

Usual starting dosages of propranolol are 20 mg twice daily, nadolol 20 mg daily, and carvedilol 6.25 mg once daily. Selective β-blockers (eg, atenolol and metoprolol) have little effect on mesenteric arterioles and have not been shown to be effective in primary prophylaxis.[92,131]

Propranolol or nadolol, given in dosages to reduce the resting heart rate to 55 to 60 beats/minute or by 25%, have been shown to prevent or delay the first episode of variceal bleeding.[15] Nonselective β-blockers are considered first-line drug therapy in the prevention of variceal hemorrhage based on numerous randomized, placebo-controlled trials and meta-analyses.[110,132] For example, Pascal and Cales[133] conducted a prospective, randomized, multicenter, single-blinded trial of propranolol compared with placebo in the prevention of bleeding in patients with large esophageal varices without previous bleeding. Patients received either propranolol or placebo, with the endpoints of the study being bleeding and death. The dosage of propranolol was progressively increased to decrease the heart rate by 20% to 25%. The cumulative percentages of patients free of bleeding 2 years after inclusion in the study (74% vs 39%; $P < .05$) and cumulative 2-year survival (72% vs 51%; $P < .05$) were higher in the propranolol group compared to the placebo group.[133]

Sarin et al[134] conducted a prospective, randomized, controlled trial comparing EVL plus propranolol with EVL alone as primary prophylaxis for the prevention of first variceal bleeding among patients with high-risk varices. The mean duration of follow-up for both groups was about 12.2 months (±10.7 months). EVL was performed at 2-week intervals until obliteration of varices. Propranolol was administered at a dosage sufficient to reduce heart rate to 55 beats/minute or 25% reduction from baseline, and continued after obliteration of varices. No significant differences were seen in the rates of bleeding or survival between groups, although more patients in the EVL alone group had recurrence of varices ($P = .03$).[134]

In a prospective, randomized, double-blind, placebo-controlled trial of propranolol for the primary prevention of variceal hemorrhage, Abraczinskas et al[135] found that when propranolol was tapered off,

the risk of variceal hemorrhage increased from 4% (while on propranolol therapy) to 24% (after propranolol withdrawal) and was comparable to the risk of bleeding in an untreated population (22% in the placebo group from the previous study). Importantly, patients who abruptly discontinued β-blockers experienced increased mortality compared with the untreated population (48% vs 21%; $P < .05$).[135] Therefore, avoiding sudden discontinuation of β-blockers in this population is essential.

The AASLD guidelines recommend nonselective β-blockers for primary prophylaxis in patients with small varices that have not bled, but are at increased risk of hemorrhage (presence of red wale marks and/or occurring in a Child–Turcotte–Pugh class C patient). For patients with medium or large varices that have not bled, nonselective β-blockers, carvedilol or EVL, may be recommended. Choice of treatment may be based on patient preference and characteristics, contraindications to therapy, and adverse events. The β-blocker should be titrated to the maximal tolerated dose.[92]

Isosorbide-5-mononitrate

Isosorbide-5-mononitrate monotherapy for primary prophylaxis for variceal hemorrhage has not proven to be effective.[136,137] Garcia-Pagan et al[137] conducted a prospective, multicenter, double-blind, randomized, controlled trial evaluating whether isosorbide-5-mononitrate prevented variceal bleeding in cirrhotic patients with gastroesophageal varices, who had contraindications or could not tolerate β- blockers. Patients received isosorbide-5-mononitrate or placebo. No significant differences were noted in the 1- and 2-year actuarial probability of bleeding or survival between the two treatment groups.[137] When combined with a β-blocker, isosorbide-5-mononitrate lowers the HVPG more than a β-blocker alone. However, trial data show a higher rate of withdrawal with combination therapy than with β-blocker monotherapy because of side effects.[138]

The AASLD guidelines suggest that nonselective β-blockers in combination with EVL, nitrates (either alone or in combination with β-

blockers), TIPS, or sclerotherapy should not be used in the primary prophylaxis of variceal hemorrhage.[92,139]

Depending on the size of C.V.'s varices on endoscopy and the risk of hemorrhage, C.V. should have been given propranolol 20 mg two times a day, nadolol 20 mg daily, or carvedilol 6.25 mg daily titrated to reduce the resting heart rate to 55 to 60 beats/minute (or by 25%), or EVL to prevent or delay the first episode of variceal bleeding.

SECONDARY PROPHYLAXIS

Case 25-2, Question 6: C.V.'s hepatologist would like to start treatment to prevent further variceal hemorrhage. What are the long-term objectives for the treatment of C.V.? What treatment approaches can be used to prevent a recurrence of bleeding (secondary prevention)?

Secondary prevention or secondary prophylaxis is therapy used to prevent rebleeding. All patients who survive a variceal bleeding episode should receive therapy to prevent recurrent episodes. It is important that the initiation of β-blockers be delayed until after recovery of the initial variceal hemorrhage. Initiation of a β-blocker during the treatment of an acute bleed would block the patient's acute tachycardia in response to his or her hypotension, which may adversely impact survival. The benefit of nonselective β-blockers in the prevention of rebleeding episodes has been demonstrated by a number of trials.[113,140,141] For example, Colombo et al[140] randomized cirrhotic patients with a history of variceal hemorrhage to propranolol, atenolol, or placebo. Oral propranolol was titrated until the resting pulse rate was reduced by ~25%, and atenolol was given at a fixed dose of 100 mg daily. The incidence of rebleeding was significantly lower in patients receiving propranolol than those receiving placebo (P = .01). Bleeding-free survival was higher for patients on active drugs than for those on placebo (propranolol vs placebo, P = .01; atenolol vs placebo, P = .05).[140]

Eradication of varices by endoscopic procedures is also effective in preventing recurrent variceal bleeding.[15,141] A study by de la Pena et al[141] showed that nadolol plus EVL (N = 43) reduced the incidence

of variceal rebleeding compared with EVL alone (*N* = 37). Variceal bleeding recurrence rate was 14% in the EVL plus nadolol group and 38% in the EVL alone group (*P* = .006). Mortality was similar in both groups, and the actuarial probability of variceal recurrence at 1 year was lower in the EVL plus nadolol group than in the EVL alone group (54% vs 77%; *P* = .06). The adverse effects in the β-blocker group were higher, which led to the withdrawal of the β-blocker in 20% to 30% of the patients.[141]

A meta-analysis of randomized trials[142] reported that compared with EVL alone, EVL combined with β-blockers and/or isosorbide-5-mononitrate reduced overall rebleeding (32% vs 17%, respectively; *P* < .01) with no significant difference in mortality or complications. When comparing drug therapy alone to combination therapy with EVL and β-blockers and/or isosorbide-5-mononitrate, combination therapy showed a trend toward lower rebleeding (29% vs 37%, respectively; NS), but with no effect on mortality. Combination therapy with EVL plus β-blockers and/or isosorbide-5-mononitrate is effective in preventing rebleeding. Drug therapy alone is an alternative.[142]

TIPS is an option for those patients who fail both EVL and prophylaxis with β-blocker therapy. In a randomized study of Child–Turcotte–Pugh class B and C cirrhotic patients surviving their first episode of variceal hemorrhage, Escorsell et al[143] reported a lower rate of rebleeding (13% vs 39%; *P* = .007) and higher rate of encephalopathy (38% vs 14%, *P* = .007) in patients treated with TIPS versus those treated with the combination of propranolol and isosorbide-5-mononitrate. The 2-year rebleeding probability was also lower in the TIPS group (13% vs 49%; *P* = .01). Of note, drug therapy improved the Child–Turcotte–Pugh class more frequently than with TIPS (72% vs 45%; *P* = .04) and at lower costs.[143]

The AASLD guidelines suggest the combination of a nonselective β-blocker plus EVL as first-line therapy for secondary prophylaxis. TIPS should be considered in patients who experience recurrent variceal hemorrhage despite combination pharmacologic and endoscopic therapy.[86,92]

Because C.V. has a history of recurrent upper GI bleeding, the best option to prevent further bleeding is to initiate a nonselective β-blocker and begin EVL. The β-blocker should be titrated to reduce the resting heart rate to 55 to 60 beats/minute or by 25%. EVL should be repeated every 1 to 4 weeks until obliteration, with a repeat endoscopy performed 3 to 6 months after obliteration, and then every 6 to 12 months to check for variceal recurrence.[92] If this combination fails to prevent variceal hemorrhage, then TIPS would be considered as a therapeutic option.[86,92]

HEPATIC ENCEPHALOPATHY

CASE 25-3

Question 1: R.C., a 57-year-old male, was admitted to the hospital because of nausea, vomiting, and abdominal pain. He had a long history of alcohol abuse, with multiple hospital admissions for alcoholic gastritis and alcohol withdrawal. Physical examination revealed a cachectic male patient (weighing 121.25 pounds [55 kg]) with clouded mentation, who was not responsive to questions about name and place. Tense ascites and edema were noted, and the liver was percussed at 3.54 inches (9 cm) below the right costal margin. The spleen was not palpated, and no active bowel sounds were heard. Laboratory results on admission included the following:

Na, 132 mEq/L
K, 3.7 mEq/L
Cl, 98 mEq/L
Bicarbonate, 27 mEq/L
BUN, 24 mg/dL
SCr, 1.4 mg/dL
Hgb, 9.2 g/dL
Hct, 24.1%
AST, 520 IU
Alkaline phosphatase, 218 IU
Lactate dehydrogenase (LDH), 305 IU
Total bilirubin, 3.5 mg/dL
PT, 22 seconds (INR, 1.8)

A 70-g protein, 2000 kcal diet was ordered. Furosemide 40 mg IV every 12 hours was ordered in an attempt to reduce the edema and ascites. Morphine

sulfate and prochlorperazine were ordered for his abdominal pain and nausea, respectively. Two days after admission, R.C. had an episode of hematemesis. He became mentally confused and at times nonresponsive to verbal command. An NG tube was inserted and coffee-ground material was produced on continuous suctioning. Saline lavage was continued until the aspirate became clear. The next morning, R.C. was still in a confused mental state. He demonstrated prominent asterixis, and fetor hepaticus was noted on his breath. On the second day of his hospitalization, laboratory data were as follows:

Hgb, 7.4 g/dL
Hct, 21.2%
K, 3.1 mEq/L
SCr, 1.4 mg/dL
BUN, 36 mg/dL
PT, 22 seconds (INR, 1.8)
Guaiac-positive stool
HE and upper GI bleeding were added to his problem list.

What aspects of R.C.'s history are compatible with a diagnosis of HE? What classification of HE does he fall into?

HE is a spectrum of central nervous system (CNS) abnormalities ranging from subclinical alterations to coma and caused by advanced liver disease and/or portosystemic shunting of blood. According to the guidelines by the AASLD and the EASL for HE in Chronic Liver Disease, HE is classified according to four criteria: (1) underlying disease (acute liver failure [type A]; resulting from portosystemic bypass or shunting [type B]; from cirrhosis [type C]), (2) severity of manifestations, (3) according to time course (episodic, recurrent, or persistent HE), and (4) according to precipitating factors (nonprecipitated or precipitated).[144]

The gold standard to measure the severity of HE is by the West Haven Criteria (WHC), and patients with significantly altered consciousness by the Glasgow Coma Scale (GCS). For more details on WHC and GCS, please refer to the AASLD/EASL 2014 guidelines at aasld.org (https://www.aasld.org/sites/default/files/2019-06/hepaticencephalopathy82014.pdf). The ISHEN (International Society for Hepatic Encephalopathy and Nitrogen Metabolism) consensus classifies patients as having minimal HE and Grade I hepatic encephalopathy (WHC) as covert HE, whereas those with

apparent clinical abnormalities as overt hepatic encephalopathy (OHE). The ISHEN consensus defines the onset of disorientation or asterixis as the onset of OHE.[145] This chapter will focus on the treatment of OHE in cirrhosis.

During the early phase of HE, the altered mental state may present as a slight derangement of judgment and change in personality, sleep pattern, or mood. Drowsiness and confusion become more prominent as the HE progresses. Finally, unresponsiveness to arousal and deep coma ensue. Asterixis, or flapping tremor, is often present in the early to middle stages of HE that precede stupor or coma.[144]

The clinical features (as seen in R.C.) include altered mental state and asterixis. He is classified as having OHE, type C, grade III, episodic, precipitated (by upper GI bleed; see Case 25-3, Question 3).

Asterixis can be demonstrated by having the patient hyperextend his or her wrist with the forearms outstretched and fingers separated. It is characterized by bilateral, synchronous, repetitive, arrhythmic motions occurring in bursts of one flap (twitch) every 1 to 2 seconds. Asterixis is not specific for HE and may also be present in uremia, hypokalemia, heart failure, ketoacidosis, respiratory failure, and sedative overdose.[144]

As discussed in the questions that follow, the pharmacologic management of HE is guided by both an understanding of the pathogenesis of this disorder and the stage of severity demonstrated by the individual patient. In most cases, HE is fully reversible; therefore, it is likely a metabolic or neurophysiologic rather than an organic disorder.[144] Severe, progressive HE can lead to irreversible brain damage (caused by increased intracranial pressure), brain herniation, and death.[144,146,147]

Pathogenesis

Case 25-3, Question 2: What is the pathogenesis of HE?

Several theories exist about the pathogenesis of HE. The most widely referenced theories involve abnormal ammonia metabolism; altered ratio of branched chain to aromatic amino acids; imbalance in brain neurotransmitters, such as γ-aminobutyric acid (GABA) and serotonin; derangement in the blood–brain barrier; and exposure of the brain to accumulated "toxins."[148] The pathogenesis of HE is likely multifactorial.

AMMONIA

Ammonia is a by-product of dietary protein metabolism or digestion of protein-rich blood in the GI tract (eg, bleeding esophageal varices). Bacteria present in the GI tract digest protein into polypeptides, amino acids, and ammonia. These substances are then absorbed across the intestinal mucosa. Ammonia is readily metabolized in the liver to urea, which is then renally eliminated. However, when blood flow and hepatic metabolism are impaired by cirrhosis, serum and CNS concentrations of ammonia are increased. The ammonia that enters the CNS combines with α-ketoglutarate to form glutamine, an aromatic amino acid. Ammonia has been considered central to the pathogenesis of HE. An increased ammonia level raises the amount of glutamine within astrocytes, causing an osmotic imbalance, cell swelling, and ultimately brain edema. Although high serum ammonia and cerebrospinal glutamine concentrations are characteristic of encephalopathy, they may not be the actual cause of this syndrome.[147,149] According to the AASLD/EASL guidelines, high ammonia levels alone may not add any diagnostic, staging, or prognostic value.[144] However, if a level is normal, the diagnosis of HE should be questioned. In the case where ammonia-lowering drugs are used (eg, lactulose), repeated measurements of ammonia would be beneficial to assess their efficacy.[144]

AMINO ACID BALANCE

In both acute and chronic liver failure, the ratio of the branched chain to aromatic amino acids is altered. Because of the higher

permeability of aromatic amino acids across the blood–brain barrier and into the cerebrospinal fluid, some aromatic compounds can lead to production of "false neurotransmitters" that can lead to HE with altered mental status (see Chapter 38, Adult Parenteral Nutrition).[148,149]

Γ-AMINOBUTYRIC ACID

Schafer and Jones[150] proposed that in liver disease, gut-derived GABA escapes hepatic metabolism, crosses the blood–brain barrier, binds to its postsynaptic receptor sites, and causes the neurologic abnormalities associated with HE. Others hypothesize that endogenous benzodiazepine-like substances, via their agonist properties, contribute to the pathogenesis of HE by enhancing GABAergic neurotransmission. The role of GABA and endogenous benzodiazepines in HE is still not clearly defined.[151,152] Of all the toxins suspected to cause hepatic coma, ammonia and certain aromatic amino acids are most commonly studied. Other precipitating factors include infections, electrolyte disorders, GI bleeding, constipation, and overdiuresis. These factors may increase the serum ammonia and precipitate an exacerbation of HE.[144,153,154]

CASE 25-3, QUESTION 3: What are the probable precipitating causes of HE in R.C.?

The main precipitating cause of HE in R.C. was the sudden onset of upper GI bleeding. The bacterial degradation of blood in the gut results in absorption of large amounts of ammonia and possibly other toxins into the portal system. Other important contributory factors in this case are diuretic-induced hypovolemia (BUN:SCr ratio >20), hypokalemia (potassium, 3.1 mEq/L), and potentially metabolic alkalosis (continuous NG suctioning and furosemide). Overzealous diuretic therapy increases HE by inducing prerenal azotemia, hypokalemia, and metabolic alkalosis. Alkalosis promotes diffusion of nonionic ammonia and other amines into the CNS. The associated

intracellular acidosis "traps" the ammonia by converting it back to ammonium ion (NH_4^+).[155,156]

Sedating drugs such as opioids (eg, morphine, methadone, meperidine, codeine), sedatives (eg, benzodiazepines, barbiturates, chloral hydrate), and tranquilizers (eg, phenothiazines) can also precipitate HE. Encephalopathy precipitated by most drugs can be explained by increased CNS sensitivity and decreased hepatic clearance with subsequent drug and, in some cases, active metabolite accumulation. For R.C., the morphine and prochlorperazine might have contributed to the worsening of his HE. Although not applicable to this case, excessive dietary protein, infections, and constipation can also contribute to excess nitrogen load and hepatic coma.

Treatment and General Management

Case 25-3, Question 4: What nondrug steps should be taken to manage R.C.'s HE?

Correcting the precipitating factor underlying the episode of OHE can improve mental status in 90% of patients.[144] After identifying and removing precipitating causes of HE, therapeutic management is aimed primarily at reducing the amount of ammonia or nitrogenous products in the circulatory system, even though ammonia alone is not particularly useful for staging or determining prognosis for HE.[144] The 2013 ISHEN and 2014 AASLD/EASL guidelines recommend an energy intake of 35 to 40 kcal/kg of body weight/day and a protein intake of 1.2 to 1.5 g/kg of ideal body weight/day for patients with cirrhosis and those awaiting liver transplantation surgeries.[144,157–161] A study conducted by Córdoba et al[162] randomized patients with cirrhosis and HE to two dietary groups for 14 days. The first group followed a progressive increase in the dose of protein receiving 0 g of protein for the first 3 days, then increased progressively every 3 days (12, 24, and 48 g) up to 1.2 g/kg/day for the last 2 days. The

second group received 1.2 g/kg/day from the first day. Results showed that the course of HE was not significantly different between groups. The patients in the first group, however, experienced a higher degree of protein breakdown.[162]

R.C. is a cachectic male, and care should be taken in providing nutrition to malnourished patients. The 70-g protein, 2000-kcal diet ordered for R.C. is appropriate because it falls within the recommended weight-based ranges established by the ISHEN and AASLD/EASL guidelines. R.C. should be offered small meals or liquid nutritional branched chain amino acids and leucine-enriched amino acid supplements evenly distributed throughout the day along with a late-night snack.[157,159] Oral branched chain amino acids can improve episodic HE and may allow for achieving recommended nutritional target when dietary protein is not tolerated.[144,163] Vegetable and dairy proteins may be better tolerated than animal proteins.[157]

Case 25-3, Question 5: Which pharmacologic interventions are appropriate to manage R.C.'s HE?

LACTULOSE

Lactulose is broken down by GI bacteria to form lactic, acetic, and formic acids, which acidify colonic contents converting ammonia into the less readily absorbed ammonium ion. Back-diffusion of ammonia from the plasma into the GI tract can also occur. The net result is a lower plasma ammonia concentration. The absorption of other protein breakdown products (eg, aromatic amino acids) may also be reduced. Lactulose-induced osmotic diarrhea decreases intestinal transit time available for ammonia production and absorption, and it may help clear the GI tract of blood. Lactulose syrup (10 g/15 mL) has been used successfully for the treatment of HE. For OHE, lactulose 25 mL is administered every 1 to 2 hours until catharsis occurs. Doses are then titrated downward to maintain two to three bowel movements daily and clear mentation in order to avoid complications of overuse of lactulose (aspiration, dehydration,

severe perianal skin irritation, and precipitation of HE).[144] When the oral route of administration is not possible, as in the treatment of a comatose patient, it may be necessary to administer the drug through an NG tube. Alternatively, a rectal retention enema compounded with 300 mL of lactulose in 700 mL water can be prepared. The lactulose water mixture (125 mL) is retained for 30 to 60 minutes, although this is difficult in patients with altered mental status. The beneficial clinical effect of lactulose occurs within 12 to 48 hours. Patients may need long-term administration of lactulose as maintenance therapy, especially in patients with recurring HE. For prevention of recurrence of OHE, oral daily prophylactic dosing of lactulose should be maintained. If precipitating factors have been removed or liver function improved, prophylactic therapy may be tapered and potentially discontinued.[144] The administration of lactulose permits better dietary protein tolerance and is well tolerated if dosages are kept sufficiently low to avoid diarrhea.[164]

Although lactulose is the mainstay of HE treatment,[144,165] very limited data exist evaluating its efficacy. Care should be taken not to induce excessive diarrhea that could lead to dehydration and hypokalemia, both of which have been associated with exacerbation of HE. Although lactulose is generally well tolerated, 20% of patients report symptoms of gaseous distention, flatulence, or belching. Dilution with fruit juice, carbonated beverages, or water can reduce the excessive sweetness of the syrup.[146]

RIFAXIMIN

Rifaximin is a synthetic antibiotic structurally related to rifamycin. It has a wide spectrum of antibacterial activity against gram-negative and gram-positive bacteria, both aerobic and anaerobic.[166] Of note, 96.6% of the drug is recovered in the feces as unchanged drug, and what is absorbed undergoes metabolism with minimal renal excretion of unchanged drug.[82,167] It was introduced in the United States for the treatment of travelers' diarrhea,[168] but also is indicated for HE.[167] Although dosages used in HE trials ranged from 550 mg twice daily to 400 mg every 8 hours,[169,170] the FDA-approved dose

for HE is 550 mg twice daily.[167] Rifaximin is well tolerated, but can cause flatulence, nausea, and vomiting. Some urticarial skin reactions have been reported with prolonged use.[171] Bacterial superinfections (*Clostridium difficile*–associated diarrhea) with >2 months of rifaximin have also been reported.[82,167]

NEOMYCIN

Neomycin is also an antibiotic effective in reducing plasma ammonia concentrations (presumably by decreasing protein-metabolizing bacteria in the GI tract). Approximately 1% to 3% of the neomycin dose is absorbed. Chronic use in patients with severe kidney disease can cause ototoxicity and nephrotoxicity. Routine monitoring of SCr, presence of protein in the urine, and estimation of creatinine clearance are advisable for patients receiving high dosages for >2 weeks.[164] Neomycin therapy can also produce a reversible malabsorption syndrome that not only suppresses the absorption of fat, nitrogen, carotene, iron, vitamin B_{12}, xylose, and glucose but also decreases the absorption of some drugs, such as digoxin, penicillin, and vitamin K.[146] Typical HE dosage for neomycin ranges from 500 to 1000 mg four times daily, or as a 1% solution (125 mL) given as a retention enema (retained for 30–60 minutes) four times daily.[164]

FLUMAZENIL

Based on the theory of accumulation of endogenous benzodiazepine- like substances in HE, flumazenil, a benzodiazepine antagonist, has been evaluated for its role in the treatment of HE. Several trials have demonstrated both clinical and electrophysiologic improvement in patients with HE.[172] However, an IV product with modest benefits in the treatment of HE is not an ideal treatment option.

Lactulose versus rifaximin

An extensive review of rifaximin for the treatment of HE conducted by Lawrence and Klee[173] found that rifaximin was equally effective, and in some studies superior to lactulose in mild-to-moderate

disease. Patients treated with rifaximin required fewer, shorter, and less costly hospitalizations than patients who are treated with lactulose.[173] Bucci and Palmieri[174] conducted a double-blind study comparing rifaximin (1200 mg/day) and lactulose (30 g/day) for 15 days in patients with moderate-to-severe HE. After 7 days, ammonia concentrations normalized and at the end of the treatment period, cognitive function test scores improved in both groups. Rifaximin therapy was better tolerated.[174] Although the data reported from these and other trials suggest a benefit with rifaximin for the treatment of HE, larger trials must be conducted to determine its superiority over lactulose. In addition, the current cost of rifaximin is considerably higher than both lactulose and neomycin (estimated cash price: lactulose [60–100 g daily] ~$75–$120/month; neomycin [500 mg four times daily] ~$150/month; and rifaximin [550 mg twice daily] ~$2660/month; data per goodrx.com).

Rifaximin versus neomycin

Miglio et al[175] conducted a randomized, controlled, double-blind study to evaluate the efficacy and tolerability of rifaximin (400 mg three times daily) in comparison to neomycin (1 g three times daily) treatment for 14 days each month over 6 months. During the study, blood ammonia concentrations in both the rifaximin and neomycin groups decreased similarly.[173] Pedretti et al[176] compared rifaximin 400 mg every 8 hours to neomycin 1 g every 8 hours in patients with cirrhosis and reported a higher rate of adverse events (increases in BUN, creatinine, nausea, abdominal pain, and vomiting) in the neomycin group after 21 days of therapy. Both drugs significantly decreased blood ammonia concentrations. However, rifaximin produced an earlier reduction of blood ammonia.[176] Because of the lower adverse effect profile and considerable efficacy, rifaximin has taken over as second-line therapy for HE over neomycin at many institutions.

Lactulose versus neomycin

Orlandi et al[177] found that lactulose and neomycin appear to have similar efficacy for the acute treatment of HE. However, in the treatment of an acute exacerbation, particularly in an acute GI bleed, lactulose may produce a faster response than neomycin. Interestingly, although lactose therapy is considered the standard of practice in OHE treatment and prevention, a meta-analysis evaluating the efficacy of lactulose in patients with HE questions its benefit.[178] Large randomized controlled trials are needed to determine the optimal treatment for HE management.[147] The AASLD/EASL guidelines consider neomycin as an alternative choice for the treatment of OHE.[144]

Lactulose would be the preferred option to treat R.C.'s HE because it would shorten the time to clear the blood from his GI tract and hopefully lead to a rapid resolution of his confusion. Although neomycin is not contraindicated for R.C., the potential for worsening of his coagulopathy (by interfering with vitamin K absorption) and risk of nephrotoxicity (SCr, 1.4 mg/dL) makes this a less optimal choice. If R.C.'s renal function continues to decline, neomycin may become contraindicated. Lactulose can be initiated at 25 mL every 1 to 2 hours until at least two soft or loose stools per day are produced. The dose can then be reduced to maintain two to three soft stools per day and improved mental status. R.C. may receive lactulose by NG tube if necessary in the early treatment period.

COMBINATION THERAPY WITH LACTULOSE

Case 25-3, Question 6: Would combination therapy provide any additive beneficial effect for R.C.?

A randomized, double-blind, placebo-controlled trial by Bass et al[169] compared rifaximin versus placebo in the prevention of HE and hospitalization in patients recovering from recurrent HE (at least two episodes within the previous 6 months). Patients were assigned to either rifaximin at a dose of 550 mg twice daily or placebo for 6 months. The study allowed the use of lactulose (~90% of patients

received concomitant therapy). The results of the study showed that a breakthrough episode of HE occurred in 22.1% with rifaximin and 45.9% with placebo. Hospitalization involving HE was lower with rifaximin (13.6%) than with placebo (22.6%). Adverse events were similar among the two groups.[169] A randomized controlled trial compared the efficacy of rifaximin and lactulose combination with lactulose monotherapy for the treatment of OHE. Neurologic status improved in the lactulose monotherapy group than in the combination therapy group.[179] In contrast, a systematic review of five randomized and five observational studies reported better efficacy and lower mortality with the combination of lactulose and rifaximin than lactulose alone in their overall analysis. However, in their pooled analysis, they reported similar efficacy outcomes in their combination therapy and lactulose monotherapy groups.[180] The AASLD/EASL considers rifaximin as an effective add-on therapy to lactulose for the prevention of OHE recurrence.[144] Previous HE guidelines (American College of Gastroenterology) stated that combination therapy of lactulose and neomycin may be reasonable in patients who do not respond to monotherapy.[164] The current AASLD/EASL guidelines do not address this combination.[144] Combination therapy would not be appropriate for R.C. at this time.

HEPATORENAL SYNDROME

Case 25-3, Question 7: Lactulose treatment was initiated at 25 mL every hour and titrated to effect with some improvement in R.C.'s mental status. A few days after resolution of his GI bleeding, his SCr increased from 1.4 to 2.7 mg/dL and he became progressively oliguric. His BP was 85/65 mm Hg, pulse rate was 70 beats/minute, and respiratory rate was 16 breaths/minute. Furosemide was discontinued, and R.C. was treated with albumin infusions to allow volume expansion and improve urine output. A renal ultrasound did not reveal any specific abnormalities. Minimal improvement occurred in his BP and urine output. Laboratory results included the following:

Na, 123 mEq/L
K, 3.6 mEq/L

Cl, 98 mEq/L
Bicarbonate, 25 mEq/L
BUN, 96 mg/dL
SCr, 2.7 mg/dL
Hgb, 8.4 g/dL
Hct, 27.1%
AST, 640 IU
Alkaline phosphatase, 304 IU
LDH, 315 IU
Total bilirubin, 4.1 mg/dL
PT, 22 seconds (INR, 1.8)
A 24-hour urinalysis showed the following:
Protein, 50 mg/day
Red blood cells, 1 to 2 per high-power field
Negative for WBC, glucose, and ketones

After exclusion of other possible causes of kidney disease, R.C. is diagnosed with HRS. What are potential treatment options for R.C.'s HRS?

Pathogenesis

HRS is a complication of advanced cirrhosis characterized by cholestasis, worsening inflammation and/or microcirculatory dysfunction, bile salt direct tubular damage, increased proinflammatory cytokines and chemokines, splanchnic vasodilation, impaired cardiac function, activation of RAAS and an intense renal vasoconstriction, which leads to a very low renal perfusion and glomerular filtration rate, as well as a severe reduction in the ability to excrete sodium and free water.[181,182] A summary of the pathogenesis of HRS can be found in the EASL Clinical Practice Guidelines for the management of patients with decompensated cirrhosis.[183] HRS is diagnosed by exclusion of other known causes of kidney disease in the absence of parenchymal disease. The International Ascites Club (IAC) has revised criteria for the diagnosis and classification of HRS.[183–185] In the revised classification of HRS, the former type 1 HRS is now referred to as HRS-acute kidney injury (AKI) and type 2 HRS is now referred to as non-AKI-HRS, although the criteria are somewhat different.[183]

HRS can be classified into two categories. HRS-AKI (type 1 HRS) was previously characterized by an acute and progressive kidney failure defined by doubling of the initial SCr concentrations to a level >2.5 mg/dL in <2 weeks. The new criteria require an increase in SCr of 0.3 mg/dL and/or ≥50% increase from baseline within 48 hours along with the presence of cirrhosis and ascites, no improvement in SCr after 2 days of discontinuation of diuretics and plasma expansion with albumin, no shock, no nephrotoxic medications, and no parenchymal kidney disease.[183] HRS-AKI (type 1 HRS) is precipitated by factors such as SBP or large-volume paracentesis, but can occur without a precipitating event. This usually occurs within the setting of an acute deterioration of circulatory function characterized by hypotension and activation of endogenous vasoconstrictor systems. It may be associated with impaired cardiac and liver functions as well as HE. The prognosis of patients exhibiting HRS-AKI (type 1 HRS) is very poor.[186,187] In contrast, non-AKI-HRS (type 2 HRS) is a progressive deterioration of kidney function, which fulfills criteria for HRS, but not for AKI. The prior definition of type 2 HRS was SCr between 1.5 and 2.5 mg/dL.[183] Non-AKI-HRS (type 2 HRS) is often associated with refractory ascites and has a better survival rate than that of patients with HRS-AKI (type 1 HRS).[184,186,188] HRS develops in ~30% of patients with SBP.[182]

Treatment

HRS is associated with a high mortality rate with median overall survival being 3 months (~2 weeks for HRS-AKI [type 1 HRS] and 6 months for non-AKI-HRS [type 2 HRS]).[182] The definitive treatment for HRS is liver transplantation, which is the only treatment that ensures long-term survival.[68] The main goal of pharmacologic therapy is to manage HRS sufficiently so that the patient can survive long enough to obtain a suitable donor liver.[184,186] Diuretic therapy worsens HRS and should be discontinued.[188] Excessive fluid

administration should be avoided to prevent fluid overload and dilutional hyponatremia.

Solanki et al[189] randomized patients with HRS-AKI (type 1 HRS) to terlipressin 1 mg IV every 12 hours or placebo. Both groups also received albumin. Urine output, creatinine clearance, mean arterial pressures, and survival (42% vs 0%) were significantly better with terlipressin than with placebo ($P < .05$). All survivors in the terlipressin group had a reversal of HRS.[189] Sanyal et al[190] conducted a prospective, double-blind, placebo-controlled clinical study in which patients with HRS-AKI (type 1 HRS) were randomly assigned to terlipressin (1 mg IV every 6 hours) or placebo. If, after 3 days of therapy, the SCr level had not decreased by ≥30% from baseline, the dose was increased to 2 mg every 6 hours. All patients in this study also received albumin. The primary endpoint on day 14 was SCr ≤1.5 mg/dL on two occasions at least 48 hours apart, without dialysis, death, or recurrence of HRS-AKI (type 1 HRS). The primary endpoint was achieved twice as often with terlipressin than with placebo (25% vs 12.5%, respectively), although this did not reach statistical significance. In addition, terlipressin did not improve survival. However, terlipressin was superior to placebo for HRS-AKI (type 1 HRS) reversal as defined by SCr ≤ 1.5 mg/dL (34% vs 13%; $P = .008$). Adverse events were similar between groups.[190] Continuous infusions are being studied to try and reduce side effects and maintain stable effects on portal pressure. In 2009, the FDA accepted the final section of the New Drug Application seeking marketing approval for terlipressin for the treatment of HRS-AKI (type 1 HRS) and granted priority review and fast-track designation. In 2013, terlipressin was granted Orphan Drug Status.

A meta-analysis of four randomized controlled trials reported similar efficacy for norepinephrine (initial dose 0.5 mg/hour, max dose 3 mg/hour) and terlipressin for the treatment of HRS.[191] Other nonrandomized studies suggest that vasoconstrictor therapy with norepinephrine (combined with albumin and furosemide) or midodrine (combined with octreotide and albumin) improves renal function in patients with HRS-AKI (type 1 HRS).[192–194] Duvoux et al[194] conducted a pilot study describing the efficacy and safety of

norepinephrine in combination with IV albumin and furosemide in patients with HRS-AKI (type 1 HRS). Norepinephrine was given for 10 ± 3 days, at a mean dosage of 0.8 ± 0.3 mg/hour. Reversal of HRS was observed in 83% of patients after a median of 7 days, with a reduction in SCr (358 ± 161 to 145 ± 78 μmol/L; $P < .001$), a rise in creatinine clearance (13 ± 9 to 40 ± 15 mL/minute; $P = .003$), an increase in mean arterial pressure (65 ± 7 to 73 ± 9 mm Hg, $P = .01$), and a marked reduction in active renin and aldosterone plasma concentrations ($P < .05$).[194] Two small, open-label, randomized, pilot studies evaluated the efficacy and safety of norepinephrine compared to terlipressin in the treatment of HRS.[195,196] All subjects also received albumin. Both drugs significantly improved renal function and had similar effects with respect to efficacy and safety. These preliminary data suggest that norepinephrine may be a safe, effective, and less costly alternative to terlipressin in the treatment of HRS-AKI (type 1 HRS). Both terlipressin and norepinephrine can cause ischemic and cardiovascular events. Patient screening prior to their use is recommended. Optimum albumin dosage for the treatment of HRS has not been determined. However, a meta-analysis has demonstrated a dose–response relationship for albumin cumulative dose and survival such that the 30-day survival with a cumulative dose of 200 g is 43.2%, 400 g is 51.4% and 600 g is 59.0%.[197]

Esrailian et al[198] conducted a retrospective chart review of HRS-AKI (type 1 HRS) patients who received a combination of octreotide, midodrine, and albumin compared to untreated controls who received albumin only. Octreotide administration started at 100 μg subcutaneous TID, with the goal to increase the dose to 200 μg subcutaneous TID. Midodrine administration started at 5, 7.5, or 10 mg TID orally, with the goal to increase the dose to 12.5 or 15 mg TID if necessary. Adjustment in medication dose was based on a goal of increasing the mean arterial pressure by ≥15 mm Hg from baseline. All patients received IV expansion of plasma volume with 1.5 L of saline combined with an average of 120 g of human albumin after diuretic withdrawal. The authors found that at 30 days, 40% of treated patients had a sustained reduction in SCr compared with

10% of the concurrent untreated controls (*P* = .01). In that same time period, 43% of patients in the treatment group had died, compared with 71% of controls (*P* = .03).[198]

The IAC and EASL guidelines recommend vasoconstrictors and albumin for first-line treatment of HRS-AKI (type 1 HRS).[183,186] They advocate for the use of terlipressin (2–12 mg/day) in combination with albumin (20–40 g/day after 1 g/kg on the first day) with 64% to 76% having complete or partial response and 46% to 56% a complete response.[183,186] The IAC and EASL recommend norepinephrine as an alternative to terlipressin, although there are much less data to support norepinephrine for HRS.[183,186] The AASLD guidelines also recommend albumin plus norepinephrine as a treatment option of HRS-AKI (type 1 HRS); however, this approach requires an intensive care unit.[38] Midodrine, octreotide, and albumin are alternative options if terlipressin and norepinephrine are not available, as this combination is much less effective than terlipressin with albumin.[183,199] The latest AASLD recommendation is to consider the use of albumin plus octreotide and midodrine (largely because of the lack of availability of terlipressin in the United States).[38] Studies mention that the combination of both octreotide and midodrine is required to be effective.[200,201] Vasoconstrictor efficacy and safety requires further evaluation in large, randomized clinical trials.[192–194]

Non-AKI-HRS (type 2 HRS) manifests itself as a progressive disease and, therefore, patients do not present acutely with deterioration in kidney function. Although vasoconstrictors with albumin improve SCr concentrations in patients with non-AKI-HRS (type 2 HRS), following discontinuation of treatment, non-AKI-HRS (type 2 HRS) returns. There are also some concerns regarding the potential impact of non-AKI-HRS (type 2 HRS) treatment on post–liver transplantation outcomes.[183,202,203] The main clinical problem in non-AKI-HRS (type 2 HRS) is refractory ascites, which can be controlled by large-volume paracentesis along with IV albumin or TIPS.[188,192,204] Studies are needed to determine the place in therapy for vasoconstrictors and other potential treatments in patients with non-AKI-HRS (type 2 HRS).[186]

R.C. should continue to receive albumin 20–40 g IV per day and either norepinephrine or terlipressin IV should be initiated. Norepinephrine or terlipressin along with albumin is more effective than albumin, octreotide, and midodrine for HRS-AKI and therefore the preferred treatment for R.C. However, because of the recent variceal hemorrhage, careful monitoring of BP is necessary to avoid rebleeding. Albumin, octreotide, and midodrine could be considered. Because of the poor prognosis associated with HRS, R.C. should be evaluated for liver transplantation.

Case 25-3, Question 8: Why should liver transplantation be considered in patients with end-stage liver disease such as R.C.?

Liver transplantation for appropriate candidates may be the best option for end-stage liver disease and its complications leading to improved quality and duration of life. Transplantation is generally considered in patients with refractory ascites, severe HE, esophageal or gastric varices, and HRS.[205] Because of the shortage of organs available and significant complications associated with transplantation, therapeutic alternatives should be considered to avoid the necessity for transplantation. For patients such as R.C., who are candidates for transplantation, therapeutic strategies to improve outcomes after transplantation should be considered in therapeutic decision-making before transplantation (see Chapter 34, Kidney and Liver Transplantation, for further information on the indications for liver transplantation).[204]

Acid–Base Disturbances

Mary P. Kovacevic, Jeremy R. DeGrado, and Kevin E. Anger

CORE PRINCIPLES		CHAPTER CASES
1	Acquisition and interpretation of diagnostics and laboratory tests used in acid–base analysis is key to identifying and managing acid–base disturbances.	**Case 26-1 (Question 1) Case 26-2 (Questions 1, 3, 4) Case 26-3 (Question 1) Case 26-4 (Questions 1, 2)Case 26-5 (Questions 1–3) Case 26-6 (Question 1)**
2	Acid–base status assessment in patient care should be conducted using a stepwise approach.	**Case 26-1 (Question 1) Case 26-2 (Questions 1, 3, 4) Case 26-3 (Question 1) Case 26-4 (Questions 1, 2) Case 26-5 (Questions 1–3) Case 26-6 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	A metabolic acidosis with a normal anion gap (or “non-anion gap”) is associated with a loss of bicarbonate. The decrease in serum bicarbonate in non–anion gap metabolic acidosis can be secondary to gastrointestinal loss or alterations in reabsorption. A urine anion gap can be used to determine the cause of a normal anion gap metabolic acidosis.	**Case 26-1 (Questions 1, 2)**
4	A metabolic acidosis with an elevated anion gap (“anion gap acidosis”) is associated with a decrease in bicarbonate related to the buffering of acids. An anion gap develops because of the increase in unmeasured anions. Common causes of anion gap metabolic acidosis include increased production of endogenous acids (eg, lactic acid, ketoacids) and exposure to toxins that produce acids (eg, methanol and ethylene glycol).	**Case 26-2 (Questions 1–4)**
5	Metabolic alkalosis can be classified according to a patient’s volume status and responsiveness to the administration of chloride-containing solutions.	**Case 26-3 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
6	A respiratory acidosis can be acute, chronic, or acute-on-chronic. The best way to differentiate these disturbances is with a careful patient history and review of previous blood gas values.	**Case 26-4 (Questions 1–3) Case 26-5 (Questions 1, 2)**
7	Respiratory alkalosis stems from a small number of conditions that increase either the rate or depth of respirations leading to decreased $Paco_2$.	**Case 26-6 (Questions 1–3)**

INTRODUCTION

Acid–base disturbances are common in patients who are acutely ill and in some chronic diseases such as chronic bronchitis. Severe acid–base disturbances can contribute significantly to morbidity and mortality. Although most cases of acid–base disturbances are mild and self-limiting, extreme changes in pH can have a significant impact on organ function.[1,2] Generally, acidemia is defined as a serum pH <7.35 and is associated with disturbances or process of acidosis, whereas alkalemia is a pH >7.45 and associated with disturbances or process of alkalosis.[1–3] In this chapter, we discuss basic physiology, stepwise assessment, etiologies, and (briefly) various management strategies for acid–base disturbances.

NORMAL ACID–BASE PHYSIOLOGY

The human body is constantly working to maintain homeostasis of many physiologic parameters. Under normal conditions, the balance between extracellular acid load and baseload is tightly controlled to

maintain arterial pH between 7.35 and 7.45.[4–6] Maintenance of this pH range is needed to protect many physiologic/organ functions within the body. Acid–base balance is maintained by complex buffer systems that control ventilation to expel carbon dioxide (CO_2) through the respiratory system and renal elimination of acids and reabsorption of bicarbonate (HCO_3^-) and other extracellular buffers. The renal system is recognized as the metabolic pathway.[4,7–9] **Figure 26-1** summarizes the buffer systems in the body that are responsible for maintaining acid–base homeostasis.

Figure 26-1 Acid–base buffering systems. Regulation/buffering of acid–base balance is rooted in metabolic and respiratory regulation mechanisms. Respiratory regulation is rooted in ventilation and subsequent CO_2 elimination. The speed and quantity of carbon dioxide make respiratory regulation a powerful buffering system in the body. Renal regulation is another important regulatory system that involves acid ion secretion and bicarbonate

excretion/reabsorption. Chemical buffers are a lower capacity buffering system involving serum proteins such as albumin that bind acid ions.

Figure 26-2 depicts the application of the Henderson–Hasselbalch principles to acid–base physiology and the principles by which the body maintains its acid and baseload. The major acid–base buffering system in the blood involves the bicarbonate–carbon dioxide buffering system.[1,3,7,8] Carbon dioxide, bicarbonate, and carbonic acid are interconverted according to the following equation ($H_2O + CO_2 \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$) in which changes in pH shift the direction of the equation toward more production of CO_2 (considered as the acid, because in this equation it gave a hydrogen ion (H^+) or HCO_3^- (considered as the base, because it accepted an [H^+]). Although CO_2 is not an acid itself, it diffuses out of cells into plasma to combine with water to form carbonic acid (H_2CO_3).[10–12] When conceptualizing, it is easy to link CO_2 as an acid that is associated with the respiratory system, and given that HCO_3^- is eliminated through the kidneys, HCO_3^- is linked to the renal system and to the metabolic pathway.

Figure 26-2 Applying Henderson–Hasselbalch principles to blood gas analyzers that measure pH and PCO_2 and calculate bicarbonate. Simply, blood pH is largely driven by the ratio of base upon the blood pH, and shifts in pH swing the direction of dissociation. This sets up the core principles by which the body regulates CO_2 (acid) elimination and HCO_3^- (base) elimination by respiratory and metabolic mechanisms to maintain target pH. Note: $[HCO_3^-]$ is the concentration of bicarbonate in the blood (mEq/L or mmol/L), and $Paco_2$ (Pco_2) is the partial pressure of carbon dioxide in the arterial blood (mm Hg); pK = 6.1.

Respiratory buffering involves changes in ventilation and CO_2 concentrations in the blood in response to changes in pH. Ventilation is regulated by central and peripheral chemoreceptors that are sensitive to arterial pH, arterial carbon dioxide tension ($Paco_2$), and arterial oxygen tension (Pao_2) concentrations.[6,11,13] Ventilation can be altered in a matter of minutes, resulting in the ability to excrete or retain high amounts of CO_2 (acid) in response to pH changes.[1,2,12]

Metabolic regulation of acid–base balance is rooted in the kidneys reclaiming filtered bicarbonate by secreting hydrogen ions and other acid salts by glomerular filtration.[3,5] Under normal conditions, proximal tubule carbonic anhydrase converts CO_2 and water into protons and bicarbonate ions, which are then reclaimed into the blood while the hydrogen is secreted into the proximal tubule.[5,6,13] The kidney can retain or excrete large amounts of bicarbonate under normal conditions; however, the speed of its mechanism results in a much slower response compared to respiratory buffering.[6,13]

Approaches to Acid–Base Balance

Approaches to acid–base balance vary in their incorporation of buffering capacity, hydrogen ion balance, and weak versus strong ion effect.[1,2,13–15] Newer approaches to assessing acid–base status such as the base excess and physiochemical approaches are

gaining popularity in routine clinical use among specialists; however, discussion of these approaches is beyond the scope of this chapter. The traditional physiologic approach is the current predominant means of assessing acid–base status in clinical practice and is discussed throughout this chapter.

Classification of Acid–Base Disturbances

Acid–base disturbances can be simply classified into four disturbances of either respiratory or metabolic origins (**Table 26-1**). Simple (single) acid–base disturbances involve one acid–base abnormality, whereas mixed disturbances involve two or three simple disturbances.[1,12,16] Patients with a double mixed disturbance can have a respiratory and metabolic disturbance or a mixture of two different metabolic disturbances that complete or synergize the patient's imbalance. Although rare, triple mixed disturbances involved two metabolic imbalances with a respiratory imbalance. Patients can have one respiratory and multiple metabolic disturbances at the same time; however, they cannot have two respiratory disturbances at the same time.[1,16]

Table 26-1
Simple Acid–Base Disturbances

Acid–Base Disorder	Pathophysiologic Associated System	Compensating System and Response
Metabolic acidosis	↓HCO_3^- to <22 mmol/L	↓$Paco_2$
Respiratory acidosis	↑$Paco_2$ to >42 mm Hg	↑HCO_3^-
Metabolic alkalosis	↑HCO_3 to >26 mmol/L	↑$Paco_2$
Respiratory alkalosis	↓$Paco_2$ to <38 mm Hg	↓HCO_3

Note: Simple acid–base disturbances are often referred to as single acid–base disturbances.

Laboratory Assessment

Depending on the patient's clinical status and established disease physiology, a variety of laboratory tests are used to evaluate acid–base status.[12,17,18] Arterial pH, arterial carbon dioxide tension ($Paco_2$), and serum bicarbonate (HCO_3^-) are the laboratory values needed for the traditional approach assessment. These values are obtained routinely with an arterial blood gas (ABG) determination. Normal ABG values are listed in **Table 26-2**. ABG is the gold standard for acid–base assessment; however, availability of ABG may be limited to patients with respiratory distress or low oxygenation states. Familiarity with venous blood gas (VBG) parameters is also important, because this may be the first laboratory data available on patient presentation. The VBG provides useful information for assessment of acid–base balance, and can be used clinically because the arteriovenous differences in pH and PCO_2 are relatively consistent.[1,5,19] Although oxygen does not directly impact the blood pH, low oxygenation status of the blood does drive acid–base disturbances or is a result of ventilatory compensation of an acid–base disturbance.[19] In clinical practice, the serum HCO_3- concentration is either estimated from the total carbon dioxide content on electrolyte panels (such as the basic metabolic panel [BMP] or the complete metabolic panel [CMP]), or it is calculated from the pH and $Paco_2$ from an ABG using the Henderson–Hasselbalch equation shown in Figure 26-2. It is important to note that the estimated serum HCO_3^- from the electrolyte panels is a more accurate estimate of the total carbon dioxide concentration (TCO_2) than is the calculated bicarbonate obtained from the ABG. In this chapter, the serum bicarbonate concentration obtained from the electrolyte panels is referred to as TCO_2. Serum TCO_2 from the electrolyte panels should be used when assessing acid–base status.[2] In addition, in clinical practice and in all the equations used when referring to bicarbonate in this chapter, the

value used in these equations will be obtained from the electrolyte panel rather than the HCO_3^- from the ABG.

Table 26-2
Normal Arterial and Venous Blood Gas Values

Variable	Arterial	Venous
pH	7.4 (7.35–7.45)	7.36 (7.33–7.43)
Pco_2 mm Hg	40 (35–45)	41–51
TCO_2 mEq/L	24 (22–26)	24–28
O_2 mm Hg	80–100	35–40
O_2 saturation, %	≥95	70–75

A stepwise approach to acid–base assessment is discussed later in the chapter, and highlights how specific laboratory testing works its way through the assessment as the patient's acid–base status is evaluated. Secondary laboratory tests for acid–base assessment involve looking at a variety of whole blood, plasma, and urine samples.

STEPWISE APPROACH TO THE EVALUATION OF SIMPLE ACID–BASE DISTURBANCES

Acid–base assessment is a complex clinical task in which a systematic approach is warranted.[1,2] A stepwise approach to the evaluation of simple acid–base disturbances can be summarized as follows:

1. Evaluate pH as acidosis or alkalosis.
2. Evaluate $Paco_2$ and HCO_3^- levels.
3. Identify the dominant acid–base disorder, presence of compensation, and potential for mixed disorder status.

4. If a respiratory disorder, determine whether acute or chronic.
5. For metabolic acidosis or metabolic alkalosis, further assess laboratory parameters:
   - If the disorder is a metabolic acidosis, determine whether it is a normal- or high-anion gap (AG) acidosis:
     - Winter formula
     - Calculate corrected AG
     - If high AG, check Delta (δ) gap
   - If high-AG metabolic acidosis, assess clinically for anion source:
     - Lactate, serum osmolality, serum ketones, serum/urine toxicology screen
   - If normal-AG metabolic acidosis, assess clinically:
     - Serum K^+, renal function, urine osmolality, urine pH, urine NH_4^+, renal bicarbonate reabsorption
   - If the disorder is metabolic alkalosis, determine if Cl^- sensitive or Cl^- resistant
     - Urine chloride assessment

Evaluation of a patient's acid–base status involves looking at their medical history, current physical examination/findings, and laboratory data. Clinicians should be mindful to follow through on the stepwise assessment and avoid channeling toward prior history or certain laboratory variables that will mislead the assessment. **Table 26-3** outlines the predicted degree of compensation for the simple acid–base disturbances.[1,5,6] The expected degree of compensation is important for delineating acute versus chronic disturbances as well as the presence of mixed disturbances.

Table 26-3
Predicted Degrees of Compensation

Acid–Base Disturbance	Primary Change	Compensatory Response
Metabolic acidosis	1 mEq/L ↓ HCO_3^-	1.2 mm Hg ↓ $Paco_2$
Respiratory acidosis	10 mm Hg↑ $Paco_2$	1 mEq/L (acute) or 3.5 mEq/L (chronic) ↑ HCO_3^-

Acid–Base Disturbance	Primary Change	Compensatory Response
Metabolic alkalosis	1 mEq/L ↑ HCO_3^-	0.7 mm Hg ↑ $Paco_2$
Respiratory alkalosis	10 mm Hg↓ $Paco_2$	2 mEq/L (acute) or 4 mEq/L (chronic) ↓ HCO_3^-

METABOLIC ACIDOSIS

Metabolic acidosis is a condition defined by a pH <7.35 with low serum bicarbonate.

Metabolic acidosis is caused by a reduction in serum bicarbonate or an increased acid load from endogenous or exogenous sources.[10] The body compensation for a metabolic acidosis is typically by an attempt of the lungs to expel CO_2, thus lowering the $Paco_2$ to balance the pH. Depending on the underlying cause of the acid–base disturbance, metabolic acidosis can be classified into two categories: normal AG versus increased or elevated AG.[1,9,12,20] The AG represents the concentration of unmeasured negatively charged substances (anions) in excess of the concentration of unmeasured positively charged substances (cations) in the extracellular fluid (Eq. 26-1). The concentrations of total anions and cations in the body are equal, to allow the body to remain electrically neutral.[21–23] Other unmeasured anions in serum include phosphate, urate, and sulfate. Unmeasured cations include potassium (in the United States, where potassium is not included in the AG calculation), ionized calcium, magnesium, and certain abnormal proteins.[1,9,10,20] For this chapter, all AG calculations use the equation provided in Eq. 26-1. The concentration of unmeasured anions normally exceeds the concentration of unmeasured cations by 6 to 12 mEq/L, and the AG can be calculated as follows:

Anion gap **(Eq. 26-1)**

$$\text{Anion gap (AG)} = Na^+ - (Cl^- + HCO_3^-)$$

Adjusted anion gap

$$\text{Adjusted AG} = \text{AG} + 2.5 \times (\text{normal albumin [mg/dL]} - \text{measured albumin [mg/dL]})$$

(Eq. 26-2)

Of the unmeasured anions, albumin is perhaps the most important.[21–23] In patients with hypoalbuminemia, the calculated AG should be adjusted using Eq. 26-2. A normal albumin concentration is assumed to be 4.0 g/dL.[2,24,25] For example, a patient with hypoalbuminemia (serum albumin, 2.0 g/dL) with early sepsis and lactic acidosis might have a calculated AG of 11 mEq/L; however, after the calculation is corrected for the effect of the abnormal serum albumin concentration, the presence of elevated AG acidosis is more prominent (the calculated AG = 11 mEq/L + 2.5 × [$4.0_{(\text{normal albumin})}$ − $2.0_{(\text{measured albumin})}$]), or a calculated AG of 16 mEq/L.

Increased-AG and normal-AG metabolic acidosis etiologies are displayed in **Tables 26-4** and **26-5**. The compensation equations for both can be found in Table 26-3. Metabolic acidosis with a normal AG (eg, hyperchloremic metabolic acidosis) usually is caused by loss of bicarbonate and can be further characterized as hypokalemic or hyperkalemic.[6,10,11,26,27] Bicarbonate loss can be secondary to gastrointestinal (GI) loss (diarrhea, pancreatic fistula, laxative use) or alterations in reabsorption related to renal (proximal or distal renal tubular acidosis [RTA] or use of carbonic anhydrase inhibitors) or exogenous (administration of chloride-rich solutions such as 0.9% sodium chloride) etiologies.[1,10–12] The serum chloride concentration usually increases in proportion to the decrease in bicarbonate in normal-AG metabolic acidosis, and the urine anion gap (UAG) can be used to determine the etiology.[28,29] The UAG = urine ($Na^+ + K^+ - Cl^-$) and has a normal range of ~20 to 90 mEq/L.[28,29] In patients with significant diarrhea, sodium and potassium are bound to bicarbonate that is lost. Urine chloride is largely bound to ammonium ($NH4^+$) and exceeds the urine concentration of sodium and potassium, leading to a negative UAG. In contrast, patients with RTA have reduced $NH4^+$

excretion (in addition to a lack of loss of Na^+ and K^+ through the GI tract), resulting in an elevated UAG.[1,2,28]

Table 26-4
Etiologies of Anion Gap Metabolic Acidosis

Etiology	Associated Acid
Renal failure	Phosphoric, sulfuric acid
Ketosis Diabetic ketoacidosis Alcoholic ketoacidosis Starvation ketosis	Acetoacetate, acetone, β-hydroxybutyrate
Lactic acidosis Type A: septic shock, mesenteric ischemia, hypovolemic shock, carbon monoxide poisoning, cyanide Type B: medications (metformin, isoniazid, nonnucleoside reverse transcriptase inhibitors, β-1 agonists) thiamine deficiency, seizure, liver dysfunction	Lactic acid
Ingestions Methanol Ethylene glycol Salicylates Toluene[a]	Formic acid, oxalic acid, glyoxylic acid, salicylic acid
Rhabdomyolysis	Uric acid, lactic acid
Glutathione deficiency	Pyroglutamic acid (5-oxoproline)

[a]Toluene may also cause a non-AG acidosis (see Table 26-5).

Table 26-5
Common Etiologies of Non–Anion Gap Metabolic Acidosis

Loss of bicarbonate
Gastrointestinal conditions Diarrhea Ureteral diversions Biliary or pancreatic drainage Renal conditions Type 2 (proximal) RTA

Toluene ingestion Medications (tenofovir, topiramate, carbonic anhydrase inhibitors)
Decreased renal acid excretion
Type 1 (distal) RTA Type 4 RTA Early uremic acidosis
Other
Fluid resuscitation with saline Hyperalimentation with HCl-containing amino acid solutions Cholestyramine

RTA, renal tubular acidosis.

In contrast to non-AG acidosis, elevated-AG metabolic acidosis is usually associated with an excess in either endogenous or exogenous acids (see Table 26-4).[1,5,9] Acids present because of increased production (eg, ketoacids, lactic acid) or exposure (eg, formic acid, glycolic acid) are buffered by extracellular bicarbonate, with resultant consumption of bicarbonate and appearance of an unmeasured anion (eg, formate, lactate).[1,5,9] In simple AG metabolic acidosis, the decrease in serum bicarbonate approximates the increase in the AG, the latter being a good estimate of the circulating anion level. Common etiologies of increased endogenous acid production include tissue hypoxemia (lactic acid), hyperglycemic emergencies (ketoacids), and renal failure (sulfate and phosphate).[1,5,9,27] Table 26-4 further highlights common causes of elevated-AG metabolic acidosis, along with the associated acids.

Normal-Anion Gap Hyperchloremic Metabolic Acidosis

EVALUATION

CASE 26-1

Question 1: M.N. is a 35-year-old, 62-inch (157.48-cm), 121.25-pound (55-kg) female with a history of a recent enterococcal urinary tract infection (UTI) who

was recently prescribed amoxicillin for 10 days. She presents to the emergency department with several days of significant diarrhea, and her admission laboratory values are as follows:

Na^+: 136 mEq/L
K^+: 3.2 mEq/L
Cl^-: 112 mEq/L
TCO_2: 14 mEq/L
Blood urea nitrogen (BUN): 25 mg/dL
Serum creatinine (SCr): 1.2 mg/dL (baseline 0.8 mg/dL)
Glucose: 123 mg/dL
Albumin: 4.2 g/dL
ABGs: pH 7.33; $Paco_2$ 27 mm Hg; Pao_2 91 mm Hg; HCO_3^- 14 mmol/L
Assess M.N.'s acid–base status.

What are possible etiologies and what compensatory response (laboratory and physical exam) would you expect?

We can begin using the stepwise approach.

Step 1: Evaluate pH as acidemia or alkalemia—M.N. has a low pH, indicating that she is acidemic.

Step 2: Evaluate $Paco_2$ and bicarbonate—She has a low $Paco_2$ and a low bicarbonate.

Step 3: Identify the dominant acid–base disorder, presence of compensation, and potential for mixed disorder status—A decrease in the bicarbonate can be linked to the presence of an acidosis, whereas a decrease in $Paco_2$ would not primarily drive a decrease in pH. Therefore, M.N. has a metabolic acidosis because a low bicarbonate is the primary factor. To evaluate the degree of respiratory compensation and determine whether there is a secondary primary respiratory disturbance, we should evaluate the $Paco_2$ and compare the observed value to what we would "expect" based on the change in bicarbonate. This can be accomplished using the ratio in Table 26-3, or utilizing the Winter formula to calculate the compensatory response (Eq. 26-3). If we use the ratio approach, we would expect a decrease of 1.2 mm Hg for every 1-point drop in bicarbonate (1.2 × 10 = 12); therefore, an expected $Paco_2$ would be ~28 mm Hg (40 − 12 = 28). Utilizing the

Winter formula ([1.5 × HCO_3^-] + 8 ± 2), we obtain a similar answer for the expected $Paco_2$: ([1.5 × 14] + 8 ± 2 = 27–31). Therefore, we can determine that M.N. has appropriately compensated for her metabolic acidosis, and there is no secondary respiratory acid–base disturbance. If M.N.'s $Paco_2$ had been <27, she would have an additional respiratory alkalosis due to breathing out more $Paco_2$ than would be expected from a purely compensatory perspective. On the other hand, if her $Paco_2$ was >31, we can determine that she has an additional respiratory acidosis secondary to the buildup of $Paco_2$. An additional respiratory acidosis would have produced a higher than expected $Paco_2$, whereas an additional respiratory alkalosis would have produced a lower than expected $Paco_2$.

Winter formula **(Eq. 26-3)**

$$\text{Expected } Paco_2 = (1.5 \times HCO_3^-) + 8 \pm 2$$

Step 4: For metabolic acidosis, further assess laboratory parameters. Determine whether it is normal- or high-AG acidosis. Calculate the AG to determine the type of metabolic acidosis— M.N.'s AG = 136 − (112 + 14) = 10, which is within the normal range. Therefore, M.N.'s acid–base disturbance is a normal-AG metabolic acidosis. Because her albumin is normal, we do not need further adjustment of the AG calculation. Etiologies of normal-AG metabolic acidosis are displayed in Table 26-5. M.N.'s recent history and clinical presentation support this diagnosis because diarrhea results in the loss of bicarbonate and retention of chloride to maintain ionic neutrality, leading to hyperchloremia.[30] A UAG could be measured to confirm the etiology of M.N.'s non-AG metabolic acidosis. A negative UAG usually indicates increased NH_4^+ excretion and would be expected if the etiology was secondary to GI losses, such as diarrhea. A positive UAG indicates low or normal NH_4^+ excretion, and likely is secondary to RTA.[1,2,30]

RTA is characterized by the kidney's failure to adequately excrete acids into the urine. Many medical conditions and chemical substances have been associated with RTA. The recognized forms are type 1 (distal), type 2 (proximal), and type 4 (distal, hypoaldosteronism).[1,5,9,11] Type 3 has features of both proximal and distal RTA. Type 1 RTA is caused by a defect in the distal tubule's ability to acidify the urine. The most common causes in adults are autoimmune disturbances, toluene sniffing in recreational drug users, and marked volume depletion.[1,5,9] Type 2 RTA may be caused by a specific deficiency in bicarbonate reabsorption (eg, acetazolamide use), but is more commonly noted with a defect in proximal tubular function, leading to impaired reabsorption of solutes such as phosphate, glucose, uric acid, and amino acids. Type 4 is characterized by hypoaldosteronism, leading to hyperkalemia, impaired ammonium excretion, and subsequent hyperchloremic (normal-AG) metabolic acidosis.[1,5,9]

TREATMENT

Case 26-1, Question 2: What treatment should be considered for M.N.?

As with all acid–base disturbances, the cornerstone of management is to treat the underlying cause.[1,5] M.N. has signs of intravascular and total body fluid depletion, likely secondary to severe diarrhea. The type of fluid to administer should be carefully considered. She already has a hyperchloremic metabolic acidosis, and the administration of a chloride-rich solution (eg, 0.9% sodium chloride) would likely further precipitate that. If intravenous (IV) fluids are needed, a balanced solution (lactated Ringer) would be preferred to 0.9% sodium chloride (known as normal saline).[5,9]

The use of alkali therapy for the treatment of normal-AG metabolic acidosis is controversial and largely depends on the etiology, severity, and patient presentation. Alkali therapy in the form of isotonic sodium bicarbonate may be reasonable for the treatment of M.N.'s normal-AG acidosis because she is also hypovolemic.

Sodium bicarbonate, or organic acids such as sodium acetate that are converted to bicarbonate, may be administered IV or enterally depending on the available formulations as well as the nature of the non-AG acidosis (ie, chronic or acute).

There is no consensus approach to the administration of sodium bicarbonate in a patient with metabolic acidosis. Generally, the goal is to estimate the bicarbonate deficit and administer the amount that will correct the serum bicarbonate level to the desired goal concentration. The goal bicarbonate concentration should generally be a modest increase from baseline to avoid complications such as hypernatremia and should be reassessed following sodium bicarbonate therapy. Alternatively, a goal of 24 mEq/L can be chosen, but it may be necessary to slowly administer sodium bicarbonate to avoid electrolyte abnormalities. Sodium bicarbonate rapidly distributes to the extracellular space following IV administration. This distribution is estimated at ~50% of the total body weight, and therefore the approximate total dose of sodium bicarbonate to administer can be calculated by the following equation:

$$\text{Bicarbonate dose (mEq)} = 0.5\ (\text{L/kg}) \times \text{total body weight (kg)} \times \text{desired increase in serum } HCO_3^- \text{ (mEq/L)}$$

For M.N., the dose of sodium bicarbonate would be ~250 mEq (0.5 L/kg × 55 kg × [24–14]). This could be replaced by administering isotonic sodium bicarbonate (150 mEq/1000 mL) at a rate of 100 to 125 mL/hour for ~12 to 15 hours.

Elevated Anion Gap Metabolic Acidosis

EVALUATION

CASE 26-2

QUESTION 1: K.S. is a 45-year-old, 143.30-pound (65-kg) female with hypertension, type 1 diabetes (T1D), and hyperlipidemia who presents to the emergency department with generalized weakness, polyuria, polydipsia, altered mental status, and signs of dehydration on physical exam. K.S. reports having fever, chills, frequent urination, and abdominal pain over the past 4 days. K.S. is suspected to have a UTI. Her vital signs are as follows: heart rate 115 *beats/minute*, blood pressure 85/55 mm Hg (mean arterial pressure [MAP] 65), respiratory rate 31 breaths/minute, temperature 100.8 °F (38.22 °C). K.S. receives 1000 mL of 0.9% sodium chloride, and her laboratory results are as follows:

Na^+: 130 mEq/L
K^+: 4.9 mEq/L
Cl^-: 95 mEq/L
TCO_2: 10 mEq/L
BUN: 27 mg/dL
SCr: 1.5 mg/dL
Glucose: 412 mg/dL
Albumin: 3.1 g/dL
β-Hydroxybutyrate: 10.9 mmol/L
Lactate: 4.5 mmol/L
ABGs: pH 7.12; $Paco_2$ 22 mm Hg; Pao_2 85 mm Hg; HCO_3^- 10 mmol/L
Assess K.S.'s acid–base status.

What are possible etiologies, and what compensatory response (laboratory and physical exam) would you expect?

We use the stepwise approach.

Step 1: Evaluate pH as acidemia or alkalemia—K.S. is acidemic given the low pH (pH = 7.12).

Step 2: Evaluate $Paco_2$ and bicarbonate—The stepwise approach highlights the low bicarbonate and low $Paco_2$.

Step 3: Identify the dominant acid–base disorder, presence of compensation, and potential for mixed disorder status—Given the abovementioned information, we can conclude that K.S. has a metabolic acidosis secondary to low serum bicarbonate. To evaluate the respiratory compensation, we apply the Winter formula (expected $Paco_2$ = [1.5 × 10] + 8 ± 2 = 21–25). Because K.S. has a $Paco_2$ of 22 within the range of the expected $Paco_2$ by

the Winter formula, we can determine that there is no secondary respiratory disturbance on top of the primary metabolic acidosis.

Step 4: For metabolic acidosis, further assess laboratory parameters. Determine whether it is normal- or high-AG acidosis. Calculate the AG to determine the type of metabolic acidosis—The next step is to evaluate the AG (130 − [95 + 10] = 25). After correction for hypoalbuminemia (AG = 25 + 2.5 × [4 − 3.1]), K.S. has an elevated AG of ~27. There are several possible etiologies for the elevated AG. K.S. has a history of T1D and presents with a blood glucose >400 mg/dL. Diabetic ketoacidosis (DKA), therefore, needs to be on the differential. K.S.'s β-hydroxybutyrate was positive at 10.9 mmol/L, confirming the presence of ketones. Common causes of DKA include infection and insulin nonadherence, both of which may be possible with K.S. In DKA, a relative or absolute deficiency of insulin leads to an inability to utilize glucose for adenosine triphosphate (ATP) production. In this state, fatty acids are metabolized to ketone bodies, specifically acetoacetate, acetone, and β-hydroxybutyrate.[1,2,9,27] Serum levels of bicarbonate decrease secondary to buffering of these acids, particularly acetoacetic acid and β-hydroxybutyric acid. Although the presence of acetone and acetoacetate can be detected through urine studies, β-hydroxybutyrate can only be assessed through serum levels. As with all etiologies of elevated-AG metabolic acidosis, treatment of the underlying cause is critical. If DKA is suspected or confirmed, fluid resuscitation and insulin therapy are required to allow the clearance of ketones and prevent further ketone body formation.[5,9–11]

However, other causes should be ruled out. K.S. clearly has signs of organ dysfunction and shock, with altered mental status and elevated SCr and a serum lactate level of 4.5 mmol/L. A lack of perfusion of oxygen to tissues leads to anaerobic metabolism and, subsequently, the production of lactic acid.

Case 26-2, Question 2: Does K.S. have a separate metabolic process in addition to her elevated-AG metabolic acidosis?

To further evaluate K.S.'s metabolic acidosis, we can use the δ ratio and compare the change in her AG to the change in her bicarbonate. The δ ratio can be calculated using Eq. 26-4. If the bicarbonate decreases in proportion with the elevation in AG, the decreased bicarbonate is likely secondary to acid buffering, and there is no additional metabolic process.[1,5,9] If the bicarbonate is lower or higher than expected, a concurrent metabolic acidosis or alkalosis may be present. Physiologically, this occurs because the amount of acid buffered by the carbonic acid buffer system is in proportion with the amount of bicarbonate lost (see Fig. 26-1). Therefore, if the drop in the bicarbonate is out of proportion with the increase in AG from normal, there is likely a secondary metabolic process going on to cause a higher (alkalosis) or lower (non-AG acidosis) bicarbonate concentration than is expected from a purely AG acidosis. Interpretation of the δ ratio can be found in **Table 26-6**. For K.S., her δ ratio is calculated to be 1.1 ([27–12] ÷ [24–10]). A δ around 1 indicates the presence of a pure high-AG metabolic acidosis.

δ ratio **(Eq. 26-4)**

$$\delta\,\text{ratio} = \text{AG} - 12 \div 24 - \text{HCO}_3^-$$

Table 26-6
Delta Ratio

Ratio	Acid–Base Disturbance
<0.8	Normal anion gap acidosis or respiratory alkalosis
0.8–1.2	Pure high anion gap acidosis
>1.2	High anion gap acidosis and metabolic alkalosis, or a preexisting compensated respiratory acidosis

TREATMENT

Case 26-2, Question 3: Should K.S. receive sodium bicarbonate for her elevated-AG metabolic acidosis?

The administration of alkali therapy, such as sodium bicarbonate, in elevated-AG metabolic acidosis is controversial and debated, and often is determined by the overall severity of the acidosis.[31,32] Adverse effects of severe acidosis (pH <7.1), such as impaired cardiac contractility, decreased responsiveness to catecholamines, and increased likelihood of arrhythmias, may warrant consideration of alkali therapy. Sodium bicarbonate is usually preferred given its immediate onset of action, as opposed to salts of organic acids (eg, sodium acetate) that require metabolism for activation.[5,9,31] However, the use of sodium bicarbonate is controversial for several reasons. Although it may improve arterial pH, the effects are often temporary given its lack of effect on the underlying problem causing metabolic acidosis. In addition, sodium bicarbonate may be limited owing to the volume of fluid that accompanies administration, particularly in some patient populations such as those with reduced ejection fraction. Also, there are limited data demonstrating the clinical benefits of utilizing sodium bicarbonate in elevated-AG metabolic acidosis. Finally, bicarbonate is converted to carbonic acid, leading to an increase in $Paco_2$, thus potentially worsening the acidosis if the patient is unable to increase ventilation adequately.[5,9] Although arterial pH may improve transiently, intracellular pH likely is unchanged or potentially even worsened secondary to changes in the intracellular ratio of HCO_3^- to CO_2. Tromethamine (THAM) is a proton acceptor that may have theoretical benefits over sodium bicarbonate, including increased buffering capacity and the ability to significantly reduce $Paco_2$.[31–36] However, data demonstrating the role of THAM are limited. Although there are no consensus dose recommendations, the approximate dose of THAM to administer for metabolic acidosis can be calculated by the following equation:

$$\text{THAM volume (mL)} = \text{body weight (kg)} \times \text{base deficit (mEq/L)}$$
[35]

THAM, unlike sodium bicarbonate, may also be effective in the treatment of respiratory acidosis because it acts a proton acceptor. Dosing strategies for dosing of THAM acetate 0.3 mol/L in respiratory acidosis differ, but a daily dose limit of ~15 mmol/kg is recommended.[35]

CASE 26-2, QUESTION 4: K.S. receives 6 L of normal saline total for the management of her possible DKA and septic shock. Her updated laboratory values are:

Na^+: 142 mEq/L
K^+: 3.8 mEq/L
Cl^-: 115 mEq/L
TCO_2: 18 mEq/L
BUN: 22 mg/dL
SCr: 0.7 mg/dL
Glucose: 197 mg/dL
Albumin: 3 g/dL
ABGs: pH 7.32; $Paco_2$ 22 mm Hg; HCO_3^- 19 mmol/L; Pao_2 95 mm Hg

What is her current acid–base disturbance?

K.S. has received treatment for her DKA in the form of isotonic fluid administration and IV insulin. Using the stepwise approach, we see that she continues to have an acidosis with a pH <7.35. With a low $Paco_2$ and a low bicarbonate, we can further classify it as a metabolic acidosis. The AG (142 − [115 + 18] = 9) is normal even after correction for hypoalbuminemia (9 + (2.5 × [4 − 3]) = 12.5). Potential etiologies for normal-AG metabolic acidosis include diarrhea and RTA; however, the most likely cause here is the administration of isotonic chloride-containing fluid in the form of 6 L of normal saline.

METABOLIC ALKALOSIS

Metabolic alkalosis is a condition defined by an elevated pH (>7.45) with a high plasma bicarbonate concentration. Compensation for metabolic alkalosis is demonstrated by hypoventilation by the lungs in an attempt to increase the $Paco_2$ to balance the pH.

Metabolic alkalosis can be caused by either an accumulation of bicarbonate or a loss of hydrogen ions (**Table 26-7**). The most common etiologies include vomiting or gastric suction (loss of chloride-rich fluid), diuresis (secondary to loss of both chloride and potassium), or an excess in mineralocorticoid activity (eg, Cushing syndrome and hyperaldosteronism).[1,2] Another less-common cause of metabolic alkalosis is through ingestion of large amounts of bicarbonate-containing products (eg, antacids).

Table 26-7
Metabolic Alkalosis

Chloride Status	Urine Chloride	Etiology
Chloride sensitive	<10–20 mEq/L	Gastrointestinal Vomiting Nasogastric suctioning Cl^- wasting diarrhea Diuretic therapy Post hypercapnia Cystic fibrosis
Chloride resistant	>20 mEq/L	Adrenal disorders Hyperaldosteronism Cushing disease Exogenous steroids Licorice Bartter syndrome Milk alkali syndrome

The cause of metabolic alkalosis can typically be determined based on the patient's presentation, but a urinary chloride concentration can further classify the disturbance.[1,2,5,9] Chloride-responsive metabolic alkalosis refers to disturbances that are secondary to loss of chloride-rich fluid. Urinary chloride is typically

<20 mEq/L in patients with chloride-responsive disturbances. Metabolic alkalosis secondary to severe hypokalemia or excessive mineralocorticoid activity often presents with urinary chloride concentrations >20 mEq/L.[1,5]

Evaluation

CASE 26-3

QUESTION 1: D.K. is a 62-year-old male with a history of hypertension and systolic heart failure who presented to the emergency department 5 days ago with shortness of breath and signs of volume overload consistent with a heart failure exacerbation thought to be secondary to stopping his loop diuretic regimen of furosemide 80 mg daily. He has been receiving IV furosemide during his hospitalization (doses ranging from 80 to 160 mg once or twice daily) and has been 1 to 2 L net negative each day. On day 5 of his hospital admission, he is experiencing some dizziness and slowed breathing. His laboratory values are:

Na^+: 138 mEq/L
K^+: 2.5 mEq/L
Cl^-: 92 mEq/L
TCO_2: 34 mEq/L
BUN: 28 mg/dL
SCr: 0.9 mg/dL
Glucose: 167 mg/dL
Albumin: 3.9 g/dL
Urine chloride: 15 mEq/L
ABGs: pH 7.49; $Paco_2$ 46 mm Hg; HCO_3^- 33 mmol/L; Pao_2 92 mm Hg
Assess D.K.'s acid–base status.

What are possible etiologies, and what compensatory response (laboratory and physical exam) would you expect?

Use the stepwise approach.

Step 1: Evaluate pH as acidemia or alkalemia—D.K. has an elevated pH >7.45, indicating that DK is alkalemic.

Step 2: Evaluate $Paco_2$ and bicarbonate—An elevated bicarbonate is consistent as the primary cause, and the increased $Paco_2$ can

be attributed to compensation.

Step 3: Identify the dominant acid–base disorder, presence of compensation, and potential for mixed disorder status— Based on the abovementioned information, D.K. has a metabolic alkalosis. Referring to Table 26-3 to assess compensation, we see that D.K. has appropriate respiratory compensation (expected $Paco_2$ ~45.6 mm Hg), indicating there are no secondary respiratory disturbances present. Physical findings, such as dizziness or orthostatic hypotension, may accompany metabolic alkalosis.

Step 4: For metabolic alkalosis, further assess laboratory parameters and the etiology. Determine whether it is chloride sensitive or chloride resistant—D.K. has a metabolic alkalosis with appropriate respiratory compensation. Given D.K.'s acute increase in diuretic dose, significant loss of volume during the hospital admission, and his current electrolytes, it seems likely that his alkalosis is secondary to diuresis. In addition, his urine chloride is <20 mEq/L, indicating a chloride-responsive metabolic alkalosis.[1,5,9] In a "contraction alkalosis," total body HCO_3^- remains relatively constant. However, an increase in serum HCO_3^-, and subsequently pH, is seen due to extracellular fluid contraction.

Treatment

Case 26-3, Question 2: How can D.K.'s acid–base disturbance be treated?

Because we believe D.K. has a metabolic alkalosis secondary to loss of chloride-rich volume, cessation of (or at least slower) diuresis should be attempted. In addition, because the urine chloride is <20 mEq/L, D.K. likely will respond to chloride administration.[5,9–11] Chloride administration should help restore balance to the extracellular fluid and allow for adequate bicarbonate clearance. The form of chloride repletion should be based on the patient's overall volume status. In patients who are hypovolemic, chloride

administration with 0.9% sodium chloride is warranted. In patients who are euvolemic or hypervolemic, or who may not tolerate large volumes of fluid because of renal failure or decreased ejection fraction, use of potassium chloride is indicated.[1,2,30] Other chloride-containing therapeutic options, such as diluted hydrochloric acid and arginine hydrochloride, may be considered as options in certain patients with chloride-responsive metabolic alkalosis. Because both agents contain similar amounts of chloride, dosing can be approximated by the following equation: mEq HCl = 0.5 L/kg × actual body weight (kg) × (observed bicarbonate − 24).[37] Hydrochloric acid has been shown to be relatively safe; however, challenges in operational compounding and administration limit its use to extreme and severe conditions. The administration of hydrochloric acid requires central line access and pharmaceutical compounding in glass containers. Acetazolamide, a carbonic anhydrase inhibitor, decreases the breakdown of HCO_3^- to CO_2 and H_2O, leading to an increase in bicarbonate excretion via the urine.[1,2] Although acetazolamide may decrease serum bicarbonate levels, it likely will not "fix" the metabolic alkalosis.[1,5,9,20] In addition, it may lead to hypokalemia secondary to increased potassium excretion. Patients with chronic obstructive pulmonary disease (COPD) may additionally have more difficulty to expel CO_2, and administration of acetazolamide in these patients is controversial.

RESPIRATORY DISTURBANCES

Respiratory acidosis or alkalosis results from $Paco_2$ retention or enhanced gas exchange.[1,2,5,6] The compensatory response to respiratory disturbances occurs in the kidneys via bicarbonate absorption or excretion. An inverse relationship exists between the $Paco_2$ and pH (as $Paco_2$ increases, the pH will decrease), as seen in Table 26-1.

Respiratory Acidosis

Respiratory acidosis can manifest from hypoventilation or impaired gas exchange of CO_2 (hypercapnia) in the lungs. When the lungs cannot excrete CO_2 effectively, the $Paco_2$ rises. This elevation in $Paco_2$ causes a decrease in pH. Common causes and the management of respiratory acidosis can be found in **Table 26-8**. Generally, causes of respiratory acidosis can be categorized into conditions of airway obstruction, central nervous system (CNS) depression leading to reduction in the respiratory drive, failure of the heart or lungs, and disturbances of the peripheral nerves or skeletal muscles that impair or weaken the diaphragm.[1,5,11]

Table 26-8
Respiratory Acidosis

Mechanism	Pathophysiology	Treatment Modalities
Central nervous system Depression	Central sleep apnea CNS depressant drugs Opiates Benzodiazepines Barbiturates Sedatives Status epilepticus Cerebral vascular accident Tumor	Invasive/noninvasive ventilation Antidotal reversal (eg, naloxone for opioid overdose)
Airway obstruction	Foreign body aspiration Tumor Bronchospasm COPD	Invasive/noninvasive ventilation Steroids Bronchodilators

Mechanism	Pathophysiology	Treatment Modalities
Neuromuscular dysfunction	Guillain–Barré syndrome Amyotrophic lateral sclerosis Myasthenia gravis Brainstem or spinal cord injury Severe hypophosphatemia	Invasive/noninvasive ventilation
Cardiopulmonary disorders	COPD ARDS Pulmonary edema Cystic fibrosis Pulmonary fibrosis Pulmonary embolism Cardiac arrest/circulatory collapse	Invasive/noninvasive ventilation Steroids Antimicrobials Antifibrinolytics/ anticoagulants

ARDS, acute respiratory distress syndrome; CNS, central nervous system; COPD, chronic obstructive pulmonary disease.

Patients who present with acute respiratory acidosis will have an elevated $Paco_2$ and a decline in the pH. The kidneys will begin to retain HCO_3^- as a compensatory mechanism. Compensation will begin 6 to 12 hours after the development of academia, with only modest increases in serum HCO_3^- and full metabolic compensation after 48 to 72 hours.[1,5,12]

Patients with chronic respiratory conditions, such as COPD or neuromuscular dysfunction, may present with stably elevated $Paco_2$; however, the pH will be maintained at a near-normal value because of full metabolic compensation.[38]

EVALUATION

CASE 26-4

Question 1: B.G. is a 69-year-old male who was brought to the emergency department after being found with new altered mental status at home. B.G. has a past medical history of insomnia, anxiety, and chronic pain for which he takes extended-release oxycodone, and he was recently was started on diazepam for back spasms. Upon arrival at the hospital, his vital signs were the following: temperature 99.8 °F (37.67 °C), heart rate 95 beats/minute, blood pressure 100/65 mm Hg, respiratory rate 10 breaths/minute, O2 saturation 90% on 5 L/minute of oxygen via nasal cannula.

The patient is noted to have the following laboratory values:

Na^+: 135 mEq/L
K^+: 4.4 mEq/L
Cl^-: 98 mEq/L
TCO_2: 29 mEq/L
BUN: 20 mg/dL
SCr: 1.25 mg/dL
Glucose: 124 mg/dL
Albumin: 3.5 g/dL

What type of acid–base disturbance is present?

B.G. has a respiratory acidosis. Acidemia is present as the pH < 7.35 (pH is 7.15). Given the Paco2 > 42, with bicarbonate slightly increased, the primary process is respiratory acidosis.

Case 26-4, Question 2: Is this an acute or chronic process?

Acute: $\Delta Paco_2 = 90 - 40 = 50$; $\Delta HCO_3^- = 29 - 24 = 5$

Using the compensation ratios seen in Table 26-3, we can see that this is an acute process. Comparing the change in $Paco_2$ to the change in bicarbonate, we calculate a ratio of 10:1.

Case 26-4, Question 3: What is most likely to contribute significantly to B.G.'s acid–base abnormality?

As seen in Table 26-8, CNS depressant medications can lead to CO_2 retention and respiratory acidosis.[1,2,5,12] The addition of diazepam to B.G.'s chronic pain management can cause respiratory

depression, leading to B.G.'s low respiratory rate and $Paco_2$ accumulation.

TREATMENT

The treatment for respiratory acidosis should focus on identifying and correcting the underlying cause of the patient's decompensation, which is further discussed in Table 26-8.[2,10,11] Supplemental oxygen for patients presenting with hypoxemia may be necessary to maintain tissue oxygenation. In the event of severe or worsening respiratory acidosis, mechanical ventilation may be necessary to reduce the $Paco_2$. Reductions in $Paco_2$ should be made gradually and, in patients with chronic $Paco_2$ elevations, should be reduced to baseline levels.[2,5,10,11] The administration of exogenous bicarbonate therapy (such as sodium bicarbonate) is not recommended, because there is not a total body deficit of bicarbonate.[31,39,40]

EVALUATION

CASE 26-5

QUESTION 1: J.A. is an 87-year-old male who presents to his primary care provider for a routine follow-up. J.A.'s past medical history includes hypertension, hyperlipidemia, type 2 diabetes, and COPD for which he is on home oxygen. J.A. does not endorse any new shortness of breath or changes in sputum production. He does note that he was recently babysitting his grandson who had cold-like symptoms. The patient is noted to have the following laboratory values: temperature 98.7 °F (37.05 °C), heart rate 90 beats/minute, blood pressure 145/90 mm Hg, respiratory rate 16 breaths/minute, O_2 saturation 92% on 2 L/minute of oxygen via nasal cannula. From his previous outpatient pulmonologist appointments, J.A.'s baseline blood gases are:

Na^+: 146 mEq/L
K^+: 4.1 mEq/L
Cl^-: 107 mEq/L
TCO_2: 31 mEq/L
BUN: 16 mg/dL
SCr: 1.2 mg/dL

Baseline ABGs: pH: 7.34; $Paco_2$: 60 mm Hg; Pao_2: 67 mm Hg; HCO_3^- 31 mEq/L

Does J.A. have an acid–base disorder?

Using the stepwise approach, we can see that J.A. has a respiratory acidosis. Acidemia is detected, because the pH is <7.35 (pH 7.34, although relatively normal, is still on the low side of normal). The PCO_2 is elevated, with an increase in bicarbonate as a potential metabolic compensation.

CASE 26-5, QUESTION 2: Is this an acute or a chronic process?

$$\text{Chronic: } \Delta Paco_2 = 60 - 40 = 20;\ \Delta HCO_3^- = 31 - 24 = 7$$
$$\text{Compensation ratio: } \Delta Paco_2 \text{ to } \Delta HCO_3^- = 10{:}3.5$$

Although J.A. has a significantly elevated $Paco_2$, this is an example of a fully compensated chronic respiratory acidosis. Although J.A.'s $Paco_2$ is elevated, the compensation of the kidneys and retention of bicarbonate maintains close to normal pH.

EVALUATION

CASE 26-5, QUESTION 3: Five days later, J.A. presents to the emergency department with cough, shortness of breath, and increased sputum production. A chest x-ray reveals a left lower lobe consolidation, and J.A. has the following vital signs: temperature 101.2 °F (38.44 °C), heart rate 102, and a respiratory rate of 16. J.A. is noted to be more confused and has an O_2 saturation of 87% for which the physician orders a STAT ABG and initiates him on 5 L supplemental oxygen.

ABGs: pH 7.25; $Paco_2$ 75 mm Hg; Pao_2 63 mm Hg; HCO_3^- 33 mEq/L

What type of acid–base disturbance is now present?

J.A. has a respiratory acidosis. Acidosis is present, because the pH is <7.35, and the $Paco_2$ is elevated, with an increase in bicarbonate. As we know from admission and J.A.'s past medical history, his current $Paco_2$ of 75 is elevated from his baseline (60 mm Hg).[38] J.A.'s new blood gas is exhibiting an acute-on-chronic respiratory acidosis, most likely due to a COPD exacerbation based on his chest x-ray and presenting symptoms.

Evaluating his new acidosis on top of his baseline, we can see the acute nature of his respiratory acidosis.

$$\Delta Paco_2 = 75 - 60 = 15; \Delta HCO_3^- = 33 - 31 = 2;$$
$$\Delta Paco_2 \text{ to } \Delta HCO_3^- = 15{:}2$$

As seen in the calculation, J.A.'s "normal" $Paco_2$ of 60 mm Hg and HCO_3^- of 31 mEq/L are elevated as compared to standardly accepted values ($Paco_2$ 35–45 mm Hg and HCO_3^- 22–26 mEq). In patients with chronic acid–base disorders, patient-specific baseline values should be used to evaluate changes in acid–base status, because new homeostasis has been achieved.

Respiratory Alkalosis

Respiratory alkalosis typically results from excessive rate or the depth of respiration leading to increased pulmonary gas exchange and elimination of carbon dioxide. The fall in $Paco_2$ causes a rise in arterial pH. Dyspnea, chest pain, and palpitations are the most common presenting symptoms in patients with respiratory alkalosis.[1,2,11,12,40] Both acute and chronic conditions can lead to a respiratory alkalosis with common causes, as listed in **Table 26-9**. As with respiratory acidosis, the treatment for respiratory alkalosis is the treatment of the underlying cause.[1,6,12]

Table 26-9
Respiratory Alkalosis

Mechanism	Pathophysiology	Treatment Modality
Respiratory rate stimulation	Anxiety Severe pain Sepsis Pregnancy Tumor Salicylate overdose	Rebreathe into a closed system (paper bag) Urinary alkalization or dialysis (salicylate toxicity)
Impaired oxygen extraction or carrying capacity	Pneumonia Pulmonary embolism Congestive heart failure Pulmonary fibrosis High altitude/acute altitude changes Anemias	Supplemental oxygen Invasive/noninvasive ventilation Steroids Thrombolysis Bronchodilators Carbonic anhydrase inhibitors (altitude changes)
Iatrogenic	Excessive mechanical ventilation	Ventilation changes

EVALUATION

CASE 26-6

QUESTION 1: R.W. is a 35-year-old female who presents to the emergency department with severe shortness of breath and cough since the previous night. R.W. has no noted past medical history. She appears to be in respiratory distress, using accessory muscles to breathe. A chest radiograph shows bilateral lower lung infiltrates. Her current vital signs are temperature 101.2 °F (38.44 °C), heart rate 104 beats/minute, blood pressure 110/83, respiratory rate 35 breaths/minute, and O_2 saturation 90% on room air. The patient is noted to have the following laboratory values:

Na^+: 145 mEq/L
K^+: 4.5 mEq/L
Cl^-: 110 mEq/L
TCO_2: 23 mEq/L
BUN: 10 mg/dL
SCr: 0.6 mg/dL
ABGs: pH: 7.54; $Paco_2$: 21 mm Hg; Pao_2: 77 mm Hg; HCO_3^- 19 mEq/L

What type of acid–base disturbance is present?

R.W. has a respiratory alkalosis. Alkalemia is present, because the pH is >7.35 (pH 7.54, and the $Paco_2$ is <38), with bicarbonate slightly decreased. The primary process is respiratory.

Case 26-6, Question 2: What is the most likely cause of R.W.'s acid–base abnormality?

R.W.'s chest x-ray with bilateral infiltrates, severe shortness of breath, and cough are consistent with pneumonia. R.W. also presents with a fever and an elevated white blood cell count, which are consistent with a bacterial infection.

TREATMENT

Case 26-6, Question 3: What is the appropriate treatment for R.W.'s respiratory alkalosis?

Similar to respiratory acidosis, treatment of respiratory alkalosis usually involves correcting the underlying disturbance. Initiation of appropriate antibiotic therapy for a community-acquired pneumonia is indicated in this case. If R.W. were to become hypoxic, supplemental oxygen therapy may be indicated.

Fluid and Electrolyte Disorders

Priscilla P. How and Alan H. Lau

CORE PRINCIPLES		CHAPTER CASES
FLUID AND SODIUM DISORDERS		
1	Plasma osmolality is maintained within normal limits through a delicate balance between water intake and excretion. Antidiuretic hormone (ADH) plays an important role in maintaining fluid balance in the body.	**Case 27-1 (Question 1), Figure 27-1**
2	Signs of volume depletion include orthostatic hypotension, dry mucous membranes, and poor skin turgor. Because water and sodium are inherently linked, the assessment of volume status and selection of replacement fluid require examination of sodium concentration.	**Case 27-2 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
3	Aldosterone is the main regulatory hormone for sodium homeostasis. A patient may have hypotonic, isotonic, or hypertonic hyponatremia depending on the plasma osmolality. Normal serum sodium concentration is 135 to 145 mEq/L.	**Case 27-4 (Question 1) Case 27-5 (Questions 1, 2) Case 27-6 (Question 1) Case 27-7 (Questions 1, 2, 3, 4)**
4	Hypovolemic hypotonic hyponatremia can occur with volume depletion and decreased extracellular fluid. Calculation of sodium deficit will determine how much sodium replacement is required.	**Case 27-5 (Questions 1, 2)**
5	Hypervolemic, hypotonic hyponatremia is caused by a disproportionate accumulation of ingested water relative to sodium. It is also observed in patients with heart failure, liver and kidney failure, and nephrotic syndrome. Management includes sodium and water restriction, as well as the use of diuretics.	**Case 27-6 (Question 1) Case 27-3 (Questions 1, 2)**
6	Syndrome of inappropriate ADH is a common cause of normovolemic hypotonic hyponatremia. Persistent ADH secretion together with water ingestion results in hyponatremia.	**Case 27-7 (Question 1) Case 27-7 (Question 2)**

CORE PRINCIPLES		CHAPTER CASES
7	Neurologic symptoms may be manifested in acute or severe hyponatremia. Low plasma osmolality causes water to move into the brain, resulting in cerebral edema, increased intracranial pressure, and central nervous system symptoms. Rapid or overly aggressive correction of hyponatremia can result in osmotic demyelination.	**Case 27-7 (Questions 1-4)**
POTASSIUM DISORDERS		
1	The sodium–potassium adenosine triphosphatase pump plays a pivotal role in maintaining potassium homeostasis. Normal serum potassium concentration is 3.5 to 5.0 mEq/L. Clinical manifestations of hypokalemia include muscle weakness and electrocardiography (ECG) changes.	**Case 27-8 (Questions 1, 2)**
2	Potassium repletion should be guided by close monitoring of serum potassium. Oral supplementation is usually preferred. Patients who cannot tolerate oral potassium or who have severe/symptomatic hypokalemia can receive intravenous potassium. In general, the rate of potassium infusion administered via a peripheral vein should not exceed 10 mEq/hour to prevent phlebitis.	**Case 27-8 (Question 3)**

CORE PRINCIPLES		CHAPTER CASES
3	Hyperkalemia can be caused by chronic kidney disease and medications that inhibit the renin–angiotensin–aldosterone system. Intravenous calcium is administered to antagonize the cardiac effects (ECG changes and ventricular arrhythmias) of hyperkalemia. Other treatment strategies include the use of insulin and glucose, β_2-agonists, sodium polystyrene sulfonate, patiromer, sodium zirconium cyclosilicate, sodium bicarbonate, and dialysis.	**Case 27-9 (Question 1)** **Case 27-10 (Questions 1, 2), Table 27-3**
CALCIUM DISORDERS		

CORE PRINCIPLES		CHAPTER CASES
1	Normal serum calcium is 8.5 to 10.5 mg/dL (corrected for serum albumin because calcium is protein bound). Hypercalcemia can be caused by dehydration, malignancy, hyperparathyroidism, vitamin D intoxication, sarcoidosis, and other granulomatous diseases. Clinical presentation of hypercalcemia includes signs and symptoms involving the neurologic, cardiovascular, pulmonary, kidney, gastrointestinal, and musculoskeletal systems. First-line treatment for hypercalcemia is hydration and diuresis. Calcitonin and bisphosphonates are alternative agents used in the management of hypercalcemia.	**Case 27-11 (Questions 1–3), Table 27-4**
PHOSPHATE DISORDERS		
1	Hypophosphatemia can develop as a result of impaired intestinal phosphorus absorption, increased kidney elimination, or shift of phosphorus from extracellular to intracellular compartments. Normal serum phosphorus concentration is 2.7 to 4.7 mg/dL.	**Case 27-12 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
2	Clinical effects of hypophosphatemia can involve multiple organ systems and are attributed to impaired cellular energy stores and tissue hypoxia secondary to ATP depletion. Phosphorus supplementation can be administered orally or intravenously, depending on the signs and symptoms, and severity of hypophosphatemia. Kidney function, serum phosphorus, calcium, and magnesium need to be monitored closely. Diarrhea is a common dose-related side effect of oral phosphorus replacement.	**Case 27-12 (Questions 3, 4)**
MAGNESIUM DISORDERS		
1	Magnesium depletion (normal serum magnesium, 1.8–2.4 mEq/L) can result in abnormal function of the neurologic, neuromuscular, and cardiovascular systems. Typical findings include Chvostek and Trousseau signs, muscle fasciculation, tremors, muscle spasticity, convulsions, and, possibly, tetany. Because serum magnesium does not reflect total body stores, symptoms are more important determinants of the urgency and aggressiveness of magnesium replacement.	**Case 27-13 (Questions 1, 2)**

	CORE PRINCIPLES	CHAPTER CASES
2	Oral magnesium replacement is indicated in asymptomatic patients with mild depletion. Urinary excretion of magnesium increases during intravenous replacement. Thus, replenishment of magnesium stores usually takes several days. After intravenous magnesium administration, the patient should be monitored for hypotension, marked suppression of deep tendon reflexes, ECG and respiration changes, as well as hypermagnesemia.	**Case 27-13 (Questions 3, 4)**
3	A common cause of hypermagnesemia is the use of magnesium-containing laxatives and antacids by patients with kidney impairment. Potentially life-threatening complications of severe hypermagnesemia include respiratory paralysis, hypotension, and complete heart block. Intravenous calcium should be administered to antagonize the respiratory and cardiac manifestations of magnesium. Diuretics may be given to patients with good kidney function to enhance urinary magnesium excretion.	**Case 27-14 (Questions 1–3)**

INTRODUCTION

Body Water Compartments and Electrolyte Composition

In newborns, ~75% to 85% of body weight is water. After puberty, the percentage of water per kilogram of weight decreases as the amount of adipose tissue increases with age. Body water constitutes 50% to 60% of the lean body weight (LBW) in adult males but only 45% to 55% in females because of their greater proportion of adipose tissue. The water content per kilogram of body weight further decreases with advanced age. Total body water (TBW) is usually calculated as 0.6 × LBW in males and 0.5 × LBW in females.[1]

Two-thirds of the TBW resides in the cells (intracellular water). The extracellular water can be divided into different compartments—the interstitial fluid (12% LBW) and plasma (5% LBW) are the two major compartments. Other compartments of the extracellular fluid (ECF) include the connective tissues and bone water, the transcellular fluids (eg, glandular secretions), and other fluids in sequestered spaces, such as the cerebrospinal fluid.

The electrolyte composition differs between the intracellular and extracellular compartments. Potassium, magnesium, and phosphate are the major ions in the intracellular compartment, whereas sodium, chloride, and bicarbonate are predominant in the extracellular space. Water travels freely across the cell membranes of most parts of the body. The cell membrane, however, is only selectively permeable to solutes. The impermeable solutes are osmotically active and can exert an osmotic pressure that dictates the distribution of water between fluid compartments. Water moves across the cell membrane from a region of low osmolality to one of high osmolality. Net water movement ceases when osmotic equilibrium occurs. Each fluid compartment contains a major osmotically active solute: potassium in the intracellular space and sodium in the ECF. The volumes of the two compartments reflect the asymmetrically larger number of solute particles or osmoles inside the cells.[1]

The capillary wall separates the interstitial fluid from plasma. Because sodium moves freely across the capillary wall, its

concentration is identical across both sides of the wall. Therefore, no osmotic gradient is generated, and water distribution between these two spaces is not affected. Plasma proteins, which are confined in the vascular space, are the primary osmoles that affect water distribution between the interstitium and the plasma. In contrast, urea, which traverses both the capillary walls and most cell membranes, is osmotically inactive.

Plasma Osmolality

Osmolality is defined as the number of particles per kilogram of water (mOsm/kg). It is determined by the number of particles in solution and not by particle size or valence. Nondissociable solutes, such as glucose and albumin, generate 1 mOsm/mmol of particles; and dissociable salts, such as sodium chloride, liberate two ions in solution to produce 2 mOsm/mmol of salt. The osmolality of body fluid is maintained between 280 and 295 mOsm/kg. Because all body fluid compartments are iso-osmotic, plasma osmolality reflects the osmolality of TBW. Plasma osmolality can be measured by the freezing point depression method, or estimated by Eq. 27-1, which takes into account the osmotic effect of sodium (Na), glucose, and blood urea nitrogen (BUN):

$$P_{osm} = 2(\text{Na})(\text{mmol/L}) + \text{Glucose (mg/dL)}/18 + \text{BUN (mg/dL)}/2.8 \quad \textbf{(Eq. 27-1)}$$

This equation predicts the measured plasma osmolality within 5 to 10 mOsm/kg. Although BUN contributes to the measured osmolality, it is an ineffective osmole because it readily traverses cell membranes and, therefore, does not cause a significant fluid shift within the body. Hence, the effective plasma osmolality (synonymous with tonicity, the portion of total osmolality that has the potential to induce transmembrane water movement) can be estimated by Eq. 27-2:

$$P_{osm} = 2(\text{Na})(\text{mmol/L}) + \text{Glucose (mg/dL)}/18 \quad \textbf{(Eq. 27-2)}$$

An osmolal gap exists when the measured and calculated values differ by >10 mOsm/kg; it signifies the presence of unidentified particles. When the individual solute has been identified, its contribution to the measured osmolality can be estimated by dividing its concentration (mg/dL) by 1/10 of its molecular weight. Calculating the osmolal gap is used to detect the presence of substances, such as ethanol, or antifreeze ingredients (methanol and ethylene glycol) that have high osmolality. Occasionally, the osmolal gap can also result from an artificial decrease in the serum sodium secondary to severe hyperlipidemia or hyperproteinemia.[1]

CASE 27-1

QUESTION 1: J.F., a 31-year-old male, is admitted to the inpatient medicine service for methanol intoxication. Routine laboratory analysis reveals the following:

Serum sodium (Na^+), 145 mEq/L
Serum potassium (K^+), 3.4 mEq/L
BUN, 10 mg/dL
Serum creatinine (SCr), 1.1 mg/dL
Serum glucose, 90 mg/dL
The blood methanol concentration was 108 mg/dL and the measured plasma osmolality was 333 mOsm/kg.

What is J.F.'s calculated osmolality? Are other unidentified osmoles present?

Using Eq. 27-1, J.F.'s total calculated osmolality is

$$P_{osm} = 2(145\ \text{mEq/L}) + 90\ \text{mg/dL}/18 + 10\ \text{mg/dL}/2.8 \quad \text{(Eq. 27-3)}$$
$$= 290 + 5 + 3.6$$
$$= 299\ \text{mOsm/kg}$$

$$\text{Osmolal gap} = 333\ \text{mOsm/kg} - 299\ \text{mOsm/kg} = 34\ \text{mOsm/kg} \quad \text{(Eq. 27-4)}$$

In J.F., the entire osmolal gap calculated in Eq. 27-4 can be accounted for by the presence of the methanol (because 108 mg/dL

of methanol will provide 108/3.2 = 33.7 mOsm/kg). It is unlikely, therefore, that other unmeasured osmoles are present (eg, ethylene glycol, isopropanol, and ethanol). The laboratory determination of osmolality measures the total number of osmotically active particles but not their permeability across the cell membrane. Methanol increases plasma osmolality but not tonicity because the cell membrane is permeable to methanol. Therefore, no net water shift occurs between the intracellular and extracellular compartments.

Tubular Function of Nephron

The kidney plays an important role in maintaining a constant extracellular environment by regulating the excretion of water and various electrolytes. The volume and composition of fluid filtered across the glomerulus are modified as the fluid passes through the tubules of the nephron.[1]

The kidney tubule is composed of a series of segments with heterogeneous structures and functions: the proximal tubule, the medullary and cortical thick ascending limb of the Henle loop, the distal convoluted tubule, and the cortical and medullary collecting duct (**Fig. 27-1**). The mechanism for sodium reabsorption is different for each nephron segment, but it is generally mediated by carrier proteins or channels located on the luminal membrane of the tubule cell. Na^+/K^+-ATPase (sodium–potassium adenosine triphosphatase) actively pumps sodium out of the kidney tubule cell in exchange for potassium in a 3:2 ratio. Hence, the intracellular sodium concentration is kept at a low level. The potassium that is pumped into the cell leaks back out through potassium channels in the membrane, rendering the cell interior electronegative. The low intracellular sodium concentration and a negative intracellular potential produce a favorable gradient for passive sodium entry into the cell. Na^+/K^+-ATPase also indirectly provides the energy for active sodium transport and the reabsorption and secretion of other solutes across the luminal membrane of the kidney tubule. The distal

segments are mainly involved in the reabsorption of sodium and chloride ions and the secretion of hydrogen and potassium ions.

Figure 27-1 Sites of tubule salt and water absorption. Sodium is reabsorbed with inorganic anions, amino acids, and glucose in the proximal tubule against an electrical gradient that is lumen negative. In the distal part of the proximal tubule (pars recta), sodium and water are reabsorbed to a lesser extent and organic acids (hippurate, urate) and urea are secreted into the urine. The electrical potential is lumen positive in the pars recta. Water, but not salt, is removed from tubule fluid in the thin descending limb of the Henle loop; but in the ascending portion, salt is reabsorbed without water, rendering the tubule fluid hyposmotic with respect to the interstitium. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb; the lumen potential is

positive. Sodium is reabsorbed and potassium and hydrogen ions are secreted in the distal tubule and collecting ducts. Water absorption in these segments is regulated by antidiuretic hormone (ADH). The electrical potential is lumen negative in the cortical sections and positive in the medullary segments. Urea is concentrated in the interstitium of the medulla and assists in the generation of maximally concentrated urine. (Used with permission of McGraw Hill LLC from Chonko AM et al. Treatment of edema states. In: Narins RG, ed. *Maxwell & Kleeman's Clinical Disorders of Fluid and Electrolyte Metabolism*. 5th ed. McGraw-Hill, 1994:545; permission conveyed through Copyright Clearance Center, Inc.)

Iso-osmotic reabsorption of the glomerular filtrate occurs in the proximal tubule such that two-thirds of the filtered sodium and water and 90% of the filtered bicarbonate are reabsorbed. The Na^+/H^+ antiporter (exchanger) in the luminal membrane is instrumental in the reabsorption of sodium chloride, sodium bicarbonate, and water. The reabsorption of most nonelectrolyte solutes, such as glucose, amino acids, and phosphates, are coupled to sodium transport.

Both the thick ascending limb of the Henle loop and the distal convoluted tubule serve as the diluting segments of the nephron because they are impermeable to water. Sodium chloride is extracted from the filtrate without water. Sodium transport in both of these segments is flow dependent and varies with the amount of sodium ions delivered from the proximal segments of the nephron. Decreased sodium ions in the tubular fluid will limit sodium transport in the thick ascending limb of the Henle loop and the distal convoluted tubule.

Reabsorption of sodium in the thick ascending limb of the Henle loop accounts for ~25% of the total sodium reabsorption. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb, but the leakage of reabsorbed potassium ions back into the tubular lumen, via potassium channels, makes the tubular lumen electropositive. This electrical gradient promotes the passive reabsorption of cations, such as sodium, calcium, and magnesium, in the distal convoluted

tubules. Because the thick ascending limb of the Henle loop is impermeable to water, it contributes to the interstitial osmolality in the medulla. This high osmolality is key to the reabsorption of water by the medullary portion of the collecting duct under the influence of antidiuretic hormone (ADH), or vasopressin. Therefore, the thick ascending limb of the Henle loop is important for both urinary concentration and dilution.

Because, as noted previously, the distal convoluted tubule is also impermeable to water, the osmolality of the filtrate continues to decline as sodium is being reabsorbed. In the distal convoluted tubule and collecting duct, sodium is reabsorbed in exchange for hydrogen ions and potassium. When sodium ions are reabsorbed, the tubule lumen becomes electronegative, which promotes potassium secretion in the lumen via potassium channels. Aldosterone enhances sodium reabsorption in the collecting duct by increasing the number of opened sodium channels.

The collecting duct is usually impermeable to water. Under the influence of ADH, however, water permeability is increased through an increase in the number of water channels along the luminal membrane. The amount of water reabsorbed depends on the tonicity of the medullary interstitium, which is determined by the sodium reabsorbed in the thick ascending limb of the Henle loop and urea.

Osmoregulation

A reduction in intracellular volume often increases effective plasma osmolality; conversely, decreased effective plasma osmolality is associated with cellular hydration. Water homeostasis is important in the regulation of plasma osmolality, and plasma tonicity is maintained within normal limits through a delicate balance between the rates of water intake and excretion.[1]

The amount of daily water intake includes the volume of water ingested (sensible intake), the water content of ingested food, and the metabolic production of water (insensible intake). To maintain homeostasis, these should be equal to the amount of water excreted

by the kidney and the gastrointestinal (GI) tract referred to as *sensible losses* plus water lost from the skin and respiratory tract known as *insensible losses*.

Changes in plasma tonicity are detected by osmoreceptors in the hypothalamus, which also houses the thirst center and is the site for ADH synthesis. When the plasma tonicity falls <280 mOsm/kg as a result of water ingestion, ADH release is inhibited, water is no longer reabsorbed in the collecting duct, and a large volume of dilute urine is excreted. Conversely, when the osmoreceptors in the hypothalamus sense an increased plasma osmolality, ADH is released to increase water reabsorption. A small volume of concentrated urine is then excreted. The threshold for ADH release is 280 mOsm/kg, and maximal ADH secretion occurs when the plasma osmolality is 295 mOsm/kg. Thus, urine osmolality varies from 50 mOsm/kg in the absence of ADH to 1200 mOsm/kg during maximal ADH release. As predicted, the volume of urine produced depends on the solute load to be excreted, as well as the urine osmolality:

$$\text{Urine volume (L)} = (\text{Solute load (mOsm)}/\text{Urine osmolality (mOsm/kg)}) \times (1/\text{Density of water (kg/L)}) \quad \textbf{(Eq. 27-5)}$$

Therefore, for a typical daily solute load of 600 mOsm:

$$= (600\ \text{mOsm}/50\ \text{mOsm/kg})(1/1\ \text{kg/L}) = 12\ \text{L (No ADH)} \quad \textbf{(Eq. 27-6)}$$

$$= (600\ \text{mOsm}/1200\ \text{mOsm/kg})(1/1\ \text{kg/L}) = 0.5\ \text{L (Max ADH)} \quad \textbf{(Eq. 27-7)}$$

Although the kidney has a remarkable ability to excrete free water, it is not as efficient in conserving water. ADH minimizes further water loss, but it cannot correct water deficits. Therefore, optimal osmoregulation requires increased water intake stimulated by thirst. Both ADH and thirst can be stimulated by nonosmotic stimuli. For

example, volume depletion is such a strong nonosmotic stimulus for ADH release that it can override the response to changes in plasma osmolality. Nausea, pain, and hypoxia are also potent stimuli for ADH secretion.[1]

Volume Regulation

The afferent sensors for the changes in the effective circulating volume are the intrathoracic volume receptors, the baroreceptors in the carotid sinus and aortic arch, and the afferent arteriole in the glomerulus.

When the effective circulating volume is decreased, both the renin– angiotensin–aldosterone and the sympathetic nervous systems are activated. Angiotensin type 2 (AT_2) and norepinephrine enhance sodium reabsorption at the proximal convoluted tubule. In addition, aldosterone stimulates sodium reabsorption at the collecting tubule. The decrease in effective arterial volume also stimulates ADH release, which enhances water reabsorption at the collecting duct. Conversely, after a salt load, the increases in atrial pressure and kidney perfusion pressure suppress the production of renin and, subsequently, AT_2 and aldosterone. The release of atrial natriuretic peptide secondary to increased atrial filling pressure and intrarenal production of urodilators increase urinary excretion of the excess sodium.[2]

Although the kidney can excrete a 20-mL/kg water load in 4 hours, only 50% of the excess sodium is excreted on the first day.[3] Sodium excretion continues to increase until a new steady state is reached after 3 to 4 days when intake equals output. It is important to recognize that osmoregulation and volume regulation occur independently of each other.[2,3] The two homeostatic systems regulate different parameters and possess different sensors and effectors. However, both systems can be activated simultaneously.

DISORDERS IN VOLUME REGULATION

Volume Depletion

CASE 27-2

QUESTION 1: A.B., a 17-year-old female, presented to the emergency department (ED) with anorexia, nausea, vomiting, and generalized weakness for the past 3 days. She denied other medical problems and had not used any medications. On examination, her supine blood pressure (BP) was 105/70 mm Hg, with a pulse of 80 beats/minute. Her standing BP was 85/60 mm Hg, with a pulse of 100 beats/minute, and she felt dizzy when she stood up. Her mucous membranes were dry, but her skin turgor was normal. Her jugular venous pressure was not elevated and peripheral or sacral edema was not present. Laboratory blood tests showed the following:

Na^+, 134 mEq/L
K^+, 3.5 mEq/L
Chloride (Cl^-), 95 mEq/L
Total CO_2, 35 mEq/L
BUN, 18 mg/dL
Creatinine, 0.8 mg/dL
Glucose, 70 mg/dL

Random urinary sodium was 40 mEq/L, potassium was 40 mEq/L, and chloride was <15 mEq/L. The hemoglobin was 14 g/dL, and white cell and platelet counts were normal.

Based on the clinical and laboratory data, what is the most probable explanation for A.B.'s presentation?

The signs and symptoms in A.B. are consistent with volume depletion. The loss of gastric fluid owing to vomiting and decreased oral intake secondary to anorexia led to moderate-to-severe volume depletion. She exhibits orthostatic changes in both her BP (a drop in systolic BP of 20 mm Hg) and pulse (an increase of 20 beats/minute). The dry mucous membranes, the nonelevated jugular vein pressure, and the absence of edema support volume depletion as well, and dizziness on standing indicates extracellular volume depletion. Her hypochloremic metabolic alkalosis was probably

initiated by the loss of acidic gastric contents through vomiting. Her volume depletion increased bicarbonate reabsorption by the kidneys, perpetuating the metabolic alkalosis. The decreased kidney perfusion brought about by volume depletion enhanced proximal tubular reabsorption of urea, resulting in an increased BUN-to-creatinine ratio suggestive of prerenal azotemia. When kidney perfusion is decreased and the renin–angiotensin–aldosterone system is activated, the proximal reabsorption of sodium and chloride is increased. Excretion of the poorly permeable bicarbonate ions, however, results in obligatory urinary sodium loss to maintain luminal electroneutrality. A.B.'s urinary sodium was therefore elevated (40 mEq/L). In this situation, the urinary chloride remained low, and this is a better index of volume status.[3] Both urinary sodium and chloride are elevated, however, in patients using diuretics, in those undergoing osmotic diuresis, and in those with underlying kidney disease or hypoaldosteronism, even in the face of volume depletion. Physical examination should therefore be conducted as part of the volume status assessment. A.B.'s volume depletion increased the concentration of red blood cells, which could explain her slightly elevated hemoglobin concentration of 14 g/dL.

Case 27-2, Question 2: How should A.B.'s volume depletion be managed?

The etiology of A.B.'s vomiting should be sought, and the cause removed. Because the patient is neither hypernatremic nor hyponatremic, 0.9% sodium chloride should be administered via intravenous (IV) infusion to replenish the extracellular volume and improve tissue perfusion. If the patient is hypernatremic (having a greater deficit of water than of solute), 0.45% sodium chloride or dextrose in 5% water (D5W), which contains more free water, should be administered. In contrast, patients with hyponatremic hypovolemia have a greater deficit of solute than of water; 0.9% sodium chloride or hypertonic saline such as 3% sodium chloride should then be given. The amount of volume deficit is often difficult to ascertain. Because A.B. was severely orthostatic, 1 or 2 L of 0.9

% sodium chloride can be given over the course of 2 to 4 hours. The subsequent rate of infusion will depend on A.B.'s response and the prevailing symptoms. The clinician should monitor her body weight, skin turgor, supine and upright BP, jugular venous pressure, urine output, and urine chloride concentration to assess the adequacy of volume repletion. Because the treatment goal is to achieve a positive fluid balance where fluid intake is more than fluid output, the infusion rate should be 50 or 100 mL/hour in excess of the sum of urine output, insensible losses, and other losses, such as emesis and diarrhea (eg, 200–300 mL/hour), until the patient is hemodynamically stable.[4]

Volume Excess

CASE 27-3

Question 1: L.J., a 45-year-old male, presented to the clinic with swollen legs and puffy eyelids. He also noticed that his urine had been foamy recently. On examination, his BP was 180/100 mm Hg, and his pulse was 80 beats/minute. Bilateral periorbital edema and 2+ bilateral pitting edema up to the thigh were noted. On auscultation, his heart was normal, and his lungs had bilateral crackles. His jugular venous pressure was elevated at 10 cm H_2O. Laboratory blood tests revealed the following:

Serum Na^+, 132 mEq/L
K^+, 3.8 mEq/L
Cl^-, 100 mEq/L
Total CO_2, 26 mEq/L
BUN, 40 mg/dL
Creatinine, 2.5 mg/dL
Glucose, 120 mg/dL
Albumin, 2 g/dL
Serum cholesterol, 280 mg/dL,
Triglycerides, 300 mg/dL

The serum transaminases, alkaline phosphatase, and bilirubin were within normal limits. Urinalysis showed the following:

Specific gravity, 1.015
Random urinary sodium, 20 mEq/L
pH, 7.0

Protein, >300 mg/dL
24-hour urinary protein excretion, 6 g
Creatinine clearance (CrCl), 40 mL/minute

Urinalysis also showed oval fat bodies and fatty casts. L.J. was taking no medications and he denied illicit drug use. Hepatitis B serology and human immunodeficiency virus (HIV) antibody test results were negative. The impression was anasarca (total body edema) secondary to nephrotic syndrome.

What is nephrotic syndrome? What could be the cause of L.J.'s volume excess state?

Nephrotic syndrome is characterized by hypoalbuminemia, urine protein excretion >3.5 g/day, hyperlipidemia, lipiduria, and edema.[5] The heavy proteinuria is a result of damage to the selective barrier of the glomerulus. The causes of nephrotic syndrome are multiple and diverse. The causes can be idiopathic (primary glomerular disease) or secondary to chronic systemic diseases (eg, diabetes mellitus, amyloidosis, sickle cell anemia, lupus), cancer (eg, multiple myeloma, Hodgkin disease), infections (eg, HIV, hepatitis B, syphilis, malaria), IV drug abuse, and medications (eg, gold, penicillamine, captopril, nonsteroidal anti-inflammatory drugs [NSAIDs]).

A heavy urinary protein loss results in various extrarenal complications.[6] Hypoalbuminemia reduces plasma oncotic pressure and contributes to the increased hepatic synthesis of both albumin and lipoproteins. This, coupled with the decreased catabolism of lipoproteins, resulted in L.J.'s hyperlipidemia. Urinary loss of inhibitors of coagulation predisposes these patients to thromboembolism.

Specific therapy of nephrotic syndrome ranges from simple removal of the offending medication and treatment of the underlying comorbidities to the use of immunosuppressive agents in specific glomerular diseases.

L.J.'s anasarca results from changes in both capillary hemodynamics and sodium and water retention.[6] The hypoalbuminemia (2 g/dL) and proteinuria (>300 mg/dL) produce an imbalance in the Starling forces across the capillary wall, namely, the hydrostatic and oncotic pressures in the capillary and interstitial compartments. The reduced capillary oncotic pressure favors the

movement of fluid from the vascular space into the interstitium. This leads to contraction of the effective arterial blood volume, which in turn activates humoral, neural, and hemodynamic mechanisms that signal the kidney to retain sodium and water. This underfill hypothesis has been challenged by data, suggesting that hypoalbuminemia plays a minor role in nephrotic edema and the observation that patients with nephrotic syndrome can have increased, normal, or decreased plasma volumes.

A defect in the intrarenal sodium handling mechanism that causes inappropriate sodium retention also contributes to nephrotic edema.[6] According to this overflow hypothesis, proteinuric kidney disease leads to increased sodium reabsorption in the distal nephron. The mechanism is not well defined but may be related to cellular resistance to atrial natriuretic peptide. It is likely that the interaction between the underfill and overflow mechanisms results in the production of nephrotic edema. Patients with severe hypoalbuminemia (ie, serum albumin level <1.5 g/dL), who have a severe reduction in plasma oncotic pressure, are most likely to exhibit evidence of the underfill phenomenon.

CASE 27-3, QUESTION 2: How should L.J.'s volume excess state be managed?

DIURETICS

Usually, loop diuretics are the mainstay of therapy in the management of nephrotic edema.[6] In most of these patients, the edema can be removed safely with rapid diuresis without compromising the systemic circulation, probably because of the rapid refilling of the plasma volume by interstitial fluid. IV diuretics are usually initiated in severe edema. As the edema resolves, the rate of fluid removal and weight loss should be decreased to avoid compromising the effective circulating volume, and IV diuretics may be switched to the oral route. The patient should be monitored for the development of orthostatic hypotension while on diuretic therapy.

Infusions of albumin can expand the plasma volume; however, it is expensive, the relief is temporary, and it should therefore be used

only for resistant edema.[6] In patients who are resistant to the aforementioned measures, extracorporeal fluid removal, namely, ultrafiltration, may be necessary.

In addition, bed rest reduces orthostatic stimulation of the renin–angiotensin–aldosterone and sympathetic systems, thereby favoring the movement of interstitial fluid into the vascular space. The central blood volume is thus increased, and natriuresis and diuresis are facilitated. Prolonged bed rest might, however, predispose these patients who are hypercoagulable to thromboembolism. Similarly, use of support stockings may reduce the stimulation for sodium retention by redistributing blood volume to the central circulation.

L.J. was initially treated with IV furosemide 60 mg twice daily and placed on a low-sodium (50 mEq), low-fat, high–complex carbohydrate diet that consisted of 0.8 g/kg protein of high biologic value with additional protein to match gram-per-gram of urinary protein loss. Fluid was restricted to 1000 mL/day.[7] He had 5 L of diuresis in 2 days, with resolution of respiratory symptoms and a reduction in the anasarca. Parenteral furosemide was discontinued on the fifth day of hospitalization and oral furosemide 120 mg twice daily was started (conversion of IV to oral furosemide is often done based on a 1:2 conversion ratio). After a total weight loss of 24.45 pounds (12 kg), he was discharged with instructions to maintain strict water and dietary sodium intake, as well as daily weight monitoring for further adjustment in his furosemide dose.

SODIUM DISORDERS

Sodium resides almost exclusively in the ECF; the amount of total body sodium, therefore, determines the extracellular volume.[1] Because daily sodium intake varies from 100 to 250 mEq, the body must rely on adjustments in urinary sodium excretion to maintain the extracellular volume and tissue perfusion. The ability of the kidney to retain sodium is so remarkable that a person can survive with a daily sodium intake of as low as 20 to 30 mEq.

Hyponatremia

Serum sodium concentration reflects the ratio of total body sodium to TBW and is not an accurate indicator of total body sodium.

Because the kidney can excrete >12 to 16 L of free water daily, hyponatremia does not occur unless the water intake overwhelms the kidney's ability to excrete free water (eg, psychogenic polydipsia),[1] or free-water excretion is impaired.

Free-water formation requires a normal glomerular filtration rate (GFR), the reabsorption of sodium chloride without water in the thick ascending limb of the Henle loop and the distal convoluting tubule, and the excretion of dilute urine in the absence of ADH (see Fig. 27-1). Therefore, hyponatremia can occur when the kidney's diluting ability is exceeded or impaired owing to volume depletion and nonosmotic stimulation of ADH release or inappropriate stimulation of ADH production.

Although plasma sodium is the primary determinant of plasma tonicity, hyponatremia does not always represent hypotonicity. In patients with severe hyperlipidemia or hyperproteinemia (eg, multiple myeloma), pseudohyponatremia can occur because the increased amounts of lipids and proteins displace plasma water, in which sodium ions dissolve, resulting in a lower concentration of sodium per unit volume of plasma. Normally, water accounts for 93% of the plasma volume, and lipids and proteins make up the rest. The increase in plasma lipid and protein contents expands plasma volume, displaces water, and increases the percentage of solids in plasma, resulting in isotonic hyponatremia. Hyponatremia resulting from severe hyperlipidemia and hyperproteinemia is sometimes also referred to as *pseudohyponatremia*. Another example of isotonic hyponatremia can be found when a large volume of isotonic sodium-free solution is infused (eg, when mannitol irrigant is used during prostate surgery); see **Table 27-1**.

Table 27-1

Clinical Presentation and Treatment of Hyponatremia

Na^+ and H_2O Status	Clinical Presentation/Cause	Treatment
Edematous, Fluid Overload (Hypervolemic, Hypotonic)		
↑ Total body Na^+–↑↑ Total body H_2O	Cirrhosis/HF/nephrotic syndrome: A ↓ in kidney blood flow activates renin–angiotensin system. ↑ Aldosterone leads to ↑ Na^+, and ↑ ADH leads to free H_2O retention. Urine Na^+ is low (0–20 mEq/L) and urine osmolality ↓. Diuretics can induce paradoxical effects on urine Na^+ and osmolality. This form can also occur in patients with renal failure who drink excessive amounts of water. Patients have symptoms of fluid overload (ascites, distended neck veins, edema).	Fluid and Na^+ restriction. Correct underlying disorder (eg, paracentesis for ascites). Diurese cautiously[a]; avoid ↓ ECF and accompanying ↓ tissue perfusion. ↑ BUN may indicate overly rapid diuresis. Conivaptan: Loading dose of 20 mg IV for 30 minutes, followed by 20 mg IV as continuous infusion for 24 hours for an additional 1–3 days; may titrate up to maximal dose of 40 mg/day; maximal duration is 4 days after the loading dose. Dedicated IV line is recommended and site of peripheral IV lines should be changed every 24 hours. Caution if used together with fluid restriction. Tolvaptan: Start 15 mg PO once daily. Dose may be increased at intervals of at least 24 hours to 30 mg PO once daily and then to a maximum of 60 mg PO once daily as needed. Caution if used together with fluid restriction. Initiate therapy in a hospital setting.
Nonedematous Hypovolemic (Hypotonic With Extracellular Fluid Depletion)		

Na^+ and H_2O Status	Clinical Presentation/Cause	Treatment
↓↓ Total body Na^+ ↓ Total body H_2O	Occurs in GI fluid loss (eg, diarrhea) with hypotonic electrolyte-poor fluid replacement, overdiuresis, "third spacing," Addison disease, renal tubular acidosis, osmotic diuresis. Replacement of fluid losses with solute-free fluid predisposes these patients to hyponatremia. Kidneys concentrate urine to conserve fluid (urine Na^+ < 10 mEq/L). Symptoms: nonedematous; ECF depletion (collapsed neck veins, dehydration, orthostasis). Neurologic symptoms (see sections Hyponatremia and Neurologic Manifestations in text).	Discontinue diuretics. Replace fluid and electrolyte (especially K^+) losses. Saline 0.9% preferred unless Na^+ deficit[a] severe, then use 3%–5% saline.
Nonedematous, Normovolemic (Euvolemic, Hypotonic)		
↓ Total body Na^+ ↑ Total body H_2O	SIADH[b]: Hyponatremia, hypo-osmolality, kidney Na^+ wasting (>40 mEq/L), absence of fluid depletion, U_{osm} > P_{osm}, normal kidney and adrenal function. Free H_2O retained while Na^+ lost. *Causes:* (a) ADH production (infectious disease, vascular disease, cerebral neoplasm, cancer of lung, pancreas, duodenum); (b) exogenous ADH administration; (c) drugs; (d) psychogenic polydipsia.	See earlier text for dosing of VRA (conivaptan and tolvaptan) Chronic treatment: Restrict fluids to less than urine loss. Demeclocycline (300–600 mg bid) induces reversible diabetes insipidus. Emergency treatment for unresponsive patients includes furosemide diuresis to achieve negative H_2O balance with careful replacement of Na^+ and K^+ using hypertonic saline solutions.[c]

ADH, antidiuretic hormone; bid, twice daily; BUN, blood urea nitrogen; ECF, extracellular fluid; GI, gastrointestinal; HF, heart failure; IV, intravenous; NS, normal saline (0.9% sodium chloride); PO, orally; SIADH, syndrome of inappropriate antidiuretic hormone; TBW, total body weight; VRA, vasopressin receptor antagonist.

[a]Remove estimated excess free water with intravenous (IV) furosemide (1 mg/kg). Repeat as necessary. Because furosemide generates urine that resembles 0.5% NaCl, urine losses of sodium and potassium must be carefully measured and replaced hourly with hypertonic salt solutions. Correction rate: 1 to 2 mEq Na/hour in symptomatic patients; 0.5 mEq/hour in asymptomatic patients.

[b]Estimate sodium deficit: (mEq) = total body water (TBW) (sodium desired − sodium observed). Rate of sodium and fluid repletion used depends on severity. Mild: replace with normal saline (NS). First one-third for 6 to 12 hours at a rate of <0.5 mEq/L/hour, remaining two-thirds for 24 to 48 hours. Severe (eg, seizures): Use 3% to 5% saline, rate gauged by patient's ability to tolerate sodium and volume load. Monitor central nervous system function, skin turgor, blood pressure (BP), urine sodium, signs of sodium or water overload, especially in patients with cardiovascular, kidney, and pulmonary disease.

[c]Total body water (TBW) = 0.6 L/kg × weight in kg (for males) and 0.5 L/kg × weight in kg (for females).

TBW excess = TBW − [TBW (observed serum sodium)/(desired serum sodium)].

Neurologic Manifestations

As the plasma osmolality declines, the osmotic gradient created across the blood–brain barrier favors the movement of water into the brain and other cells. Water movement from the cerebrospinal fluid into the cerebral interstitium results in cerebral edema. Brain swelling is limited by the meninges and cranium, however, giving rise to increased intracranial pressure and neurologic symptoms. The degree of cerebral overhydration and the rapidity of its development appear to correlate with the severity of symptoms.

When hyponatremia develops in <2 to 3 days or the rate of decline in serum sodium is >0.5 mEq/L/hour, the situation is regarded as acute.[8,9] The patient often becomes symptomatic when serum sodium concentration falls to 125 mEq/L; early presentation include nausea, vomiting, and malaise.[8,9] Severe symptoms occur more commonly when the serum sodium falls to <120 mEq/L and the rate of decline is >0.5 mEq/L/hour. The patient may present with headache, tremors, incoordination, delirium, lethargy, and obtundation. As the serum sodium drops <110 to 115 mEq/L, seizure and coma may result.[9] On occasion, severe brain edema leads to

transtentorial herniation and, eventually, death. Females, especially those who are premenopausal, apparently are more susceptible to the development of severe neurologic symptoms and irreversible neurologic damage than are males.[10]

In contrast to acute hyponatremia, patients who are chronically hyponatremic are usually asymptomatic. If present, symptoms are usually vague and nonspecific and tend to occur at lower serum sodium concentrations than do those associated with symptomatic acute hyponatremia.[9] The patient may experience anorexia, nausea, vomiting, muscle weakness, and cramps. Irritability, hostility, confusion, and personality changes may also be seen. At extremely low sodium levels, stupor and, rarely, seizures have been reported.

Brain Adaptation to Hyponatremia

The difference in symptoms between acute and chronic hyponatremia is related to cerebral adaptation to hypotonicity.[8,9] Two adaptive mechanisms are important in minimizing cerebral edema. First, cerebral overhydration increases the hydrostatic pressure in the cerebral interstitium, which results in the movement of fluid from the cerebral interstitial space to the cerebrospinal fluid. Second, the extrusion of intracellular solutes reduces cellular osmolality, which in turn enhances water movement out of the cells. Sodium and potassium ions are the initial solutes extruded, followed over a period of hours to days by osmolytes such as inositol, glutamine, glutamate, and taurine.[11] Therefore, when the serum sodium concentration falls faster than the onset of brain osmotic adaptation processes, serious and permanent neurologic damage can occur.[8,9,11] On the other hand, when hyponatremia develops over the course of 2 to 3 days, symptoms are not usually seen unless the serum sodium concentration is reduced markedly.

It is often difficult to determine the acuity and chronicity of hyponatremia. Unless an obvious cause for acute hyponatremia is found, assume that the condition is chronic. A rapid decline in serum sodium concentration usually suggests that hypotonic fluid was

administered to a patient with a condition that overwhelms or impairs water excretion. These conditions include psychogenic polydipsia[12]; postoperative hyponatremia[10]; postprostatectomy syndrome[13]; and administration of thiazide diuretics,[14] parenteral cyclophosphamide,[15] oxytocin,[16] and arginine vasopressin (AVP) or its analogs.[17]

CASE 27-4

QUESTION 1: T.T., a 63-year-old male with kidney failure secondary to diabetic kidney disease, is receiving chronic ambulatory peritoneal dialysis. Because of dietary and fluid noncompliance, T.T. reported shortness of breath (SOB), and his dialysis prescription was adjusted to include six cycles of 2.5% peritoneal dialysis solutions daily. Today, his blood laboratory values are as follows:

Na^+, 128 mEq/L
K^+, 4 mEq/L
Cl^-, 98 mEq/L
Total CO_2, 24 mM
BUN, 50 mg/dL
Creatinine, 6 mg/dL
Glucose, 600 mg/dL
Evaluate T.T.'s plasma osmolality.

What is T.T.'s plasma osmolality?

T.T.'s effective plasma osmolality is calculated to be 289 mOsm/L, according to Eq. 27-1, of which 33 mOsm/L is contributed by hyperglycemia. The slow utilization of glucose, because of the lack of insulin, causes water to move from the intracellular compartment into the plasma space because of the increased tonicity, thereby lowering the plasma sodium concentration.[4] Despite the lowered plasma sodium concentration, the plasma osmolality is normal because of hyperglycemia. Hence, no symptoms attributable to hypo-osmolality are observed. Indeed, when serum glucose is normalized with insulin and hydration, the serum sodium level will increase to ~136 mEq/L. For each 100-mg/dL increment in serum glucose, serum sodium decreases by 1.3 to 1.6 mEq/L.[4]

Hypotonic Hyponatremia With Decreased Extracellular Fluid

CASE 27-5

Question 1: Q.B., a 30-year-old male athlete who has had multiple bouts of diarrhea for the past several days, has been drinking a sports drink to keep himself from getting dehydrated. His vital signs include supine BP, 145/80 mm Hg, and pulse, 70 beats/minute; standing BP, 128/68 mm Hg, and pulse, 90 beats/minute. Respiratory rate (RR) is 12 breaths/minute, and he is afebrile. His skin turgor is mildly decreased, and laboratory blood data are the following:

Na^+, 128 mEq/L
K^+, 3.0 mEq/L
Cl^-, 100 mEq/L
Total CO_2, 17 mEq/L
BUN, 27 mg/dL
Creatinine, 1.2 mg/dL

Urinary sodium and chloride were both <10 mEq/L. Assess Q.B.'s electrolyte and fluid status.

What is the etiology of Q.B.'s hyponatremia?

Q.B. has true hypotonic hyponatremia with ECF depletion, suggesting that his total body sodium deficit is greater than that of TBW. His poor skin turgor, orthostasis, prerenal azotemia, and low urinary sodium are consistent with volume depletion. The urinary sodium concentration helps distinguish between kidney and non-kidney losses that result in sodium and water deficits. When the plasma volume is depleted, the urinary sodium concentration is <10 mEq/L, suggesting appropriate sodium conservation. This is usually seen in patients such as Q.B. with GI fluid loss as in vomiting, diarrhea, or profuse sweating.

Other causes of hypotonic hyponatremia are less likely in Q.B. They include surreptitious cathartic abuse and "third spacing," or accumulation of ECF in the abdominal cavity during acute pancreatitis, ileus, or pseudomembranous colitis.[4] If the urinary sodium is <20 mEq/L in the face of volume depletion, salt wastage should be considered.[4] The potential causes of this latter problem

include diuretic use,[14,18] adrenal insufficiency,[18] and salt-wasting nephropathy[12] (eg, chronic interstitial nephritis, medullary cystic disease, polycystic kidney disease, obstructive uropathy, and cisplatin toxicity).[18] In patients with kidney insufficiency, neither the urinary sodium nor chloride concentration is a reliable index of volume status.[3]

Volume depletion leads to increased reabsorption of sodium and water in the proximal tubule and, thus, decreased sodium delivery to the diluting segments for free-water formation.[4] Decreased effective arterial volume is also a potent nonosmotic stimulus for ADH release. These factors combine to dampen the ability of the kidney to form dilute urine and result in high urine osmolality despite a low serum sodium concentration. Although the fluid lost in diarrhea is hypotonic, it is the replacement of fluid lost with an even more hypotonic fluid such as the sports drink or tap water that causes hyponatremia in patients such as Q.B.

Q.B.'s diarrhea probably caused loss of potassium and bicarbonate through the GI tract, resulting in hypokalemia and hyperchloremic metabolic acidosis. The potassium depletion can sensitize ADH secretion in response to hypovolemic stimuli, and the hypokalemia can also lead to hyponatremia. The cellular efflux of potassium causes cellular uptake of sodium, further reducing the serum sodium concentration.

Case 27-5, Question 2: How should Q.B.'s hyponatremia be treated?

The treatment of hypovolemic hyponatremia involves sodium replacement to correct the deficit. The sodium deficit can be estimated by the following formula:

$$\text{Na deficit} = \text{TBW} \times (\text{Desired} - \text{Current Na concentration})$$
$$= 0.6\frac{\text{L}}{\text{kg}} \times 70\ \text{kg} \times (140 - 125\ \text{mEq/L})$$
$$= 630\ \text{mEq}$$

(Eq. 27-8)

Recall that TBW = 0.6 L/kg × weight in kg for males and 0.5 L/kg × weight in kg for females.

Approximately one-third of the deficit can be replaced over the course of the first 12 hours at a rate of <0.5 mEq/L/hour. The remaining amounts can be administered over the course of the next several days.

The use of isotonic sodium chloride solution is ideal for the treatment of hyponatremia associated with volume depletion. As kidney perfusion is restored, free water will be excreted with appropriate retention of sodium. Because Q.B. has only mild volume depletion, oral rehydration salts may also be considered. Oral rehydration salts contain a mixture of electrolytes (salts) and carbohydrates (in the form of glucose) and are ideal for the management of persistent fluid loss in the outpatient setting. Glucose not only provides calories but also promotes the intestinal absorption of ingested sodium.

When hypokalemia occurs concurrently with hyponatremia, potassium replacement should be given to correct hypokalemia because this will help correct and reverse the accompanying hyponatremia. When this happens, the serum sodium concentration may rise faster than expected because as tissue perfusion is restored, sodium delivery to the distal tubules will increase and ADH secretion will be suppressed appropriately. In the absence of ADH, increased free-water excretion will improve the serum sodium concentration faster than is initially estimated.

In patients with chronic kidney salt wasting resulting in hyponatremia, the ongoing daily sodium loss should also be taken into consideration when estimating the amount of replacement.

Hypervolemic Hypotonic Hyponatremia

CASE 27-6

Question 1: T.W., a 55-year-old male with a longstanding history of alcoholic liver cirrhosis, is admitted to the hospital for worsening SOB. His medical history includes portal hypertension, esophageal varices, and noncompliance with dietary restriction and medications. His BP is 120/60 mm Hg; pulse, 100 beats/minute; and RR, 20 breaths/minute. He is afebrile. Physical examination reveals a jaundiced male in respiratory distress. His jugular vein is flat and lung examination reveals bilateral basal rales. Abdominal examination shows tense ascites with hepatomegaly and spider angiomas (telangiectasias resembling a spider). He has 1+ pedal edema bilaterally. Laboratory data on admission are as follows:

Serum Na^+, 127 mEq/L
K^+, 3.4 mEq/L
Cl^-, 95 mEq/L
Total CO_2, 24 mEq/L
BUN, 10 mg/dL
SCr, 1.2 mg/dL
Albumin, 2.5 g/dL
Urine Na, <10 mEq/L
Urine osmolality, 380 mOsm/L

Identify the possible causes of hyponatremia in T.W. and discuss its pathophysiology.

How should he be treated?

T.W. had no history of vomiting or diarrhea and had stopped using diuretics before admission. The physical findings of ascites and bilateral edema are not consistent with volume depletion but indicate a sodium- excess state. Both sodium and water retention occur, but the disproportionate accumulation of ingested water relative to sodium leads to hyponatremia.

Patients with cirrhosis who are susceptible to developing hyponatremia have a decreased effective arterial blood volume.[19,20] The low urinary sodium concentration suggests that the effective arterial blood volume was decreased. The high urinary osmolality in the face of hypotonic hyponatremia suggests, however, that the

release of ADH has been stimulated, impairing free-water excretion. Peripheral vasodilation causes decreases in systemic arterial BP despite a normal-to-high cardiac output. This, along with splanchnic venous pooling and decreased oncotic pressure secondary to hypoalbuminemia, decreases kidney perfusion in patients with cirrhosis, such as T.W.[19] Decreased kidney perfusion activates the renin–angiotensin–aldosterone system, the sympathetic nervous system, and the release of ADH. Reabsorption of sodium and water in the proximal tubules is enhanced, diminishing sodium and water delivery to the distal segments of the nephron. The diluting capacity of the kidney is thus impaired. Increased secretion of ADH also promotes free-water reabsorption at the collecting tubule and contributes to the hyperosmolality of urine and hyponatremia. Hypervolemic hyponatremia is also seen in patients with heart failure (HF) and nephrotic syndrome and in patients with chronic kidney disease who drink excessive amounts of water[4] (see Chapter 14, Heart Failure). As the GFR decreases, distal delivery of sodium is reduced and the ability to generate free water is impaired. In addition, the capacity to conserve sodium is impaired in these patients.[3]

Most patients who are edematous and hyponatremic are asymptomatic, but the degree of hyponatremia probably reflects the severity of the underlying disease.[19,20] Unless an acute decrease in serum sodium occurs, rapid therapeutic correction is not warranted.[19,20] Water restriction, the mainstay of therapy, is determined by the degree of hyponatremia and the severity of symptoms. Sodium restriction and judicious use of diuretics may help reduce the edematous state, but the patient must be monitored closely to avoid prerenal azotemia, which suggests overaggressive diuresis. Furthermore, diuretics can induce or worsen hyponatremia and volume depletion by impairing the diluting capacity of the kidney.[19,20]

T.W. had abdominal paracentesis to relieve respiratory discomfort with no sequelae. He was then prescribed a 1000-mg sodium diet, and water was restricted to 500 mL/day. Diuretic therapy was resumed.

CASE 27-7

QUESTION 1: C.C., a 50-year-old male who was diagnosed recently with small-cell lung carcinoma, was brought to the ED by his family because he had become progressively lethargic and stuporous during the past week. Laboratory data revealed the following:

Serum Na^+, 110 mEq/L
K^+, 3.6 mEq/L
Cl^-, 78 mEq/L
Total CO_2, 22 mEq/L
BUN, 10 mg/dL
SCr, 0.9 mg/dL
Glucose, 90 mg/dL
Serum osmolality, 230 mOsm/kg
Urine osmolality, 616 mOsm/kg
Urine Na, 60 mEq/L

Arterial blood gas (ABG) examination at room air showed pH, 7.38; Pa_{CO_2}, 38 mm Hg; and Pa_{O_2}, 80 mm Hg. On physical examination, C.C. was normotensive, appeared to be euvolemic, and had no edema detected. Review of his medical records showed normal adrenal and thyroid function. C.C. was currently not using any medications. On admission to the ward, C.C. weighed 132.28 pounds (60 kg) and was given 1 L of 0.9 % sodium chloride (normal saline), after which his serum sodium concentration was 108 mEq/L. Identify the cause of hyponatremia in C.C.

What is its pathophysiology?

Euvolemic Hypotonic Hyponatremia

In a patient with hypotonic hyponatremia with a volume status that is apparently normal, the differential diagnosis includes hypothyroidism, cortisol deficiency, a reset osmostat, psychogenic polydipsia, and the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, which is a diagnosis of exclusion.[4] C.C.'s normal thyroid and adrenal function tests exclude hypothyroidism and cortisol insufficiency as causes of his hyponatremia. The inappropriately elevated urine osmolality (>100 mOsm/kg) is inconsistent with psychogenic polydipsia or a reset osmostat, because free-water excretion is usually not impaired in these disorders. These findings, in addition to a urine sodium concentration

>40 mEq/L and a normal acid–base and potassium balance, are consistent with SIADH.

In SIADH, the ADH secretion is considered inappropriate because of its persistence in the absence of appropriate osmotic and hemodynamic stimuli. Water ingestion is essential to the development of hyponatremia in SIADH because persistent ADH activity impairs water excretion, resulting in the expansion of body fluids and hypotonic hyponatremia. Edema rarely is apparent because only one-third of the retained water resides in the extracellular space and the sodium homeostatic mechanisms are intact. The ECF expansion activates volume receptors and results in natriuresis. At steady state, urinary sodium excretion reflects sodium intake and is usually >40 mEq/L, as in C.C.'s case. Nonetheless, if sodium intake is reduced severely, the urinary sodium concentration may become <40 mEq/L.

The causes of SIADH are diverse and are shown in Table 27-1. Drug-induced SIADH may occur in patients taking certain medications. These include selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine; antiepileptics, such as phenytoin, carbamazepine, and oxcarbazepine; chlorpropamide; indomethacin; diuretics; and clofibrate.[4,21] Mechanisms for drug-induced SIADH include ADH-like action on the collecting tubule, central stimulation of ADH release, and potentiation of the ADH effect.[21]

The most likely cause of C.C.'s SIADH is his small-cell lung carcinoma that results in ADH production.

Case 27-7, Question 2: Why was C.C.'s serum sodium concentration lower after the 0.9% sodium chloride infusion?

Isotonic sodium chloride solution contains 154 mEq/L each of sodium and chloride ions, or 308 mOsm/L. Initially, it will increase the plasma sodium concentration because its osmolality is higher than that of C.C.'s. C.C., however, has a relatively fixed urine osmolality of 616 mOsm/kg owing to persistent ADH activity; thus, he must excrete an osmolar load of 616 mOsm in a volume of 1000 mL of

urine at steady state. Because a total of 1 L of fluid containing 308 mOsm was administered, all the solutes were excreted in 500 mL of urine output, and 500 mL of free water was retained to cause a further dilution of sodium and a reduction in serum sodium concentration.

Rate of Correction of Hyponatremia

CASE 27-7, QUESTION 3: How should C.C.'s hyponatremia be managed?

C.C.'s symptoms appear to have developed over the course of 7 days and are consistent with chronic hyponatremia. C.C.'s water excess should be calculated to estimate the amount of water that should be removed to achieve the desired sodium concentration.

$$\text{Water excess} = \text{TBW} - \text{TBW (Observed serum Na/Desired serum Na)} = 36\ \text{L} - 36\ \text{L}\ (110\ \text{mEq/L}/120\ \text{mEq/L}) = 3.0\ \text{L} \quad \textbf{(Eq. 27-9)}$$

where

$$\text{TBW} = 0.6\ \text{L/kg} \times 60\ \text{kg} = 36\ \text{L} \quad \textbf{(Eq. 27-10)}$$

The treatment of hyponatremia has been controversial. Severe hyponatremia is associated with high rates of morbidity and mortality, but its treatment can also result in morbidity. The rate of correction has been implicated as the main cause of complications.[4,22–25]

It takes time for the brain to lose osmolytes to reduce cerebral swelling during hyponatremia; conversely, the rate of reaccumulation of these osmolytes must keep pace with the rise in serum sodium concentration to avoid brain dehydration and damage. Indeed, rapid correction of hyponatremia can cause a constellation of neurologic findings known as *osmotic demyelination syndrome (ODS)*. Clinical manifestations usually are delayed and occur 1 day to several days after the treatment has been started. Neurologic findings include

transient behavioral changes, seizures, akinetic mutism in mild cases, and features of a pontine disorder in severe cases (pseudobulbar palsy, quadriparesis, and coma). In some patients, the damage is irreversible, and central pontine myelinolysis can be documented in fatal cases. Patients at greatest risk for osmotic demyelination are those with severe hyponatremia lasting >2 days and those in whom the rate of correction of hyponatremia is >12 mEq/L in any 24-hour period.[4,22–25] Hypokalemia, which was found in about 90% of patients with ODS associated with rapid hyponatremia correction, has been suspected as a predisposing factor in the development of ODS.[26] This is because correction of hypokalemia often increases serum sodium concentration; and if clinicians do not take this into consideration when determining the rate and amount of sodium repletion, overcorrection may occur, resulting in ODS. The increase in serum sodium concentration from potassium repletion alone thus needs to be factored in when treating hyponatremia.

Retrospective reviews suggest that acute hyponatremia can be treated safely at a rate of 1 mEq/L/hour initially until the serum sodium concentration reaches 120 mEq/L. Thereafter, the rate of correction should be reduced to ≤0.5 mEq/L/hour, such that an increment in sodium concentration does not exceed 12 mEq/L in the first 24 hours.[4] Although limited, more recently available literature also suggests that an increase in serum sodium of 4 to 6 mEq/L in 1 to 2 hours is adequate to reverse serious complications associated with acute hyponatremia.[4,27] Slow correction is indicated for severe chronic hyponatremia. No neurologic complications were seen in patients with severe hyponatremia when the average rate of correction to serum sodium was <0.55 mEq/L/hour or when the increase in serum sodium was <12 mEq/L in 24 hours or <18 mEq/L in 48 hours. For patients at high risk for developing ODS such as patients with chronic hyponatremia or quickly rising serum sodium, a slower correction in serum sodium of 4 to 6 mEq/L in 24 hours is recommended.[22]

C.C.'s symptoms appear to have developed over the course of 7 days and are consistent with chronic hyponatremia. Thus, his serum sodium concentration should be raised to ~120 mEq/L at a

correction rate of ~0.5 mEq/L/hour, using 3% sodium chloride and furosemide. Serum sodium concentrations should be monitored closely because the equation for calculating water excess does not take into account insensible loss, which can increase the rate of sodium correction.[28]

The use of normal saline is not suitable for C.C. because he excretes salt normally (urine sodium, 60 mEq/L). C.C.'s sodium deficit is as follows:

$$(0.6\ \mathrm{L/kg})(60\ \mathrm{kg})(120 - 110\ \mathrm{mEq/L}) = 360\ \mathrm{mEq} \quad \textbf{(Eq. 27-11)}$$

Because 1 L of 3% sodium chloride solution contains 513 mEq of sodium, ~700 mL of 3% sodium solution, which contains 360 mEq of sodium, will be required to correct the sodium deficit. The recommended serum sodium concentration correction rate is 0.5 mEq/L/hour; therefore, a minimum of 20 hours will be needed to raise the serum sodium concentration by 10 mEq/L (from 110 to 120 mEq/L). The amount of sodium replacement to safely increase the serum sodium concentration can be determined by the product of the rate of replacement (0.5 mEq/L/hour) and TBW (36 L, Eq. 27-10)—that is, 18 mEq/hour. The maximal rate of infusion of 3% saline, which contains 0.513 mEq/mL of sodium, is therefore 35 mL/hour (18 mEq/hour)/(0.513 mEq/mL). A rate of 30 mL/hour, therefore, is appropriate to safely replace C.C.'s sodium deficit.

Although current guidelines on the management of severe symptomatic hyponatremia recommend administering 3% sodium chloride as a small, fixed bolus rather than as a continuous infusion, there have been few good-quality comparative trials studying the safety and efficacy between these two methods of administration. However, a recently published randomized controlled trial comparing rapid intermittent bolus versus slow continuous infusion therapy with hypertonic saline demonstrated that both methods were effective and safe, with similar risk in overcorrection.[28] However, rapid intermittent bolus administration was found to have a lower incidence

of relowering treatment and thus deemed to be the preferred way of treating symptomatic hyponatremia.

Because calculations for water excess and sodium deficits are only approximations, the patient's serum osmolality, serum sodium, and clinical response must be monitored closely, such as every 4 to 6 hours initially and daily afterward, until the serum sodium concentration has stabilized.[29] In addition, urinary losses can be replaced with 3% sodium chloride solution and appropriate amounts of potassium.

When treating hyponatremia, patients should also be monitored closely for excessive free-water losses from diuresis. Desmopressin has been shown to be effective in minimizing urinary free-water losses and avoiding rapid autocorrection of serum sodium concentration during the correction of hyponatremia.[30]

Management of the Syndrome of Inappropriate Antidiuretic Hormone Secretion

Case 27-7, Question 4: How should C.C.'s SIADH be managed long term?

SIADH is usually transient if the underlying cause can be removed. Chronic SIADH can occur, however, as illustrated by C.C. Water restriction sufficient to create a negative water balance is the primary therapy and should be attempted first.[22] In general, all fluids, not just water, should be included in the restriction. Salt intake, however, should not be reduced or solute depletion can occur. The extent of fluid restriction depends on urine output, the amount of insensible water loss, and urine osmolality. For a given amount of solute excretion, patients with a high urine osmolality require a smaller volume of urine (ie, more water retained) than those with a lower urine osmolality (ie, less water retained). Hence, more stringent water restriction is required in patients with a high urine osmolality. Commonly, several days of restriction are needed before a significant increase in plasma osmolality is observed.

When fluid restriction fails to reverse the hypo-osmolar state or when the patient is unwilling or unable to comply with the severe fluid restriction, urea, vasopressin receptor antagonists (VRAs), and other drugs that antagonize the effect of ADH can be used.[22] These include loop diuretics and demeclocycline. Furosemide (20–40 mg/day) reduces urine osmolality by blocking the concentrating ability of the kidney. Demeclocycline directly impairs the response to ADH at the collecting tubule, inducing nephrogenic diabetes insipidus, and may be used at a dose of 300 to 600 mg twice daily. Its effect on water excretion is delayed for a few days, and it dissipates over a similar period of time after the drug is stopped. Nephrotoxicity has been reported after its use in patients with cirrhosis.[31] Limited data suggest that phenytoin may inhibit ADH secretion, but its questionable effectiveness and toxicity limit its use in clinical practice.[32] Urea can correct hypo-osmolality by increasing solute-free water excretion and reducing urinary sodium excretion.[33] It has been used effectively, at 30 to 60 g/day, both short term and long term, to reduce the need for fluid restriction. For oral administration, 30 g of urea crystals can be dissolved in 10 mL of aluminum–magnesium antacid and 100 mL of water. Orange juice or other strongly flavored liquids can be used to improve palatability.

VASOPRESSIN RECEPTOR ANTAGONISTS

Nonpeptide VRAs, also known as the “vaptans” or “aquaretic agents,” constitute a class of agents used for the treatment of hyponatremia. AVP, a neuropeptide hormone, plays an important role in maintaining serum osmolality, as well as circulatory and sodium homeostasis.[34,35] AVP exerts its physiologic effects by acting on V1A, V1B, and V2 receptors, causing effects such as vasoconstriction,[36,37] corticotropin release,[38] and water excretion,[39] respectively. V2 receptors are located in the kidney collecting tubules and mediate the antidiuretic effects of AVP. Antagonism of the V2 receptors results in aquaresis, which is a unique solute-free and electrolyte-sparing (sodium and potassium) water excretion process in the kidneys. Because circulating levels of AVP are elevated in

SIADH, cirrhosis, and HF, VRA can be beneficial in the management of hyponatremia associated with these conditions.

Conivaptan, a mixed V1A and V2 receptor antagonist, was the first VRA approved by the U.S. Food and Drug Administration (FDA) for the treatment of euvolemic and hypervolemic hyponatremia in hospitalized patients.[40] Randomized, double-blind, placebo-controlled trials demonstrated its efficacy in increasing serum sodium concentrations in patients with euvolemic and hypervolemic hyponatremia associated with SIADH and HF, respectively.[40,41] It is administered as an IV infusion and its use is restricted to a short-term (4 days) inpatient use only. Close monitoring of serum sodium concentration is necessary to prevent overly rapid correction of hyponatremia and central pontine myelinolysis that may ensue. Because conivaptan is a potent inhibitor of the cytochrome P450 3A4 (CYP3A4) enzyme, drug interactions with medications that undergo CYP3A4-mediated metabolism are possible.[34] There are also concerns with conivaptan's effects on antagonizing the V1 receptors, which can result in hypotension and splanchnic vasodilation.[22]

In addition, patients may experience infusion site reactions with conivaptan caused by the organic solvent, polypropylene glycol.

Tolvaptan, a selective oral VRA, was approved by the FDA in 2009 for the treatment of hypervolemic and euvolemic hyponatremia in patients with HF, cirrhosis, and SIADH. Because of its selectivity for the V2 receptor, tolvaptan increases urinary excretion of free water (aquaresis) and has less of a BP-lowering effect. As such, it may be more suitable for use in patients with low to normal BP, such as those with HF or cirrhosis. Tolvaptan has been shown to increase serum sodium concentration significantly and correct hyponatremia in patients with SIADH, chronic HF, or cirrhosis.[42] It has also been studied extensively in chronic HF where improvement in signs and symptoms such as reduction of edema and weight, as well as normalization of serum sodium concentrations, were shown.[43,44] However, the use of tolvaptan in HF had no effect on long-term cardiovascular mortality or hospitalization for HF.[45] Tolvaptan is also approved for use in patients with autosomal dominant polycystic

kidney disease (ADPKD), at higher doses than that used in hyponatremia.[46,47] Hepatic injury was noted in some patients in earlier trials of tolvaptan in ADPKD, thus resulting in the release of a safety announcement by the FDA to limit tolvaptan's use to no more than 30 days for the treatment of hyponatremia and the removal of the indication for use in patients with cirrhosis.[48] It should not be used also in patients with underlying hepatic disease.

Common adverse effects of VRAs include thirst, dry mouth, polyuria, and BP reduction. Aquaretics increase thirst by increasing blood tonicity and urine volume; orthostatic hypotension has been reported.[35,49] These agents are thus contraindicated in hypovolemic hyponatremia. The risk of excessive correction of hyponatremia and the resultant neurologic complications from osmotic demyelination exists with VRAs, especially when used in combination with fluid restriction. These agents should therefore be initiated in the inpatient setting at the lowest possible dose and titrated slowly, with close monitoring of serum sodium concentrations and volume status. In addition, the VRAs are substrates and inhibitors of the CYP3A4 enzyme. As a result, there is a potential for clinically significant drug interactions, particularly with concomitant administration of moderate or strong CYP3A4 inducers or inhibitors.

The VRAs should be used in patients with hyponatremia who are refractory to or cannot take other therapies. Not only have they been shown to maintain normal serum sodium concentrations both in the short and long term but their aquaretic effect could also reduce or eliminate the need for fluid restriction normally required of patients.[42,50] The effectiveness of VRAs to correct serum sodium concentration in euvolemic and hypervolemic hyponatremia has been shown. However, their long-term safety with chronic use and their potential benefits on morbidity and mortality still need to be assessed. The high cost of using these agents remains a major barrier to routine clinical use.

Hypernatremia

Hypernatremia can occur under the following conditions: (a) normal total body sodium with pure water loss, (b) low total body sodium with hypotonic fluid loss, and (c) high total body sodium as a result of pure salt gain.[22,51] Therefore, as in hyponatremia, it is important to assess the volume status of the ECF when evaluating hypernatremia.

Pure water loss can result from the inability of the kidney to conserve water (diabetes insipidus) or from extrarenal water loss through the respiratory tract or the skin. Usually, pure water loss does not cause hypernatremia unless the thirst center is damaged or access to free water is limited.

Hypotonic fluid loss can occur via the kidneys as a result of osmotic diuresis, use of loop diuretics, postobstruction diuresis, or intrinsic kidney disease. Extrarenally, hypotonic fluid loss can result from diarrhea, vomiting, burns, and excessive sweating.

Pure salt gain can result from the use of hypertonic saline during abortion, sodium bicarbonate administration during cardiopulmonary resuscitation, hypertonic feedings in infants, and, rarely, mineralocorticoid excess.

The management of hypernatremia includes correcting the underlying cause of the hypertonic state, replacing the water deficits, and administering adequate water to match ongoing losses.[22,51] The pure water deficit can be estimated as follows:

$$\begin{aligned}\text{Water deficit} &= \text{TBW}\,(\text{Observed serum Na}/\text{Desired serum Na}) - \text{TBW} \\ &= \text{TBW}\,(\text{Observed serum Na}/\text{Desired serum Na} - 1)\end{aligned} \quad \textbf{(Eq. 27-12)}$$

where desired serum sodium is usually 140 mEq/L.

The rate at which hypernatremia should be corrected depends on the severity of symptoms and degree of hypertonicity. Too rapid a correction can precipitate cerebral edema, seizures, and irreversible neurologic damage, and can be fatal. For asymptomatic patients, the rate of correction probably should not exceed changes of 0.5

mEq/L/hour in plasma sodium. Less aggressive correction is also recommended in patients at risk for developing neurologic complications. A rule of thumb is to replace half the calculated deficit with hypotonic solutions over the course of 12 to 24 hours, depending on the severity of hypernatremia. Any ongoing water loss, including insensible loss, should also be replenished while carefully monitoring the patient's neurologic status. The remaining deficit can then be replaced during the ensuing 24 to 48 hours. Concomitant solute deficits and ongoing solute losses should also be replaced as appropriate. If hypernatremia is caused only by pure water loss, free water can be administered as 5% dextrose in water. Half-normal saline or quarter-normal saline is used if a sodium deficit is also present. In patients with hypotension or shock, the effective arterial blood volume should be restored with normal saline or colloids before the plasma tonicity is corrected.

POTASSIUM

Homeostasis

The total amount of potassium stored in the body is ~45 to 55 mEq/kg and varies with age, sex, and muscle mass. Lower total body potassium is found in older adults, females, and individuals with a low lean body mass to fat ratio. Potassium is distributed unevenly between the intracellular and extracellular compartments; 98% of the total body potassium resides in the intracellular compartment, predominantly in the muscle, and only 2% is found in the extracellular space.[52] The disproportionate intracellular distribution of potassium is maintained by the Na^+/K^+-ATPase pump, which transports sodium out of the cell in exchange for potassium. The cell membrane resting potential is determined by the ratio of intracellular/extracellular potassium concentrations. As this ratio increases, hyperpolarization of the cell membrane occurs.

Conversely, cellular depolarization results when the ratio decreases. In both situations, generation of the action potential is impaired.

The plasma potassium concentration is maintained within a narrow range of 3.5 to 5.0 mEq/L. Although the plasma potassium concentration can be affected by the total body potassium store, total body potassium excess or deficit cannot be estimated accurately based solely on the plasma concentration. In fact, a normal plasma potassium concentration does not imply normal total body potassium because multiple factors affect the plasma potassium concentration independent of total body potassium.[52]

Potassium homeostasis is maintained by both the kidney and extrarenal processes. The kidney process regulates total body potassium by matching potassium excretion to dietary intake (external balance), whereas the extrarenal process regulates potassium distribution across the cell membrane (internal potassium balance).[52]

The normal daily intake of potassium ranges between 50 and 100 mEq. Approximately 90% of the ingested potassium is eliminated by the kidneys and ~10% is eliminated via the GI tract.[52] Potassium is filtered freely through the glomerulus and then reabsorbed. By the time the filtrate reaches the distal convoluted tubule, ~90% of filtered potassium has already been reabsorbed. The amount of potassium excreted is determined by the distal tubular potassium secretion in the principal cells of the cortical collecting duct, which is under the influence of aldosterone. Hyperkalemia, increased potassium load, and AT_2 can all stimulate aldosterone secretion.

Factors that affect kidney potassium excretion include tubular flow, sodium delivery to the distal segments of the nephron, the presence of poorly absorbable anions that increase luminal electronegativity, acid–base status, and aldosterone activity. Potassium excretion increases during hyperkalemia and decreases during potassium depletion. Excretion of an acute potassium load is a slow process, with only half the potassium load excreted in the first 4 to 6 hours. Lethal hyperkalemia would ensue without the extrarenal process that regulates intracellular/extracellular potassium distribution.

The Na^+/K^+-ATPase pump, which extrudes sodium from the cell in exchange for potassium, is pivotal in maintaining internal potassium balance. Different hormonal factors regulate the activity of the Na^+/K^+-ATPase pump, namely, insulin, catecholamines, and aldosterone. Insulin, the most important regulator, enhances potassium uptake by the muscle, liver, and adipose tissue by stimulating Na^+/K^+-ATPase. Indeed, basal insulin secretion is essential for potassium homeostasis. β_2-adrenergic agonists activate the Na^+/K^+-ATPase pump via cyclic adenosine monophosphate and cause hypokalemia, whereas α-adrenergic stimulation promotes hepatic potassium release and causes hyperkalemia. Epinephrine, an α- and β-agonist, causes a transient increase in plasma potassium (α-agonism) followed by a more sustained decrease in plasma potassium (β-agonism). Besides its kaliuretic effect and enhanced potassium secretion in the colon, aldosterone also stimulates Na^+/K^+-ATPase.[52]

Other factors that affect the transcellular distribution of potassium include systemic pH, plasma tonicity, and exercise. The effect of the acid–base balance on potassium distribution is not readily predictable and depends on both the nature and the direction of the underlying disorder.[53] The concomitant effect of the acid–base disorder on potassium excretion further complicates the relationship between plasma potassium concentration and pH. In acute non–anion gap metabolic acidosis, plasma potassium concentration increases by 0.2 to 1.7 mEq/L per 0.1 unit decrease in pH. Chronic non–anion gap metabolic acidosis usually is associated, however, with hypokalemia because of the urinary potassium loss associated with both proximal (type 2) and distal (type 1) renal tubular acidosis. In contrast, anion gap metabolic acidosis commonly has no effect on potassium distribution.

Other associated factors in anion gap acidosis may, however, affect cellular potassium distribution.[53] For example, hyperglycemia in diabetic ketoacidosis may increase the serum potassium concentration because of the hypertonic effect of glucose.[54] Hypertonicity causes cell shrinkage and increases the intracellular to

ECF potassium gradient, favoring potassium egress from the cell. Acute metabolic alkalosis only modestly decreases the plasma potassium concentration: 0.3 mEq/L for each 0.1 unit pH increment.[53] As with chronic metabolic acidosis, chronic metabolic alkalosis causes profound kidney potassium wasting and is associated with hypokalemia. Respiratory acid–base disorders usually are associated with less significant changes in plasma potassium concentration than are metabolic acid–base disorders. Exercise often causes an increase in the serum potassium concentration to a degree that varies with the intensity of the exercise.[55]

Hypokalemia

ETIOLOGY

CASE 27-8

Question 1: J.P., a 60-year-old female, presents to the ED with malaise, generalized weakness, nausea, and vomiting for 3 days. Her medical history includes hypertension for 20 years. J.P.'s current medications include hydrochlorothiazide 25 mg/day and nifedipine XL 30 mg/day. She has not been able to take her medications in the past few days, however, because of vomiting. J.P. denies recent diarrhea or use of laxatives. Her BP is 130/70 mm Hg with a pulse of 80 beats/minute while sitting and 120/70 mm Hg with a pulse of 95 beats/minute on standing. Physical examination reveals a thin, older female with poor skin turgor, dry mucous membranes, and a flat jugular vein. T-wave flattening is noted on the electrocardiogram (ECG). Laboratory tests show the following:

Serum Na^+, 138 mEq/L
K^+, 2.1 mEq/L
Cl^-, 100 mEq/L
Total CO_2, 32 mEq/L
BUN, 30 mg/dL
Creatinine, 1.2 mg/dL
Glucose, 100 mg/dL

ABG shows pH, 7.50; $PaCO_2$, 45 mm Hg; and PaO_2, 70 mm Hg at room air. Urine electrolytes are sodium, 30 mEq/L; potassium, 60 mEq/L; and chloride,

<15 mEq/L. J.P.'s presentation is consistent with gastroenteritis.
What are the causes of J.P.'s hypokalemia?

When evaluating hypokalemia, the clinician should determine whether the hypokalemia is a result of low intake, increased cellular uptake of potassium, or excessive loss of potassium via the kidneys, GI tract, or skin.[56] History and physical evidence of potassium depletion, medication history (including use of over-the-counter medicines), and assessment of the patient's BP, extracellular volume, and concurrent acid–base status can provide clues to the causes of hypokalemia.[56] Concomitant magnesium deficiency is often associated with hypokalemia because it can augment potassium wasting by increasing distal potassium secretion.[57] It may therefore aggravate hypokalemia and render it refractory to treatment. Correction of hypomagnesemia before potassium replacement is thus necessary.

Because J.P. has been unable to eat for the past few days, decreased oral intake may have contributed to her hypokalemia. Because most foods are rich in potassium, however, inadequate intake rarely is the sole cause of potassium depletion unless inappropriate and continued kidney or extrarenal losses occur, or potassium intake is severely restricted to <10 to 15 mEq/day.[52,56] Alkalosis insulin administration, hypertonic solution administration, periodic paralysis, β_2-agonists, barium poisoning, and treatment of megaloblastic anemia with vitamin B_{12} all have been associated with increased cellular potassium uptake (**Table 27-2**). Although the relationship between the degree of hypokalemia and increase in blood pH varies widely,[53] J.P.'s metabolic alkalosis probably enhances the cellular uptake of potassium. However, the transcellular shift of potassium should not result in total body potassium depletion.

Table 27-2

Drugs That Most Commonly Induce Hypokalemia

Drug	Mechanism	Predisposing Factors

Drug	Mechanism	Predisposing Factors
Acetazolamide	Marked ↑ in kidney K^+ loss	Most profound with short-term therapy
Amphotericin	Kidney K^+ loss (renal tubular acidosis)	Concurrent piperacillin, ticarcillin
β_2-Agonists	Intracellular shift of K^+	
Cisplatin	Kidney K^+ loss secondary to renal tubular damage	May be dose related but can occur after a single 50-mg/m^2 dose
Corticosteroids	Kidney K^+ loss. Enhanced Na^+ reabsorption at distal tubule and collecting ducts in exchange for K^+ and H^+	Supraphysiologic doses of agents with moderate to strong mineralocorticoid activity (eg, prednisone, hydrocortisone)
Insulin with glucose	Intracellular shift of K^+	Predictable effect when insulin administered to patients with diabetic ketoacidosis combination used to treat hyperkalemia
Penicillins (piperacillin, ticarcillin)	High Na^+ load and nonresorbable anions can ↑ K^+ loss	Was more common with carbenicillin when it was available; newer penicillins are used in lower doses; less likely to produce hypokalemia
Thiazide and loop diuretics	Kidney K^+ loss. ↑ Na^+ delivery to the late distal tubule, resulting in Na^+ resorption in exchange for K^+	Patients with hyperaldosteronism (eg, cirrhosis, HF) predisposed; may be dose related

HF, heart failure.

The GI tract is an important site of potassium loss, particularly through vomiting and diarrhea. Because the potassium content of gastric secretion (5–10 mEq/L) is much less than that of the intestinal secretion (up to 90 mEq/L),[52,56] loss of a large volume of gastric secretion is needed to produce substantial potassium depletion. Potassium deficit induced by vomiting, however, is commonly secondary to kidney potassium loss, especially within the initial 24 to 48 hours. The loss of hydrogen ion in gastric juice results

in an elevated plasma bicarbonate concentration. The increased amount of bicarbonate ion, as a nonresorbable anion, increases water delivery to the distal nephron and enhances sodium reabsorption and potassium secretion, resulting in hypokalemia. The potassium wasting is often transient because increased proximal reabsorption of sodium and bicarbonate will result in diminished bicarbonate delivery to the distal site. Reduced potassium excretion will ensue, commonly within 48 to 72 hours. Subsequent potassium loss will then be primarily consequent to gastric secretion removal.

The absence of diarrhea in J.P. excludes the GI tract as the source of potassium loss. Potassium loss through the skin is also unlikely in J.P. because the potassium concentration of sweat is <10 mEq/L. Therefore, profuse sweating, such as that induced by vigorous exercise in a hot, humid environment, or severe burns are needed to cause substantial loss.

J.P.'s inappropriately high urinary potassium concentration indicates that the kidney is the source of the potassium loss.[52,56] The urinary potassium concentration is a good marker for differentiating various hypokalemic syndromes. A urinary potassium excretion of <20 mEq/day suggests extrarenal potassium loss. Kidney potassium wastage cannot be excluded, however, unless the low urinary potassium excretion is accompanied by a sodium intake of at least 100 mEq/day, because a low-sodium diet can reduce kidney potassium excretion. In J.P., metabolic alkalosis and hypovolemia promote kidney potassium wastage.[53] The distal delivery of a large sodium bicarbonate load and increased aldosterone activity (from hypovolemia) enhance potassium secretion and severely impair the kidney's ability to conserve potassium. The hydrochlorothiazide, which J.P. had been taking until 3 days before admission, could also have induced hypokalemia through volume depletion, hypochloremic metabolic alkalosis, and kidney potassium wastage. The diuretic is unlikely, however, to be the cause of J.P.'s hypokalemia because she has stopped taking the medication, and this is reflected by the low urinary chloride concentration.[52] Bartter syndrome, which presents as normotension, hypokalemia, hypochloremic metabolic alkalosis, and kidney potassium wastage, is characterized by impaired kidney

sodium and chloride reabsorption.[58] The low urinary chloride concentration in J.P. can rule out Bartter syndrome. Other causes of hypokalemia are listed in Table 27-2.

In a patient with asymptomatic hypokalemia with no apparent causes for potassium depletion or transcellular redistribution, pseudohypokalemia should be excluded before pursuing an intensive evaluation. Spurious hypokalemia can occur in patients with leukemia whose leukocyte count ranges from 100,000 to 250,000 cells/μL.[59] The potassium in serum is taken up by the large number of leukemic cells when the blood specimen is allowed to stand at room temperature.

Case 27-8, Question 2: What clinical manifestations of hypokalemia are evident in J.P.?

CLINICAL MANIFESTATIONS

The clinical presentation of hypokalemia, which depends on the severity of potassium depletion, is a result of changes in cell membrane polarization.[52,56] Patients are usually asymptomatic when the plasma potassium level is 3.0 to 3.5 mEq/L, but they may present with malaise, weakness, fatigue, and myalgia. J.P.'s muscle weakness and ECG changes reflect the muscular and cardiac manifestations of hypokalemia, respectively.

Potassium depletion can lead to hyperpolarization of myocardial cells and a prolonged refractory period. When serum potassium concentrations fall <3 mEq/L, T-wave flattening, straight tubule segment depression, and prominent U waves are seen on the ECG.

Mild hypokalemia (potassium concentration of 3.0–3.5 mEq/L) is potentially arrhythmogenic in patients with underlying coronary artery disease. The incidence of ventricular arrhythmia increases with the degree of hypokalemia. Patients without underlying heart disease may be susceptible to these myocardial effects during exercise, especially if the patient's pre-exercise potassium concentration is <3.5 mEq/L, because the potassium concentration may drop to <3.0 mEq/L as a result of β_2-adrenergic receptor–mediated cellular

potassium uptake. Potassium depletion may also increase the BP, which can be lowered with potassium supplementation.[56]

When the serum potassium concentration is <2.5 to 3.0 mEq/L (moderate hypokalemia), muscle weakness, cramps, general malaise, fatigue, restless leg syndrome, and paresthesia can occur, probably because potassium is necessary for vasodilation in skeletal muscle. In addition, severe potassium depletion (<2.5 mEq/L) can result in elevation of serum creatine phosphokinase, aldolase, and aspartate aminotransferase levels. Rhabdomyolysis can ensue when the serum potassium concentration falls <2.0 mEq/L.[56]

Chronic potassium depletion can alter kidney function and structure, which can manifest as decreased GFR and kidney blood flow, disturbance in tubular sodium handling, impaired urinary concentrating ability with polydipsia, and ADH-resistant nephrogenic diabetes insipidus.[56] Reversible pathologic changes include kidney hypertrophy and epithelial vacuolization of the proximal convoluted tubule. Interstitial scarring and tubular atrophy have been reported with prolonged potassium depletion.

Other effects of hypokalemia and potassium depletion include decreased insulin secretion resulting in carbohydrate intolerance, metabolic alkalosis, and increased kidney ammoniagenesis, which may play a role in the development of hepatic encephalopathy.

TREATMENT

Case 27-8, Question 3: How should J.P.'s hypokalemia be treated?

J.P.'s protracted vomiting should be corrected, and fluids and electrolytes (sodium, potassium, and chloride) should be replaced to correct the volume deficit, hypokalemia, and hypochloremic metabolic alkalosis. Hydrochlorothiazide should continue to be withheld.

The amount of potassium deficit and the rate of continued potassium loss should be determined to guide replacement therapy. It has been estimated that a 1-mEq/L fall in serum potassium from 4

to 3 mEq/L represents a total body deficit of ~200 mEq. When the serum potassium falls to <3 mEq/L, the total body deficit increases by 200 to 400 mEq for each 1 mEq/L reduction in serum concentration. Other data suggest that even greater degrees of potassium loss can occur—a deficit of 100 mEq per 0.27-mEq/L fall in the serum potassium concentration.[52,56] Transcellular redistribution of potassium may, however, significantly alter the relationship between serum concentration and total body deficit. Therefore, potassium repletion should be guided by close monitoring of serum concentrations and analysis of J.P.'s urine for potassium content to help assess the need for additional replacement.

The route of potassium administration depends on the acuity and severity of hypokalemia,[56] but oral supplementation is usually preferred. The parenteral route is indicated for patients who cannot tolerate high dosages of oral potassium supplements and for those with severe or symptomatic hypokalemia. J.P.'s potassium deficit is estimated to be 300 to 500 mEq. With the ECG T-wave flattening, immediate treatment is necessary with parenteral potassium supplementation.

For severe hypokalemia, parenteral potassium can be given as chloride, acetate, or phosphate. The chloride salt is preferred in J.P., who has concurrent hypochloremic metabolic alkalosis. The acetate preparation is useful in cases of concomitant metabolic acidosis. Potassium phosphate is indicated if hypophosphatemia coexists. In the latter condition, the serum calcium concentration should also be monitored because hypocalcemia may ensue. IV potassium chloride in normal saline as diluent is preferred because dextrose-containing solutions may trigger insulin release, shifting potassium into cells, and result in hypokalemia.[56]

Potassium chloride–containing infusions must be administered slowly, commonly at 10 mEq/hour and should not exceed 20 mEq/hour.[60] Rates >20 mEq/hour are highly irritating to the peripheral veins and should be given via a large central vein instead. When potassium is given as maintenance fluid to a peripheral vein, the concentration should not exceed 60 to 80 mEq/L. Exceptions may be considered when severe hypokalemia is associated with

cardiac arrhythmias or diabetic ketoacidosis, where extreme caution would be needed for concentrations of 40 to 60 mEq/L. When given to a central vein, the rate should be 20 mEq/hour, with a maximum concentration of 20 mEq/50 mL. IV potassium should never be given as IV push, even during an emergency, because it always needs to be diluted.

Continuous ECG monitoring and serial measurements of plasma potassium concentrations every 4 hours are essential during IV potassium administration, especially when the rate of administration is >20 mEq/hour.

Parenteral potassium solutions should be given only in well-hydrated patients with adequate urine flow and very cautiously in postsurgical patients and those with kidney impairment, including geriatric patients, owing to the risk of hyperkalemia with excessive correction. In addition, serum magnesium concentration should be obtained when the potassium concentration is <2.8 mEq/L. If the patient has concomitant hypomagnesemia, magnesium supplementation should first be given. Refer to the section on Hypomagnesemia: Treatment for the suggested dosing of magnesium supplementation.[57,61]

For mild and moderate hypokalemia, potassium repletion may be given orally. Potassium chloride may be given orally as medications or salt substitutes. Salt substitutes, containing 50 to 65 mEq of potassium per level teaspoon, are widely available, safe, well tolerated, and much less expensive than are the medicinal preparations.[62] Potassium chloride is also available as liquid or slow-release tablet or capsule. The liquid preparations are unpalatable, albeit being inexpensive. Slow-release preparations are commonly well tolerated but may cause GI ulceration and bleeding, owing to local exposure to high potassium concentrations. The risk is generally low with the wax matrix tablets and is further lower with the microencapsulated preparations. Potassium chloride is most often used because chloride depletion is common in the presence of metabolic alkalosis, secondary to diuretic therapy or vomiting. As such, non–chloride potassium salts are not as effective in restoring body potassium. In contrast to bicarbonate, chloride does not enter

cells to the same extent, thereby helping to maintain potassium in the ECF. In addition, potassium bicarbonate may exacerbate metabolic alkalosis, thus reducing the efficacy of potassium administration. However, potassium bicarbonate is preferred in patients with concurrent hypokalemia and metabolic acidosis. Potassium chloride tablets may be given as 10 to 40 mEq two to four times daily, depending on the severity of the hypokalemia.[60]

For J.P., IV potassium replacement should first be initiated at 10 to 40 mEq/hour and adjusted based on frequent serum potassium, as well as continuous ECG monitoring. Once her potassium levels are replenished to a concentration of >3 mEq/L, she has no more ECG abnormalities, and she is no longer vomiting, oral potassium chloride can be started.[60]

Hyperkalemia

ETIOLOGY

CASE 27-9

Question 1: A.B., a 25-year-old female with type 1 diabetes and hypertension, returns to the clinic for follow-up. Her BP is 170/90 mm Hg with a pulse of 80 beats/minute, and her physical examination is remarkable for 2+ pedal edema. Laboratory tests show the following:

Plasma Na^+, 135 mEq/L
K^+, 5.8 mEq/L
Cl^-, 108 mEq/L
Total CO_2, 20 mEq/L
BUN, 28 mg/dL
Creatinine, 2 mg/dL
Glucose, 200 mg/dL

Current medications include oral captopril 25 mg three times daily, hydrochlorothiazide 25 mg/triamterene 37.5 mg one capsule daily, human isophane insulin 30 units subcutaneously every morning, and ibuprofen 200 mg as needed for menstrual cramps. She uses a salt substitute occasionally.

What is the etiology of her hyperkalemia?

Before conducting any extensive evaluation to identify the etiology of hyperkalemia, the serum potassium concentration ought to be repeated to confirm the presence of hyperkalemia. Also to be ruled out are the different causes of spurious hyperkalemia, which can result from severe leukocytosis (>500,000/μL), thrombocytosis (>750,000/μL), or hemolysis within the blood collection tube.[56] Pseudohyperkalemia is a test-tube phenomenon that occurs when potassium is released from lysis of leukocytes, platelets, or erythrocytes during blood coagulation. The laboratory normally reports this as a hemolyzed sample. These disorders can be confirmed easily by comparing serum (clotted) and plasma (unclotted) potassium concentrations from the same blood sample. The two values should agree within 0.2 to 0.3 mEq/L. Improper tourniquet technique, causing strangulation of the patient's arm before blood sampling, may also result in spurious hyperkalemia.

Identifying the etiology of hyperkalemia can be approached systematically by considering possible disturbances in internal and external potassium balance. The former involves transcellular flux of potassium from the intracellular to the extracellular space, whereas the latter involves either increased intake, including increased endogenous potassium load (eg, rhabdomyolysis, tumor lysis syndrome, or decreased elimination).[52,56] A thorough medication history is important to identify drugs associated with hyperkalemia.[56] (Also see Chapter 28, Chronic Kidney Disease, for additional information on hyperkalemia.)

A dietary history should ascertain whether A.B.'s consumption of potassium-rich foods, salt substitutes, or potassium supplements has increased. Dietary intake alone will not induce hyperkalemia unless kidney excretion is impaired. Usually, the GFR must be <10 to 15 mL/minute, unless there is concurrent hypoaldosteronism or distal tubular potassium secretory defects. A.B.'s kidney insufficiency is mild, with an estimated CrCl of 40 mL/minute.

Conditions associated with low renin and aldosterone, which usually present as hyperkalemia and hyperchloremic metabolic acidosis,[53] decrease potassium excretion by the kidneys. These include diabetes, obstructive uropathy, sickle cell disease, lupus

nephritis, and various tubulointerstitial diseases (eg, gouty nephropathy, analgesic nephropathy). Adrenal insufficiency presents commonly with hyperkalemia because of mineralocorticoid deficiency.[56] A.B.'s hyperglycemia because of poorly controlled diabetes may cause movement of potassium-rich fluid from the intracellular space to the extracellular space because of the increased tonicity. Elevating the plasma tonicity by 15 to 20 mOsm/kg will increase the plasma potassium concentration by 0.8 mEq/L.[52,56] Patients with diabetes, mineralocorticoid deficiency, or end-stage kidney failure, which commonly results in hyporeninemic hypoaldosteronism, are particularly susceptible.

A.B. is also taking several medications that may impair her ability to excrete potassium. Captopril, as with all angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers, indirectly decreases aldosterone secretion by decreasing the formation of AT_2.[56,63] Ibuprofen and all other NSAIDs inhibit prostaglandin production as well as renin and aldosterone secretion. Other drugs that cause hyperkalemia by impairing renin and aldosterone production include AT_2 receptor antagonists, β-adrenergic blockers, lithium, chronic heparin administration, and pentamidine. Triamterene, a component of her diuretic, inhibits tubular potassium secretion, as do amiloride, spironolactone, high-dose trimethoprim, cyclosporine, tacrolimus, and digoxin. By inhibiting Na^+/K^+-ATPase, digoxin decreases tubular potassium secretion and reduces cellular potassium uptake. Arginine, succinylcholine, β-blockers, α-agonists (such as phenylephrine), and hypertonic solutions also cause hyperkalemia by impairing transcellular potassium distribution into the intracellular space.

CLINICAL MANIFESTATIONS

CASE 27-10

QUESTION 1: V.C., a 44-year-old female with chronic kidney failure, returns to the outpatient unit for routine hemodialysis with severe muscle weakness. Her vital signs are BP, 120/80 mm Hg; pulse, 90 beats/minute; RR, 20

breaths/minute; and temperature, 98 °F (36.67 °C). Laboratory data are as follows:

Serum K^+, 8.9 mEq/L
Total CO_2, 15 mEq/L
BUN, 60 mg/dL
Creatinine, 9 mg/dL
Glucose, 100 mg/dL

The ECG reveals an increased PR interval and a widened QRS complex. What clinical manifestations of hyperkalemia are evident in V.C.?

Hyperkalemia decreases the intracellular/extracellular potassium ratio. Hence, the resting membrane potential becomes less negative and moves closer to the threshold excitation potential. Muscle weakness and flaccid paralysis result when the resting membrane potential approaches the threshold potential, rendering the excitable cells unable to sustain an action potential.

The cardiac toxicity of hyperkalemia is a major cause of morbidity and mortality, with ECG findings paralleling the degree of hyperkalemia. When plasma potassium is >5.5 to 6.0 mEq/L, narrow, peaked T waves and a shortened QT interval are seen. As the plasma potassium concentration increases further, the QRS complex widens and the P-wave amplitude decreases. As the level reaches 8 mEq/L, the P wave disappears and the QRS complex continues to widen and merge with the T wave to form a sine wave pattern. If these ECG changes are not recognized and no treatment is initiated, ventricular fibrillation and asystole will ensue. Hyponatremia, hypocalcemia, and hypomagnesemia all reduce the threshold potential, thereby increasing the patient's susceptibility to the cardiac effects of hyperkalemia.[52,56,57] V.C.'s muscle weakness, ECG, chronic kidney failure, and serum potassium concentration all are consistent with severe hyperkalemia.

TREATMENT

Case 27-10, Question 2: How should V.C.'s hyperkalemia be treated?

Hyperkalemia with ECG changes requires urgent treatment.[56,64] Three therapeutic modalities are available: (a) agents that antagonize the cardiac effects of hyperkalemia, (b) agents that shift potassium from the extracellular into the intracellular space, and (c) agents that enhance potassium elimination. A combination of these modalities is often used because it mitigates the potassium cardiac effect without affecting its concentration, while it reduces serum potassium concentration by shifting into cells. Agents that actually increase potassium elimination are necessary for long-term control. Considering V.C.'s severe ECG changes, 10% calcium gluconate IV should be administered at a dose of 10 to 20 mL over the course of 1 to 3 minutes. Calcium counteracts the depolarizing effect of hyperkalemia by increasing the threshold potential, thus making it less negative and moving it away from the resting potential. The onset of action occurs in a few minutes, but the effect is short-lived, lasting ~15 to 60 minutes. The dose can be repeated in 5 minutes if ECG changes do not resolve and as needed afterward for recurrence. With no response after the second dose, additional attempts, however, are not beneficial. When hyperkalemia presents with a digitalis overdose, calcium should be used cautiously because it can worsen the cardiotoxic effects of digoxin. In the absence of ECG changes, there is no justification for using calcium for hyperkalemia treatment.

Because the serum potassium concentration is not affected by calcium administration, maneuvers should be used to shift potassium from plasma into the cells. Three modalities are available: insulin and glucose, β_2-agonists, and sodium bicarbonate.

Insulin rapidly shifts potassium into the cell in a dose-dependent manner. The maximal effect occurs at insulin concentrations >20 to 40 times the basal levels. Therefore, endogenous insulin secreted in response to dextrose administration is insufficient, and exogenous insulin must be administered.[64] Although high concentrations of dextrose may worsen hyperkalemia, particularly in patients with diabetes because intracellular potassium may be shifted to the extracellular space owing to the elevated plasma tonicity, it is always

administered with insulin to prevent hypoglycemia. Regular insulin (5–10 units) can be given with 50 mL of 50% dextrose as IV boluses. The insulin– dextrose combination lowers serum potassium by direct stimulation of cellular potassium uptake and potentiates the potassium-lowering effect of β_2-adrenergic stimulation. The reduction in potassium is apparent 15 to 30 minutes after administering insulin and persists for 4 to 6 hours. In a patient with diabetes who is both hyperkalemic and hyperglycemic, insulin alone may be insufficient. If the patient has end-stage kidney disease, the insulin–glucose combination is more predictable in lowering plasma potassium concentrations than is sodium bicarbonate.

β_2-Agonists, by binding with the β_2-adrenoreceptor to activate adenylate cyclase, have an additive effect with the insulin–dextrose combination in decreasing serum potassium.[64] When albuterol nebulization is used alone, the hypokalemic effect may be inconsistent. Although side effects of albuterol nebulization are minimal, these agents can cause tachycardia and should be used cautiously in patients with underlying coronary artery disease. Nebulization is easy to set up and is less likely to be associated with tachycardia, but multiple doses are often necessary to attain an adequate response. In conjunction with the insulin–dextrose combination, albuterol (20 mg dissolved in 4 mL of saline) can be administered by nebulization and inhaled over the course of 10 minutes to further decrease serum potassium, if necessary.

Although sodium bicarbonate has long been recommended for the acute treatment of hyperkalemia, its efficacy in this setting has been questioned.[64] The usual dose, 50 mEq, is infused slowly over the course of 5 minutes and repeated in 30 minutes when necessary. Alternatively, it can be added to dextrose and saline solution to form an isotonic sodium bicarbonate infusion. The hypokalemic effect is variable and may be delayed up to 4 hours, and it is reportedly ineffective in patients on maintenance hemodialysis. Although bicarbonate therapy is not a reliable option in the acute management of hyperkalemia, it may be beneficial in patients with severe

metabolic acidosis (pH < 7. 20). Potential complications of sodium bicarbonate therapy are volume overload and metabolic alkalosis.

The definitive treatment of hyperkalemia is the removal of potassium from the body. Sodium polystyrene sulfonate (SPS) is an ion-exchange resin that binds potassium in the bowel and enhances its excretion in the stools.[64] Calcium polystyrene sulfonate is also available and is especially useful in patients with HF. It can be administered without the concern for fluid retention secondary to SPS sodium content. Each gram of SPS exchanges 0.5 to 1.0 mmol of potassium for an equal amount of sodium. SPS can be administered orally or rectally; the latter route is preferred in the symptomatic hyperkalemic patient because intestinal potassium exchange occurs mainly in the ileum and colon. A dose of 50 g of SPS in sorbitol can be given as an enema, retained for at least 30 to 60 minutes, at 4- to 6-hour intervals. For nonemergent removal of body potassium, 15 to 60 g of SPS suspension can be given orally, which can be repeated as needed. The onset of action is ~1 to 2 hours after administration. The major side effects are GI intolerance, including constipation, diarrhea, and sodium overload. Potentially fatal intestinal necrosis, although rare, has been reported with the use of SPS with sorbitol.[65] It is unclear if intestinal injury is caused by SPS or sorbitol, but the FDA has released a safety warning against the use of SPS in individuals with impaired bowel function.[66] In fact, sorbitol is no longer recommended together with SPS.

Hemodialysis is the most efficient way to remove potassium; potassium clearance by peritoneal dialysis is lower than that for hemodialysis.[64] The hypokalemic effect is immediate and lasts for the duration of dialysis; however, the amount of potassium removed is variable. Dialysis with a glucose-free dialysate will remove 30% more potassium than one containing 200 mg/dL of glucose. **Table 27-3** summarizes the treatment alternatives for hyperkalemia. Although V.C. is receiving chronic maintenance hemodialysis, the severe cardiac effects of hyperkalemia she experienced warrant immediate institution of the aforementioned measures while awaiting preparation for dialysis. Loop diuretics, which enhance kaliuresis, are

rarely useful in managing severe hyperkalemia, especially in patients with kidney dysfunction.

Table 27-3
Treatment of Hyperkalemia

Drug	Mechanism	Dose	Comment
Calcium gluconate	Reverse cardiotoxicity caused by K^+	10–20 mL 10% calcium gluconate IV over 1–3 minutes; may repeat once	*Onset:* 1–3 minutes *Duration:* 30–60 minutes. (K^+) remains unchanged
Insulin and glucose[a]	Redistribution of K^+ intracellularly	5–10 units regular insulin with 50 mL 50% dextrose (if hypoglycemic, may need supplemental dextrose afterward)	*Onset:* 15–30 minutes *Duration:* several hours Watch for hypoglycemia and hypokalemia. Does not ↓ total body K^+
β_2-Agonists (eg, albuterol)	Redistribution of K^+ intracellularly	Inhalation: 20 mg in 4 mL saline via nebulizer	*Onset:* 30–60 minutes *Duration:* 2 hours
Sodium polystyrene sulfonate	Cationic binding resin. 1 g of resin binds 0.5–1 mEq K^+ in exchange for Na^+.	Oral: 15–20 g every 4–6 hours; PRN preferred Retention enema: 50 g in 50 mL. Retain 30 minutes and follow with nonsaline irrigation.	*Onset:* slow; 50 g will lower (K^+) by 0.5–1 mEq/L over 4–6 hours; watch for Na^+ overload (100 mg Na^+/1 g SPS).
Patiromer	Nonabsorbed, cation exchange polymer containing a calcium–sodium cation	Recommended starting dose is 8.4 g PO daily; dose can be adjusted at 1-week or longer intervals, as needed to reach desired K target range; maximum oral dose of 25.2 g/day	*Onset:* generally slow, but may start to see effect in 1 hour *Duration*: shown to provide significant reductions in serum K within 7 hours of dosing and maintained for 48 hours
Sodium zirconium cyclosilicate	Nonabsorbed zirconium silicate that binds potassium in exchange for hydrogen and sodium	Initial treatment dose: 10 g tid for up to 48 hours Continued treatment: 10 g once daily; dose can be adjusted at 1-week or longer intervals, as needed to reach desired K^+ target range Recommended maintenance dose: 5 g every other day to 15 g daily	*Onset:* generally slow, but may start to see effect in 1 hour
Sodium bicarbonate	Redistribution of K^+ intracellularly	50 mEq IV over 5 minutes. Repeat as needed.	*Onset:* variable, ≈30 minutes May work best in acidosis Watch for Na^+ overload and hyperosmolar state. No change in total body K^+.
Dialysis	Removal of K^+		Use as last resort

bid, twice daily; IV, intravenous; PRN, as needed; SPS, sodium polystyrene sulfonate; tid, three times daily.

[a]Glucose unnecessary in patients with high glucose concentrations.

Two newer oral agents, patiromer and sodium zirconium cyclosilicate (SZC), were approved by the FDA in 2015 and 2018, respectively, for the treatment of mild-to-moderate hyperkalemia.[67,68] Patiromer binds to potassium in exchange for calcium in the GI tract, increasing fecal excretion of potassium. SZC binds to potassium in exchange for hydrogen and sodium. Both agents have been shown

to be effective in reducing serum potassium concentrations consistently and safely, thus allowing the continued use of renin–angiotensin–aldosterone antagonists in patients with HF and chronic kidney disease while minimizing the side effect of hyperkalemia.[69] However, their effects on clinical outcomes such as cardiac arrhythmias and all-cause mortality are still lacking. Both agents need to be administered separately from other medications by 2 to 6 hours because of their binding effect. The agents are generally considered safe because studies have not revealed any serious adverse effects.

Patiromer has been evaluated for acute hyperkalemia (>6.0 mEq/L) treatment. Single 25.2-g oral patiromer dose with standard of care (SOC) was found to reduce serum potassium within 2 hours, but did not show any difference at 6 hours, when compared with SOC. The observation needs to be confirmed by more rigorous studies because this was an open-label, convenience sampling study with no standardization of SOC. In addition, there were only 15 subjects in both study groups.[70]

SZC 10 g or placebo, up to three times during a 10-hour period, with insulin and glucose, were evaluated for acute treatment of blood potassium ≥5.8 mmol/L. This pilot study suggested that SZC with insulin and glucose may provide an incremental benefit in the emergency treatment of hyperkalemia over insulin and glucose alone. The serum potassium reduction was greater at 2 hours but not later. The study might be underpowered to delineate the effect of SZC because the subjects received different therapies that might affect serum potassium.[71]

Because new agents with novel mechanisms of action and improved efficacy and safety data become available, older and more traditional agents such as SPS are becoming less popular.

After V.C.'s condition stabilized, she admitted to eating a lot of fruits in the past few days. Because noncompliance with dietary potassium restriction is the most common cause of acute and chronic hyperkalemia in a patient on dialysis, V.C. should be counseled to consume potassium-rich foods in moderation. Medications that impair V.C.'s extrarenal potassium handling should

be avoided. If V.C. remains chronically hyperkalemic, an exchange resin such as SPS will then be needed, probably three or four times weekly. There is a growing preference to use newer agents such as patiromer and SZC that have more data on efficacy and safety, albeit being more expensive. For V.C., patiromer may be used at a dose of 8.4 g orally three to four times weekly. Alternatively, SZC 5 g every other day may be considered. In the case of V.C., either agent is appropriate, and thus the final choice may be based on her preference and cost. If hyperkalemia is associated with metabolic acidosis, however, an alkalinizing agent, such as sodium bicarbonate, should be added to maintain a serum bicarbonate concentration of about 24 mEq/L.

CALCIUM

Homeostasis

Healthy adults have ~1400 g of calcium in the body, of which >99% is stored in bone. Nonetheless, the 0.1% of the total body calcium that is in the plasma and extravascular fluid plays a critical role in many physiologic and metabolic processes.[72,73] Calcium is important in maintaining nerve tissue excitability and muscle contractility. It regulates the secretory activities of exocrine and endocrine glands and serves as a cofactor for enzyme systems and the coagulation cascade. It is also an essential component of bone metabolism.

Plasma calcium concentration is normally maintained within a relatively narrow range: 8.5 to 10.5 mg/dL. This is accomplished through a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin, as well as the effect of these hormones on calcium metabolism in bone, the GI tract, and the kidneys.

Normally, about 40% of the plasma calcium is protein bound, primarily to albumin, and is nondiffusible.[72] Of the 60% that is diffusible, about 13% is complexed to various small ligands: phosphate, citrate, and sulfate. The remaining 47% is ionized, free,

and physiologically active. Changes in serum protein concentration will alter the concentrations of both protein-bound and total calcium. Therefore, the serum albumin concentration needs to be monitored to adequately interpret the total serum calcium concentration. Each 1-g/dL increase in serum albumin concentration is expected to increase the protein-bound calcium by 0.8 mg/dL, thus increasing the total serum calcium concentration by the same amount. The total serum calcium therefore can be corrected by Eq. 27-13:

$$\text{Correct Ca} = \text{Observed Ca} + 0.8\,(\text{Normal albumin} - \text{Observed albumin}) \quad \textbf{(Eq. 27-13)}$$

where normal albumin = 4 g/dL.

Calcium is also bound to plasma globulins at the rate of 0.16 mg of calcium for each gram of globulin. When the total globulin concentration exceeds 6 g/dL, moderate hypercalcemia may be seen. Changes in pH have an effect on calcium protein binding; acidosis decreases calcium binding, resulting in an increase in free-calcium fraction, whereas an increase in pH reduces the amount of ionized calcium. Changes in serum phosphate and sulfate concentrations are expected to alter the fraction of ionized calcium because of the formation of calcium complexes with these anions. The presence of abnormal plasma proteins with a high affinity for calcium binding, as in patients with multiple myeloma, also affects Eq. 27-13 for serum calcium concentration correction.

Serum calcium concentration is regulated by the combined effect of GI absorption and secretion, kidney reabsorption, and turnover of the skeletal calcium pool. Several hormones, such as PTH, 1,25-dihydroxyvitamin D_3, and calcitonin, have significant effects on these processes. Balanced diets generally contain 600 to 1000 mg of calcium, although the minimum daily requirement is 400 to 500 mg. Calcium is primarily absorbed in the duodenum and jejunum via saturable and nonsaturable processes. The nonsaturable process is diffusive in nature and varies with luminal calcium concentration. The saturable carrier-mediated component is stimulated by 1,25-

dihydroxyvitamin D_3. Absorption of calcium is enhanced when the calcium intake is low and also when the demand is increased, such as in pregnancy and when total body calcium is depleted. Conversely, protein deficiency can reduce intestinal calcium absorption, presumably because of the reduced amount of specific calcium-binding protein. Calcium is also secreted into the bowel lumen, which may account for the presence of a negative calcium balance when there is no oral calcium intake.

The portion of plasma calcium that is not bound to protein is filtered by the glomerulus. Approximately 97% to 99.5% of the filtered calcium is reabsorbed: 60% in the proximal tubule, 20% in the ascending limb, 10% in the distal tubule, and 3% to 10% in the collecting duct. Approximately 20% of the calcium in the kidney tubule is ionized, whereas the remainder is bound to anions such as citrate, sulfate, phosphate, and gluconate. The extent of calcium reabsorption depends on the presence of specific anions and also on the urine pH, which affects the fraction of calcium bound to anions. Passive reabsorption at the proximal convoluted tubule is linked closely to sodium transport and is increased by ECF contraction and decreased by volume expansion. At the proximal straight tubule, the transport process is active and dissociable from sodium and water transport. PTH increases the calcium reabsorption at the distal tubule and also at the collecting duct independent of sodium reabsorption. Acidosis can also increase kidney calcium excretion by inhibiting tubular reabsorption and by increasing the ultrafiltrable calcium through reduced binding of calcium to plasma proteins. Conversely, alkalosis promotes calcium protein binding, thus reducing the amount of ultrafiltrable calcium. It also induces hypocalciuria independent of PTH. Phosphorus administration reduces kidney calcium excretion, whereas phosphorus depletion increases urinary calcium elimination. Normally, ~50 to 300 mg of calcium is excreted by the kidneys daily, but this can be increased to 600 mg/day.

The other important factor regulating plasma calcium concentration is bone metabolism. The rate of bone turnover and

calcium resorption is influenced by PTH, 1,25-dihydroxyvitamin D_3, and calcitonin.

Hypocalcemia

ETIOLOGY

Hypocalcemia may be caused by factors such as PTH abnormalities or PTH resistance, vitamin D deficiency or resistance, abnormal magnesium metabolism, and extravascular calcification.[72,73]

Hypoparathyroidism secondary to parathyroidectomy, thyroidectomy, radiation therapy, congenital defects of the parathyroid glands, or autoimmune disease can result in low serum calcium concentrations.[74–77] In such cases, administration of oral calcium and vitamin D is necessary to increase GI calcium absorption. Conversely, hyperparathyroidism in the setting of vitamin D deficiency, vitamin D resistance, or chronic kidney disease is another common cause of hypocalcemia. Furthermore, patients with kidney impairment often present with hyperphosphatemia due to reduced phosphate excretion. The elevated serum phosphate concentration in turn binds with calcium, causing hypocalcemia. Hypomagnesemia causes PTH resistance and hypocalcemia.[72] In such cases, repletion of magnesium is necessary to correct the calcium disorder. Severe hypermagnesemia can also result in hypocalcemia by suppressing PTH secretion.[78]

Medications such as bisphosphonates,[79] denosumab,[80] calcimimetics,[81] foscarnet,[82] and certain chemotherapeutic agents such as cisplatin[83] can also cause hypocalcemia. Other causes of hypocalcemia include bone metastases,[84] acute pancreatitis,[85] sepsis,[86] and the use of citrate as an anticoagulant in blood transfusions.[87]

Regardless of the cause, the diagnosis of hypocalcemia should be confirmed either by repeated measurements of its laboratory value, correction for hypoalbuminemia, or direct measurement of ionized calcium.

CLINICAL MANIFESTATIONS

The clinical presentation of hypocalcemia depends on its severity and chronicity.[72] Most patients with mild hypocalcemia are asymptomatic, but those with significant or abrupt changes in calcium concentrations may be symptomatic. The most common symptoms of severe or acute hypocalcemia involve the neuromuscular system such as parasthesias, carpopedal spasms, and seizures and may progress to tetany. Neuromuscular signs of hypocalcemia include the Chvostek and Trousseau signs. The Chvostek sign is contraction of the ipsilateral facial muscles elicited by tapping the facial nerve anterior to the ear. The Trousseau sign is the induction of carpal spasm by inflation of a sphygmomanometer above systolic BP for 3 minutes. Of these two signs, the Trousseau sign is more specific. It is recommended that both clinical signs be confirmed with a measurement of ionized calcium.

Other than the neuromuscular system, cardiovascular and psychiatric manifestations such as hypotension, ECG changes (eg, QT prolongation, emotional instability, anxiety, depression, and confusion) may also be evident.

TREATMENT

The management of hypocalcemia depends on the severity of symptoms.[73] IV calcium therapy is recommended in patients with acute symptomatic hypocalcemia (serum-corrected calcium concentration <7.5 mg/dL), whereas oral calcium and vitamin D supplements are usually adequate in mildly symptomatic or chronic hypocalcemia (serum-corrected calcium concentration >7.5 to 8.0 mg/dL).

IV calcium gluconate is preferred over calcium chloride because of its lower propensity to cause extravasation and tissue necrosis. It may be given as 1 or 2 g calcium gluconate (equivalent to 90 or 180 mg elemental calcium) in 50 mL of D5W or normal saline over 10 to 20 minutes. The infusion rate should not be faster because of the risk of cardiac complications. Subsequently, a slow calcium infusion can be continued in patients whose hypocalcemia persists. Oral

calcium and vitamin D (eg, calcitriol) should be initiated, and the IV calcium supplementation stopped after achieving optimal serum calcium concentration. Patients with concurrent hypomagnesemia should be treated with IV and/or oral magnesium repletion before correcting hypocalcemia. Refer to the section on magnesium disorders for the management of hypomagnesemia.

Patients with mild hypocalcemia, are mildly symptomatic (eg, oral paresthesias), or have chronic hypocalcemia can receive oral calcium supplementation. Elemental calcium 1500 to 2000 mg in the form of calcium salts (eg, calcium carbonate or calcium citrate) may be given daily in divided doses. In addition, patients with hypoparathyroidism or vitamin D deficiency will require vitamin D supplementation in the form of nutritional (vitamin D_2, ergocalciferol or vitamin D_3, cholecalciferol) or active vitamin D (calcitriol) therapy. An advantage of vitamin D is that it enhances gut absorption of calcium and thus can possibly reduce the dose requirement of calcium.

Hypercalcemia

ETIOLOGY

CASE 27-11

Question 1: A.C., a 62-year-old female, is brought to the hospital by family members because she has become increasingly lethargic and unresponsive during the past several days. Approximately 4 years ago she underwent a radical mastectomy and node dissection followed by radiation and chemotherapy for breast carcinoma. Despite several courses of chemotherapy, she developed metastasis to the bone. About 1 week before this admission, A.C. experienced fatigue, muscle weakness, and anorexia. Since then, she has spent most of her time in bed and has had very limited oral intake. Medications taken before admission included hydrochlorothiazide, oral morphine sulfate, and tamoxifen. Physical examination reveals a dehydrated, cachectic female responsive only to painful stimuli. Vital signs include BP, 100/60 mm Hg, and RR, 16 breaths/minute. Pertinent laboratory values are as follows:

Na^+, 138 mEq/L

K^+, 4.5 mEq/L
Cl^-, 99 mEq/L
Total CO_2, 33 mEq/L
BUN, 40 mg/dL
Creatinine, 1.2 mg/dL
Calcium, 19 mg/dL
Phosphate, 4.5 mg/dL
Albumin, 3.0 g/dL
The ECG revealed a shortened QT interval.

What are the common causes of hypercalcemia? Which of these might be responsible for the hypercalcemia seen in A.C.?

Malignancy and primary hyperparathyroidism are the most common causes of hypercalcemia.[88] Hematologic malignancies, such as multiple myeloma, tend to be responsible for more hypercalcemia than are solid tumors. Cancer of the breast, lung, head and neck, and kidney cell carcinoma are solid tumors commonly associated with hypercalcemia. Malignancy can cause paraneoplastic hypercalcemia secondary to bone metastasis, which results in increased bone resorption. Alternatively, patients may exhibit hypercalcemia in the absence of bone metastasis owing to the production of osteolytic humoral factors by the tumor. The mediators secreted may be PTH, PTH-like substances, prostaglandins, cytokines, transforming growth factor-α, and tumor necrosis factor.[88]

Hyperparathyroidism is the other common cause of hypercalcemia.[89] Although the etiology of primary hyperparathyroidism is unclear, females tend to experience the condition more frequently, especially in the fourth to sixth decades of life. Approximately 75% of patients have a single adenoma, whereas much smaller percentages of patients have multiglandular disease, hyperplasia, or carcinoma.[88] Other conditions that can result in hypercalcemia include post–kidney transplantation, immobilization, vitamin A intoxication, hyperthyroidism,[72] Addison disease, and pheochromocytoma. Hypercalcemia can also occur secondary to increased intestinal calcium absorption because of vitamin D intoxication, sarcoidosis, and other granulomatous diseases. Use of

thiazide diuretics, lithium, estrogens, and tamoxifen, as well as excessive calcium ingestion together with alkali (milk–alkali syndrome), may result in hypercalcemia.

A.C.'s breast cancer bone metastasis, volume contraction, and use of hydrochlorothiazide and tamoxifen may all contribute to her hypercalcemia.

CLINICAL MANIFESTATIONS

CASE 27-11, QUESTION 2: How is hypercalcemia manifested in A.C.?

The clinical presentations of hypercalcemia vary substantially among patients, but the severity of the symptoms correlates well with free-calcium concentrations.[72] The specific presentation depends on the rate of serum calcium concentration elevation, the presence of malignancy, the PTH concentration, and the patient's age. Concurrent electrolyte and metabolic abnormalities and underlying diseases will also have an effect. Because calcium is an important regulator of many cellular functions, hypercalcemia can produce abnormalities in the neurologic, cardiovascular, pulmonary, kidney, GI, and musculoskeletal systems. As seen in A.C., the signs and symptoms can be nonspecific: fatigue, muscle weakness, anorexia, thirst, polyuria, dehydration, and a shortened QT interval on the ECG.

The effect of hypercalcemia on the central nervous system includes lethargy, somnolence, confusion, headache, seizures, cerebellar ataxia, altered personality, acute psychosis, depression, and memory impairment. The neuromuscular manifestations include weakness, myalgia, hyporeflexia or areflexia, and arthralgia.

Symptoms of impaired kidney function include polyuria, nocturia, and polydipsia. These may reflect a defective concentrating ability, possibly because of resistance to the effects of ADH. The GFR may be decreased because of afferent arteriolar vasoconstriction, and if hypercalcemia is prolonged, nephrolithiasis, nephrocalcinosis, chronic interstitial nephritis, and renal tubular acidosis may be

present. Hypermagnesuria and metabolic alkalosis may also be observed.

Calcium has a positive inotropic effect and reduces heart rate, similar to cardiac glycosides. ECG changes indicative of slow conduction, with prolonged PR and QRS intervals and shortened QT intervals, are commonly seen. In severe hypercalcemia, increased QT intervals, widened T waves, and arrhythmia may be present.

The GI symptoms of hypercalcemia are related primarily to the depressive action of calcium on smooth muscle and nerve conduction. Constipation, anorexia, nausea, and vomiting result from reduced GI motility and delayed gastric emptying. Duodenal ulcer can occur because of increased acid and gastrin secretion. Pancreatitis can occur during acute hypercalcemia owing to the blockade of the pancreatic ducts caused by intraductal calcium deposits. Proteolytic enzymes may also be activated by calcium, causing tissue damage. Both ulcer disease and pancreatitis are more common in hypercalcemia associated with primary hyperparathyroidism; they are less likely to be seen in patients with malignancy-induced hypercalcemia.

Treatment

Case 27-11, Question 3: After vigorous fluid resuscitation with IV saline at a regimen of normal saline 75 to 100 mL/hour and increased by 50 to 100 mL/hour every 6 to 8 hours to a goal rate of 200 to 300 mL/hour, combined normal saline and furosemide diuresis at a furosemide dose of 40 mg IV every 4 hours was instituted in A.C. Her serum calcium concentration declined very slowly, prompting the use of calcitonin. Despite initial success, the serum calcium concentration rose to pretreatment values within 24 hours. Higher dosages of calcitonin could have been attempted at this point; however, pamidronate 90 mg IV infused over 4 hours was used instead. Her serum calcium concentration finally stabilized at 8 mg/dL after several days of therapy. What was the rationale for each of these regimens? What other agents are available for hypercalcemia treatment?

Several therapeutic approaches are used to lower serum calcium concentration: increasing urinary calcium excretion, inhibiting release

of calcium from bone, reducing intestinal calcium absorption, and enhancing calcium complex formation with chelating agents. The underlying disease that causes hypercalcemia should also be treated, if possible. The specific treatment used depends on the serum ionized calcium concentration, the presenting signs and symptoms, and the severity and duration of hypercalcemia. Immediate therapy was needed for A.C., who had symptoms consistent with severe hypercalcemia.

Specific interventions are described in the subsequent paragraphs, but as an overview, hydration and diuresis with furosemide in patients at risk for fluid overload are generally the first steps in the acute treatment of hypercalcemia. If these measures fail to reduce the serum calcium concentration adequately, several other agents can be added. Calcitonin provides a rapid onset of hypocalcemic effect, but its duration of action is relatively short. Thus, a bisphosphonate could be used to elicit a longer hypocalcemic response. Other agents, such as denosumab, calcimimetics, and glucocorticoids also have been used to treat hypercalcemia and may be used as alternatives (**Table 27-4**).

Table 27-4

Treatment of Hypercalcemia

Intervention	Dose	Comment

Intervention	Dose	Comment
Normal saline (NS) and furosemide	1–2 L NS; then furosemide 80–100 mg every 2–4 hours. Establish and maintain normovolemia. Replace other electrolytes as needed. Alternatively, administer NS alone at an initial rate of 200–300 mL/hour followed by titration in rate to maintain urine output of 100–150 mL/minute, to treat dehydration and restore euvolemia, along with the use of other agents such as calcitonin and bisphosphonates.	Saline diuresis and volume expansion depresses Ca^{2+} reabsorption in tubules. Lowers Ca^{2+} within 24 hours. Treatment of choice in patients without HF or kidney failure. Use loop diuretics with NS hydration in patients with kidney or heart failure.
Calcitonin	4 IU/kg SQ or IM every 12 hours. ↑ Dose or use another therapy if unresponsive after 24 hours (Max: 8 IU/kg every 6 hours).	Inhibits osteoclast resorption and kidney reabsorption of calcium. Preferred second-line agent because it has a rapid onset (6 hours) and is nontoxic. It can be used safely in HF and kidney failure. Nausea is the major adverse effect. Tolerance occurs in 24–72 hours. Concomitant plicamycin can lead to hypocalcemia. Only the salmon-derived product is available.

Intervention	Dose	Comment
Bisphosphonates (pamidronate, zoledronic acid, ibandronate)	Pamidronate: 60–90 mg IV for 4 hours × 1. Repeat in 7 days PRN. Zoledronic acid: 4 mg IV administration for 15 minutes. Repeat in 7 days PRN. Ibandronate: 2 mg IV administered over 2 hours. Doses up to 6 mg shown to be safe and well tolerated	Potent effect on bone resorption. Inhibits osteoclast reabsorption in malignancy state. Efficacy 75%–100%. Onset 48 hours. Duration, days. Concomitant hydration is imperative. Use with caution in kidney failure; adjustment in dose and infusion rate recommended. Adverse effects: ↑ phosphorus, ↑ SCr, osteonecrosis of jaw
Denosumab	120 mg SQ every 4 weeks, with additional doses on days 8 and 15 during the first month of therapy. In kidney impairment, recommend lower starting dose of 0.3 mg/kg SQ followed by a second dose if goal calcium is not attained within a week.	Recommended in patients refractory to or in whom bisphosphonate therapy is contraindicated (eg, severe kidney impairment). Monitor serum calcium and vitamin D levels, and repeat with oral/IV calcium and/or vitamin D as needed; closer monitoring needed in kidney impairment
Corticosteroids	Prednisone: 60–80 mg/day Hydrocortisone: 5 mg/kg/day IV × 2–3 days	Impair GI absorption and bone resorption. Onset several days. Best in patients with multiple myeloma, vitamin D intoxication, granulomatous conditions. Can be used in HF, kidney failure

GI, gastrointestinal; HF, heart failure; IM, intramuscularly; IV, intravenously; PO, orally; PRN, as needed; SQ, subcutaneously; SCr, serum creatinine.

HYDRATION AND DIURESIS

As noted, the first-line emergency treatment for hypercalcemia is hydration and volume expansion.[90] Most patients with hypercalcemia are volume depleted because of the accompanying polyuria, nausea, and vomiting. Normal saline 1 to 2 L/day is commonly given to correct the fluid deficit and to expand extracellular volume, which will

increase urinary calcium excretion by increasing the GFR and inhibiting calcium reabsorption in the proximal tubule. Because both sodium and calcium are reabsorbed at the same site in the proximal tubule, saline hydration will reduce the reabsorption of both cations simultaneously. A.C. was hypotensive and appeared dehydrated; therefore, saline hydration was used initially to treat hypercalcemia.

In patients who have kidney failure or HF, saline hydration alone should be used with caution to avoid fluid overload. Alternatively, a loop diuretic may be used in conjunction with saline hydration to prevent volume overload in these patients. Careful monitoring of these patients is recommended.

After adequate volume repletion has been established, IV furosemide can be administered to augment calciuresis. Furosemide blocks the reabsorption of sodium, chloride, and calcium at the thick ascending limb of the Henle loop. Doses of 80 to 100 mg every 2 to 4 hours can be used until a sufficient decline of the serum calcium concentration is attained. Smaller doses (20–40 mg) commonly are given to avoid the significant loss of fluid and electrolytes caused by the more aggressive regimen. Adequate amounts of sodium, potassium, magnesium, and fluid should be used to replace any therapy-induced electrolyte abnormalities. Fluid balance as well as serum and urine concentrations of these electrolytes must be monitored closely. Urine flow must be maintained, and the kidney loss of sodium chloride must be replaced to preserve the calciuric effect of furosemide. In A.C., the decline in serum calcium concentration was slow, possibly because of inadequate restoration of plasma volume, replacement of kidney sodium loss, or both. More aggressive hydration with adequate sodium replacement ensures that the efficacy of furosemide is not compromised.

In current practice, the use of loop diuretics together with saline hydration is less common except in patients with reduced kidney function and HF. As such, administration of normal saline alone at an initial rate of 200 to 300 mL/hour followed by a titration in rate to maintain urine output of 100 to 150 mL/minute, to treat dehydration and restore euvolemia, along with the use of other agents such as

calcitonin and bisphosphonates, should be reasonable and sufficient in most patients.

CALCITONIN

Calcitonin is useful when used in combination with saline hydration for the initial management of moderate-to-severe hypercalcemia and can result in a rapid reduction in serum calcium concentration.[90] Calcitonin reduces serum calcium concentration by inhibiting osteoclastic bone resorption. It may also increase the excretion of calcium and phosphorus by the kidneys. Only the salmon-derived calcitonin product is available in the United States.

The serum calcium concentration is often reduced several hours after calcitonin is administered, and the response may last ~6 to 8 hours. The drug is relatively nontoxic compared with organic phosphates and may be used in patients with dehydration, HF, or kidney failure. Nausea, vomiting, diarrhea, and facial flushing are the more common side effects; soreness and inflammation at the injection site may also be seen. Because of the potential for developing a hypersensitivity reaction to salmon calcitonin, the manufacturer recommends skin testing with 1 IU of the salmon calcitonin before the first dose. As seen in A.C., tolerance to the hypocalcemic effect of calcitonin can develop after 24 to 72 hours of therapy. This “escape phenomenon” may be secondary to the altered responsiveness of the hormone receptors and might be prevented by concurrent use of corticosteroids. After long-term therapy, antibodies may develop as well resulting in tachyphylaxis.

The dosage of salmon calcitonin is 4 IU/kg given subcutaneously or intramuscularly (IM) every 12 hours; the maximal dosage is 8 IU/kg every 6 hours. The hypocalcemic response is often limited, and serum calcium concentration seldom drops to the normal range.

BISPHOSPHONATES

Bisphosphonates are synthetic analogs of pyrophosphate that form stable bonds that are resistant to phosphatase degradation during osteoclast-mediated bone mineralization and resorption. The

compounds adsorb to the hydroxyapatite crystals of the bone, inhibiting their growth and dissolution. In addition, the compounds may have a direct effect on osteoclasts.[90] The two distinct pharmacologic classes of bisphosphonates that exist have different mechanisms of action. Etidronate, which does not contain any nitrogen atom, is metabolized to cytotoxic, nonhydrolyzable adenosine triphosphate (ATP) analogs. In contrast, nitrogen-containing bisphosphonates, such as pamidronate, zoledronic acid, and ibandronate inhibit the prenylation of proteins and have potent inhibitory effects on osteoclast-mediated bone resorption. In addition, they induce apoptosis of osteoclasts as well as certain tumor cells. Further antitumor activities may be mediated through their inhibitory effect on angiogenesis, stimulation of the γ-T-cell fraction in blood, and reduction of cancer cells' adherence to bone matrix. At present, etidronate, pamidronate, zoledronic acid, and ibrandronate are approved in the United States for the treatment of hypercalcemia secondary to malignancy. However, etidronate use has resulted in kidney failure, which probably is caused by the formation of bisphosphonate–calcium complexes in the serum. Furthermore, its relatively weak potency and its inconvenient IV dosing schedule have made it a less preferred agent among the other newer bisphosphonates. As such, it will not be elaborated on in this chapter. Osteonecrosis of the jaw is a concern with long-term, high-dose IV bisphosphonate therapy. However, this concern may not be of critical importance because acute hypercalcemia does not usually require long-term treatment. Patients with elevated SCr concentration and reduced kidney function would benefit from dosage adjustment of IV bisphosphonates because of their potential for nephrotoxicity. As such, caution should be exercised when using IV bisphosphonates to treat hypercalcemia in such patients. Sufficient normal saline hydration and the use of a lower dose accompanied by a slower infusion rate (eg, pamidronate 30–45 mg IV over 4 hours, zoledronic acid 4 mg IV over 30–60 minutes, and ibandronate 2 mg IV over 1–2 hours) may be considered to reduce the risk.

Pamidronate

For moderate hypercalcemia (albumin-corrected serum calcium concentration of 12.0–13.5 mg/dL), a single dose of 60 to 90 mg of pamidronate is commonly infused over the course of 3 to 4 hours. For severe hypercalcemia (albumin-corrected serum calcium concentration >13.5 mg/dL), the dose is 90 mg. The advantages of pamidronate are that it requires only a single dose and produces a superior response compared with three doses of etidronate.

If the hypercalcemia recurs, the pamidronate regimen may be repeated after an interval of ≥7 days. Long-term treatment may result in osteomalacia; however, the limited life expectancy of most patients may diminish the significance of this adverse effect. Dosing adjustment is recommended in patients with kidney impairment (SCr <30 mL/minute), as described in the section on Bisphosphonates.

Zoledronic acid

Among the bisphosphonates approved for the treatment of hypercalcemia of malignancy, zoledronic acid has the most potent effect on bone resorption. It is superior to pamidronate with respect to the number of complete responses, time needed to attain calcium normalization, and duration of effect.[91] Because 8-mg doses are not superior to 4-mg doses, 4-mg doses are administered IV over the course of 15 minutes. The drug is well tolerated at 4-mg doses. Furthermore, the lower dose accompanied by longer infusion duration (4 mg IV over 30–60 minutes) makes it safer for patients with reduced kidney function such as SCr >4.5 mg/dL. Zoledronic acid's superior efficacy and convenience of administration make it the preferred bisphosphonate for hypercalcemia of malignancy. Emerging studies show that zoledronic acid may also have promising effects in reducing skeletal complications secondary to bone metastasis associated with breast cancer, prostate cancer, non-small-cell lung cancer, and multiple myeloma.[92]

Ibandronate

Ibandronate has been shown to be effective in the treatment of hypercalcemia of malignancy. When administered as a 2- or 4-mg IV dose, it demonstrated efficacy similar to that of pamidronate and is thus a suitable option if zoledronic acid or pamidronate is not available.[93] Doses up to 6 mg were also safe and well tolerated.[94,95] Just like the other bisphosphonates, a reduction in dose and/or infusion rate is recommended in patients with impaired kidney function (CrCl <30 mL/minute).

DENOSUMAB

Denosumab is a monoclonal antibody that binds to the nuclear factor-κ ligand (RANKL) and inhibits the interaction between RANKL and RANK (a receptor found on surfaces of osteoclasts).[96] Its actions include preventing osteoclast formation or decreasing osteoclastic activity, and ultimately decreasing bone mass and bone-related adverse events.

Because denosumab is not cleared by the kidneys, its use is especially useful for patients with kidney impairment in whom bisphosphonates are contraindicated. It can also be considered in patients with hypercalcemia who do not respond to other therapies.

Unlike bisphosphonates that are administered IV, denosumab is given subcutaneously at a dose of 120 mg on days 8 and 15 during the first month, followed by every 4 weeks for the treatment of hypercalcemia of malignancy. However, because patients with kidney failure are at a higher risk for developing hypocalcemia when treated with denosumab, a lower starting dose of 0.3 mg/kg followed by a second dose if goal calcium is not attained within a week is recommended.[97,98] In addition, closer monitoring of serum calcium and vitamin D levels and repletion with oral/IV calcium and/or vitamin D may be necessary.

CALCIMIMETICS

Cinacalcet and etelcalcetide are the oral and IV forms of calcimimetic agents, respectively, currently available in the United States. Cinacalcet is used in the treatment of hypercalcemia

secondary to primary hyperparathyroidism and parathyroid carcinoma, whereas both agents are approved for use in secondary hyperparathyroidism in hemodialysis patients.[99] Their use in hypercalcemia of malignancy is less well established.

CORTICOSTEROIDS

Several possible mechanisms that may explain the hypocalcemic effect of corticosteroids exist. Vitamin D_3–mediated intestinal calcium absorption may be impaired[100] and the action of osteoclast-activating factor, which mediates bone resorption in malignancy, may be inhibited. Corticosteroids may also have a direct cytolytic effect on tumor cells and inhibit the synthesis of prostaglandins. Prednisone in daily doses of 60 to 80 mg is given initially, with subsequent dosage reduction based on the calcemic response. Alternatively, hydrocortisone (5 mg/kg/day for 2–3 days) may be given. The hypocalcemic effect will not be apparent for at least 1 to 2 days. Patients with hematologic malignancies and lymphomas tend to have a better response than do those with solid tumors. Corticosteroids are also effective in treating hypercalcemia associated with vitamin D intoxication, sarcoidosis, and other granulomatous conditions.[101] They are not generally used for long-term therapy because of their potential for serious adverse reactions.

DIALYSIS

Kidney replacement therapy such as hemodialysis and peritoneal dialysis may be considered in patients with severe malignancy who do not respond to other therapies or in those with kidney or HF who do not tolerate saline hydration therapy. Of note, the use of low-calcium or calcium-free dialysate is necessary to avoid exacerbating hypercalcemia.

PHOSPHORUS

Homeostasis

Phosphorus is found primarily in bone (85%) and soft tissue (14%); <1% of the total body store resides in the ECF.[71] Virtually, all of the "free" or active phosphorus exists as phosphates in the plasma. Most clinical laboratories, however, measure and express the concentrations of elemental phosphorus contained in the phosphate molecules. Phosphate of 1 mmol contains 1 mmol of phosphorus, but 1 mmol of phosphate is three times the weight of 1 mmol of phosphorus. Therefore, it is incorrect to equate a certain milligram weight of phosphorus as the same milligram weight of phosphate. Of the total plasma phosphorus, 70% exists as the organic form and 30% as the inorganic form. Organic phosphorus, primarily phospholipids and small amounts of esters, is bound to proteins. About 85% of inorganic phosphorus, or orthophosphate, is unbound or "free." The relative amounts of the two orthophosphate components, $H_2PO_4^-$ and HPO_4^{2-}, vary with pH. At pH 7.40, the ratio of the two species is 1:4, giving rise to a composite valence of 1.8 for the orthophosphate. Serum phosphate concentrations reported by clinical laboratories reflect only the inorganic portion of the total plasma phosphate. To avoid confusion related to the pH effect on valence, phosphate concentrations are reported as mg/dL or mmol/dL rather than mEq/volume.

The normal range of serum phosphate concentration in healthy adults is 2.5 to 4.5 mg/dL. The value is higher in children, possibly because of the increased amount of growth hormone and the reduced amount of gonadal hormones.[72,101] In postmenopausal females, the range is slightly higher; it is lower in older males. The serum phosphate concentration is also affected by dietary intake. Phosphate-rich foods can transiently increase the serum phosphate concentration. In contrast, glucose decreases the serum phosphate concentration because of the flux of sugar and phosphate into cells and because of the phosphorylation of glucose. Similarly, administration of insulin and epinephrine decreases the serum phosphate concentration because of their effects on glucose. The

serum concentration of phosphate is reduced in alkalosis and increased in acidosis.[101]

A balanced diet contains 800 to 1500 mg/day phosphorus. Both the organic and inorganic forms of phosphorus are present in food substances. Most of the phosphorus in milk is the organic form; the phosphorus in meat, vegetable, and other nondairy sources represents organic forms bound to proteins, lipids, and sugars, which usually are hydrolyzed before absorption. In general, 60% to 65% of the phosphorus ingested is absorbed, mostly in the duodenum and jejunum through an energy-dependent, saturable, active process. Phosphorus absorption is linearly related to the dietary intake when the intake is 4 to 30 mg/kg/day. The amount of phosphorus ingested probably is the most important factor in determining net absorption. Phosphorus absorption is also stimulated during periods of increased demand, such as active growth and pregnancy. Increased intake of calcium and magnesium and concurrent use of aluminum hydroxide antacids may reduce phosphorus absorption owing to formation of a nonabsorbable complex. In addition, absorption is also affected by vitamin D, PTH, and calcitonin.[72]

Phosphorus excretion by the kidneys depends on the dietary phosphorus intake. Normally, >85% of the filtered phosphate load is reabsorbed; however, the fractional urinary excretion can vary from 0.2% to 20%. Phosphate excretion by the kidneys is also affected by acid–base balance, ECF volume, and calcium and glucose concentrations.[72,101] In addition, PTH, thyroid hormone, thyrocalcitonin, vitamin D, insulin, glucocorticoid, and glucagon can also alter phosphate excretion.

Hypophosphatemia

ETIOLOGY

CASE 27-12

Question 1: M.R., a 72-year-old female, was admitted to the hospital with a 1-week history of increasing malaise, confusion, and decreased activity. M.R. has

a history of HF, hypertension, type 2 diabetes, and peptic ulcer disease. She was receiving hydrochlorothiazide, aluminum–magnesium antacid, sucralfate, and insulin. She is febrile and in significant respiratory distress. ABG results at admission were pH, 7.5; PaO_2, 42 mm Hg; and $PaCO_2$, 20 mm Hg. Respiratory function continued to deteriorate, requiring intubation and mechanical ventilation. Serum electrolyte concentrations were as follows:

Na^+, 128 mEq/L
K^+, 3.2 mEq/L
Cl^-, 96 mEq/L
Total CO_2, 23 mEq/L
Glucose, 320 mg/dL
Phosphorus, 0.9 mg/dL

What may have contributed to the low serum phosphorus concentration in M.R.?

Hypophosphatemia can develop as the result of a phosphorus deficiency or secondary to a net flux of phosphorus out of the plasma compartment without a total body deficit. Moderate hypophosphatemia is defined as a serum phosphorus concentration of 1 to 2 mg/dL. A concentration of <1 mg/dL, as in M.R., is considered severe.[102] The extent of hypophosphatemia may not be assessed accurately by a single plasma phosphorus concentration determination because of diurnal variation. Patients receiving large doses of mannitol may have pseudohypophosphatemia owing to the binding of mannitol with molybdate, which is used in the calorimetric assay for phosphorus.

Hypophosphatemia is commonly caused by conditions that impair intestinal absorption, increase kidney elimination, or shift phosphorus from the extracellular to the intracellular compartments. Hypophosphatemia secondary to low dietary phosphorus is exceedingly rare because phosphorus is ubiquitous.[71,102] In addition, phosphorus excretion is reduced and intestinal phosphorus absorption is increased to prevent a deficiency state. Starvation in itself does not result in severe hypophosphatemia because the phosphorus content in plasma and muscles is often normal. Hypophosphatemia, however, can develop during refeeding with a high-calorie diet low in phosphorus. Therefore, hyperalimentation

without phosphorus supplementation is likely to cause severe hypophosphatemia.

Impaired phosphorus absorption secondary to malabsorptive conditions, prolonged nasogastric suction, and protracted vomiting can also result in hypophosphatemia. In M.R., the use of aluminum-containing and magnesium-containing antacids may further reduce phosphorus absorption. The antacids bind with endogenous and exogenous phosphorus in the GI tract and cause severe hypophosphatemia in patients with or without kidney failure.[103] In addition, M.R. was taking sucralfate, which contains aluminum and can bind phosphorus in the GI tract.[103] Similarly, iron preparations can bind phosphorus.[104]

Hyperglycemia-induced osmotic diuresis and diuretic use may have increased the kidney loss of phosphorus in M.R. Other conditions associated with phosphorus wasting include renal tubular acidosis, hyperparathyroidism, hypokalemia, hypomagnesemia, and extracellular volume expansion.[72,101,102] None of these situations, however, was evident in M.R. Shifting of phosphorus into the intracellular compartment by glucose or insulin and profound respiratory alkalosis may also have contributed to M.R.'s hypophosphatemic state.[101,102]

Case 27-12, Question 2: What other conditions are commonly associated with hypophosphatemia?

Diabetic ketoacidosis, chronic alcoholism, chronic obstructive airway disease, and extensive thermal burns are other conditions commonly associated with hypophosphatemia.[72,101,102] They are characterized by a combination of factors that result in phosphate loss and intracellular phosphate use. In patients with diabetic ketoacidosis, metabolic acidosis enhances the movement of phosphate from the intracellular compartment to plasma, whereas the concurrent osmotic diuresis secondary to hyperglycemia increases the kidney elimination of extracellular phosphate. The net result is a depletion of total body stores. Correction of the acidosis

and administration of insulin then promotes the rapid uptake of phosphorus by tissues, and volume repletion dilutes the extracellular concentration. This sequence of events can ultimately lead to severe hypophosphatemia. The hypophosphatemia associated with chronic alcoholism and acute alcohol intoxication is also thought to be related to several factors, including reduced intestinal phosphorus absorption caused by vomiting, diarrhea, and antacid use; repeated acidosis that results in increased urinary phosphate excretion; and a shift of phosphorus into cells because of respiratory alkalosis. Phosphorus wasting can also result from hypomagnesemia or as a direct effect of alcohol.[102]

CLINICAL MANIFESTATIONS

Case 27-12, Question 3: What are the signs and symptoms associated with hypophosphatemia?

The clinical effects associated with chronic phosphorus depletion are often insidious and gradual in onset. In contrast, a rapid decline in plasma phosphorus concentrations results in sudden and serious organ dysfunction. Most of the effects can be attributed to impaired cellular energy stores and tissue hypoxia secondary to depletion of ATP or erythrocyte 2,3-diphosphoglycerate.[72,102] Severe hypophosphatemia can result in generalized muscle weakness, confusion, paresthesias, seizures, and coma. In addition, reduced cardiac contractility, hypotension, respiratory failure, and rhabdomyolysis have been observed with acute severe hypophosphatemia. Chronic phosphorus depletion has been associated with decreased mentation; muscle weakness; osteomalacia; rickets; anorexia; dysphagia; cardiomyopathy; tachypnea; reduced sensitivity to insulin; and dysfunction of red blood cells, white blood cells, and platelets. Kidney function is altered, as manifested by hypophosphaturia, hypercalciuria, hypermagnesuria, bicarbonaturia, and glycosuria. M.R.'s decreased

mentation, weakness, and respiratory failure are consistent with severe hypophosphatemia.

CASE 27-12, QUESTION 4: How can phosphate depletion be assessed? Outline a treatment regimen that would effectively and safely correct the phosphorus deficit in M.R. How should her therapy be monitored?

TREATMENT

Phosphorus resides primarily in the intracellular space; the amount in the ECF is only a small percentage of the total body store. Because the patient's pH, blood glucose concentration, and insulin availability may affect phosphorus distribution, it is difficult to determine the magnitude of the phosphorus deficit based on the serum concentration alone. As discussed, a patient may have hypophosphatemia secondary to a rapid shift of phosphorus into the intracellular space without a total body deficit. The duration of the hypophosphatemia is often limited because it may be corrected by kidney phosphorus conservation and oral intake of phosphorus-containing foods. Aside from serum phosphorus concentrations, urinary phosphorus excretion may be used to further assess the phosphorus deficit. Typically, phosphorus excretion is severely limited in patients with significant deficits. A phosphorus excretion of <100 mg/day (fractional phosphorus excretion < 10%) confirms appropriate phosphorus conservation when the serum phosphorus is <2 mg/dL. It also suggests a non-kidney etiology (eg, impaired GI absorption) or some type of internal redistribution (eg, respiratory alkalosis).

Prophylactic supplementation should be used in situations that predictably increase the risk of developing hypophosphatemia. These include patients who are receiving total parenteral nutrition or large doses of antacids for an extended period, patients who are alcoholic, and those with diabetic ketoacidosis.

The specific treatment of hypophosphatemia depends on the presence of signs and symptoms, as well as the anticipated duration and severity of hypophosphatemia. In an asymptomatic patient with

mild hypophosphatemia (2–2.5 mg/dL), who has no evidence of phosphorus depletion, phosphorus supplementation is generally not necessary because the condition is usually self-limited. In other patients with mild and moderate hypophosphatemia who have evidence of phosphorus deficit, oral supplementation is the safest and preferred mode of replacement. Skim or low-fat milk is a convenient source of phosphorus and calcium. Whole milk, because of its high fat content, can cause diarrhea if a large amount is consumed. Several oral phosphorus preparations can be used in patients who cannot tolerate milk products.

When hypophosphatemia is severe, as in M.R.'s case, or when the patient is vomiting or unable to take oral medication, parenteral phosphorus replacement is needed.

Either potassium phosphate or sodium phosphate injection may be used for parenteral phosphate replacement. Owing to its propensity to cause adverse consequences such as hyperkalemia or phlebitis and risk of medication errors if inadequately diluted or administered too rapidly, potassium phosphate is less preferred nowadays, unless the patient has combined hypokalemia and hypophosphatemia. Sodium phosphate injection provides the same phosphate content and is a safer alternative in patients without concurrent hypokalemia.

Several empiric regimens have been evaluated. Because potassium phosphate is less commonly used for reasons mentioned earlier, the following dosing recommendations refer to sodium phosphate preparations. IV administration of 0.08 to 0.5 mmol/kg body weight of phosphorus is safe and effective in restoring the serum phosphorus concentration.[102] Rates of administration ranging from 1 to 3 mmol/hour are suggested to be safe. More aggressive regimens using higher doses have also been suggested for patients who are critically ill or have undergone surgery because lower doses may not be effective.[102,105] If parenteral phosphate replacement is necessary, the dose used will depend on the severity of the hypophosphatemia and the patient's weight. A suggested regimen is to give 0.08 to 0.24 mmol/kg over 6 hours (up to a maximum total dose of 30 mmol) if serum phosphate concentration is at least 1.25 mg/dL and to give 0.25 to 0.50 mmol/kg over 8 to 12 hours (up to a

maximum dose of 80 mmol) if the serum phosphate is <1.25 mg/dL.[106,107] Parenteral phosphorus replacement should be stopped once the serum phosphorus concentration reaches 1.5 to 2 mg/dL and also when oral supplementation could be started. Regardless of the regimen used, serum phosphorus, calcium, and magnesium concentrations should be monitored closely because IV phosphorus administration can induce hyperphosphatemia quite rapidly as well as hypocalcemia and hypomagnesemia. In particular, serum phosphate, calcium and magnesium concentrations should be monitored 6 hours after parenteral phosphate is given. Kidney function should also be checked daily. Metastatic soft tissue calcification, hypotension, and, depending on the preparation used, potassium, sodium, or volume overload may occur. This could be significant in patients such as M.R. who have a history of HF and hypertension. Therefore, kidney function and volume status should be monitored during therapy.

Phosphorus can be administered orally in doses of 30 to 60 mmol/day, usually given in two to four divided doses to minimize GI adverse events.[102] Oral phosphate supplements contain varying ratios of sodium and potassium phosphate. Therefore, a product should be selected based on its sodium and potassium content, as well as the patient's serum concentrations of these electrolytes. Any commercially available oral supplement such as Fleet®, Neutra-Phos®, or Neutra-Phos K® may be used. Each packet of Neutra-Phos® contains 8 mmol of phosphorus and can be given four times daily and at bedtime, whereas Fleet Phospho-Soda® can be given as 5 mL twice daily), both of which deliver 40 mmol/day of phosphorus. Skim milk, the preferred agent for diluting the supplement, contains ~7 mmol of phosphorus/cup and provides calcium and potassium as well. Diarrhea, a common dose-related side effect of oral phosphorus replacement, can be minimized by diluting the supplement and slowly titrating the dose. Large doses can also result in metabolic acidosis. Regardless of whether it is given orally or via IV, phosphate supplementation should also be avoided or used with caution in patients with kidney disease because of the risk

of developing hyperphosphatemia and calcium phosphate precipitation.

In M.R., oral supplementation was not feasible because she had intermittent diarrhea and vomiting. Potassium phosphate 15 mmol (providing 22 mEq of potassium) was therefore infused IV in 250 mL of normal saline over the course of 3 to 6 hours, in view of both hypokalemia and hypophosphatemia. The regimen was repeated once until the serum phosphorus concentration reached 2 mg/dL. Oral supplementation with Fleet Phospho-Soda® then was begun by adding 1 tsp twice daily to her enteral tube feeding.

Hyperphosphatemia

Refer to the section on Mineral and Bone Disorders in Chapter 28, Chronic Kidney Disease.

MAGNESIUM

Homeostasis

Magnesium is an intracellular cation found primarily in bone (65%) and muscle (20%). Only 2% of the total body store of 21 to 28 g (1750–2400 mEq) is located in the extracellular compartment. Serum magnesium concentrations, therefore, do not reflect the total magnesium body store accurately. In healthy adults, the serum magnesium concentration is 1.5 to 2.4 mEq/L, with ~20% of the serum magnesium bound to proteins.

Magnesium plays an important role in different metabolic processes, particularly in energy transfer, storage, and utilization. Cation deficiency can impair many ATP-mediated energy-dependent cellular processes as well as the action of phosphatases.[72] Magnesium is necessary for many enzymes involved in the metabolism of carbohydrates, fat, and protein, as well as RNA aggregation, DNA transcription, and degradation. The normal

operation of many sodium, proton, and calcium pumps and the regulation of potassium and calcium channels are all dependent on the availability of intracellular magnesium.[72,108] In addition, adequate magnesium stores are needed to maintain normal neuronal control, neuromuscular transmission, and cardiovascular tone.

The average diet in North America contains about 20 to 30 mEq of magnesium. The daily requirement is ~18 to 33 mEq for young persons and 15 to 28 mEq for females. Normally, 30% to 40% of the elemental magnesium is absorbed, primarily in the jejunum and ileum. However, absorption may be increased to 80% in deficiency states and reduced to 25% during high magnesium intake. In patients with uremia, GI absorption of magnesium is decreased; however, absorption in the jejunum can be normalized by physiologic doses of 1α,25-dihydroxyvitamin D_3. In addition, PTH also modulates magnesium absorption.[72,108]

Magnesium is eliminated primarily by the kidneys; only 1% to 2% of the endogenous magnesium is eliminated by the fecal route.[72,108] The magnitude of kidney removal is determined by GFR and tubular reabsorption. Approximately 20% to 30% of the tubular reabsorption takes place in the proximal tubule, whereas the Henle loop, primarily the thick ascending limb, is responsible for up to 65% of the total reabsorption. Only about 5% to 6% of the filtered magnesium is generally eliminated in the urine. The extent of magnesium reabsorption changes in parallel with sodium reabsorption, which is affected by the ECF volume. The kidney threshold for urinary magnesium excretion is 1.3 to 1.7 mEq/L, which is similar to the normal plasma magnesium concentration. Slight changes in plasma magnesium concentration, therefore, may substantially alter the amount of magnesium excreted in the urine.

Urinary magnesium reabsorption is affected by many factors, including sodium balance; ECF volume; serum concentrations of magnesium, calcium, and phosphate; and metabolic acidosis and alkalosis.[72,108] Concurrent use of loop and osmotic diuretics will also modulate the reabsorption. Hormones, such as PTH, and, possibly,

calcitonin, glucagon, and mineralocorticoids may affect the routine maintenance of magnesium balance as well.

Hypomagnesemia

ETIOLOGY

CASE 27-13

QUESTION 1: R.J., a 61-year-old male, is admitted to the hospital because of trauma to his forehead after falling at home. He has a long history of conditions related to his alcohol abuse: liver disease, ascites, seizures, pancreatitis, and malabsorption. R.J. reported abdominal pain, nausea, vomiting, and diarrhea for the past several days. At admission, R.J. was confused, apprehensive, and combative, and he had marked tremors. He also had delirium, as evidenced by hallucinations, screaming, and delusions, and he was having multiple tonic–clonic seizures. The medical record revealed that R.J. had been taking furosemide for the past 2 months. Pertinent laboratory test results obtained at admission were as follows:

K^+, 2.5 mEq/L
Magnesium, 0.8 mEq/L
Creatinine, 0.8 mg/dL

Phenytoin was administered for seizure control, and R.J. was placed on nasogastric suction. Fluid restriction was instituted, and furosemide therapy was continued to control his ascites.

What circumstances have contributed to R.J.'s hypomagnesemia?

Magnesium body stores are difficult to assess because magnesium is primarily an intracellular ion, and serum magnesium concentrations do not provide an accurate indication of the total body load. In fact, cellular magnesium depletion may be present with low, normal, or even high serum magnesium concentrations. Conversely, hypomagnesemia may be seen without a net loss of body magnesium. Refeeding after starvation will result in increased trapping of magnesium by newly formed tissue, resulting in hypomagnesemia. Similarly, acute pancreatitis and parathyroidectomy can cause hypomagnesemia without a net loss of the cation.

The prevalence of hypomagnesemia in ambulatory and hospitalized patients is ~6% to 12%.[109,110] The incidence increases to 40% to 60% in patients who are hypokalemic. Diuretic treatment and diarrhea may result in both hypokalemia and hypomagnesemia. In addition, hypomagnesemia induces potassium wasting by increasing potassium secretion into the kidney tubules.

As many as 60% to 65% of patients in the intensive care unit may develop hypomagnesemia, resulting in increased mortality.[109,110]

Magnesium depletion and hypomagnesemia can develop owing to GI, kidney, and endocrinologic causes. Depletion can occur in patients whose dietary magnesium intake is severely restricted and in those who have protein-calorie malnutrition.[72,108–110] Also at risk are patients who receive prolonged parenteral nutrition and those who undergo prolonged nasogastric suction. Hypomagnesemia may be present in patients who have increased magnesium requirements, such as pregnant females and infants. Conditions associated with steatorrhea, such as nontropical sprue and short bowel syndrome, can result in reduced GI magnesium absorption. Insoluble magnesium soaps may be formed in the GI tract because of the presence of unabsorbed fat. Hypomagnesemia can also occur in patients with a bowel resection and severe diarrhea. A rare genetic disorder has also been reported in patients with defective GI magnesium absorption. An impaired carrier- mediated magnesium transport system is believed to be responsible for the symptomatic deficiency, which requires high oral magnesium intake to overcome the defect.

Magnesium wasting can be caused by a primary defect or be secondary to systemic factors. A rare form of magnesium wasting is congenital. Various drugs can induce hypomagnesemia through increased kidney loss: cisplatin,[111] aminoglycosides,[112] cyclosporine,[113] proton-pump inhibitors (PPIs),[114] and amphotericin B.[115] Use of loop and thiazide diuretics can also result in hypomagnesemia, which can be reversed with the concurrent use of amiloride or triamterene. Magnesium depletion can be associated with phosphate depletion, calcium infusion, and ketoacidosis.[109,110] Acute and chronic ingestion of alcohol will result in increased

magnesium loss. Various endocrinologic disorders, such as SIADH, hyperthyroidism, hyperaldosteronism, and post-parathyroidectomy, are also associated with hypomagnesemia.[109,110]

R.J. could be hypomagnesemic for many reasons. His long history of alcohol use, malnutrition, and malabsorption may all have contributed to his magnesium deficit. The vomiting and diarrhea that he experienced could have reduced GI magnesium absorption. Use of furosemide and nasogastric suction while in the hospital could also have exacerbated his magnesium depletion through kidney and GI losses, respectively.

CLINICAL MANIFESTATIONS

Case 27-13, Question 2: What are the clinical manifestations of hypomagnesemia in R.J.?

Magnesium depletion can result in abnormal function of the neurologic, neuromuscular, and cardiovascular systems.[72,107–110] Hypomagnesemia lowers the threshold for nerve stimulation, resulting in increased irritability. Typical findings include Chvostek and Trousseau signs, muscle fasciculation, tremors, muscle spasticity, generalized convulsions, and, possibly, tetany. The patient may experience weakness, anorexia, nausea, and vomiting, as seen in R.J. Hypokalemia, hypocalcemia, and alkalosis may be present as well. In patients who are moderately depleted, changes in the ECG include widening of the QRS complex and a peaking T wave. In severe depletion, a prolonged PR interval and a diminished T wave may be seen. Ventricular arrhythmias have also been reported in some patients.

TREATMENT

Case 27-13, Question 3: Outline a regimen to replenish the body stores of magnesium for R.J. What monitoring plan could you develop to assess efficacy and potential adverse effects?

As discussed in Case 27-13, Question 1, serum magnesium concentration is a poor reflection of total body magnesium store. The specific regimen and the route of magnesium replenishment depend on the clinical presentation of the patient and the severity of the manifestations. Symptomatic patients require more aggressive parenteral therapy, whereas oral replacement may suffice for asymptomatic hypomagnesemia. Patients with life-threatening symptoms, such as seizures and arrhythmias, need immediate magnesium infusion. Because serum magnesium concentrations do not reflect total body stores, symptoms are more important determinants of the urgency and aggressiveness of therapy. As such, severity of clinical presentations is used instead of serum magnesium concentration to determine therapeutic regimens. However, the following classification of severity of hypomagnesemia based on serum concentrations may be used to guide replacement therapy in stable patients: mild (1.6–1.9 mg/dL), moderate (1–1.5 mg/dL), and severe (<1 mg/dL).[116]

The body stores of magnesium must be replenished slowly. Serum magnesium concentrations may return to the normal range within the first 24 hours, but total replenishment of body stores may take several days. Furthermore, ~50% of the administered IV dose of magnesium will be excreted in the urine.[107] Because the threshold for urinary magnesium excretion is low, the abrupt increase in serum magnesium after an IV dose will result in increased urinary magnesium excretion despite a total body magnesium deficit. Conversely, in patients with kidney impairment, decreased excretion of magnesium will place the patient at risk for hypermagnesemia. A reduced rate of magnesium administration and frequent monitoring of serum magnesium concentrations are therefore necessary in patients with kidney dysfunction.

Oral replacement of magnesium is indicated for asymptomatic patients with mild depletion.[107] Magnesium-containing antacids, milk of magnesia, and magnesium oxide are effective choices for replacement. Sustained-release preparations, such as Slow Mag® (magnesium chloride) or Mag-Tab® SR (magnesium lactate), are preferred to minimize magnesium elimination by avoiding high serum

concentration. With 5 to 7 mEq (2.5–3.5 mmol or 60–84 mg) of magnesium per tablet, six to eight tablets should be given daily in divided doses for severe magnesium depletion. For mild and asymptomatic disease, two to four tablets per day may be sufficient. A diet high in magnesium (chocolate, cereals, nuts, meat, fruits, fish, legumes, and vegetables) will also help replenish body stores and prevent depletion.

For patients with symptomatic hypomagnesemia, such as R.J., parenteral magnesium replacement is indicated.[107] The magnesium deficit in patients with chronic alcoholism is estimated to be 1 to 2 mEq/kg. Because up to half of the IV magnesium dose will be excreted in the urine during replacement, ~2 to 4 mEq/kg will be needed to replenish R.J.'s body store. Magnesium of 1 mEq/kg, as magnesium sulfate 10% solution, should be administered IV in the first 24 hours. This dose may be repeated to keep the serum magnesium concentration >1.0 mg/dL. Later, 0.5 mEq/kg of magnesium may be replenished daily for up to 4 additional days. Magnesium levels should be checked several hours after the completion of infusion to allow distribution to take place. Magnesium sulfate 1 g contains 98.6 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. Magnesium can be given IM as 50% solution, but the injections are painful and potentially sclerosing, and multiple administrations are needed. Therefore, the IV route is the preferred mode of parenteral administration. For patients with symptomatic hypomagnesemia who are unstable, such as those experiencing seizures or life-threatening arrhythmias, 1 to 2 g (8–16 mEq or 4–8 mmol) of magnesium sulfate may be administered as a short IV infusion over the course of 2 to 15 minutes. The dose may be repeated if the patient remains hemodynamically unstable. If the patient is hemodynamically stable with severe symptomatic hypomagnesemia (<1 mg/dL [0.4 mmol/L or 0.8 mEq/L]), 1 to 2 g of magnesium sulfate (8–16 mEq [4–8 mmol]) in 50 to 100 mL of 5% dextrose in water can be given initially over 5 to 60 minutes followed by an infusion of 4 to 8 g of magnesium sulfate (32–64 mEq [16–32 mmol]) administered slowly over 12 to 24 hours. This dose can be repeated as needed to maintain plasma magnesium concentration

>1 mg/dL (0.4 mmol/L or 0.8 mEq/L) if the patient continues to be symptomatic. In patients who are normomagnesemic with hypocalcemia, this dose may be repeated daily for 3 to 5 days.[116]

If rapid IV magnesium administration is necessary, the patient should remain in a supine position to avoid hypotension.[107] The patient should also be monitored carefully for marked suppression of deep tendon reflexes (magnesium, 4–7 mEq/L); ECG, BP, respiration changes, and serum magnesium levels should be frequently monitored. Facial flushing, a sensation of warmth, and sweatiness may result from vasodilation secondary to a rapid magnesium infusion.

Typically, patients with kidney dysfunction should not receive magnesium-containing medications. However, magnesium repletion would be needed for those with severe hypomagnesemia (<1 mg/dL). The repletion should be administered with caution because there is no published data to guide therapy. It has been suggested that for symptomatic patients with moderate kidney impairment (GFR 15–30 mL/minute/1.73 m^2) and severe hypomagnesemia, 2 to 4 g of IV magnesium sulfate would be administered slowly over 4 to 12 hours. Serum magnesium concentration should be monitored after each dose or daily if doses are given less frequently. If the patient is asymptomatic, oral treatment at half of the doses for normal kidney function may be given. Serum magnesium concentration should be monitored afterward before subsequent doses. Particular caution is warranted in patients with renal impairment, in whom the rate of magnesium repletion should be reduced. These patients should be monitored frequently to avoid toxicities related to hypermagnesemia.

IV magnesium should also be administered cautiously in patients with severe atrioventricular heart block or bifascicular blocks because magnesium possesses pharmacologic properties similar to that of calcium channel blockers.[107]

In patients who exhibit hypomagnesemia secondary to a thiazide or loop diuretic, amiloride may be added to reduce magnesium loss by increasing reabsorption in the cortical collecting tubule.[117]

Long-term use of PPIs can cause hypomagnesemia by reduced intestine active magnesium absorption.[114] Patients at risk for serious

complications associated with hypomagnesemia (cardiac arrhythmias, underlying heart disease, etc) should be monitored closely or use H_2 antagonists instead of PPIs. For those patients who develop hypomagnesemia but require continued PPI treatment, oral magnesium supplementation can restore plasma concentrations to normal by increasing GI absorption via the passive paracellular pathway.

Case 27-13, Question 4: For the initial 2 days of hospitalization, R.J. received 3 mEq/kg of IV magnesium sulfate. However, his serum magnesium concentration remained <1.5 mEq/L. What might have contributed to the lack of favorable response to the magnesium therapy?

The total amount of magnesium administered to R.J. during the past 2 days was higher than the usual recommended rate (4–5 days) of magnesium replenishment, leading to kidney excretion of a large portion of the dose. Furthermore, the use of nasogastric suction and furosemide has increased the magnesium loss during the replacement period, and hypokalemia may have reduced the effectiveness of magnesium replacement. In a patient whose serum magnesium concentration does not increase after appropriate magnesium therapy, a 24-hour urine collection to assess magnesium excretion can be helpful. A low urinary magnesium concentration is consistent with magnesium depletion, whereas a high urinary magnesium excretion in the presence of hypomagnesemia suggests magnesium wasting.[72,108–110]

Hypermagnesemia

ETIOLOGY

CASE 27-14

Question 1: J.O., a 63-year-old male with kidney insufficiency, was admitted to the hospital because of increasing weakness during the past several days. J.O. began taking a magnesium–aluminum hydroxide antacid several times daily 2

weeks ago when he exhibited stomach upset. Physical examination reveals hypotension and depressed deep tendon reflexes. The ECG reveals prolonged PR and QRS intervals. The serum magnesium concentration is 6.5 mEq/dL.

What is the most likely cause of hypermagnesemia in J.O.?

Because the kidney is the primary route of magnesium elimination, kidney impairment is a virtual requisite for hypermagnesemia (see Chapter 28, Chronic Kidney Disease). A common cause of hypermagnesemia is the use of magnesium-containing medications, such as antacids and laxatives, by patients with impaired kidney function, including older adults. When a patient with kidney failure, such as J.O., takes magnesium-containing medications, the serum magnesium concentration can increase substantially, resulting in toxicities.[118] Hypermagnesemia may be seen when the CrCl drops to <30 mL/minute; an inverse relationship is observed between the serum magnesium concentrations and the CrCls. Hypermagnesemia is also seen in patients with acute kidney failure during the oliguric phase, but not the diuretic phase. Other potential causes of hypermagnesemia include adrenal insufficiency, hypothyroidism, lithium, magnesium citrate used as a cathartic for drug overdose, and parenteral magnesium given for preeclampsia.[72]

CLINICAL MANIFESTATIONS

Case 27-14, Question 2: What is the usual clinical presentation of a patient with hypermagnesemia?

An elevated magnesium serum concentration alters the normal function of the neurologic, neuromuscular, and cardiovascular systems. When the serum magnesium concentration is >4 mEq/L, deep tendon reflexes are depressed; they are usually lost at >6 mEq/L. Flaccid quadriplegia can develop when the concentration is >8 to 10 mEq/L. Respiratory paralysis, hypotension, and difficulty talking and swallowing may also be present. Changes in the ECG may include a prolonged PR interval and widening of the QRS complex. Complete heart block may be seen at concentrations of

~15 mEq/L. In mild hypermagnesemia, the patient may experience nausea and vomiting.

Drowsiness, lethargy, diaphoresis, and altered consciousness may be present at higher serum magnesium concentrations. J.O.'s increasing weakness, hypotension, depressed deep tendon reflexes, and ECG findings are consistent with hypermagnesemia.

TREATMENT

CASE 27-14, QUESTION 3: How should J.O.'s hypermagnesemia be treated?

If magnesium-containing medications are discontinued in patients with hypermagnesemia, the serum magnesium concentration will usually return to the normal range through kidney elimination. When potentially life-threatening complications are present, as in J.O., 5 to 10 mEq of IV calcium chloride should be administered to antagonize the respiratory and cardiac manifestations of magnesium.[72] The dose of the calcium can be repeated as necessary because its effect is short-lived. In patients with good kidney function without life-threatening complications, IV furosemide, plus 0.45% sodium chloride to replace lost urine volume, will enhance urinary magnesium excretion while preventing volume depletion. Hemodialysis or peritoneal dialysis is indicated for patients with significant kidney function impairment and possibly for those with severe hypermagnesemia.

Chronic Kidney Disease

Adinoyi Garba

CORE PRINCIPLES		CHAPTER CASES
1	Chronic kidney disease (CKD) is progressive, irreversible kidney damage characterized by decreased estimated glomerular filtration rate (eGFR) or evidence of kidney damage for at least 3 months.	**Case 28-1 (Question 1)**
2	Classification of CKD staging should be determined based on kidney function, defined by the Kidney Disease: Improving Global Outcomes (KDIGO). Each stage is associated with certain action plans.	**Case 28-1 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	Many equations exist for calculating creatinine clearance (CrCl) or eGFR. The Modification of Diet in Renal Disease (MDRD) equation is used to quantify glomerular filtration rate (GFR) to detect or stage the degree of CKD and to follow progression. The Cockcroft–Gault (CG) equation is used to adjust the doses of medications that are eliminated by the kidneys.	**Equation 28-3**
4	Diabetes is the number one cause of CKD in the United States. Optimal control of blood glucose levels and albuminuria is essential to slow the progression of CKD and reduce morbidity and mortality.	**Case 28-1 (Questions 2–4)**
5	Fluid accumulation and electrolyte abnormalities secondary to CKD often complicate the treatment of hypertension and can have cardiotoxic effects.	**Case 28-1 (Questions 5, 6)**
6	Metabolic acidosis presents in late stages of CKD from reduced hydrogen ion excretion and bicarbonate production. Metabolic acidosis can worsen bone disease and other metabolic processes.	**Case 28-1 (Question 7)**

	CORE PRINCIPLES	CHAPTER CASES
7	Treating anemia of CKD is essential to reducing cardiovascular disease (CVD) complications. Management of anemia includes administration of iron supplementation and erythropoiesis-stimulating agents.	**Case 28-1 (Questions 8, 9)**
8	CVD is the number one cause of morbidity and mortality in CKD. Cardioprotective measures should be addressed at all stages.	**Case 28-2 (Question 1)**
9	Hypertension is the second leading cause of CKD in the United States. Treating hypertension to target goals is necessary to slow the progression of CKD and reduce mortality.	**Case 28-2 (Question 2)**
10	Treating dyslipidemia in CKD reduces the risk of major cardiovascular events but does not affect the risk of progression of kidney disease	**Case 28-2 (Question 3)**
11	Mineral and bone disorders (MBD) characterized by biochemical abnormalities in calcium, phosphate, parathyroid hormone, and vitamin D metabolism may occur and lead to alterations of bone morphology or vascular calcification as CKD progresses. Vascular calcification increases the risk for cardiovascular mortality.	**Case 28-3 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
12	Hyperphosphatemia is managed with dietary phosphorus restriction and phosphate-binding agents.	**Case 28-3 (Question 2)**
13	Activated forms of vitamin D (calcitriol, paricalcitol, and doxercalciferol) or a calcimimetic agent (cinacalcet) may be necessary to achieve proper biochemical balance and bone metabolism.	**Case 28-3 (Question 2)**
14	Glomerulonephropathies (GNs) are a collection of glomerular diseases caused by a variety of immunologic mechanisms and the third leading cause of CKD. Patients with GN may present with nephrotic syndrome and require treatment with immunosuppressant therapy.	**Case 28-4 (Questions 1)** **Case 28-5 (Questions 1, 2) Case 28-6 (Question 1)**

INTRODUCTION

Chronic kidney disease (CKD) is the continuum of kidney dysfunction from early to late-stage disease. It is generally defined as an estimated glomerular filtration rate (eGFR) <60 mL/minute/1.73 m^2 persisting for more than 3 months. The most advanced stage of CKD formerly referred to as end-stage kidney disease will be referred to as kidney failure within this chapter. At this stage, chronic kidney replacement therapy (KRT) in the form of dialysis or kidney transplantation is necessary to sustain life.[1] There are several complications associated with CKD, including fluid and electrolyte abnormalities, anemia, cardiovascular disease (CVD),

mineral and bone disorders (MBDs), and malnutrition. The optimal management of CKD is best achieved using a multidisciplinary approach to slow its progression and address the concurrent medical problems and complex pharmacotherapeutic regimens.

Implementation of clinical practice guidelines in the diagnosis, monitoring, and treatment of CKD leads to improved patient outcomes and reduced variability in patient care.[2] In the United States, the National Kidney Foundation (NKF) established the Kidney Disease Outcomes Quality Initiative (K/DOQI) to provide evidence-based clinical practice guidelines for all stages of CKD and related complications. However, because CKD is a worldwide public health issue and the problems faced by patients with CKD around the world are universal, the Kidney Disease: Improving Global Outcomes (KDIGO) was established in 2003. The mission of KDIGO is to improve the care and outcomes of patients with CKD worldwide by promoting coordination, collaboration, and integration of initiatives. KDIGO is managed by the NKF. Contact information for K/DOQI and KDIGO and corresponding web addresses for clinical practice guidelines can be found in **Table 28-1**.

Definition and Classification of Chronic Kidney Disease

CKD is characterized by a progressive deterioration in kidney function over months to years, characterized by irreversible structural damage to existing nephrons. The KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease defines CKD as abnormalities or damage to kidney structure or function that persists for at least 3 months with implications for the patient's health. Structural abnormalities or damage are often determined by imaging studies, kidney biopsy, or the excretion of plasma proteins like albumin in the urine (albuminuria) (**Table 28-2**). Glomerular filtration rate (GFR) is a measure of the amount of blood filtered across the glomerulus each minute. The eGFR is the widely accepted measure of kidney function. KDIGO classifies kidney function based on eGFR into five broad categories (G1–G5) (**Table 28-3**). Unlike previous K/DOQI guidelines, KDIGO divides category G3 GFR into two subcategories, G3a (GFR of 45–59 mL/minute/1.73 m^2) and G3b (GFR 30–44 mL/minute/1.73 m^2), to better stratify patients based on the different outcomes and risks associated with these levels of GFR.[1]

Table 28-2

Criteria for Chronic Kidney Disease

Markers of Kidney Damage
Albuminuria (AER ≥30 mg/24 hours; ACR ≥30 mg/g [≥3 mg/mmol])
Urine sediment abnormalities
Electrolyte and other abnormalities because of tubular disorders
Abnormalities detected by histology
Structural abnormalities detected by imaging
History of kidney transplantation

Must be at the defined GFR range or damage persisting for 3 months or greater.

AER, albumin excretion rate; ACR, albumin-to-creatinine ratio; GFR, glomerular filtration rate.

Estimation of GFR alone may not be sufficient for identifying early stages of CKD because GFR may be normal or borderline normal. In such cases, kidney damage is indicated by pathologic abnormalities of the kidneys or markers of kidney injury like albuminuria could add help to assess overall kidney status.[1] There are three categories of albuminuria (A1–A3) (**Table 28-4**). A comprehensive classification of CKD should include CGA (**c**ause of CKD, **G**FR, **a**lbuminuria).[1] For examples of CKD classification using CGA categories, see **Table 28-5**. The GFR and albuminuria categories can be used to evaluate the CKD risk. For instance, an individual with G1A1 is placed in low CKD risk category, whereas another individual with G1A3 is considered to be in high CKD risk category.[3] (For risk categories, see **Table 28-6**.)

Table 28-4

Albuminuria Categories: Description and Range

	A1	A2	A3
Description	Normal to mildly increased	Moderately increased	Severely increased
Albumin-to-creatinine ratio (mg/g)	<30	30–300	>300
Albumin excretion rate (mg/24 hours)	<30	30–300	>300

A substantial decline in kidney function leads to *azotemia*, which is the accumulation of nitrogenous wastes in the blood, and uremia, which is an accumulation of urea in the blood. These lead to a myriad of complications affecting most major organ systems. Laboratory biochemical abnormalities, oftentimes present in late-stage CKD, may lead to hyperphosphatemia, hypocalcemia, secondary hyperparathyroidism, hyperkalemia, gout, metabolic acidosis, and anemia. Clinical signs of CKD and its associated complications, including hypertension, uremic symptoms (eg, nausea, anorexia, itching), fatigue, bone disease, swelling in extremities, and bleeding, are observed as the disease advances to categories G3a through G5. Interventions to slow the progression of CKD are critical. Patients with eGFR of <30 mL/ minute/1.73 m^2 will ultimately progress to kidney failure with or without KRT and are referred to as CKD G5 without KRT and KFRT, respectively. The stage of CKD G1–G5 after transplantation is referred to CKD G1T–G5T.[3]

Epidemiology of Chronic Kidney Disease

The United States Renal Data System (USRDS) is a national data system that collects, analyzes, and distributes information about all

categories of CKD in the United States. Data describing CKD incidence and prevalence are made available annually by the USRDS, and the USRDS provides the latest pertinent data on CKD. The 2018 USRDS reports that the overall prevalence of CKD in the U.S. population was about 14%.[4] Over the period between 2001 and 2016, there was a small increase in the prevalence of stage 3 CKD that rose from 6.1% to 6.4%. The NKF's Kidney Early Evaluation Program (KEEP) screens high-risk individuals at high risk across the United States with high blood pressure (BP), diabetes mellitus, or a family history of kidney failure. Based on the high-risk participants from the KEEP screenings from 2000 to 2011, 24% of the participants had CKD. According to 2019 USRDS data, the 2017 prevalence and incidence of kidney failure were 746,557 and 124,500, respectively.[5,6] The African American population had the highest prevalence per million of the population that was 2-fold higher than Native Americans, 2.5-fold higher than Asians, and 4-fold higher than Whites.[5]

CKD is a health priority identified as a disease prevention target for the Healthy People 2020 (HP2020) national health initiative; one of the specific CKD-related objectives is to reduce the number of cases of kidney failure.[7] The HP2020 target rate of kidney failure cases is 13.3% of the population. Current data suggest that this target will not be met. A new target of 12.8% of the adult population was set for Healthy People 2030.[8] Recent data from the 2020 USRDS annual data report show that 14.9% of U.S. adults surveyed between 2016 and 2018 had CKD.[9] Additional objectives such as increasing awareness, improving cardiovascular care, and reduction of mortality in patients with CKD can be found at the HealthyPeople.gov website.

ETIOLOGY

In CKD, the progressive loss or damage to functioning nephrons as a function of time is the result of a primary disorder or disease of the kidney, a secondary complication of certain systemic diseases (eg, diabetes mellitus or hypertension), or an acute injury to the kidney

that results in irreversible kidney damage. The leading causes of kidney failure in American patients were diabetes mellitus (38%), hypertension (26%), and chronic glomerulonephritis (GN) (16%).[10] The remaining cases of kidney failure can be attributed to a variety of other pathologies; examples include polycystic kidney disease, congenital anomalies of the kidney and urinary tract (CAKUT), kidney stones, interstitial nephritis, kidney artery stenosis, carcinoma of the kidney, and human immunodeficiency virus–associated kidney disease.

A variety of risk factors associated with development, initiation, and progression of CKD have been identified. Initiation factors are medical conditions that directly cause kidney damage. Risk factors for the progression of CKD exacerbate kidney damage and are related to an accelerated decline in kidney function with time. Most susceptibility factors are not modifiable but may identify people who are at high risk for developing CKD. In contrast, pharmacotherapy and lifestyle interventions have been shown to modify CKD-related initiation and progression factors (see Prevention of Chronic Kidney Disease and Its Progression section). A summary of risk factors associated with CKD can be found in **Table 28-7**.

Table 28-7

Risk Factors for Chronic Kidney Disease

Susceptibility	Initiation	Progression
Advanced age Reduced kidney mass Low birth weight Racial/ethnic minority Family history Low income or education Systemic inflammation Dyslipidemia	Diabetes mellitus Hypertension Glomerulonephritis Drug-induced kidney toxicity Smoking Obesity	Hyperglycemia Hypertension Proteinuria Smoking Obesity

MORBIDITY, MORTALITY, AND ECONOMIC IMPACT

According to the USRDS annual data report, ~73.7% of patients with CKD were enrolled in the Medicare Part D program (including both standalone and Medicare Advantage plans) in 2016 compared to 69.5% in the general Medicare population.[4] Based on 2019 USRDS data, rates of hospitalizations and mortality are much greater in those with CKD compared with the non-CKD population.[4,6] Patients with CKD had a mortality rate of 122.6 per 1000 patient-years. After adjusting for sex, age, and race, this rate remained double that of patients without CKD.[4] The adjusted mortality rate in male patients with CKD was higher than in females, 114.4 versus 94.9 per 1000 person years, respectively. When adjusting for age and sex, the mortality rate was 106.6 per 1000 patient-years for Black patients versus 104.2 per 1000 patient-years for White patients. When stratified by stages, there was no difference between Black and White patients with CKD G1–G3; however, Black patients have a higher mortality rate than White patients with CKD G4–G5, 183 versus 170 per 1000 patient-years, respectively. Overall, the morbidity and mortality risk tend to increase with progressing stages of CKD, patient health complexity, and age.

Patients with CKD not on dialysis are typically on 6 to 8 medications on average, whereas those with kidney failure can be prescribed as many as 12 medications to manage the comorbidities of CKD. These patterns of medication use are reflective of the higher prevalence of complications and comorbidities in the latter stages of CKD, which require additional drug therapies. The extent of medication use and the complexity of prescribed drug regimens contribute to nonadherence and medication-related problems (MRPs) in the kidney failure population.[11] To manage MRPs, some dialysis units use a clinical pharmacist as part of the multidisciplinary health care team to provide pharmaceutical care to patients with kidney failure. Services provided by a clinical pharmacist have been shown to be cost-effective and associated with maintenance of health-related quality of life.[12,13]

PATHOPHYSIOLOGY

Progression of CKD to kidney failure generally occurs over the course of months to years and is assessed by the rate of GFR decline. Each kidney contains approximately one million nephrons (the functional units of the kidney), and every nephron maintains its own single-nephron GFR. In the face of nephron loss, the remaining functional nephrons maintain renal function by increasing their single-nephron GFR via compensatory glomerular hemodynamic changes.[13] With time, this compensatory increase in single-nephron GFRs eventually leads to hypertrophy and an irreversible loss of nephron function from sustained increases in glomerular pressure. Furthermore, glomerulosclerosis (glomerular arteriolar damage) develops from prolonged elevation of glomerular capillary pressure and increased glomerular plasma flow, resulting in a continuous cycle of nephron destruction. Regardless of the cause, a predictable and continuous decrease in kidney function occurs in patients when the eGFR drops below a critical value, approximately one-half of normal.[14] Usually, the rate of decline in kidney function remains fairly constant for an individual, but can vary substantially among patients and disease states. A rapid rate of decline in kidney function has been associated with Black race, proteinuria, male sex, older age, and smoking.[15–17] Rapid progression of CKD is defined as persistent decline in GFR >5 mL/minute/1.73 m^2/year.[1] Although early changes in kidney function can be detected through routine laboratory monitoring (eg, urine albumin-to-creatinine ratio [ACR], serum creatinine [SCr]), most patients are asymptomatic and do not develop signs and symptoms of uremia until they have progressed to the more severe stages of the disease (ie, CKD categories G4 and G5).

As the leading causes of kidney failure in the United States, diabetes mellitus, hypertension, and glomerular diseases have been the focus of research to identify their associated mechanisms of kidney damage. In the case of diabetes mellitus, excess filtration of glucose, excessive glucose contact with the glomerular and tubular cells leads to increased cellular osmotic pressure and thickening of the capillary basement membrane and other anatomic changes. Systemic hypertension is a potent stimulus for the development and

progression of CKD caused by the association with increased single-nephron GFRs.[13,17] Hypertension, whether as the primary cause of CKD or a as coexisting disease in the presence of other etiologies, can promote kidney damage through transmission of elevated systemic pressure to glomeruli. The result is glomerular capillary hyperperfusion and hypertension leading to progressive kidney damage as nephron destruction continues. Glomerular ischemia induced by damage to the preglomerular arteries and arterioles also occurs. People with coexistent diabetes mellitus and hypertension increase the risk of developing kidney failure by fivefold to sixfold compared with those with hypertension alone.[14] In contrast, glomerular diseases responsible for GN are mediated by immune mechanisms. The deposition and formation of immune complexes in the glomerulus cause injury, resulting in increased glomerular permeability to macromolecules (eg, proteins).[18] As stated above, the presence of albumin in urine is one of the diagnostic signs of kidney damage. Albuminuria is associated with progression of CKD.[19] Immunologic and hemodynamic mechanisms have been identified to explain the glomerular injury. Inflammatory cytokines may be responsible for fibrosis and kidney scarring, ultimately resulting in loss of nephron function.

Dyslipidemia is common in patients with CKD and often observed concurrently with proteinuria. Increased low-density lipoprotein (LDL) cholesterol, total cholesterol, and apolipoprotein B, as well as decreased high-density lipoprotein (HDL) cholesterol, have been observed in patients with progressive CKD.[18] Hypercholesterolemia has been associated with loss of kidney function in patients with and without diabetes.[20,21] LDL is thought to promote glomerular damage by initiating a series of cellular events in mesangial cells and through oxidation to a more cytotoxic derivative once within these cells. Although serum total cholesterol, triglycerides, and apolipoprotein B, all correlate with the rate of decline in eGFR, it is not clear that they directly increase the rate of progression of CKD, particularly when present with concomitant conditions that also cause kidney damage. Some evidence, however, suggests that treatment of

hypercholesterolemia with statin therapy in patients with CKD may reduce albuminuria and progression of CKD.[21]

CLINICAL ASSESSMENT OF KIDNEY FUNCTION

Quantifying Glomerular Filtration Rate

The estimation of GFR (eGFR) is the most widely used clinical tool for assessing baseline kidney function and for monitoring the progression of CKD. The ideal marker of eGFR should be a nontoxic substance that is freely filtered at the glomerulus and not secreted, reabsorbed, or metabolized by the kidney. Inulin and exogenous radioactive markers, such as ^{125}I-iothalamate or ^{51}CrEDTA, have been used to assess GFR because they meet these criteria; however, they are not readily available to clinicians, require intravenous (IV) administration, and are costly. So, other endogenous biomarkers like creatinine are used to estimate GFR in the clinical setting.

Creatinine is a substance that is produced at a relatively constant rate by nonenzymatic hydrolysis of muscle stores of the amino acid derivatives creatine and phosphocreatine. Under steady-state conditions, the urinary excretion of creatinine equals the creatinine production rate, and the SCr concentration remains relatively stable. Creatinine is excreted primarily by glomerular filtration—thus, creatinine clearance (CrCl) has been used as a reasonable surrogate for eGFR. There are limitations to consider when using methods to assess eGFR that incorporate creatinine. Creatinine is eliminated not only through glomerular filtration but also by tubular secretion. Consequently, the CrCl overestimates the true GFR by 10% to 20%. As nephron function declines, tubular secretion of creatinine contributes more substantially to overall elimination such that CrCl overestimates true GFR. Elimination of creatinine by other organs besides the kidney, like the gastrointestinal (GI) tract may

also lead to overestimation of actual GFR.[22] As a result of these processes, disease progression may be underestimated. Commonly used drugs also need to be taken into consideration when interpreting SCr values. For example, drugs like trimethoprim and cimetidine can inhibit the secretion of creatinine, increase SCr, and decrease CrCl without affecting GFR.[19]

The use of SCr alone as an index of kidney function has several limitations. In the initial stages of CKD, SCr may remain within the normal range and is relatively insensitive in detecting early CKD or estimating the progression of the disease. The generation of creatinine is proportional to the total muscle mass; it is also affected by diet (notably by the ingestion of meats), age, and gender. Generally, muscle mass declines with age and is lower in females. Thus, an SCr that is in the upper limit of normal (eg, 1.2 mg/dL) for a young male athlete is likely to be associated with a high CrCl, whereas the same SCr in a 70-year-old female could indicate compromised kidney function. Because of the substantial variation seen in the calibration of SCr among laboratories, the National Kidney Disease Education Program Laboratory Working Group initiated the creatinine standardization program to improve and normalize SCr results, reduce interlaboratory variability, and enable more accurate eGFR determinations.[23] Although SCr can provide a rough estimate of kidney function, other markers of early kidney damage, such as albuminuria, should also be evaluated in patients at risk for CKD.

Estimations of CrCl and eGFR will be compared, next. Several equations have been developed to calculate CrCl or eGFR.

The Cockcroft–Gault (CG) equation (Eq. 28-1) has been the most commonly used method to estimate kidney function for drug dosing, which provides an estimated CrCl in patients with stable kidney function.[22,24]

$$\mathrm{CrCl} = \frac{(140 - \mathrm{Age})(\mathrm{IBW})}{(72)} \qquad \textbf{(Eq. 28-1)}$$

where age is in years, IBW is ideal body weight in kg (male IBW = 50 + [2.3 × height >60 inches (152.4 cm)]; female IBW = 45.5 + [2.3 × height >60 inches (152.4 cm)]); and SCr is the serum creatinine concentration (mg/dL). For females, the CG equation is multiplied by 0.85 to account for decreased muscle mass. The recommended weight used in the CG equation is the IBW. The exception to this rule is when the actual body weight is less than the IBW, then use actual body weight. For individuals where the actual body weight is 1.3 times or more higher than the IBW, use the *adjusted* IBW (IBW + 0.4 × [actual body weight – IBW]).[25]

The CG equation is not reliable for estimating GFR in patients with rapidly changing SCr concentrations because it was derived from normal, healthy subjects with stable kidney function. The CG equation is also inaccurate in populations that have low muscle mass—such as elderly, obese, or cachectic patients. Equations have been studied for estimating GFR in older individuals like the Berlin Initiative Study 1 (BIS1) equation, which is a tool for estimating kidney function in older adults (>70 years old), and the full age spectrum (FAS) equation.[26] These equations will not be addressed in detail in this chapter.

There are several creatinine-based equations for calculating eGFR in children 1 to 16 years old; however, the updated "bedside" Schwartz equation (Eq. 28-2) from the 2009 Chronic Kidney Disease in Children (CKiD) study is currently the recommended equation for estimating GFR.[27]

$$\text{Cr Cl (mL/minute)} = \frac{(k \times \text{length [in cm]})}{\text{SCr}} \qquad \textbf{(Eq. 28-2)}$$

The most commonly used method for kidney function assessment in adults is the prediction equation developed using data from the Modification of Diet in Renal Disease (MDRD) study, a multicenter trial that evaluated the effects of dietary protein restriction and BP control on progression of CKD. The MDRD equation was derived using GFR measured directly by urinary clearance of a radiolabeled marker ^{125}I-iothalamate as opposed to creatinine and included a

relatively large and diverse population (>500 White and Black individuals with varying degrees of CKD) for derivation and validation of the equation.[28] To address the lack of validation in other populations, modifications to the MDRD equation to account for other populations are being explored.[29] An abbreviated version was developed and is referred to as the four-variable MDRD equation. This version is the widely used equation and does not require blood urea nitrogen (BUN) or serum albumin. Subsequently, this equation was further revised in 2005 for use with a standardized SCr assay enabling consistent results across clinical laboratories to improve accuracy in eGFR determinations (Eq. 28-3).[22]

Estimated GFR

$$(\text{mL/minute/1.73 m}^2) = 175 \times (\text{standardized SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if black})$$

(Eq. 28-3)

The MDRD equation was found to be biased and imprecise at higher GFRs with the potential of misidentifying patients with high GFR as having poor kidney function.[1] The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) research group established by the National Institute of Diabetes and Digestive and Kidney Diseases pooled studies of different populations to develop and validate a new estimating equation for GFR that is more complex but uses the same variables as the MDRD equation.[1,30] This equation was found to be more accurate than the MDRD equation, especially at high GFRs >60 mL/minute/1.73 m^2. These two approaches estimate GFR using serum creatinine ($eGFR_{cr}$).

Cystatin C is another endogenous marker of kidney function that is freely filtered at the glomerulus. Subsequently, it is reabsorbed and catabolized by proximal tubular epithelial cells. Unlike SCr, cystatin C is not influenced by gender, age, body mass, and nutritional status. Although cystatin C has gained wider acceptance and utility in

clinical practice, it is still relatively under-utilized because of its longer turnaround time from laboratories. CKD-EPI equations based on serum cystatin C levels either alone ($eGFR_{cys}$) or in combination with SCr and other demographic variables have been developed.[1] The CKD-EPI creatinine–cystatin C equation that uses a combination of both SCr and cystatin C ($eGFR_{cr\text{-}cys}$) has shown to be a better estimate of kidney function in CKD than equations using either biomarker alone.[31] Because of the complexity of these equations, several online calculators and apps are used by clinicians to estimate renal function. Some examples of calculators are included on the NKF and the National Institute of Diabetes and Digestive and Kidney Disease (NIDDK) websites. Others include MDCalc, GlobalRPH, ClinCalc, and so on.

%

The results from the MDRD, CKD-EPI, and CG equations are not interchangeable. eGFR calculated from the MDRD and CKD-EPI equations are used to quantify GFR, to classify or stage the degree of CKD, and to follow progression, whereas CrCl calculated from the CG equation is still the most frequently used estimation used to evaluate the appropriate doses of drugs that are eliminated by the kidney. Both CrCl and eGFR are approved by the Food and Drug Administration (FDA) for drug dosing labels. (See Chapter 31, for more on Dosing of Drugs in Kidney Failure.)

ALBUMINURIA

The term “albuminuria,” which was briefly discussed earlier in this chapter, is often used interchangeably with “proteinuria,” which technically refers to the total protein excreted (including albumin). In this chapter, we will focus mainly on albuminuria and discuss proteinuria only in the context of glomerular disease. Large molecules like proteins, such as albumin, are not normally filtered across the glomerulus; thus, only trace amounts are present in the urine of individuals without CKD. The amount of protein present in the urine has been shown to be a predictor of CKD progression. As a result, protein excretion should be annually screened using a

semiquantitative urine test strip or dipstick in patients at risk for CKD. A dipstick positive for albuminuria should be followed by a quantitative assessment of albuminuria, which is a better indicator of early CKD because it is primarily indicative of glomerular damage as opposed to total protein, which is not specific for glomerular damage.[1]

There are several tests to quantify albuminuria. Determination of albuminuria can be done using timed urine samples (see Table 28-2). The gold standard is a 24-hour urine collection period used to determine albumin excretion rate (AER). A timed sample collected overnight may be more reliable because albumin excretion can vary throughout the day and with postural changes (ie, orthostatic proteinuria). Both tests are inconvenient and prone to miscalculations because of potential urine spillage or incomplete collections by the patient. Untimed or “spot” urine samples for measurement of ACR are more convenient. A first morning urine sample is preferable because it correlates best with 24-hour albumin excretion. Albuminuria is present when two out of three spot urine ACR samples are >30 mg/g. Thereafter, KDIGO has provided recommended frequency of ACR test according to CKD stage. The AER can also be performed but has limitations as indicated above. The KDIGO Guidelines for Evaluation and Management of CKD provide criteria for albuminuria categories (see Table 28-4).[1]

Because of the importance of albuminuria in the progression of CKD, several strategies have been recommended to decrease albuminuria to decrease progression of CKD, such as a renin–angiotensin–aldosterone system (RAAS) blockade should be instituted when albuminuria occurs. Aldosterone antagonists (spironolactone and eplerenone) have also been shown to decrease albuminuria when used in combination with angiotensin converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) in adults who has mild-to-moderate CKD but could increase the risk of hyperkalemia.[32] In phase 2 clinical trials, finerenone, a selective, nonsteroidal mineralocorticoid receptor antagonist reduced albuminuria and progression of CKD in patients with type 2 diabetes

(T2D) compared to placebo. ACEI and ARBs will be discussed in detail later in the chapter.[33]

Although albuminuria is the most common biomarker for assessing kidney damage in CKD, newer biomarkers are being studied. Some of these novel biomarkers include asymmetric and symmetric dimethylarginine (ADMA and SDMA), uromodulin, kidney injury molecule 1 (KIM-1), neutrophil gelatinase-association lipocalin (NGAL), miRNA, and proteomic and metabolomic biomarkers.[34] The validation and clinical utility of these biomarkers remains a key area requiring further research.

COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Complications specific to CKD begin to develop as kidney disease progresses, most often when patients reach CKD G3 (eGFR <60 mL/minute/1.73 m^2). These complications include fluid and electrolyte abnormalities, metabolic acidosis, anemia, MBD, CVD, and poor nutritional status. Often, these complications go unrecognized or are inadequately managed during the earlier stages of CKD, leading to poor outcomes by the time a patient requires dialysis. As CKD progresses into the later stages (G4 and G5), patients develop more severe clinical signs and symptoms. For some manifestations and metabolic consequences of advanced CKD, see **Table 28-8**. Low serum albumin levels and anemia were identified in more than 50% of a population of patients with CKD new to dialysis therapy, and these findings were associated with a decreased quality of life.[35] Late referral to a nephrologist to manage CKD and its associated complications has also been associated with increased mortality in the kidney failure population.[35]

The KDIGO guidelines recommend referral of patients to a nephrologist in any of the following circumstances: acute kidney injury (AKI) or an abrupt fall in GFR, a GFR <30 mL/minute/1.73 m^2, persistent albuminuria (ACR ≥ 300 mg/g), progression of CKD, unexplained persistence of red blood cell (RBC) casts and >20 RBCs per high-power field in urinalysis (UA), persistent abnormalities in potassium, extensive kidney stones, hereditary kidney disease, CKD with resistant hypertension on four or more antihypertensive agents, and in all patients in whom the risk of progression to kidney failure in the next year is estimated at 10% to 20% or greater.[1]

Complications of CKD will be presented in more detail throughout this chapter, and complications associated with dialysis therapy are discussed in Chapter 30, Dialysis Treatment for Chronic Kidney Failure.

PREVENTION OF CHRONIC KIDNEY DISEASE AND ITS PROGRESSION

Appropriate management of CKD includes measures to slow progression of the disease and regular evaluation of kidney function to assess changes in disease severity and to monitor therapy. This includes aggressive strategies to manage the disorders that cause CKD or are known to accelerate the disease process, such as diabetes mellitus, hypertension, high protein intake, and dyslipidemias (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; Chapter 9, Essential Hypertension; and Chapter 53, Diabetes Mellitus). Systematic reviews and meta-analyses have shown that a protein-restricted diet might delay the progression of CKD but does not significantly reduce the overall mortality rates.[36–38] KDIGO Guidelines for Evaluation and Management of CKD currently recommends lowering protein intake to 0.8 g/kg/day while avoiding high protein intake (ie, >1.3 g/kg/day) in adults at risk for progression.[1] The potential benefits of protein restriction in patients with CKD must be weighed against the potential for malnutrition, which is prevalent in patients with CKD.[39] As mentioned, inflammatory cytokines may be responsible for fibrosis and kidney scarring, ultimately resulting in the progression of CKD. Anti-inflammatory drugs like pentoxifylline and pirfenidone, which exhibit antifibrotic properties have been studied for slowing the progression of CKD. Studies have demonstrated that pentoxifylline in combination with ACEI or ARBs slowed the progression of CKD.[40,41] Pirfenidone has been shown to slow progression of CKD in patients with focal segmental glomerulosclerosis.[42] A phase 2 clinical trial looking at the effect of pirfenidone on the progression of advanced CKD to kidney failure, Trial of Pirfenidone to Prevent Progression in Chronic Kidney Disease (TOP-CKD), is currently in progress.[43]

Antihypertensive Therapy

Antihypertensive therapy prevents kidney damage and slows the rate of progression of CKD in both diabetic and nondiabetic patients.[44] In addition, the added benefit of reduced cardiovascular mortality further supports the use of antihypertensive therapy in patients at risk for progressive CKD. The 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults (commonly referred to as JNC-8) and the KDIGO/Management of Blood Pressure in Chronic Kidney Disease Guideline recommends a BP <140/90 mm Hg.[44,45] Controversy exists as to the optimal BP target in patients with CKD with albuminuria (ACR > 30 mg/g in 24 hours or equivalent). Furthermore, the KDIGO guidelines recommend a BP target of ≤130/80 mm Hg in patients with CKD with albuminuria (ACR > 30 mg/g in 24 hours or equivalent), whereas JNC-8 suggest a target of 140/90 mm Hg for patients with albuminuria. In 2017, the American College of Cardiology (ACC), the American Heart Association (AHA), and several other organizations released new guidelines for the management of hypertension in adults.[46] These guidelines recommend a BP goal of <130/80 mm Hg in patients with CKD with or without albuminuria. These recommendations were made based on three trials. The combined previous analyses of cohorts from the African American Study on Kidney Disease (AASK) and MDRD trials suggested strict BP control was kidney-protective in patients with albuminuria but a mortality benefit was not reported.[47,48] In contrast, the Systolic Blood Pressure Intervention Trial (SPRINT) showed aggressive BP control (systolic BP of <120 mm Hg) was associated with better cardiovascular events and all-cause mortality compared to the standard control (systolic BP of <140 mm Hg).[49] Recent analysis of the MDRD study and AASK study suggests that like the SPRINT there is an all-cause mortality benefit to intensive BP control in individuals with CKD.[50]

ACEIs and ARBs are the most commonly recommended as first-line treatment options for hypertension in those with CKD, especially those with albuminuria by the KDIGO hypertension guidelines.[44] In individuals with decreased eGFR, angiotensin II primarily causes compensatory vasoconstriction of the efferent arteriole, thereby

increasing glomerular capillary pressure (P_{GC}) and eGFR (**Fig. 28-1**). This effect is beneficial in conditions of AKI; however, sustained increases in P_{GC} cause hypertrophy of individual nephrons and progressive CKD. ACEI and ARB therapy prevents the chronic increase in glomerular pressure mediated by angiotensin II. Benefits of ACEIs have been demonstrated in patients with diabetes with some degree of proteinuria, suggesting that ACEI use be considered in this population regardless of BP.[44] In patients without diabetes mellitus, ACEIs have been shown to reduce BP, decrease proteinuria, and slow the progression of CKD when compared with other agents. ARBs offer similar benefits to ACEIs based on their ability to decrease efferent arteriolar resistance by blockade of the angiotensin type 1 (AT_1) receptor.[51–53]

Figure 28-1 Kidney hemodynamics are dependent on afferent and efferent arteriolar tone and glomerular capillary pressure (P_{GC}). With reduced nephron mass, afferent arteriolar vasodilation (mediated primarily by prostaglandins [PG] I_2 and E_2) and efferent arteriolar constriction (mediated primarily by angiotensin II) occur within remaining functioning nephrons to compensate. This leads to an increase in blood flow, intraglomerular capillary filtration pressure (P_{GC}), and hyperfiltration (increased single-nephron effective GFR). Sustained increases in plasma flow and hydrostatic pressure lead to hyperfiltration injury and glomerular sclerosis. With time, these changes contribute to continued loss of nephron function (ie, progression of kidney disease). Angiotensin converting enzyme inhibitors and angiotensin receptor blockers prevent vasoconstriction of the efferent arteriole and reduce the P_{GC}.

The optimal kidney-protective doses of ACEI/ARBs in CKD have been an area of controversy. In a study looking into optimization of ACEI (benazepril) and ARB (losartan) in CKD, higher doses of >20 mg for benazepril and >50 mg for losartan had better kidney-protective outcomes than conventional doses.[54] Patients must be closely monitored when using doses of ACEI/ARB above the antihypertensive doses because of the potential for adverse effects. An initial and mild decrease in eGFR is expected with ACEI/ARB therapy; therefore, an increase in SCr of 30% within the first 2 months of therapy is acceptable.[55] Hypotension, AKI, and severe hyperkalemia are reasons to consider temporarily stopping or discontinuing therapy (also see Chapter 14, Heart Failure). Another controversial issue is the use of ACEI/ARBs in patients with advanced CKD (categories G4 and G5). A study looking at the effect of stopping RAAS blockage in patients with advanced CKD (eGFR < 30 mL/minute/1.73 m^2) found that compared to continuing RAAS inhibitors, stopping RAAS inhibitors increased the 5-year absolute risk of mortality and major adverse cardiovascular events, but lowered the risk of initiation of KRT.[56] Another study showed that discontinuing RAAS blockage in advanced CKD significantly increased mortality and major adverse cardiovascular events without improving the risk of kidney failures.[57] The STOP-ACEI trial, currently in progress, is also looking at the effect of discontinuing RAAS blockage in advanced CKD.[58]

Aliskiren is a direct renin inhibitor. However, its role as monotherapy for BP control or kidney protection is unclear.[59] Aliskiren has been associated with a reduction in GFR and filtration fraction in patients receiving optimal heart failure therapy.[60] The therapy that involves the combination of ACEIs with ARBs or ACEIs/ARBs with aliskiren is not recommended because of the increased risk of CKD progression to kidney failure, hyperkalemia, and AKI.[46,60–62]

Because fluid or volume overload is usually part of clinical presentation in CKD, diuretics are often a part of BP control in most patients with CKD. Thiazides and thiazide-like diuretics are typically used in patients with eGFR >30 mL/minute/1.73 m^2, as their efficacy

in reducing fluid retention diminishes as the GFR drops to 30 to 50 mL/minute/73 m^2. For patients with CKD with eGFR <30 mL/minute/1.73 m^2, loop diuretics can be used as an alternative.[63]

Calcium channel blockers have been considered for preventing progression of CKD owing to their effects on kidney hemodynamics and cytoprotective and antiproliferative properties (prevention of mesangial expansion and kidney scarring). Non-dihydropyridine agents (eg, diltiazem and verapamil) have been beneficial in reducing albuminuria when compared with dihydropyridines (eg, amlodipine), which was found to worsen albuminuria.[64,65] Dihydropyridine calcium channel blockers have the effect of increasing albuminuria and should not be used alone in patients with albuminuria, but can be used safely in combination with an ACEI or ARB. Combination therapy with an ACEI and non-dihydropyridine agents has resulted in greater reductions in albuminuria in patients with diabetes mellitus than with either agent alone, suggesting that it may be rational to use multiple agents in this population.[64]

β-Blockers may offer benefits in the treatment of diabetic kidney disease (DKD) as demonstrated by the United Kingdom Prospective Diabetes Study, which showed similar effects of atenolol and captopril on decreasing the incidence of albuminuria in patients with diabetes.[66] β-Blockers offer several benefits to patients with CKD, such as attenuation of excessive sympathetic output and reduction in sudden cardiac death seen in patients on dialysis.[67] β-Blocker selection should take into account the dialyzability of the drug and/or the risk for drug accumulation.[68]

DIABETIC KIDNEY DISEASE

CASE 28-1

Question 1: G.B. is a 44-year-old, African American female (weight, 175 pounds [79.38 kg]; height, 65 inches [165.1 cm]) with a 20-year history of T2D. She presents to the diabetes clinic for her quarterly checkup. She has been

noncompliant with appointments, and her blood glucose has generally remained >200 mg/dL. She had a hemoglobin A_{1c} of 10.1% (goal, <7%) and a urine ACR of 200 mg/g (albumin category A2) obtained 3 months ago. Lately G.B. reports general nausea, fatigue, and poor appetite.

Medications: Metformin ER 500 mg PO daily and a multivitamin daily.

The workup reveals the following pertinent laboratory values:
Serum sodium (Na^+), 143 mEq/L
Potassium (K^+), 4.9 mEq/L
Chloride (Cl^-), 106 mEq/L
Total CO_2, 18 mEq/L
Serum creatinine (SCr), 2.1 mg/dL
eGFR, 31 mL/minute/1.73 m^2
BUN, 30 mg/dL
Random blood glucose, 289 mg/dL
Additional laboratory studies show the following results:
Serum phosphate, 6.6 mg/dL
Calcium (Ca), 8.8 mg/dL
Albumin (Alb), 3.6 g/dL
Magnesium (Mg), 2.1 mEq/L
Uric acid, 6.8 mg/dL
Hematologic studies show the following results:
Hematocrit (Hct), 28%
Hemoglobin (Hgb), 10.3 g/dL
Reticulocyte count, 0.5%.
Mean corpuscular volume (MCV), 95 fL
White blood cell (WBC) count, 9600/μL
Platelet count, 155,000/μL
Iron studies show the following results:
Serum ferritin, 250 ng/mL
Serum iron, 45 μg/dL
Total iron-binding capacity (TIBC), 302 μg/dL
Transferrin saturation (TSAT), 15%
Urinalysis (UA) findings: urine dipstick showed 4+ proteinuria, spot urine sample showed an ACR of 500 mg/g
Physical examination reveals a BP of 158/92 mm Hg, 2+ pedal edema, and a 10-pound (4.54 kg) weight gain.

What subjective and objective data in G.B. are consistent with a diagnosis of advanced CKD?

G.B.'s abnormal values for SCr, BUN, serum potassium, magnesium, phosphate, uric acid, total CO_2, and hemoglobin are all consistent with CKD progression and its associated complications.

Assuming relatively stable kidney function (ie, no acute changes in kidney function; has her SCr remained the same?), her eGFR is ~31 mL/minute/1.73 m^2 based on the MDRD equation, placing her in CKD category G3b (eGFR 30–44) mL/minute/1.73 m^2. As the eGFR declines, normal regulation of fluids and electrolytes is impaired. Elevations in SCr, BUN, potassium, and phosphate as well as signs of fluid accumulation are observed. G.B.'s serum potassium is slightly elevated, and the risk of hyperkalemia increases with CKD.[69] The albuminuria observed in G.B. is consistent with glomerular damage. G.B. has an ACR of 500 mg/g on today's UA, which places her in category A3, thus making her CKD stage G3b/A3 based on the KDIGO CKD classification system placing her in very high CKD risk category. Volume overload from continued intake and decreased sodium and water excretion leads to weight gain, hypertension, and edema. Metabolic acidosis results from impaired synthesis of ammonia by the kidney, which normally buffers hydrogen ions and facilitates acid excretion. Anemia associated with CKD is caused primarily by decreased erythropoietin (EPO) production by the kidneys, but it also can be caused by shortened half-life of RBCs from uremia, and iron deficiency. G.B.'s recent onset of nausea and malaise may be a consequence of the accumulation of uremic toxins (azotemia) from the decline in kidney function.

Case 28-1, Question 2: What is the cause of G.B.'s kidney disease?

Given G.B.'s presentation, her CKD is most likely caused by DKD from her 20-year history of T2D. Based on the history of present illness (HPI), her hyperglycemia is poorly controlled (A_{1c}: 10.1%), she is also African American. These are risk factors for DKD. African Americans, Native Americans, and Hispanics have an increased risk of developing kidney failure from diabetes relative to Whites.[5] Poor adherence with regular appointments, poor medication adherence, or inadequate selection or dose of antidiabetic agents may contribute to DKD. Uncontrolled diabetes associated with elevated glucose concentration and hemoglobin A_{1c} values, and albuminuria serve as

the primary causes. DKD rarely develops within the first 10 years after the onset of type 1 diabetes (T1D); however, 5% to 20% of patients with T2D have some degree of albuminuria at diagnosis.

DKD is a microvascular complication of diabetes resulting in albuminuria, hemodynamic changes in kidney microcirculation, glomerular structural changes, and a progressive decline in kidney function. DKD develops in 20% to 40% of patients with T1D or T2D within 25 years of onset.[1] With the increased prevalence and incidence of diabetes, it is likely that DKD will remain the leading cause of kidney failure in the United States. The exact mechanisms leading to the development of DKD are not clearly defined. Advanced glycosylation end products (AGEs) that form because of uncontrolled hyperglycemia have been implicated as a cause of end-organ damage. The accumulation of multiple AGE is associated with the severity of CKD in patients with DKD.[70] AGEs increase the formation of reaction oxygen species (ROS) thereby triggering inflammation, endothelial dysfunction, and interstitial fibrosis, ultimately leading to kidney damage.[71] Uncontrolled hyperglycemia alters the balance between vasoconstriction and vasodilation of the afferent and efferent arterioles.[72] It causes a shift in hemodynamics to afferent arteriole vasodilation and efferent arteriole vasoconstriction leading to increased intraglomerular pressure and consequently glomerular hyperfiltration. Certain genes and polymorphisms have also been associated with the development of DKD, and further exploration into this area may prove beneficial in identifying high-risk patients.[73,74]

Case 28-1, Question 3: What is the significance of G.B.'s albuminuria?

Albuminuria, the earliest sign of kidney involvement in patients with diabetes, correlates with the rate of progression of CKD. Albuminuria not only indicates kidney damage but is also a powerful predictor of cardiovascular morbidity and mortality.[1] For most patients, eGFR begins to decline once albuminuria is established. Because of this association, annual testing of ACR is indicated in

patients who have had T1D for more than 5 years and in all patients with T2D starting at diagnosis. The presence of severely increased albuminuria, A3, indicates irreversible kidney damage. G.B. has likely reached the point at which such damage is inevitable because her ACR exceeds ranges normally observed at the earlier stages of CKD. G.B.'s current laboratory data suggest that she has substantial CKD and has developed associated complications of the disease. Although progression to kidney failure is generally beyond prevention at this stage, appropriate intervention can slow the progression of CKD.

Management

Case 28-1, Question 4: How should G.B.'s kidney disease be managed?

Because reversal of G.B.'s kidney disease is not possible, the primary goals are to delay the need for dialysis therapy as long as possible and to manage complications. The three main risk factors for the progression of incipient CKD to clinical DKD are poor glycemic control, systemic hypertension, and high dietary protein intake (>1.3 g/kg/day). G.B.'s current random blood glucose concentration of 289 mg/dL, history of elevated glucose on prior visits, and elevated hemoglobin A_{1c} indicate poorly controlled diabetes, which will accelerate the progression of DKD and time to kidney failure. Thus, her blood glucose concentrations should be maintained within target goals while avoiding hypoglycemia. G.B.'s elevated BP is likely the result of CKD and changes in intravascular volume; reduction in BP may prevent further damage to functioning nephrons and slow the progression to kidney failure. Similarly, reductions in dietary protein intake (dietary protein intake of ~0.8 g/kg body weight/day) should be initiated to reduce the rate of further progression, although this needs to be evaluated in the context of her overall nutritional status.

INTENSIVE GLUCOSE CONTROL

Strict glycemic control can improve diabetic management, reduce albuminuria, and slow the rate of decline in eGFR. A landmark clinical trial, the UK Prospective Diabetes Study (UKPDS) demonstrated the beneficial effects of intensive glycemic control in patients with T2D. During a 10-year treatment period, intensive glucose control (fasting glucose <108 mg/dL) with either insulin or an oral sulfonylurea reduced microvascular complications (eg, retinopathy and nephropathy), including albuminuria by 33%, when compared with conventional dietary therapy (fasting glucose <270 mg/dL).[75] This benefit of intensive glucose control on development of microvascular complications was similar to the findings of another landmark study, the Diabetes Control and Complications Trial (DCCT), which was conducted in patients with T1D. This study showed that intensive glucose control slows the progression of CKD compared to conventional therapy.[76]

Other diabetes trials such as Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) evaluated the macrovascular and microvascular outcomes associated with intensive glucose control in T2D. The ACCORD trial showed a 21% reduction in the development of moderately increased albuminuria cases and a 32% reduction in severely increased albuminuria cases.[77] In the ADVANCE trial, there was a 9% reduction in moderately increased albuminuria and 30% reduction in progression to severely increased albuminuria.[78]

Recently, the role and benefit of newer anti-glycemic medications like the sodium-glucose cotransporter-2 (SGLT-2) inhibitors (eg, canagliflozin, empagliflozin, dapagliflozin) in the reduction of death and CVD in T2D have been reported. Additionally, both glycemic control and kidney protection were shown in several studies.[79,80] The Canagliflozin Cardiovascular Assessment Study (CANVAS) and Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) trials showed that canagliflozin when added to baseline T2D therapy significantly

reduced the risk of progression to kidney failure in patients with T2D.[81,82] Dapagliflozin was recently approved to reduce the risk of CKD progression because of findings of the DAPA-Kidney trial. In this trial involving patients with CKD (with or without T2D), dapagliflozin significantly delayed the decline of eGFR compared to placebo.[83] Empagliflozin is currently in a clinical trial (EMPA-Kidney) to investigate the effect of empagliflozin on kidney disease progression or cardiovascular death versus placebo on top of standard of care in patients with pre-existing CKD.[84] The potential kidney and cardioprotective properties of these agents place them in a vital position in managing patients with CKD with T2D.[79,80] Initiation of SGLT-2 inhibitors is not recommended in patients with advanced CKD (eGFR <30 mL/minute/1.73 m^2).[85–87] KDIGO 2020 Clinical Practice Guideline for Diabetes Management in CKD recommends an individualized hemoglobin A_{1c} from <6.5% for CKD G1 to <8% for CKD G5.[88] For detailed recommendations on antidiabetic management, refer to the American Diabetes Association (ADA) standards of medical care diabetes centered on evolving evidence, technology, and individualized care.

G.B. will benefit from a multifactorial approach addressing glycemic control and hypertension to slow her progression of CKD from diabetes mellitus. Appropriately dosed oral hypoglycemic can achieve these goals despite her advanced CKD. Adding an SGLT-2 inhibitor (eg, canagliflozin 100 mg daily) to the metformin could have the added benefit of reducing her albuminuria. We will discuss SGLT-2 inhibitors later in the chapter. (Also, see Chapter 53, Diabetes Mellitus for other antidiabetic therapeutic options.)

ANTIHYPERTENSIVE THERAPY

Systemic hypertension usually occurs with the development of normal to moderately increased albuminuria in patients with T1D. It is also present in about one-third of patients at the time of diagnosis of T2D and hastens the progression of CKD in both groups. The coexistence of these disorders further increases the risk of cardiovascular events. Hypertension may be a result of underlying

diabetic nephropathy and increased plasma volume or increased peripheral vascular resistance. Regardless of the etiology, virtually any level of untreated hypertension (either systemic or intraglomerular) is associated with a reduction in eGFR.[89]

Patients with diabetes and hypertension exhibit elevated systemic vascular resistance and increased vasoconstriction from angiotensin II, which are in large part responsible for the glomerular damage characteristic of diabetic nephropathy. Although the management of hypertension with virtually any agent can attenuate the progression of CKD, ACEIs, which inhibit the synthesis of angiotensin II, and ARBs, which block angiotensin II AT1 receptors, are preferred owing, in part, to the effects of these agents on kidney hemodynamics (see Fig. 28-1). KDIGO guidelines recommend an ACEI or ARB for the treatment of hypertension in all CKD patients with AER >300 mg/24 hours and diabetic CKD adults with AER ≥30 mg/24 hours. Both the JNC-8 and 2017 ACC/AHA guidelines recommend ACEI or ARB as first-line antihypertensive agents in patients with CKD regardless of race and the presence of albuminuria.[45,46]

The primary goal in G.B. is to delay the development of kidney failure and to reduce the risk of cardiovascular complications and death. Treatment with an ACEI (eg, lisinopril) should be initiated because she has substantial albuminuria (ACR of 500 mg/g) and an elevated BP (158/92 mm Hg). An ARB is a reasonable alternative to an ACEI in patients with ACEI-induced cough or other adverse effects that do not cross-react with an ARB. The initial agent selected is generally based on tolerance to therapy and cost. A goal BP for G.B., given the fact that she has diabetes and CKD, is a BP <130/80 mm Hg.[44–46] G.B. must be monitored on a long-term basis for changes in kidney function and albuminuria and for side effects of therapy, such as hyperkalemia. A moderate increase in SCr is acceptable with the initiation of therapy with ACEIs or ARBs. Contraindications for the use of ACEIs or ARBs include bilateral kidney artery stenosis and pregnancy. The risk of hyperkalemia must also be weighed against the potential beneficial effects of these agents. So, when using them for their anti-proteinuria effect, ACEI/ARBs should be started at low doses and titrated cautiously

with no effect while monitoring BP, kidney function, and potassium. Some evidence suggests that a non-dihydropyridine calcium channel blocker (eg, diltiazem, verapamil) may be beneficial alone or in combination with an ACEI.[90]

FLUID AND ELECTROLYTE COMPLICATIONS

Sodium and Water Retention

Case 28-1, Question 5: Assess G.B.'s sodium and water balance. What interventions may be used to address this problem?

As illustrated in G.B., patients in the latter stages of CKD commonly retain sodium and water. This is supported by G.B.'s elevated BP and 2+ pedal edema. Sodium and water retention also lead to weight gain. Early in CKD, glomerular and tubular adaptive processes develop as an increase in the fractional excretion of sodium (FENa). These mechanisms enable patients to maintain relatively normal sodium and water homeostasis. As G.B.'s normal serum sodium concentration indicates, this value is of little use in establishing the diagnosis of total body sodium and fluid excess because retention of sodium and water usually occurs in an isotonic fashion, leaving the serum sodium concentration relatively normal. Eventually, patients with advanced kidney dysfunction exhibit signs of sodium and fluid retention because sodium balance is maintained at the expense of increased extracellular volume, which results in hypertension. Expansion of blood volume, if not controlled, can cause peripheral edema, heart failure, and pulmonary edema. Thus, management of sodium and water retention is essential. To achieve control, most patients with advanced CKD are placed on sodium restriction (2 g/day) and fluid restriction (~1–2 L/day). These restrictions will depend on the current dietary intake, extent of

volume overload, and urine output and should be altered according to the special needs of the patient.

Diuretics may be considered for patients with diabetic nephropathy and edema, depending on their degree of kidney function. G.B.'s eGFR is 31 mL/minute/1.73 m^2, so she can be started on chlorthalidone 12.5 mg daily. Thiazide diuretics as single agents are generally not effective when the eGFR is <30 mL/minute/1.73 m^2. A possible exception is the use of thiazide-like diuretic, metolazone, which may retain its effect at reduced eGFRs.[44] Alternatively, a loop diuretic could be used in patients with eGFR <30 mL/minute/1.73 m^2. (See Chapter 27, Fluid and Electrolyte Disorders, and Chapter 9, Essential Hypertension.)

Hyperkalemia

Case 28-1, Question 6: G.B. serum potassium concentration is now 5.3 mEq/L after starting lisinopril. Describe the mechanisms by which potassium imbalance occurs in patients, such as G.B. who have progressive CKD. Is treatment of G.B.'s potassium indicated? How should chronic hyperkalemia be managed?

Hyperkalemia can result from a combination of factors, including diminished kidney potassium excretion, redistribution of potassium into the extracellular fluid owing to metabolic acidosis, excessive potassium intake or supplementation, and medications like ACEI/ARBs and potassium-sparing diuretics. The combination of CKD complication and lisinopril are both contributing to hyperkalemia in G.B.

Potassium normally is filtered at the glomerulus and undergoes nearly complete reabsorption throughout the kidney tubule. Distal tubular secretion is the primary mechanism by which potassium is excreted in the urine. A variety of factors affect this distal secretion of potassium, including aldosterone, sodium load presented to the distal tubule, hydrogen ion secretion, the amount of nonresorbable anions, urinary flow rate, diuretics, mineralocorticoids, and

potassium intake.[91,92] Serum potassium concentrations are relatively well maintained within normal limits in patients with CKD, so hyperkalemia is rare without an endogenous or exogenous load of potassium. This balance is maintained despite a decreasing nephron population and an overall drop in eGFR because the remaining nephrons undergo adaptive changes to enhance the distal tubular secretion of potassium per nephron (ie, increased fractional excretion of potassium, FEK).[91] GI excretion of potassium is also important because increased GI excretion and fecal losses may account for up to 35% of the daily potassium loss in patients with severe CKD. Additional factors that alter potassium homeostasis include metabolic or respiratory acidosis. Acidemia can cause a redistribution of intracellular potassium to the extracellular fluid. G.B. has metabolic acidosis as indicated by serum bicarbonate of 18 mEq/L, which could contribute to her mildly elevated potassium concentration.

G.B. has a mild elevation in potassium to 5.3 mEq/L; therefore, no specific treatment is required for now. Although this serum potassium concentration does not require immediate intervention, close monitoring for hyperkalemia and its manifestations is necessary. Manifestations of hyperkalemia include weakness, confusion, and muscular or respiratory paralysis. These symptoms may be absent, especially if hyperkalemia develops rapidly. Chronic management involves prevention of hyperkalemia by limiting potassium intake and avoiding the use of medications that could elevate potassium levels. Sodium polystyrene sulfonate (SPS; Kayexalate, Kionex) is a cation-exchange resin that has long been used for the chronic management of hyperkalemia.[93] Recently, two newer ion-exchange resins, patiromer (Veltassa®) and sodium zirconium cyclosilicate (SZC; Lokelma®).[94,95] These ion-exchange resins remove potassium ions from the lumen of the large intestines in exchange for sodium, sodium and hydrogen, and calcium ions, respectively. Data suggest that in spite of their comparable efficacy, tolerability is a major disadvantage. SPS has been associated with intestinal necrosis, fluid overload (because of sodium content), and other GI side effects. Patiromer and SZC have more favorable adverse effect

profiles than SPS, even though SZC has also been associated with edema.[96] Acute management of hyperkalemia is addressed in Chapter 27, Fluid and Electrolyte Disorders.

In several studies, patiromer and SZC have been shown to be effective in managing hyperkalemia in patients with CKD on RAAS inhibitors. A study investigating the safety and efficacy of patiromer in patients with kidney disease and hyperkalemia receiving RAAS inhibitors (OPAL-HK trial) found that patiromer was effective in reducing potassium in patients on RAAS inhibitors.[97] Another study that investigated the safety and efficacy of SZC in patients with hyperkalemia (HARMONIZE GL trial) also showed that SZC was effective in reducing potassium in patients with CKD on RAAS inhibitors.[98] To optimize the use of lisinopril in G.B., she can be initiated on patiromer 8.4 g once daily, titrated as needed weekly up to a maximum of 25.2 g daily if her potassium continues to rise.

Metabolic Acidosis

Case 28-1, Question 7: Assess G.B.'s acid–base status. How should her acid–base disorder be managed?

G.B.'s low total blood CO_2 and high chloride concentration are consistent with metabolic acidosis. Normal buffering of hydrogen ions by the bicarbonate–carbonic acid system as well as other extracellular and intracellular buffers, including proteins, phosphates, and hemoglobin, is essential for maintaining normal acid–base balance (ie, normal pH). Normal metabolism of ingested food produces ~1 mEq/kg of metabolic acid daily, which must be excreted by the kidneys (primarily as ammonium ion) to maintain acid–base balance. The kidney is responsible for reabsorption of bicarbonate and excretion of hydrogen ions through buffering by ammonia (produced by the kidney) and filtered phosphates. Reduced bicarbonate reabsorption and impaired production of ammonia by the kidneys are the major factors responsible for development of

metabolic acidosis in advanced CKD. As nephron function declines, production of ammonia is increased to compensate for a decrease in secretion of hydrogen ions; however, once the maximal capacity for ammonia production is reached, acidosis develops. As kidney disease progresses, metabolic acidosis with an elevated anion gap is observed owing to accumulation of organic acids (see Chapter 26, Acid–Base Disturbances).

G.B.'s mild acidosis should be treated with a goal of normalizing the plasma bicarbonate concentration or at least achieving bicarbonate levels of at least 22 mEq/L. Treatment options includes use of oral preparations containing sodium bicarbonate or sodium citrate. Each 650-mg tablet of sodium bicarbonate provides ~8 mEq of bicarbonate. Sodium citrate/citric acid (Bicitra, Shohl solution) orally delivers 1 mEq of bicarbonate/mL. These latter agents may be used in patients who experience excessive GI distress with sodium bicarbonate because of production and elimination of carbon dioxide. If a patient such as G.B. is sodium and fluid overloaded, it is important to consider that sodium bicarbonate or sodium citrate can exacerbate this problem. Polycitra, or potassium citrate, is a possible alternative; however, the potassium content limits its use in patients with more severe CKD. Citrate also promotes aluminum absorption and should not be used in patients taking aluminum-containing agents. Typical starting regimens can be two to four 650-mg sodium bicarbonate tablets/days (divided into two to three doses). Afterward, doses should be titrated to desired bicarbonate levels. This could be a new option for managing metabolic acidosis in CKD.

Once in kidney failure, dialysis can be used to chronically manage metabolic acidosis. Bicarbonate is added to the dialysate solution and is delivered through the process of diffusion from the dialysate bath into the plasma (see Chapter 30, Dialysis Treatment for Chronic Kidney Failure).

ANEMIA OF CHRONIC KIDNEY DISEASE

CASE 28-1, QUESTION 8: What findings in G.B. are consistent with the diagnosis of anemia of CKD, and what is the etiology of this disorder?

G.B.'s hemoglobin of 10.3 g/dL is substantially lower than the normal range for females, indicating that she has anemia. Her normal MCV suggests her red cells are of normal size, but the absence of an elevated reticulocyte count suggests an impaired bone marrow response for her degree of anemia. Her fatigue is consistent with the symptoms of anemia.

Characteristics and Etiology

Anemia, defined as a hemoglobin concentration of <13 g/dL (in males) and <12 g/dL (in females), affects most patients with CKD.[99] It is primarily caused by a decreased production of erythropoietin (EPO), a glycoprotein that stimulates RBC production in the bone marrow and is released in response to hypoxia. Approximately 90% of the total EPO is produced in the peritubular cells of the kidney; the remainder is produced by the liver. EPO concentrations in patients with kidney failure are lower than in individuals with normal kidney function who have the same degree of anemia and the same stimulus for EPO production and release.[99]

Anemia can appear as early as category G3a in CKD and is characterized by normochromic (normal color) and normocytic (normal size) RBCs unless a concomitant iron, folate, or vitamin B_{12} deficiency exists. A higher prevalence of anemia occurs in the population with an eGFR <60 mL/minute/1.73 m^2.[1] Pallor and fatigue are the earliest clinical signs, with other manifestations developing as anemia progresses with declining kidney function. A significant consequence of anemia is development of left ventricular hypertrophy (LVH), further contributing to cardiovascular complications and mortality in patients with CKD. LVH has been observed in ~30% of patients with eGFR 50 to 75 mL/minute/1.73 m^2 (CKD G2 and G3) and in up to 74% of patients at the start of

dialysis.[100] These findings support the need for early and aggressive treatment of anemia of CKD.

A complete workup for anemia of CKD is recommended for patients with an eGFR of <60 mL/minute/1.73 m^2.[99] This workup includes a complete blood count, including hemoglobin, assessment of iron indices, and evaluation for sources of blood loss. This workup should be done annually to every three months depending on the stage of CKD because of the association between anemia and the progressive decline in eGFR.[99]

IRON STATUS

Iron deficiency substantially contributes to anemia development even in the presence of adequate EPO. The two tests that best evaluate iron status are the TSAT percent and serum ferritin.[99] Transferrin is a carrier protein for iron within the blood. The TSAT indicates the saturation of the transferrin with iron and is determined as follows (Eq. 28-4):

$$\% \text{ TSAT} = \frac{\text{serum iron } (\mu g/dL)}{\text{TIBC } (\mu g/dL)} \times 100 \qquad \textbf{(Eq. 28-4)}$$

where TIBC is the total iron-binding capacity of the transferrin protein. The TSAT is considered iron readily available for RBC production. Serum ferritin is a marker for iron reserves, which are stored primarily in the mononuclear phagocytic system. The goal of iron supplementation therapy is to maintain the TSAT >30% and a serum ferritin >500 ng/mL for CKD to provide sufficient iron for erythrocyte production. A low ferritin level in CKD is usually indicative of absolute iron deficiency. On the other hand, patients with CKD also can present with functional iron deficiency, which is a state where the total iron stores are normal but not effectively mobilized from the storage sites in the reticuloendothelial macrophages. It is postulated that chronic inflammation in CKD plays a major role in functional iron deficiency. Hepcidin, a 25-amino acid hepatic peptide, is upregulated during inflammation, which increases

in prevalence in the later stages of CKD.[101] Hepcidin suppresses the release of iron from the stores in to circulation, which contributes to functional iron deficiency. It has been explored as a possible measure of iron status, but the diurnal variation associated with hepcidin makes it an unreliable biomarker.[101]

Other tests, including the percentage of hypochromic RBCs, reticulocyte hemoglobin content, serum transferrin receptor, RBC ferritin, and zinc protoporphyrin, have been proposed as indicators of iron status, but further investigation is warranted to determine their utility and to make such testing procedures readily available.[99]

TREATMENT

Case 28-1, Question 9: What are the goals of therapy for anemia in G.B.? Describe the options available to treat anemia of CKD and achieve the goals of therapy in G.B.

The main goals of therapy in a patient with anemia of CKD include prevention/improvement of anemia-related symptoms, avoidance of blood transfusions, and preventing long-term cardiovascular effects of anemia. G.B.'s iron status should be evaluated first and corrected if necessary. If achieving an adequate iron status does not improve hemoglobin, erythropoiesis-stimulating agent (ESA) therapy may be started (see Treatment section, and Chapter 92, Anemia).

IRON THERAPY

The KDIGO guidelines suggest a 1- to 3-month trial of oral iron supplementation for CKD patients not on dialysis; however, given the poor bioavailability of oral iron and patient noncompliance, oral iron is usually inadequate for repletion of iron in patients with advanced CKD.[99,102] Therefore, a trial of oral iron is reasonable for G.B. Oral iron supplementation should be started to treat iron deficiency. Patients may not tolerate oral iron therapy because of GI side effects, so it might be desirable to start at a low dose (65 mg of elemental iron) and titrate up to the optimal daily dose of 200 mg, as

tolerated. Many oral iron preparations are available, and their iron content varies, as will the number of tablets or capsules that must be taken per day to provide the required elemental iron (see **Table 28-9**). An acidic environment is needed for adequate iron absorption, and acid-suppression therapies (eg, proton-pump inhibitors) may limit the absorption of oral iron.

Table 28-9
Oral Iron Preparations

Preparation	Common Brand Names	Commonly Prescribed Unit Size (Amount Elemental Iron in mg)[a]	Number of Units/Day to Yield 200 mg Elemental Iron
Ferrous sulfate	Slow FE, Fer-In-Sol	325 (65)	3 tablets
Ferrous gluconate	Feratab	325 (36)	5 tablets
Ferrous fumarate	Femiron, Feostat	200 (66)	3 capsules
Iron polysaccharide	Niferex, Nu-Iron	150 (150)	2 capsules
Heme iron polypeptide	Proferrin-ES	12 (12)	17 tablets
Carbonyl iron	Fesol	45 (45)	4 tablets

[a]Unit size reflects common tablet or capsule sizes prescribed and not necessarily that of the brand names listed.

G.B. should be advised to take oral iron on an empty stomach to maximize absorption unless side effects prevent this strategy. She also should be counseled on how to avoid potential drug interactions with oral iron (eg, antacids, quinolones) and to take 2 hours apart and GI side effects (eg, nausea, abdominal pain, diarrhea, constipation, dark stools). Also, nonadherence to therapy because of side effects is a common cause of therapeutic failure with oral iron. She should be counseled to contact her physician if these adverse effects persist.

If G.B.'s condition does not respond to oral therapy, as indicated by either persistent iron deficiency based on iron indices or inadequate response to the treatment dose, IV iron might be necessary. The IV iron preparations currently available include iron dextran, iron sucrose, sodium ferric gluconate, ferric carboxymaltose, ferumoxytol, and ferric derisomaltose.[103–108] See **Table 28-10**, for a comparison of several parenteral iron preparations to assist in making appropriate choices for treating iron deficiency anemia associated with CKD in patients on dialysis and

not on dialysis.[103,107,109,110] Additionally, soluble ferric pyrophosphate citrate was approved by the FDA in 2015; this iron product is added to the dialysate used for hemodialysis.[111] Parenteral iron preparations pose the risk of hypersensitivity reactions, including anaphylactoid and sometimes fatal anaphylactic reactions.[102] These serious reactions are more commonly associated with iron dextran; however, patients on parenteral iron should be monitored for at least 30 minutes after administration of any parenteral iron preparation. A test dose is required for iron dextran because of a higher incidence of anaphylactoid and anaphylaxis reactions.[103] Monitoring protocols must be put in place during and after the administration of all IV iron preparations.

Table 28-10

Intravenous Iron Preparations

Preparation	Common Brand Name(s)	Adult Dosing Information for Labeled Indication(s)	Labeled CKD Indication(s) in Adults
Iron dextran	INFed, 50 mg/mL (2 mL)	Requires test dose of 0.5 mL (25 mg) administered over 30 seconds about an hour prior to first dose Total dose (mL) = 0.0442 (Desired Hb – Observe Hb) × LBW + (0.26 × LBW) Administered in divided doses (max daily dose 100 mg)	Iron deficiency anemia (no longer favored in CKD but could still be an option)
Iron sucrose	Venofer® 20 mg/mL (2.5, 5, 10 mL)	HDD-CKD: 100 mg administered during each hemodialysis session (up to 10 doses) PDD-CKD: Two infusions of 300 administered 14 days apart followed by 400 mg 14 days after (total cumulative dose of 1000 mg) NDD-CKD: 200 mg administered on 5 different days within a 14-day period (total cumulative dose of 1000 mg)	For anemia in CKD G1–G5, CKD G5D
Sodium ferric gluconate	Ferrlecit 12.5 mg/mL (5 mL)	125 mg per dialysis session up to a cumulative dose of 1000 mg	For anemia in CKD G5D (hemodialysis)
Ferumoxytol	Feraheme® 510 mg/17 mL (17 mL)	Two-dose regimen: 510 mg over at least 15 minutes; repeat dose after 3–8 days	For anemia in CKD
Ferric carboxymaltose	Injectafer® 750 mg/15 mL (15 mL)	<50 kg: administer 15 mg/kg on day 1; repeat dose after at least 7 days (maximum: 750 mg per single dose; 1500 mg per course) ≥50 kg: administer 750 mg on day 1; repeat dose after at least 7 days (maximum: 750 mg per single dose; 1500 mg per course) May repeat course of therapy if anemia reoccurs	For anemia in CKD
Ferric derisomaltose	Monoferric 1000 mg/10 mL (10 mL)	<50 kg: 20 mg/kg as a single dose ≥50 kg: 1000 mg as a single dose May repeat if iron deficiency anemia reoccurs	For anemia in CKD G1–G5

ERYTHROPOIESIS-STIMULATING AGENT THERAPY

If there is no response in the hemoglobin levels after iron indices (TSAT and ferritin) are improving or normalized, then recombinant human EPO should be initiated for anemia of CKD in G.B.

The treatment target for patients on ESA therapy has been a controversial issue over the years. The KDIGO Clinical Practice Guideline for Anemia in Chronic Kidney Disease recommends a target hemoglobin of up to 11.5 g/dL.[99] Furthermore, for nondialysis CKD patients with a hemoglobin <10.0 g/dL, the decision to start ESA therapy is based on the rate of fall of the hemoglobin. Normalization of hemoglobin (ie, ≥13 g/dL) in CKD is not recommended. Three trials have evaluated the efficacy and safety of hemoglobin targets in patients with CKD not on hemodialysis (HD). In each study, the higher target hemoglobin groups (hemoglobin ≥13 g/dL) experienced increased cardiovascular events, stroke, or mortality rates; thus, the boxed warnings in CKD.[112–114] Partial correction of anemia to ~11 g/dL is shown to offer improvements in quality of life, reduction in hospitalizations, and improvement in LVH.[115,116] It is at these targets that benefits such as increased survival, exercise capacity, quality of life, cardiac output, cognitive function, and decreased risk of LVH were observed in the CKD population. As a result, FDA mandated a Black Box warning for ESA products and recommends to individualize treatment and use the lowest sufficient dose to reduce the need for blood transfusions.

It should be noted that iron deficiency is the leading cause of ESA hypo-responsiveness and must be corrected before ESA therapy is initiated. Iron deficiency can develop as a result of increased requirements for RBC production with ESA administration and from chronic blood loss owing to bleeding or HD. Identification and management of iron deficiency through regular follow-up testing and

iron supplementation is essential for adequate RBC production (see Chapter 92, Anemias).[99]

Human erythropoietin–epoetin alfa

Human EPO or epoetin alfa, the exogenous form of EPO, is produced using recombinant technology. Epoetin alfa is available in the United States, whereas epoetin beta is available primarily outside the United States. Since it became available in 1989, epoetin alfa (Epogen®, Procrit) has provided an effective treatment option for anemia in patients with CKD on dialysis and not on dialysis and has substantially decreased the need for RBC transfusions. Epoetin alfa stimulates the proliferation and differentiation of erythroid progenitor cells, increases hemoglobin synthesis, and accelerates the release of reticulocytes from the bone marrow.

For patients such as G.B. who do not yet require dialysis and for patients receiving peritoneal dialysis (PD), epoetin alfa is generally administered subcutaneously. However, patients on HD often receive epoetin alfa intravenously because intravenous (IV) access is already established. Subcutaneous administration of epoetin is preferred in patients not on dialysis because lower doses can be administered less frequently, and cost is lower than with IV administration. Starting doses for epoetin alfa IV administration are 50 to 100 units/kg three times weekly.[117] For patients being converted from IV to subcutaneous administration (half-life of epoetin alfa is 8.5 hours IV vs 24.4 hours subcutaneous) whose hemoglobin is within the target range, the dose given subcutaneously is usually two-thirds the IV dose. For patients not yet at the target hemoglobin, a subcutaneous dose equivalent to the IV dose is recommended.

The FDA recently approved epoetin alfa-epbx, Retacrit®, a biosimilar to epoetin alfa for use in the United States. Based on the results of randomized clinical trials EPOE-10-01 and EPOE-10-13 and the subsequent open-labeled supportive trials EPOE-11-03 and EPOE-11-04 conducted in patients on hemolysis, epoetin alfa-epbx showed similar efficacy and safety profiles compared to the

reference product, epoetin alfa.[118] The dosing of epoetin alfa-epbx is similar to that of epoetin alfa.[119]

Darbepoetin alfa

Darbepoetin alfa (Aranesp®) was approved in 2001 for the treatment of anemia of CKD, regardless of dialysis requirements. Darbepoetin is a hyperglycosylated analog of epoetin alfa that stimulates erythropoiesis by the same mechanism. Instead of the three N-linked carbohydrate chains on epoetin alfa, darbepoetin has five, which increase the capacity for sialic acid residue binding on the protein. The increased protein binding slows total body clearance and increases the terminal half-life to 25.3 and 48.8 hours after IV and subcutaneous administration, respectively. Darbepoetin alfa's longer half-life relative to epoetin alfa offers the potential advantage of less frequent dosing to maintain target hemoglobin values.[120]

Studies in patients with CKD G3 and G4 determined that starting subcutaneous doses of 0.45 µg/kg administered once per week and 0.75 µg/kg once every other week were both effective in achieving target hemoglobin and hematocrit values in patients who had not previously received erythropoietic therapy.[121] The approved starting dose of darbepoetin alfa in patients who have not previously received epoetin therapy is 0.45 µg/kg given either intravenously or subcutaneously once weekly.[120] Patients who are already receiving epoetin therapy may be converted to darbepoetin alfa based on the current total weekly epoetin dose (**Table 28-11**).[120]

Table 28-11

Estimated Darbepoetin Alfa Starting Doses Based on Previous Epoetin Alfa Dose

Previous Weekly Epoetin Alfa Dosage (units per week)	Weekly Starting Darbepoetin Alfa Dosage (µg/week)	
Adults	Children	
<1,500	6.25	[a]
1,500–2,499	6.25	6.25

Previous Weekly Epoetin Alfa Dosage (units per week)	Weekly Starting Darbepoetin Alfa Dosage (µg/week)	
2,500–4,999	12.5	10
5,000–10,999	25	20
11,000–17,999	40	40
18,000–33,999	60	60
34,000–89,999	100	100
≥90,000	200	200

[a]For children receiving a weekly epoetin alfa dosage of <1500 units per week, the available data are insufficient to determine a darbepoetin alfa conversion dosage.

Source: Facts & Comparisons. Accessed September 28, 2022. https://fco.factsandcomparisons.com/lco/action/home.

Epoetin alfa and darbepoetin alfa are generally well tolerated, with hypertension being the most common adverse event reported. BP should be monitored closely, and adjustment to antihypertensive therapy is made, if justified. Failure to elicit a response to erythropoietic therapy requires evaluation of factors that cause resistance, such as iron deficiency, infection, inflammation, chronic blood loss, aluminum toxicity, malnutrition, and hyperparathyroidism. Resistance to erythropoietic therapy has been observed in patients receiving ACEI, although data are conflicting.[122] Rare cases of antibody formation to epoetin therapy have been reported primarily with one epoetin alfa product manufactured outside the United States. Neutralizing anti-EPO antibodies were identified in patients with pure RBC aplasia who required blood transfusions after a course of therapy with epoetin alfa or beta.[123]

Iron supplementation is indicated, not only if G.B. is iron deficient but also to maintain adequate iron stores while receiving erythropoietic therapy (see Iron Therapy section). Although administration of iron alone may improve her anemia, epoetin alfa or darbepoetin alfa may likely be required when Hgb falls below 10 g/dL. G.B. may start darbepoetin alfa administered subcutaneously at a dose of 25 µg (0.45 µg/kg) once per week, assuming her iron status is appropriate (see Iron Status section). Another option would

be epoetin alfa at a dose of 4000 units (~50 units/kg) administered subcutaneously three times a week. She also should be counseled to administer subcutaneous epoetin alfa or darbepoetin alfa in the outer area of the upper arm, in the abdomen (2 inches or away from the navel), front middle thigh, or outer area of the buttocks.[117,120] Patient should also be counseled to change the site of injection. Dose adjustments should not be made more frequently than once every 4 weeks for either agent because of the time course for response (ie, the pharmacodynamic effects on RBC homeostasis). The time it takes to reach a new steady- state, when RBC production is equal to RBC destruction, depends on the life span of the RBC, which is ~60 days in patients with kidney failure. Therefore, it will take ~2 to 3 months to reach a plateau in measured hemoglobin. Dose adjustments should be made on the basis of G.B.'s hemoglobin, which should be monitored every 1 to 2 weeks after initiation of therapy or after a dose change. If a rapid increase in hemoglobin is observed (hemoglobin >1.0 g/dL during any 2-week period) or approaching 11.5 g/dL, then doses of either agent should be decreased by ~25%. If response is inadequate (hemoglobin increase <1 g/dL in 2–4 weeks), then the doses should be increased by 25%. Once stable, the hemoglobin should be monitored every 2 to 4 weeks. If a response is not observed despite appropriate dose titration, G.B. should be evaluated for possible reasons for nonresponse (ie, iron deficiency, bleeding, aluminum intoxication, hyperparathyroidism, infection).

OTHER ERYTHROPOIESIS-STIMULATING AGENTS

Methoxy polyethylene glycol-epoetin beta (Mircera®) is a long-acting epoetin. Continuous-erythropoietin receptor activator (CERA) has twice the molecular weight of EPO because of the addition of a single 30-kDa polymer chain into the EPO molecule resulting in a considerably longer elimination half-life compared with EPO (130 vs 4–28 hours). This allows for extended-interval dosing biweekly or once monthly, either intravenously or subcutaneously. It has an efficacy and safety profile comparable to other available ESAs.[124]

CARDIOVASCULAR COMPLICATIONS

CASE 28-2

QUESTION 1: H.B. is a 65-year-old White male with a history of autosomal dominant polycystic kidney disease (ADPKD) leading to CKD, which has progressed to G5D and has just started chronic HD. He comes in today for his third HD session (intermittent dialysis scheduled three times per week, 4-hour duration). He has a history of hypertension, which has been poorly controlled during the past 4 months (BP ranges 150–190/85–105 mm Hg) and has experienced shortness of breath and a significant weight gain during the past month. His pertinent medical history includes hypertension for the past 14 years.

Current medications: Iron sucrose 100 mg IV #8 of 10 total doses (during HD sessions), epoetin alfa 3500 units IV three times a week (during dialysis), metoprolol tartrate 50 mg bid, furosemide 80 mg bid, calcium carbonate 500 mg tid with meals, sevelamer carbonate 800 tid with meals, and Nephrocaps one by mouth (PO) every day.

Vital signs: predialysis BP was 195/100 mm Hg, and his postdialysis BP was 168/90 mm Hg. Weight 154.32 pounds (70 kg), height 70 inches (177.8 cm)
A recent echocardiogram showed evidence of LVH.
Predialysis laboratory values were as follows:
Serum sodium (Na^+), 140 mEq/L
Potassium (K^+), 5.1 mEq/L
Chloride (Cl^-), 101 mEq/L
CO_2 content, 23 mEq/L
SCr, 8.8 mg/dL
BUN, 84 mg/dL
Phosphorus, 6.5 mg/dL
Calcium, 8.6 mg/dL
Serum albumin, 3.0 g/dL
Cholesterol (nonfasting), 345 mg/dL
Triglycerides, 285 mg/dL
TSAT, 18%
Ferritin, 250 ng/mL
Hct, 27%
Hgb, 9.0 g/dL
H.B. has a urine output of 50 mL/day.

What conditions evident in H.B. place him at increased risk of cardiovascular complications and mortality?

H.B. has uncontrolled hypertension that is not adequately managed with his current drug therapy or HD. Hypertension is associated with LVH, ischemic heart disease, and heart failure, all of which are contributing factors to overall mortality in patients with CKD 5D who are undergoing dialysis.[125] H.B.'s echocardiogram shows evidence of LVH and should trigger additional evaluation to determine the extent of cardiac involvement and diagnosis of heart failure, which is associated with increased mortality in both diabetic and nondiabetic patients (see Chapter 14, Heart Failure).[100] LVH can develop early in the course of CKD and progresses as kidney disease progresses. H.B. is in the most severe stage of CKD. Anemia contributes substantially to the development of LVH and heart failure as well. H.B.'s hemoglobin of 9.0 g/dL is below the target value and requires treatment based on evaluation of his iron indices (see the section on Anemia).

Additional factors that increase the risk of cardiovascular complications and mortality in H.B. include anemia of CKD, elevated cholesterol and triglycerides levels, as well as hypoalbuminemia (serum albumin, 3.0 g/dL). Because elevated concentrations of homocysteine have been observed in conjunction with decreased folate and vitamin B_{12} levels, more aggressive supplementation of these vitamins in this population has been suggested. Because H.B.'s total corrected calcium (corrected for hypoalbuminemia; see Case 28-3, Question 2, for an explanation of this correction) is 9.4 mg/dL, his calcium will need to be monitored frequently. Metastatic calcification is common in patients with CKD on calcium-containing phosphate binders and is a risk factor associated with CVD. It has been reported that ~80% of patients with kidney failure have detectable coronary artery calcification.[126] CVD and complications continue to be the leading cause of mortality in patients with kidney failure.[1]

Hypertension

CASE 28-2, QUESTION 2: What options are available to treat H.B.'s hypertension considering his other cardiac complications and BP goal?

Hypertension is a unique complication of CKD because it is also a risk factor for CKD. We have previously discussed the pathogenesis of hypertension in CKD.

Because H.B. is just beginning dialysis therapy, it is difficult to assess the degree to which volume removal will ultimately affect his BP. (See Chapter 30, Dialysis Treatment for Chronic Kidney Failure.) H.B. has had recent findings consistent with worsening volume status (shortness of breath, weight gain) that should be considered when modifying his dialysis prescription; further workup is needed to determine whether H.B. has systolic or diastolic heart failure. It is also important to counsel H.B. on the importance of salt and fluid intake restriction between HD sessions to minimize weight gain, volume expansion, and hypertension. Restriction of salt intake to <2.4 g/day and fluid to 1 L/day is appropriate and will require regular follow-up by a dietitian.

ANTIHYPERTENSIVE THERAPY

Currently, there are no published guidelines for the management of hypertension in patients receiving hemodialysis. For some patients, initiation of dialysis alone may achieve BP target goal, and antihypertensive therapy may be withdrawn. The aim of the BP goal in patients with kidney failure on dialysis is to minimize cardiovascular complications, but it should not increase the risk for hypotension and its associated complications during dialysis. The choice of an agent is based on the patient's comorbid conditions because no single agent has a consistently proven mortality benefit in patients on HD. The complexity of managing hypertension in patients on HD is enhanced by the apparent U-shaped relationship between BP and mortality.[127] Another cohort study found a systolic BP between 100 and 125 mm Hg was associated with the lowest risk of death, and systolic BP >150 mm Hg associated with increased death.[127]

Diuretics are commonly used in patients in the early stages of CKD. As discussed, the effectiveness of diuretics depends on the amount of sodium delivered to their site of action in the kidney tubule and on the patient's kidney function. For example, a decrease in the eGFR from 125 to 25 mL/minute/1.73 m^2, theoretically, could result in an approximate 80% decrease in the amount of sodium filtered. Early during CKD, thiazides or thiazide-like diuretics are effective antihypertensive agents. As eGFR drops below 30 mL/minute/1.73 m^2, they become less effective. Potassium-sparing diuretics are also ineffective and may increase the risk of hyperkalemia. Loop diuretics, which act more proximally in the nephron, are indicated in patients with GFR <30 mL/minute/1.73 m^2.[128] They can be effective for BP and volume control in patients with advanced CKD if residual kidney function is substantial (urine output >100 mL/day). Their effect must be frequently reevaluated based on urine output and any effect on volume control. H.B.'s urine output should be assessed to determine the rationale for continued use of furosemide, and the current dose should be assessed because doses higher than his current dose of 80 mg bid are often required in patients with this degree of kidney dysfunction. It is likely that furosemide will need to be discontinued as H.B.'s residual kidney function declines.

Given the role of the RAAS in the development of hypertension in patients with CKD, ACEIs or ARBs are logical choices for antihypertensive therapy in CKD G1 to G4. Several studies have demonstrated that the initiation of ACEI, ARBs, or both in patients in CKD G5D improved BP control, lowered LVH, and reduced the cardiovascular mortality risk.[129] Most of these agents can be administered once daily; however, because of the kidney elimination of the parent drug or active metabolite, dosage adjustments are necessary in patients with CKD. ARBs offer an alternative to ACEIs in patients experiencing kinin-mediated adverse effects; however, similar side effects have been reported with ARBs.

β-Adrenergic blockers inhibit release of renin and may be useful in hypertension associated with CKD. β-Blockers can counteract the elevated sympathetic activity observed in patients on dialysis, lower the risk of sudden cardiac death, and improve survival in heart

failure.[130] Risk versus benefit should be evaluated when β-blockade is considered in conjunction with other comorbid conditions such as asthma, heart failure, and lipid abnormalities. Calcium channel blockers are effective antihypertensive agents in patients with CKD. Other agents used to treat hypertension in the CKD population include centrally acting agents (eg, clonidine, methyldopa), vasodilators (eg, minoxidil, hydralazine), and α1-adrenergic blockers (prazosin, terazosin, doxazosin). However, these agents are generally reserved as last-line therapies.

H.B. is currently taking the β-blocker metoprolol and the loop diuretic furosemide. Metoprolol is a β-blocker considered to be removed by dialysis and should be monitored closely for H.B. clinical response to the therapy while starting dialysis. It is likely that his diuretic will need to be discontinued as his residual kidney function decreases and response to therapy is inadequate. If changes imposed in H.B.'s HD prescription can improve volume control and achieve his dry weight but do not reduce his BP, another antihypertensive regimen should be selected. A reasonable antihypertensive regimen would include an ACEI or ARB. Because the agents in these drug classes have similar mechanisms of action, the choice of specific agents would depend on patient-specific factors like the ability to pay and adherence. The selection of agent will depend substantially on follow-up results of his cardiac disease, BP control with HD, and the potential for adverse effects (see Chapter 9, Essential Hypertension, and Chapter 14, Heart Failure).

Dyslipidemia

Case 28-2, Question 3: How should H.B.'s lipid abnormalities be treated?

Dyslipidemia is quite common in CKD. There is limited evidence that lowering lipids slows the progression of CKD, but studies show that the benefit of treating dyslipidemia in CKD is to reduce the cardiovascular risk. The Study of Heart and Renal Protection

(SHARP) assessed the effect of lowering LDL cholesterol in 9270 patients with CKD with ezetimibe 10 mg daily and simvastatin 20 mg daily or matching dummy placebo tablets for an average of 5 years. The results showed a 25% risk reduction in major atherosclerotic events in the treatment group. However, there was no effect on the progression of CKD. The KDIGO Clinical Practice Guidelines for Lipid Management in CKD offers some guidance for the management of dyslipidemia. For patients with CKD aged 50 years and older and not on dialysis, KDIGO recommends treatment with a statin or statin/ezetimibe combination. Patients with CKD aged 18 to 49 years with additional CVD risk factors such as known coronary disease (myocardial infarction [MI] or coronary revascularization), diabetes, prior ischemic stroke, or estimated 10-year coronary heart disease risk >10% are recommended to initiate statin therapy. The KDIGO guidelines suggest measuring a full lipid profile 6 weeks to 3 months after initiation of a statin in order to identify patients with an inadequate response to moderate-intensity statins and who require dose titration.[131] The Die Deutsche Diabetes Dialyse Studie (4D) and AURORA are two large multicenter, double-blind, placebo-controlled, randomized controlled trials that examined the effects of lowering the level of LDL-C on cardiovascular events and mortality with atorvastatin or rosuvastatin, respectively. The results of these studies along with the negative effects in patients on dialysis from the SHARP study have largely driven KDIGO recommendations to avoid initiating statin therapy in patients on dialysis unless initiated prior to starting dialysis.[132]

H.B. has elevated serum cholesterol and triglyceride concentrations, a common finding in patients with CKD. Dyslipidemia and increased oxidative stress contribute to premature atherogenesis in these patients. Several atherogenic factors in patients with CKD have been postulated, including arterial wall injury, platelet activation and adherence, smooth muscle cell proliferation, and intra-arterial accumulation of cholesterol. Lowering of serum lipids has not been shown to improve morbidity and mortality in patients on hemodialysis. Furthermore, current KDIGO Guidelines for Lipid Management in CKD do not recommend using cholesterol

values to determine who to treat or as treatment targets. Currently, H.B. is not receiving a statin that has not demonstrated the ability to reduce mortality or morbidity in dialysis. Dietary and lifestyle changes could be beneficial in reducing triglyceride and cholesterol concentrations in patients with kidney failure on dialysis.

Statins are preferred over fibrates for management of dyslipidemia in CKD.[132] Fibrates should be used cautiously in patients with CKD; all agents in this class are metabolized by the kidney and are eliminated primarily via the kidney, which may lead to an increased risk of rhabdomyolysis. However, fibric acid derivatives may be considered in patients presenting with extremely high triglycerides (>1000 mg/dL). Fenofibrate is not recommended in patients with mild-to-moderate CKD (CrCl between 30 and 80 mL/minute) and contraindicated in individuals with CrCl <30 mL/minute.[133] Gemfibrozil is to be used with caution in mild-to-moderate kidney dysfunction and not recommended in CKD G5.[134]

MINERAL AND BONE DISORDERS

CASE 28-3

Question 1: W.K. is a 24-year-old Hispanic female who has an 18-year history of T1D with complications of DKD, retinopathy, and neuropathy. She was diagnosed with kidney failure, CKD G5D 2 years ago. She started PD at that time.

Current medications: Insulin aspart 10 units subcutaneous with meals; insulin glargine 25 units subcutaneous nightly; docusate 100 mg PO every day; calcium acetate 2001 mg (three tablets, 667 mg each) PO tid with meals; epoetin alfa (Procrit, Epogen) 10,000 units subcutaneous once weekly; iron sucrose 300 mg IV (repeat in 2 weeks, then 400 mg 2 weeks later), calcitriol 0.25 PO three times weekly, and Nephrocaps one capsule every day. W.K. has a history of medication nonadherence.

At a recent clinic visit, findings on physical examination included a BP of 128/84 mm Hg, diabetic retinopathic changes with laser scars bilaterally, and diminished sensation bilaterally below the knees.

Her laboratory values were as follows:

Normal serum electrolytes
Random blood glucose, 250 mg/dL
BUN, 45 mg/dL
SCr, 8.9 mg/dL
eGFR, 5 mL/minute/1.73 m^2
Hgb, 10 g/dL
WBC count, 6200/μL
Calcium, 9.2 mg/dL
Phosphorus, 6.8 mg/dL
Intact parathyroid hormone (iPTH), 950 pg/mL
Thyroid-stimulating hormone, 5 mIU/L
Total serum protein, 5.0 g/dL
Serum albumin, 2.5 g/dL
Uric acid, 8.9 mg/dL

What is the etiology of W.K.'s abnormal calcium, phosphorus, and parathyroid hormone (PTH) findings?

Etiology

Mineral bone disease of CKD (CKD-MBD) is the term used to collectively describe the dysregulation of serum phosphorus, calcium, and PTH, leading to the demineralization of bone and soft tissue calcification as a complication of CKD.[135]

Hyperphosphatemia, hypocalcemia, hyperparathyroidism, and decreased production of active vitamin D are frequent problems in CKD. Although the interrelationships among phosphorus, calcium, vitamin D, and PTH have been reviewed extensively, fibroblast growth factor 23 (FGF23), a phosphaturic hormone, has added some new insight.[136] Increased dietary phosphorus intake stimulates FGF23 secretion. FGF23 increases phosphorus excretion via the proximal tubules, inhibits vitamin D activation, increases activated vitamin D catabolism, and is associated with CKD progression.

At a GFR above 30 mL/minute/1.73 m^2, elevations in FGF23 and PTH maintain normal serum phosphorus. This concept is referred to as the trade-off hypothesis, where the ability to maintain normal phosphorus concentrations occurs at the expense of developing secondary hyperparathyroidism (SHPT), the excessive secretion of PTH and elevated FGF23.[137,138] However, FGF23 is not typically

measured in the clinical setting. Clinically significant increases in serum phosphorus are not usually seen until the late stages of CKD, GFR <30 mL/minute/1.73 m^2, when compensatory mechanisms within the kidney are compromised.

The kidney is the principal organ responsible for systemic vitamin D production, and, as such, vitamin D metabolism is altered in the presence of uremia. Persistent hyperphosphatemia stimulates the release of excessive FGF23, which inhibits the normal conversion of 25-hydroxyvitamin D3 to its biologically active metabolite, 1,25-dihydroxyvitamin D3, by the enzyme 1-α-hydroxylase (**Fig. 28-2**). This enzyme is present in proximal tubular cells of the kidney and is necessary for the conversion of vitamin D to the active form. This active form of vitamin D, also known as calcitriol, increases gut absorption of calcium and interacts with vitamin D receptors (VDRs) on the parathyroid gland to suppress PTH release. As a result of decreased calcitriol production, the absorption of dietary calcium in the gut is diminished. Decreased suppression of PTH release by vitamin D in conjunction with hypocalcemia promotes continued stimulus for mobilization of calcium from bone and plays a major role in the development of renal osteodystrophy. Furthermore, patients who are uremic require a higher extracellular calcium concentration to suppress the secretion of PTH. This is also described as an increase in the calcium “set point” or the concentration of calcium required to inhibit 50% of maximal PTH secretion.[139]

Figure 28-2 Vitamin D biotransformation.

The chronic effects of SHPT on the skeleton lead to bone pain, fractures, and myopathy. In children, these effects may be particularly severe and usually retard growth. The metabolic acidosis of CKD also contributes to a negative calcium balance in the bone.

W.K.'s presentation is consistent with CKD-MBD based on abnormalities in serum phosphorus, calcium, and PTH; all can be attributed to her CKD.

Vitamin D levels (ie, 25-hydroxyvitamin D) should be monitored in patients with CKD. Insufficient (<30 ng/mL) and deficient (<15 ng/mL) vitamin D levels are prevalent in the majority of patients with CKD and kidney failure. Several studies have linked depressed vitamin D levels to increased vascular calcification, CVD, and mortality.[140]

Treatment

Case 28-3, Question 2: What are the goals of therapy for W.K.'s calcium, phosphorus, and PTH abnormalities? What options are available to treat these disorders in late-stage CKD?

Serum calcium and phosphorus have an inverse relationship. When phosphorus levels rise, calcium levels fall, and vice versa. The management objectives for W.K. are to (a) manage serum calcium and phosphorus concentrations, (b) prevent or manage SHPT, and (c) restore normal skeletal development without inducing adynamic bone disease (or low bone turnover). These goals are best achieved with dietary phosphorus restriction, appropriate use of phosphate-binding agents, vitamin D therapy, calcimimetic agents, and dialysis.

DIETARY RESTRICTION OF PHOSPHORUS

In general, serum phosphorus should be lowered toward near-normal levels. The KDIGO recommends normal levels for all stages of CKD. Dietary phosphorus restriction can prevent hyperphosphatemia and maintain target phosphorus concentrations. Dietary phosphorus should not exceed 800 to 1000 mg/day.[135] Predominant sources of phosphorus are protein-rich foods, which presents a challenge in tailoring a diet that lowers dietary phosphorus intake while providing adequate nutrition. However, efforts should be made to distinguish between organic (eg, plant

seeds, nuts, legumes, and meats) and inorganic phosphorus (eg, preservatives and additive salts found in processed foods) sources. Inorganic phosphorus sources are absorbed to a greater extent than organic phosphorus (90% vs 50%, respectively) and should be minimized in the diet.[141]

Additionally, the type of organic phosphorus sources, plant versus meat, has varying effects with plant sources associated with lower serum phosphorus levels and decreased FGF23 levels. Although phosphorus is removed to some extent by dialysis, neither conventional HD nor PD removes adequate amounts to warrant complete liberalization of phosphorus in the diet. Nocturnal HD is an exception where patients may require phosphate supplements because of the prolonged dialysis duration. Regular dietary counseling by a kidney dietitian specialist is necessary to reinforce the importance of phosphorus restriction and other dietary recommendations.

PHOSPHATE-BINDING AGENTS

A significant reduction in serum phosphorus is difficult to achieve with dietary intervention alone, particularly in patients with more advanced CKD (eGFR <30 mL/minute/1.73 m^2). For these patients, phosphate-binding agents used in conjunction with dietary restriction are necessary. Phosphate-binding agents limit phosphorus absorption from the GI tract by binding with the phosphorus present in dietary sources. Therefore, these agents must be administered with meals. Phosphate binders can be classified into two broad categories: calcium-based and non-calcium–based preparations.

CALCIUM-CONTAINING PREPARATIONS

Calcium-containing preparations, especially calcium carbonate and calcium acetate, are effective and frequently used to prevent hyperphosphatemia in patients with CKD. Other calcium-containing phosphate binders are available, and they vary in their calcium content and pill burden (**Table 28-12**). Correction of hypocalcemia is an added beneficial effect of the calcium-containing preparations;

however, a risk exists of hypercalcemia and cardiac calcification associated with the prolonged use of these agents.[12] Additionally, the higher bioavailable calcium in calcium carbonate may lead to a positive calcium balance.[142]

Table 28-12

Recommended Phosphate Binders in Chronic Kidney Disease

Agent	Availability (Daily Pill Burden)	Comments	Adverse Effects and Warnings
Aluminum-Based Binder			
Aluminum hydroxide	320 mg/5 mL suspension	Not recommended as first line because of potential aluminum toxicity	Constipation and sodium overload Aluminum toxicity: CNS, anemia, and bone disease Warnings: perforation, fecal impaction, ileus
Calcium-Based Binders			
Calcium acetate	667 mg caplets (3–12 caplets) 667 mg/5 mL (15–20 mL with meal)	Oral solution associated with higher diarrhea risk	N/V/D; hypercalcemia; vascular calcification; oral solution associated with greater diarrhea
Calcium carbonate	500–1250 mg tablets (3–6 tablets)	Over-the-counter	N/V/D; hypercalcemia; vascular calcification
Iron-Based Agents			
Ferric citrate	210 mg ferric iron tablet (6–12 tablets)	210 mg of ferric iron—1 g ferric citrate	N/V/D; discolored feces; iron overload Precautions: gastric/hepatic disorders CI: hemochromatosis
Sucroferric oxyhydroxide	500 mg chewable tablet (3–6 tablets)	500 mg ferric iron—2500 mg sucroferric oxyhydroxide	N/D; discolored feces; iron overload Precautions: gastric/hepatic disorders; hemochromatosis
Lanthanum-Based Binder			
Lanthanum carbonate	500, 750, and 1000 mg chewable tablets (3–6 tablets)	Chewed and crushed have similar efficacy	Accumulation in bone, brain, and liver; visible on abdominal x-ray; hypercalcemia CI: bowel obstruction, ileus, and fecal impaction
Resin Binders			
Sevelamer carbonate	800 mg caplet (3–12 caplets) 0.8 g/2.4 g powder packets	Reduces low-density lipoprotein cholesterol	N/V/D; hypercalcemia CI: bowel obstruction Warnings: perforation, fecal impaction
Sevelamer hydrochloride	400, 800 mg caplets 1–2 tablets tid (6–12 caplets)	Reduces low-density lipoprotein cholesterol	N/V/D; hypercalcemia CI: bowel obstruction Warnings: perforation, fecal impaction; risk of metabolic acidosis

CI, contraindications; N/V/D, nausea, vomiting, diarrhea.

Persistent hypocalcemia must be managed to prevent SHPT and its complications. Simultaneous administration of vitamin D preparations and calcium also increases the risk of hypercalcemia. A corrected serum calcium should be determined before therapy is started and at regular intervals thereafter.

Many clinicians often correct calcium levels for low albumin. Calculating corrected calcium adjusts for the change in the ratio of free (unbound) versus protein-bound calcium owing to reduced serum albumin concentrations (Eq. 28-5). W.K.'s corrected serum calcium concentration is 10.4 mg/dL.

$$\text{Corrected calcium (mg/dL)} = \text{measured Ca (mg/dL)} + 0.8 \times (4\ \text{g/dL} - \text{measured albumin [g/dL]})$$

(Eq. 28-5)

Calcific uremic arteriolopathy (CUA), or calciphylaxis, is characterized by calcification of the arterioles and small arteries with intimal proliferation and endovascular fibrosis. CUA manifests visually as necrosis of the skin and is most frequently seen in patients on dialysis, affecting up to 5% of patients. Calcium-based phosphate binders are one of the triggering factors associated with the development of CUA. If the patient experiences hypercalcemia or evidence of advanced calcification, the patient should be switched to a non- calcium–based phosphate binder. Although avoiding hypercalcemia should reduce the risk of cardiac calcification, calcifications still can occur because of other contributing factors in the CKD population (eg, hyperphosphatemia).

Nausea, diarrhea, and constipation are other side effects of calcium-containing products. Because calcium-containing phosphate binders may interact with other drugs, the timing of their administration relative to other agents must be considered. Fluoroquinolones and oral iron, for example, should be taken at least 1 or 2 hours before calcium-containing phosphate binders. Starting doses of common calcium-containing phosphate binders are listed in Table 28-12.

NON-CALCIUM–CONTAINING PHOSPHATE BINDERS

Sevelamer

Sevelamer is a polymer-based product that binds phosphorus in the GI tract. It exists in two salt formulations, sevelamer hydrochloride (Renagel®) and sevelamer carbonate (Renvela®).[143,144] The benefit of lowering phosphorus without significantly affecting serum calcium has led to the increased use of sevelamer in patients with CKD G5 on HD. Sevelamer also lowers LDL and total serum cholesterol, a benefit considering the increased risk of cardiovascular events in this population.[135]

Sevelamer has the potential benefit of attenuating the progression of coronary calcification, which may be related to its LDL and total serum cholesterol-lowering effects and a benefit from reduced calcium loading. The actual benefit of sevelamer on mortality is controversial. The post hoc analysis of the Renagel in New Dialysis (RIND) trial showed a survival advantage with sevelamer compared with calcium acetate; however, the Dialysis Clinical Outcomes Revisited (DCOR) trial failed to show a difference in mortality between the two agents.[145] One explanation for the disparity in results may be the difference in the population of patients on HD between the two trials. The RIND trial included incident patients on HD, whereas the DCOR trial included prevalent patients on HD who likely would have advanced CVD. Sevelamer hydrochloride showed comparable efficacy to calcium acetate for managing hyperphosphatemia in kidney failure patients on PD.[146]

The starting dose is variable and depends on the baseline serum phosphorus concentration (800 mg tid with meals if serum phosphorus is <7.5 mg/dL; 1600 mg tid with meals if serum phosphorus is >7.5 mg/dL).[143,144] Gradual adjustments can be made at 2-week intervals, based on serum phosphorus levels. The drug manufacturer of sevelamer recommends dosing guidelines when switching from calcium acetate to sevelamer. For instance, the dose of sevelamer is 2.4 g (3 × 800-mg tablets) PO tid with meals when switching from calcium acetate 2001 mg PO tid with meals.

Lanthanum carbonate

Lanthanum carbonate (Fosrenol®) is another non–calcium phosphate binder preparation indicated in patients with CKD G5. When ingested, it dissociates into a trivalent cation with a similar binding capacity as aluminum salts. Lanthanum also has been found to be as effective and tolerable as standard treatment. Both calcium and iPTH were lower in the lanthanum group.[147] Lanthanum is mainly excreted via the biliary route, with minimal kidney elimination. A prospective trial of patients on HD receiving lanthanum for 1 year found minimal deposition of lanthanum within the bone and less likelihood of adynamic bone histology compared with patients receiving calcium carbonate.[148] Lanthanum is available in 500, 750, and 1000 mg oral or chewable tablets. The starting dose is 500 mg tid with meals.

Lanthanum retains the same phosphorus-binding capabilities irrespective of whether it is chewed or crushed into powder.[149] Drug interactions with lanthanum include a reduction in the bioavailability of ciprofloxacin (approximate 50% reduction) and levothyroxine. The most frequent adverse events reported in clinical trials are nausea and vomiting.[150]

Iron-based phosphate binders

Sucroferric oxyhydroxide and ferric citrate are iron-based phosphate binders with proven efficacy at reducing serum phosphate levels in patients on HD. The newer iron-based binder ferric citrate has the advantage of providing supplemental iron and is also indicated for iron deficiency anemia of CKD in patients not on dialysis.[151] Early studies of ferric citrate demonstrate a reduction in IV iron and ESA use.[152] However, sucroferric oxyhydroxide as a chewable tablet is not systemically absorbed and not indicated for iron deficiency anemia, thus not affecting anemia management.[153]

Other phosphate binders

Aluminum preparations are very potent dietary phosphorus binders. Although these products were once used as first-line agents to decrease phosphorus, aluminum accumulation and toxicities in

patients with CKD have restricted their use. Aluminum toxicity occurs in patients on dialysis because absorbed aluminum is not removed by the diseased kidney and enters various tissues where it binds to tissue and plasma proteins. Aluminum accumulation in the bone, brain, and other organs leads to toxicities such as osteomalacia (aluminum-related bone disease), microcytic anemia, and a fatal neurologic syndrome referred to as dialysis encephalopathy.

Magnesium agents (magnesium hydroxide, magnesium carbonate) may be beneficial, but as with aluminum, their use should be limited because at the high doses required to control serum phosphorus concentrations, severe diarrhea and hypermagnesemia invariably result.

More aggressive control of W.K.'s serum phosphorus is needed to lower serum phosphorus toward normal levels. Currently, W.K. is taking a high dose of calcium-based phosphate binder, calcium acetate. Although presumably much of this calcium will be bound to phosphorus in the GI tract, a potential exists for calcium absorption. Furthermore, her corrected serum calcium levels borderline high at 10.4 mg/dL. Discontinue calcium acetate. Lanthanum carbonate, a non-calcium–containing phosphate binder, should be started to limit her calcium exposure and decrease her phosphorus levels to a target of 3.5 to 5.5 mg/dL recommended in dialysis. The recommended starting dose is 500 mg tid with meals, titrated based on follow-up phosphorus values up a maximum of 4500 mg daily. Adjustments should also be considered in conjunction with vitamin D therapy (see Vitamin D section). W.K. should be instructed to take her phosphate binder with meals. This regimen should be implemented in conjunction with a restricted phosphorus diet. Regular reinforcement of adherence with prescribed dietary phosphorus restriction and drug therapy is one of the most significant factors associated with treatment failure. Although lanthanum is more costly than sevelamer, it is preferred in W.K. because of patient's history of medication nonadherence. Lanthanum is available in chewable tablets and has a lower pill burden than sevelamer.

VITAMIN D

Nutritional vitamin D (NVD) is usually in the form of ergocalciferol (vitamin D_2) or as cholecalciferol (vitamin D_3) obtained from dietary sources and activated in the skin by sunlight in mammals. Both are inactive precursors of vitamin D. An intermediate activation step (25-hydroxylation) occurs in the liver to produce 25-hydroxy vitamin D (25-hydroxycalciferol), which is also relatively inactive. Final activation (1-hydroxylation) occurs in the kidney, yielding calcitriol (l,25-dihydroxycholecalciferol), the active form of vitamin D. Thus, the response to vitamins D_2 and D_3 in patients with compromised kidney function can vary, depending on the degree of kidney dysfunction and the ability of the kidney to metabolize 25-hydroxyvitamin D to calcitriol. Decreased levels of 25-hydroxyvitamin D occur in the early stages of CKD, reducing substrate for producing calcitriol.[135] Altered vitamin D metabolism that occurs in this population warrants measurement of 25-hydroxyvitamin D and supplementation with NVD. Another inactive form of vitamin D is calcifediol, which is available as extended-release capsules and is approved for treatment of SHPT in adults with CKD stage G3a, G3b, and G4 with 25-hydroxyvitamin D levels <30 ng/mL.[154]

Oral therapy with active vitamin D (oral calcitriol) or an analog is likely warranted only when PTH remains elevated despite normal 25-hydroxyvitamin D levels.[135] As the final, active metabolite of vitamin D, calcitriol (or another activated form of vitamin D) is usually required in patients with more severe CKD (CKD stage G4–G5). Several small studies have shown that the benefits of NVD administration extend beyond bone and mineral metabolism. Reduction in ESA doses, improved glycemic control, reduced activated vitamin D administration, and inflammation modulation have been observed from NVD supplementation in patients on dialysis.[155]

Vitamin D receptor agonist

Administration of VDR agonist, active vitamin D, in conjunction with control of serum phosphorus and calcium, is necessary in many

patients with CKD to manage CKD-MBD.

Calcitriol

Calcitriol interacts with the VDR located in the parathyroid gland, intestines, bone, and kidney. It is thought to decrease PTH messenger RNA, resulting in decreased PTH secretion. In addition, calcitriol stimulates calcium absorption from the GI tract to correct hypocalcemia and prevent SHPT. To avoid hypercalcemia, the lowest effective dose should be used, and the patient's serum calcium should be monitored at least every 2 weeks for 1 month and then monthly thereafter. Furthermore, control of serum phosphorus is critical before calcitriol is initiated, as vitamin D increases GI phosphorus absorption.

Calcitriol is available as an oral formulation or IV formulation. Administration of calcitriol by either the oral or IV route may be based on conventional dosing (usually 0.25–0.5 μg/day) or pulse dosing (intermittent dosing of 0.5–2.0 μg two to three times per week). Daily dosing of 0.25 to 0.5 μg may be preferred in patients with hypocalcemia, because this regimen primarily works to stimulate calcium absorption from the GI tract. Intermittent dosing of IV calcitriol is routine in the HD population because administration is coordinated with dialysis. In contrast, oral dosing is more convenient in patients on PD or those with CKD not on dialysis. iPTH and serum calcium concentrations are used to determine starting doses and dosing adjustments for calcitriol.

Although there have been some suggestions for PTH targets in various stages of CKD, these have been mostly from expert opinion. The 2017 updates to the KDIGO guidelines recommend iPTH that treatment should be based on rising PTH trends and not determined by any specific levels.[135]

Dose adjustments of calcitriol are generally made in 0.5- to 1.0-μg increments every 2 to 4 weeks in the early stages of therapy until iPTH and serum calcium are maintained at target levels. If hypercalcemia develops, the decision to withhold therapy or to switch to a less hypercalcemic VDR agonists must be made. Serum

iPTH should be monitored every 3 to 6 months and adjustments of calcitriol doses made to maintain the goal iPTH and to prevent hypercalcemia and hyperphosphatemia.

Vitamin analogs

The unique interactions of vitamin D with the VDR led to the development of designer vitamin D analogs, which vary in their affinity for the VDR. In the case of treatment for SHPT, some were developed to retain the suppressive effect on PTH release while decreasing the potential for hypercalcemia relative to calcitriol.

Paricalcitol

The currently approved agents for managing SHPT in the United States are paricalcitol (Zemplar®), also referred to as 19-nor-1,25-dihydroxyvitamin D_2, and doxercalciferol (Hectorol®), or 1-α-hydroxyvitamin D_2. Doxercalciferol requires conversion to the active form (1-α-25-dihydroxyvitamin D_2) by the liver.

In patients with SHPT, paricalcitol significantly decreases iPTH without significantly increasing calcium or phosphorus. Paricalcitol is ~10-fold less hypercalcemic and hyperphosphatemic than calcitriol.[156,157] The recommended conversion ratio for calcitriol to paricalcitol is 1:4 (ie, for every 1 µg of calcitriol, 4 µg of paricalcitol should be administered). This information is based on similar efficacy observed when patients treated for SHPT with calcitriol were switched to paricalcitol using this dosing strategy.[156,157]

Doxercalciferol

Doxercalciferol, another vitamin D analog, is another alternative to calcitriol and has been studied in patients with CKD 5D.[158] Doxercalciferol has similar effects on PTH as the other vitamin D analogs; however, it increases phosphorus and calcium to a greater degree than paricalcitol. Doxercalciferol is available as a capsule and IV injection. Both oral and IV therapy are effective in reducing iPTH levels in patients with SHPT; however, some evidence

indicated that intermittent IV therapy may result in less hypercalcemia and hyperphosphatemia than oral intermittent therapy.[159]

Vitamin D analogs offer an alternative for patients in whom persistent hypercalcemia develops with calcitriol therapy. Use of these agents is increasing in clinical practice because of the concerns of hypercalcemia and its adverse consequences. Repeated observational reports overall indicate lower cardiovascular-related mortality rates with activated vitamin D therapy, regardless of the agent received, than in those not receiving vitamin D therapy.[160]

CALCIMIMETICS

Calcimimetic agents increase the sensitivity of the calcium-sensing receptors (CaSR) to extracellular calcium ions and inhibit the release of PTH, lowering PTH levels within hours after administration. The discovery of extracellular CaSR prompted research with calcimimetic agents that allosterically modulate CaSR. CaSR are located in the parathyroid gland, thyroid, nephron, brain, intestine, bone, lung, and other tissues.[161] There are currently two calcimimetic agents approved for use in the United States: cinacalcet and etelcalcetide.

Cinacalcet is the first agent in this class to be approved by the FDA to treat SHPT in kidney failure.[162] Cinacalcet is an effective agent at reducing and sustaining iPTH within target concentrations in patients on HD.[163] Cinacalcet offers an additional choice of agent to lower PTH when vitamin D cannot be increased because of elevated calcium or phosphorus. The Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial was a randomized clinical trial comparing cinacalcet to placebo in 3883 patients on dialysis with a primary outcome of death, cardiovascular events, or hospitalizations. Patients were eligible to receive phosphate binders or vitamin D analogs in either arm. There was a 7% nonsignificant reduction in primary end points in the cinacalcet group.[164] However, issues plagued the large trial as several patients in the placebo arm received cinacalcet therapy. The survival benefits

of cinacalcet remained undetermined. Calcimimetics are not approved for use in patients with CKD not receiving dialysis because of the risk of hypocalcemia.[165]

Appropriate treatment for W.K. should be based on the assessment of her serum calcium, phosphorus, and PTH values. If these remain elevated after optimizing the current treatment regimen and after the addition of lanthanum carbonate, cinacalcet could be initiated. The decision to start cinacalcet as opposed to titrating the dose of calcitriol will depend on if the W.K. has persistent hyperphosphatemia even after optimizing the dose of the phosphate binder and if her adherence to her medications has been ascertained. Cinacalcet can then be initiated at a dose of 30 mg daily, with dosage titrations occurring every 2 to 4 weeks to 60, 90, 120, or a maximum of 180 mg daily to achieve target iPTH levels. While on cinacalcet, she should be maintained on low-dose calcitriol. Her current calcitriol regimen should be increased to 0.25 µg daily. Serum calcium and phosphorous levels should be drawn within 1 week after initiation or dosage increase and plasma PTH levels drawn within 4 weeks after initiation of therapy or dosage adjustment. The potential for hypocalcemia is an important factor to consider when giving a patient cinacalcet.

In phase III clinical trials, 66% of patients receiving cinacalcet experienced at least one episode of hypocalcemia (serum calcium <8.4 mg/dL), although <1% of patients discontinued treatment.[166] The high incidence of hypocalcemia is not solely caused by lowered PTH activity but is also attributed to the mechanism of action of cinacalcet. It is thought that activation of CaSR in bone, intestine, and other tissues may contribute to hypocalcemia. Most episodes of hypocalcemia occur during the initiation of cinacalcet therapy, and slowly titrating the dose reduces the risk. Seizures caused by hypocalcemia have been reported. Vitamin D or calcium-based phosphate binders can be used to increase serum calcium levels between 7.5 and 8.4 mg/dL. If serum calcium falls below 7.5 mg/dL and is associated with symptoms of hypocalcemia and vitamin D cannot be increased further, cinacalcet should be withheld until serum calcium normalizes or the patient is asymptomatic.[162]

Etelcalcetide is a drug that also modulates CaSR and is approved by the FDA for use to treat SHPT in adult patients with CKD on HD.[154] Etelcalcetide was shown to be noninferior to cinacalcet for serum PTH in patients with levels higher than 500 pg/mL.[167] In this study, the most common adverse effect was hypocalcemia.

PARATHYROIDECTOMY

The parathyroid glands enlarge as a compensatory response to disturbances of phosphorus, calcium, and calcitriol metabolism in patients with CKD. Timely administration of vitamin D therapy to prevent parathyroid hyperplasia is crucial as treatment with vitamin D cannot adequately reverse established hyperplasia. A parathyroidectomy is often reserved for patients with severe hyperparathyroidism, concomitant hypercalcemia, and failure to respond to pharmacologic therapy.[135] Parathyroidectomy can be subtotal, total, or total with auto-transplantation. One of the major complications of parathyroidectomy is the early development of postsurgical hypocalcemia.[168] Clinical symptoms of hypocalcemia include muscle irritability, fatigue, depression, and memory loss. Patients should be monitored closely after parathyroidectomy, and all patients with signs or symptoms of hypocalcemia should be treated with calcium supplementation (see Chapter 27, Fluid and Electrolyte Disorders). In patients who have had subtotal parathyroidectomy, the remaining parathyroid tissues will start functioning adequately, so the acute hypocalcemia is transient, lasting only a few days. Total parathyroidectomy requires long-term treatment with calcitriol and oral calcium supplements (1–1.5 g/day of elemental calcium). Studies investigating SHPT management with cinacalcet report reduced rates of parathyroidectomy surgeries.[164,169]

OTHER COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Altered Glucose and Insulin Metabolism

Uremia often is associated with glucose intolerance early in the course of CKD in patients who are nondiabetic. Specifically, patients with CKD often exhibit an abnormal response to an oral glucose challenge and have sustained hyperinsulinemia.[170] The fasting blood glucose is typically within normal limits. Diminished tissue sensitivity to the action of insulin is also observed. Inflammation and oxidative stress are likely contributors predisposing patients with CKD to insulin resistance.[171] Most patients who are nondiabetic with CKD do not require therapy for hyperglycemia.

A decreased clearance of insulin by muscle tissue also can occur in patients with uremia.[172] Thus, in patients who are diabetic with progressive CKD, blood glucose concentrations should be monitored and insulin doses adjusted to avoid hypoglycemia. W.K. has CKD G5D and is receiving her insulin in the peritoneal dialysate solution. Hyperglycemia is also a concern in W.K. because the glucose present in her continuous ambulatory peritoneal dialysis (CAPD) fluid to promote fluid removal will be absorbed systemically. Intraperitoneal insulin administration in the dialysis fluid can lead to delayed or sub-optimal activity.[173] So, insulin dosage adjustments should be made based on repeated home blood glucose measurements, changes in the CAPD prescription, and glycated hemoglobin determinations.

Other Endocrine Complications

Disturbances in thyroid function are frequently encountered in patients with CKD because the kidney is involved in all aspects of peripheral thyroid hormone metabolism. Common laboratory abnormalities include reduced serum concentrations of total thyroxine (T4) and 3,5,3′-triiodothyronine (T3) and a low free thyroxine index (FTI). The thyroid-stimulating hormone (TSH) concentration is usually normal, but peripheral conversion of T4 to T3 is reduced in patients who are uremic.[174]

Other endocrine abnormalities that have been observed in patients with CKD include gonadal dysfunction leading to impotence, diminished testicular size, menstrual abnormalities, and cessation of ovulation.[175] Decreased libido and infertility occur in both sexes. Uremic females of childbearing age should be counseled on the risk of becoming pregnant because of the multiple complications of pregnancy in kidney failure, including high termination rates.[176]

GASTROINTESTINAL COMPLICATIONS

GI abnormalities are extremely common in patients with CKD and include anorexia, nausea, vomiting, hiccups, abdominal pain, GI bleeding, diarrhea, and constipation. Diminished gastric motility can occur from uremia; however, this problem may improve with adequate dialysis. Dyspepsia and gastroparesis may be more prevalent in the PD population than in the HD population and in the earlier stages of CKD.[177]

UREMIC BLEEDING

Patients with CKD are at risk for bleeding from mucosal surfaces such as the stomach. Angiodysplasia of the stomach and duodenum, as well as erosive esophagitis, are the most common causes of bleeding in patients with CKD.[178] Treatment of upper GI bleeding in patients who are uremic usually consists of cautious use of H_2-receptor antagonists, which should be given in reduced doses according to the degree of kidney dysfunction. Proton-pump inhibitors are primarily eliminated by non-kidney routes and can be administered at standard doses (see Chapter 23, Upper Gastrointestinal Disorders).

Dermatologic Complications

Several dermal abnormalities have been observed in patients with CKD, including hyperpigmentation, abnormal perspiration, skin dryness, and persistent pruritus. Of these, uremic pruritus can be the most bothersome for the patient and may lead to repeated

scratching and skin excoriation. Uremic pruritis occurs in about 46% of patients with CKD on dialysis.[179] Hyperparathyroidism, hypervitaminosis A, and dermal mast cell proliferation with subsequent histamine release have been suggested as causes of pruritus.[180]

Treatment of pruritus often is a frustrating experience for the patient and clinician. Although many therapies have been advocated, few have provided sustained benefit. A trial-and-error approach is recommended. Efficient dialysis therapy relieves pruritus in some patients and pharmacologic therapy may be avoided. When necessary, initial pharmacologic treatment usually consists of oral antihistamines (eg, hydroxyzine). Topical emollients or topical steroids may provide benefit if antihistamine therapy is not completely successful. Some other options include cholestyramine, ultraviolet B phototherapy, and oral administration of activated charcoal.[180] Studies have shown that gabapentin might provide relief in patients with CKD 3 and higher, including those on dialysis.[179] Control of calcium, phosphorus, and PTH concentrations is also advocated to reduce pruritus in patients with CKD.

GLOMERULAR DISEASES

Glomerular diseases lead to many complications that result from disruption of normal glomerular structure and function. Several clinical syndromes of glomerular disease exist; however, GN, characterized as proliferation and inflammation of the glomerulus, is observed most frequently. According to the most recent USRDS report, GN as a broad category remains the third leading cause of kidney failure in the United States.[5]

Nephrotic Syndrome

Nephrotic syndrome is characterized by proteinuria >3.5 g/day, hypoalbuminemia, edema, and hyperlipidemia.[181] In more severe

conditions, hypercoagulable conditions are increased from a loss of hemostasis control proteins, including antithrombin III, protein S, and protein C. This syndrome can occur with or without a change in GFR. Nephrotic syndrome may be caused by a primary disease, such as membranous glomerulopathy, which is characterized by deposition of immune complexes, or other systemic diseases including diabetic glomerulosclerosis and amyloidosis. Elevated serum cholesterol and triglycerides are observed in patients with this degree of proteinuria (>3.5 g/day). This hyperlipidemic condition also predisposes patients with nephrotic syndrome to accelerated atherosclerosis. Hyperlipidemia itself can also contribute to progression of CKD. Because nephrotic syndrome is associated with numerous causes, further evaluation of the patient for systemic causes is required to determine the course of therapy and prognosis.

Chronic Glomerulopathies

GN can occur as a primary disease that is idiopathic in origin (eg, focal segmental glomerulosclerosis [FSGS]) or as a secondary manifestation of other systemic diseases (eg, lupus nephritis [LN], granulomatosis with polyangiitis [GPA]). Kidney biopsy is often required for definitive diagnosis. Glomerular lesions associated with glomerulopathies are characterized as diffuse, focal, or segmental, depending on the extent of involvement of individual glomeruli. Pathologic changes are characterized as proliferative, membranous, and sclerotic based on the pattern observed. Proliferative changes usually involve an overgrowth of the epithelium or mesangium, whereas membranous changes are typically described as a thickening of the glomerular basement membrane. Signs and symptoms of GN include hematuria, proteinuria, and decreased kidney function. An autoimmune reaction is the predominant pathogenic process leading to most forms of primary and secondary GN. Although a number of autoantibodies are associated with GN, their exact role in the pathogenesis of GN is still unclear.[181]

Glomerular damage generally occurs in two phases: acute and chronic. During the acute phase, immune reactions occur within glomeruli that stimulate the complement cascade, ultimately resulting in glomerular damage. Nonimmune mechanisms that occur in response to loss of nephron function and hyperfiltration of remaining nephrons are characteristic of the chronic phase.

GN often causes AKI. Patients with damage to more than 50% of glomeruli in the presence of rapid loss in kidney function (over the course of days to weeks) are classified as having rapidly progressive glomerulonephritis (RPGN).[182] If kidney involvement is severe, signs and symptoms of uremia may develop. RPGN may be classified based on the immunopathogenic etiology of the glomerular damage: (a) immune complex deposition (eg, LN); (b) nonimmune deposit-mediated mechanism (eg, GPA); and (c) sclerotic lesions of the glomerulus (eg, FSGS).[181] This chapter focuses on the treatment of the more common forms of chronic GN (ie, LN, GPA, FSGS).

LUPUS NEPHRITIS

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized by abnormalities in cell-mediated immunity, such as B-cell hyperresponsiveness and defective T-cell-mediated suppressor activity. In certain predisposed individuals, SLE can lead to the development of LN, a secondary form of GN. LN is the prototypical immune complex–mediated CKD, characterized by deposition or in situ formation of autoantibody–antigen complexes along the glomerular capillary network. LN remains an important cause of mortality. Up to 60% of adults with SLE have some degree of kidney involvement later in the course of their disease, discernible from clinical evidence of kidney damage: heavy proteinuria, hematuria, decreased eGFR, and hypertension. Early in the disease, laboratory abnormalities indicative of kidney involvement are seen in ~25% to 50% of patients.[181] See also Chapter 33, Systemic Lupus Erythematosus.

CASE 28-4

Question 1: S.L., a 34-year-old Black female with a 7-year history of SLE, presents to the nephrology clinic for follow-up of LN.

Current medications: none
Vital signs: BP 160/95
Pertinent laboratory values are as follows:
Serum Na^+, 146 mEq/L
K^+, 4.2 mEq/L
Cl^-, 100 mEq/L
CO_2 content, 25 mEq/L
SCr, 2.0 mg/dL
eGFR, 37 mL/minute/1.73 m^2
BUN, 20 mg/dL
WBC count, 9600/μL
RBC indices are normal.
Platelet count is 175,000/μL.
Her urinalysis shows 12 RBCs/high-power field (HPF; normal, 0–3). Urine ACR was 1145 mg/g.

Compared with her visit a week ago, S.L.'s kidney function and urinary indices (proteinuria, hematuria) show substantial worsening of LN. S.L. was hospitalized, and a kidney biopsy showed inflammation of 40% of the glomeruli and pathologic findings suggestive of LN class III with endocapillary hypercellularity.

S.L. has clinical evidence of kidney damage as demonstrated by her proteinuria, hematuria, and a slightly increased SCr concentration. Glomerular damage is evident by the presence of RBC or red cell casts in the urine. Her current labs place her in CKD category G3b/A3, which is very high CKD risk.

Should S.L.'s LN be treated?

Treatment

Unlike non-kidney manifestations of SLE, serologic markers of disease correlate poorly with LN. Therefore, elevations in SCr, hypertension, proteinuria, and hematuria, as seen in S.L., are used as primary markers of disease activity.

Treatment of LN must address both management of the acute disease process and maintenance therapy for the more stable chronic disease process. The consensus is that patients, such as S.L., who present with endocapillary hypercellularity (class III or IV) should be treated aggressively, with the primary goal of preventing irreversible kidney damage. The prognosis of kidney function in

patients with SLE has improved. However, the prognosis is worse in Blacks when compared with the White population treated for SLE.[183] Elevated SCr, heavy proteinuria, anemia, and disease onset during childhood or in those older than 60 years of age are other predictors of a worse prognosis. Advances in pharmacologic therapy (ie, safer immunosuppressive regimens and antihypertensives) have improved prognosis.

The treatment of LN is primarily empiric but is based, to some extent, on histologic findings. The KDIGO Clinical Practice Guideline for Glomerulonephritis provides recommendations for treatment based on disease activity.[181] Although appropriate treatment can improve patient outcomes, vigorous attempts to suppress SLE activity may lead to serious drug-related complications. The primary strategy in the treatment of LN involves immunosuppression with corticosteroids and cytotoxic agents, such as cyclophosphamide (CYC), azathioprine (AZA), calcineurin inhibitor (CNI) therapy (cyclosporine [CYA] or tacrolimus [TAC]), and mycophenolate mofetil (MMF).[184] Clinicians need to be aware of the potential complications associated with these therapies and carefully monitor patients to determine the indication for treatment and improved prognosis. Toxicities associated with immunosuppressive agents depend on both the dose and the duration of therapy. Abnormalities in hematopoiesis, such as neutropenia and thrombocytopenia, are the most common adverse effects associated with cytotoxic agents. Immunosuppression, in general, increases a patient's susceptibility to a vast array of infections and to lymphocytic malignancies. In addition, the alkylating agent CYC can cause nausea and vomiting, gonadal toxicity, hemorrhagic cystitis, and alopecia. The risk versus benefit of CYC use has to be weighed in young females who are considering pregnancy in the future. The antimetabolite AZA can cause, leukopenia, pancytopenia, myelosuppression, pancreatitis, and abnormalities in liver function. The selective inhibitor of inosine monophosphate dehydrogenase, MMF, although relatively benign compared with the other agents, can cause GI disturbances.

Induction Therapy

Therapy for LN is usually not indicated in patients with normal kidney function and proteinuria <1 g, because these patients have a good prognosis. Corticosteroids represent the cornerstone of therapy in patients with a mild form of LN. Prednisone (1 mg/kg or methylprednisolone) should be initiated for patients with class II LN with proteinuria >3 g/day or CNI. In patients with a more severe form (class III and IV), prednisone 1 mg/kg/day combined with either CYC or MMF should be initiated. For the treatment of acute exacerbations of LN, high-dose pulse therapy with methylprednisolone may be warranted. Given that S.L.'s LN has worsened, she should receive pulse methylprednisolone (0.5–1 g IV, not to exceed 1 g) for 3 days in an attempt to reduce the degree of proteinuria and improve kidney function.[181] Although generally well tolerated, rapid methylprednisolone injections can cause transient tremor, flushing, and altered taste sensation. To reduce the risk of adverse effects associated with the rate of injection, S.L. should receive methylprednisolone for 30 minutes. After a course of pulse methylprednisolone therapy, oral prednisone at a dose 10 to 20 mg daily may be initiated.[181] Suppression of S.L.'s active LN should be demonstrated by a reduction in proteinuria and hematuria and an increase in her eGFR.

The addition of cytotoxic agents is reserved for patients who do not respond to corticosteroids alone or those who have unacceptable toxicity to corticosteroids, worsening kidney function, severe proliferative lesions, or evidence of sclerosis on kidney biopsy. Induction therapy with six monthly pulse doses of IV CYC 0.5 to 1 g/m^2 or six doses of CYC given every 2 weeks at a dose of 0.5 g/m^2 along with steroid therapy was shown to have improved kidney outcomes with fewer flares and relapses.[181] Before and for 24 hours after initiating IV CYC, the patient must be well hydrated to prevent bladder toxicity. Alternatively, MMF (2000–3000 mg/day times 6 months) or TAC (0.06–0.1 mg/kg/day) has been proven to be as effective as CYC in the induction treatment for LN.[185,186] Given the significant toxicities associated with CYC (eg, gonadal toxicity and

hemorrhagic cystitis), MMF or TAC are attractive options given their anti-inflammatory properties and the lower side effect profile. Recently, rituximab, an anti-CD20 monoclonal antibody, has demonstrated similar efficacy as MMF and CYC.[187]

Maintenance Therapy

Once the acute flare resolves (generally in up to 12 weeks), low-dose, maintenance steroid therapy with 5 to 15 mg/day of prednisone can be initiated in combination with cytotoxic therapy, if indicated, based on the severity of LN. In a meta-analysis assessing the efficacy of therapeutic agents used to treat LN, improved outcomes (total mortality and kidney failure) were associated with use of oral prednisone in combination with IV CYC. As a result, the National Institutes of Health recommends the use of IV CYC pulse therapy (0.5–1 g/m^2) every 3 months for up to 2 years for maintenance therapy of LN.[181] An additional benefit of combination therapy with immunosuppressive agents is their steroid-sparing effect and, potentially, lower risk of steroid toxicity.

Steroid- and CYC-free regimens are often desired to avoid steroid and CYC adverse events. Studies have evaluated other immunosuppressive agents (AZA, MMF) for maintenance therapy considering the toxicities associated with CYC or steroids. The KDIGO Clinical Practice Guideline for Glomerulonephritis recommends AZA (1.5–2.5 mg/kg/day) or MMF (1–2 g/day) and low-dose corticosteroids (≤10 mg/day prednisone equivalent) for maintenance therapy.[181]

A multiregimen trial compared maintenance therapy with AZA (1–3 mg/day) and MMF (500–3000 mg/day) with CYC along with steroids after induction with CYC in patients with severe LN. Patients receiving AZA had a lower mortality rate than those treated with CYC, and the MMF treatment group had fewer relapses than the CYC treatment group.[188] MMF and AZA may be indicated in patients resistant to CYC therapy or with a more severe type of LN (class III and IV). The addition of AZA or MMF, along with corticosteroid therapy, should be considered in S.L. once the acute lupus flare

resolves. Once suppression of S.L.'s LN is documented, initiation of either AZA or MMF and steroids is indicated because of the severity of her LN (class III). The duration of therapy is dictated by the individual's response, but typically patients will require up to 2 years of maintenance therapy. Patients with thiopurine *S*-methyl transferase (TPMT) or nucleotide diphosphatase (NUDT15) deficiency may be at an increased risk of severe and life-threatening myelotoxicity if receiving conventional doses of AZA. Based on the genotype of a patient deficient of TPMT and NUD15 (homozygous or heterozygous), the recommendation is either to find an alternative agent like MMF or to use AZA at a reduced dose.[189]

Alternative Agents

The KDIGO practice guidelines recommend reserving CNI for those intolerant to MMF or AZA as maintenance therapy.[181] Rituximab, a monoclonal antibody that inhibits B-cell production, is being studied because B-cell hyperactivity is one of the major pathophysiologic mechanisms of LN. Small studies in patients with LN resistant to therapy have shown rituximab to be of benefit. CYA, in doses of 5 mg/kg/day, may also provide an alternative therapy to treat lupus in the maintenance phase in patients unresponsive to treatment.[181] Belimumab (Benlysta®), a monoclonal antibody blocking the binding of B-lymphocyte stimulator protein (BLyS) to receptors on the B-lymphocytes, was recently approved for maintenance treatment of LN in adults.[190] Similarly, voclosporin (Lupkynis®), a novel calcineurin inhibitor, was also approved for the treatment of LN in combination with other immunosuppressive therapy.[191]

GRANULOMATOSIS WITH POLYANGIITIS

CASE 28-5

Question 1: J.M. is a 42-year-old White male who presents to the clinic with a 1-month history of cough, nasal congestion, facial pain with headache, fever, and lethargy. During the past week, he has noted bright red blood in his phlegm,

which has worsened in the past 3 days. Pertinent laboratory values are as follows:

Serum Na, 143 mEq/L
K^+, 5.1 mEq/L
Cl^-, 102 mEq/L
CO_2 content, 24 mEq/L
SCr, 2.8 mg/dL
BUN, 41 mg/dL

This compares with last year's physical checkup visit when his SCr and BUN were within the normal range. Hematologic studies reveal an Hct of 35%, an Hgb of 11.7 g/dL, an MCV of 69 μL, a mean corpuscular Hgb concentration of 24%, and a reticulocyte count of 1.8%. RBC indices are normal, and the platelet count is 175,000/μL. His 24-hour urine contains 3.8 g of albumin (normal, <30 mg), and his eGFR is calculated to be 27 mL/minute/1.73 m^2. His urine also contains many RBC casts and 16 RBCs/HPF (normal, 0–3 RBCs/HPF). Chest radiograph shows alveolar shadowing spreading from the hilar region. The result of J.M.'s cytoplasmic-staining, antineutrophil cytoplasmic antibody (c-ANCA) is positive.

Based on his subjective and objective data, which of the chronic glomerulopathies is J.M. likely to have?

GPA, formerly called Wegener granulomatosis, is a primary systemic vasculitis characterized by granulomatous inflammation of the upper and lower respiratory tract and secondary GN. Primary systemic vasculitides, such as GPA, often cause GN. Although vasculitis involves inflammation of blood vessels of any size, the small- and medium-size vessels are most commonly affected.[192] The etiology of GPA is unclear; however, an autoimmune response is suspected for two reasons. First, GPA is a systemic inflammatory disease without a known infectious etiology. Second, good treatment response can be obtained with immunosuppressive therapy.

The clinical features of GPA include upper airway disease, such as sinusitis, epistaxis, and nasopharyngitis, as well as otitis media caused by blockage of the eustachian tube. Constitutional symptoms include fever, night sweats, arthralgia, anorexia, and malaise. After a few months, weakness may progress, severely limiting physical activity. Although the lungs are invariably affected, most patients remain asymptomatic; however, cough and hemoptysis may be

present. J.M.'s presenting symptoms are consistent with the above clinical features. The laboratory signs also are nonspecific and indicate the presence of a systemic inflammatory process. They include an elevated erythrocyte sedimentation rate in virtually all patients, anemia of chronic disease, and thrombocytosis.[192,193] Hematuria and proteinuria can be prominent features of GPA and are present on initial presentation in 80% of patients. The presence of severely diminished kidney function, seen in ~10% of patients, is an ominous sign, with nearly one-third of these patients progressing to kidney failure. All patients with GPA are at risk of developing irreversible, rapidly progressive kidney failure. Kidney histologic findings are nonspecific, with most patients exhibiting necrotizing crescentic GN.[192,193]

GPA is diagnosed primarily by the presenting signs and symptoms. According to the American College of Rheumatology 1990 classification, a person is diagnosed with GPA if any two of the following four criteria are present: (a) nasal or oral inflammation, (b) abnormal chest radiograph, (c) microhematuria (>5 RBCs/HPF) or RBC casts in the urine sediment, or (d) granulomatous inflammation on biopsy.[192] J.M. has satisfied three of the four criteria for diagnosing GPA.

Treatment

Case 28-5, Question 2: How should J.M.'s GPA be treated?

The discovery of c-ANCA and its strong association with GPA has permitted a more certain diagnosis. Because of the substantial rise in titer that commonly precedes relapse of GPA, the c-ANCA test is best used to follow the course of disease activity and guide induction of therapy. Treatment with CYC and corticosteroids results in improvement in kidney function in ~80% to 85% of patients, versus 75% with pulse steroids alone.[181] The main predictive factors for treatment success are the extent of kidney damage before therapy starts and how long therapy is delayed after symptoms develop.

Cyclophosphamide

Because GPA is considered an autoimmune inflammatory disease, immunosuppressive therapy is the mainstay of treatment. **Table 28-13** lists KDIGO guidelines-recommended treatment regimens. Therapy is generally indicated for 6 months if remission occurs and up to 12 months in resistant cases.[192] J.M. should be started on oral CYC 2 mg/kg/day, as a single morning dose, and corticosteroids to prevent irreversible glomerular scarring. High fluid intake (>3 L/day) and Mesna reduce the risk of hemorrhagic cystitis. Regular UA should be performed (every 3–6 months) to detect hematuria caused by hemorrhagic cystitis.

Table 28-13

Recommended Treatment Regimens for ANCA Vasculitis With Glomerulonephritis

Agent	Route	Initial Dose
Cyclophosphamide[a]	IV	0.75 g/m^2 q 3–4 weeks Decrease initial dose to 0.5 g/m^2 if age >60 years or GFR <20 mL/minute/1.73 m^2 Adjust subsequent doses to achieve a 2-week nadir leukocyte count >3000/mm^3
Cyclophosphamide[b]	PO	1.5–2 mg/kg/day, reduce if age >60 years or GFR <20 mL/minute/1.73 m^2 Adjust the daily dose to keep leucocyte count >3000/mm^3
Corticosteroids	IV	Pulse methylprednisolone: 500 mg IV daily × 3 days
Corticosteroids	PO	Prednisone 1 mg/kg/day for 4 weeks, not exceeding 60 mg daily Taper down over 3–4 months
Rituximab[b]	IV	375 mg/m^2 weekly × 4
Plasmapheresis[c]		60 mL/kg volume replacement Vasculitis: 7 treatments over 14 days. If diffuse pulmonary hemorrhage, daily until the bleeding stops, then every other day, total 7–10 treatments Vasculitis in association with anti-GBM antibodies: Daily for 14 days or until anti-GBM antibodies are undetectable

ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane; GFR, glomerular filtration rate; IV, intravenous; PO, orally.

[a]Given with pulse and oral steroids. An alternative IV cyclophosphamide dosing schema is 15 mg/kg given every 2 weeks for three pulses, followed by 15 mg/kg given every 3 weeks for 3 months beyond remission, with reductions for age and estimated GFR.

[b]Given with pulse and oral steroids.

[c]Not given with pulse methylprednisolone. Replacement fluid is 5% albumin. Add 150 to 300 mL fresh frozen plasma at the end of each pheresis session if patients have pulmonary hemorrhage, or have had recent surgery, including kidney biopsy.

Corticosteroids

The main role of corticosteroids is to induce remission of the disease. J.M. should receive prednisone 1 mg/kg/day in addition to CYC. The combined regimen should be continued for 2 to 4 weeks until the immunosuppressive effect of CYC becomes evident. Then, during the next 2 months, the prednisone dose can be tapered to 60 mg every other day to reduce the risk of infection. Then, the dose can be tapered by 5 mg/week to discontinue prednisone over the course of 3 to 6 months. For patients with a more fulminant form of the disease, pulse methylprednisolone 500 mg/day for three doses is administered. The dose can be repeated in 1 to 2 weeks if disease progression is uncontrolled.

Alternative Therapies

Rituximab as an induction agent has been evaluated in two randomized controlled trials. The Randomized Trial of Rituximab versus Cyclophosphamide for ANCA-associated Renal Vasculitis (RITUXVAS) trial randomized 44 subjects to rituximab (375 mg/m^2 weekly × 4) plus IV CYC or to IV CYC alone.[194] Each group received IV methylprednisolone followed by oral corticosteroids. Remission rates were 76% for the rituximab group and 82% for CYC. The

Rituximab for ANCA-associated Vasculitis (RAVE) trial rituximab was compared to oral CYC (2 mg/kg/day) for up to 3 months plus AZA (2 mg/kg/day) for 4 to 6 months.[195] IV methylprednisolone plus oral corticosteroid were given to both groups. Rituximab proved noninferior to the CYC regimen with similar rates, 64% versus 53%, respectively. There were no significant differences in adverse events rates in either trial. Although rituximab has performed well in comparison studies, the high cost limits its acceptance and applicability in clinical practice.

Azathioprine and Mycophenolate Mofetil

AZA (1–2 mg/kg/day) and MMF (up to 1000 mg/day) are effective as maintenance therapy once remission has been achieved with CYC. However, a comparative study demonstrated mycophenolate to be less effective at maintaining remissions compared with AZA; thus, AZA is the preferred maintenance therapy.[196] Maintenance therapy should be continued for a minimum of 18 months for patients in complete remission. Note the pharmacogenomic considerations for AZA stated previously.[189]

Alternative Agents

Methotrexate (MTX) may be beneficial for patients with milder disease, although one study demonstrated high relapse rates in patients treated initially with weekly MTX and daily prednisone; disease was controlled in only select patients.[197] However, MTX should be reserved for patients intolerant of AZA and MMF and GFR >60 mL/minute/1.73 m^2.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

CASE 28-6

Question 1: A.G. is a 37-year-old morbidly obese (body mass index, 40 kg/m^2), Black female who presents to the clinic with increased swelling in her extremities for the last 2 weeks, decreased urine output, and dark “foamy” urine. Her medical history is significant only for hypertension, which is well controlled

with amlodipine 5 mg PO every day. She takes no other prescription or over-the-counter medications. Pertinent laboratory values are as follows:

SCr, 2.1 mg/dL (normal, 0.6–1.2 mg/dL)
Spot urine ACR, 1200 mg/g (normal, <30 mg/g)
UA, 18 RBCs/HPF (normal, 0–3)
eGFR; 34 mL/minute/1.73 m^2

The nephrologist schedules a biopsy to obtain a definitive diagnosis for her new-onset CKD. Biopsy results are as follows: light micrograph shows a moderately large segmental area of sclerosis with capillary collapse on the upper left side of the glomerular tuft; the lower right segment is relatively normal. Electron micrograph shows diffuse epithelial cell foot process fusion with occasional loss of the epithelial cells. The other major finding is massive subendothelial hyaline deposits under the glomerular basement membrane. The pathologist's impression is FSGS.

What is the relevance of FSGS, and what are the management strategies for FSGS?

FSGS is characterized by sclerotic lesions of the glomerulus, which can be either focal or segmental in nature. The development of FSGS may be idiopathic (primary) or secondary to other diseases (ie, morbid obesity, sickle cell disease, congenital heart disease, AIDS). Currently, FSGS is the leading cause of idiopathic nephrotic syndrome and accounts for 15% to 20% of the cases. Black patients are two to four times more likely to experience idiopathic FSGS than White patients, and they have a higher incidence of kidney failure caused by FSGS.[198] Genetic variants of the apolipoprotein L1 (APOL1) gene predominate in patients of African ancestry and have been identified as a major risk factor.[199]

Most patients with FSGS will present with proteinuria, but only about half of them will initially present with the nephrotic syndrome. Patients with the nephrotic syndrome will also likely present with hypertension, increased SCr levels, and hematuria. During the early stages of FSGS, the symptoms may be indistinguishable from minimal-change nephrotic syndrome, a glomerulopathy characterized by similar lesions within the glomeruli. A kidney biopsy is necessary for diagnosis. Predictors of increased risk of progression to kidney failure include massive proteinuria (>10 g/day), higher SCr level (>1.3 mg/dL), and Black race.[198,200]

Treatment

Corticosteroids

A.G. should be placed on steroids, in addition to an ACEI or ARB and a loop diuretic, because she has FSGS and nephrotic syndrome.[181] A course of corticosteroids 1 mg/kg/day (maximum 80 mg) or 2 mg/kg every other day (maximum 120 mg) for at least 4 weeks and for up to 4 months with tapering of the dose over the course of 6 months after complete remission is achieved. Complete remission is defined as reduction of albuminuria <0.3 g/day, normal urine and SCr, and serum albumin >3.5 g/dL.[181] The median time to remission is 3 to 4 months. Patients whose proteinuria does not respond after a 4-month trial of therapy should be considered resistant to steroids and be rapidly tapered off over the course of 6 weeks.[181]

Steroid-Resistant Treatment

Calcineurin Inhibitors

The addition of cytotoxic agents (CYA, TAC) may be considered for A.G. if she is steroid resistant, intolerant of long-term steroid therapy, severely nephrotic, frequently relapsing, or steroid dependent. The data supporting the use of these agents in FSGS are limited. Retrospective studies have shown that the use of cytotoxic drugs can produce complete remission in 50% of cases. Length of therapy of these agents may predict the remission rates of FSGS. Recent prospective studies support a longer duration of therapy.

Evidence supporting the efficacy and safety of CYA in FSGS stems from randomized controlled trials. In addition to being options for steroid-resistant patients, CNIs provide a steroid-sparing effect in FSGS steroid-sensitive patients. CYA studies are the most prevalent of the CNIs. CYA response is highly dependent on the previous steroid response. Complete remission rates of 73% can be seen with CYA in steroid-sensitive patients.[200] Conversely, therapy with CYA doses of 5 mg/kg/day for 6 to 12 months has been found to be effective and can result in remission rates of up to 69% in patients

resistant to steroids.[201] The current recommendation is CYA of 3 to 5 mg/kg/day in two divided doses. If remission is achieved, continue treatment for 1 year.

However, if no remission is achieved by 6 months, discontinue CYA. Limitations of CYA therapy include high relapse rate (23%–100%) after withdrawal, side effect profile (nephrotoxicity, hypertension), and resistance to therapy. Studies evaluating TAC as a treatment option for FSGS are few and lack randomized controlled trials. Current TAC therapy should be initiated at 0.1 to 0.2 mg/kg/day in two divided doses. TAC has a similar side effect profile to that of CYA.[200] Sirolimus is associated with nephrotoxicity in FSGS and is not recommended for treatment.

Mycophenolate Mofetil

MMF has the potential for a steroid-sparing effect; however, relapses are common. MMF and high-dose dexamethasone are recommended for steroid-resistant patients intolerant to CYA therapy. A small study of patients with FSGS resistant to steroids, cytotoxic agents, or both and CYA received MMF for 6 months.[181] At the end of 6 months, 44% of patients had improved proteinuria, but no patient achieved complete remission. Other studies examining MMF therapy at doses of up to 2000 mg/day have found no clinically significant effect on remission rates.[202]

DRUG-INDUCED CAUSES OF CHRONIC KIDNEY DISEASE

Analgesic Nephropathy

Analgesic nephropathy results from habitual ingestion of analgesics for many years. Particularly, agents containing at least two antipyretic analgesics and usually caffeine or codeine are commonly associated with the development of analgesic nephropathy. It is a

tubulointerstitial kidney disease characterized by kidney papillary necrosis as a primary lesion and chronic interstitial nephritis as a secondary lesion.[203] Analgesic nephropathy is a slowly progressive disease, and the clinical signs and symptoms are like the nonspecific presentation of CKD attributable to any other etiology.

Currently in the United States, most cases are caused by long-term use or misuse of compound analgesics containing acetaminophen and aspirin along with caffeine or codeine. Similar findings in terms of the effect on kidney function have also been observed with chronic nonsteroidal anti-inflammatory drug (NSAID) therapy.[204] The uses of acetaminophen and NSAIDs have been associated with the progression of kidney disease in patients with CKD in a dose-dependent manner.[204] The cumulative amount (at least 1–2 kg of acetaminophen), rather than the duration of analgesic intake, is a primary risk factor for developing chronic analgesic nephropathy.[205,206] Thus, analgesics should be used with caution in the CKD population, and chronic analgesic therapy should be discouraged. KDIGO guidelines recommend discontinuation of NSAIDs in people with a GFR <60 mL/minute/1.73 m^2.[1]

At presentation, patients may have a reduced GFR and findings consistent with CKD, such as elevated SCr, BUN, and proteinuria. However, during acute necrosis, patients may experience flank pain, pyuria, and hematuria. As necrosis progresses, cellular debris may cause ureteral obstruction. Kidney dysfunction is characterized as a salt-wasting kidney disease, with a substantial reduction in urine-concentrating and urine-acidifying capabilities. The exact mechanism for kidney damage by acetaminophen is uncertain, but it is thought that its oxidative metabolite produced by the medullary cytochrome P-450 enzyme system may bind to macromolecules, causing cellular necrosis. Conversely, NSAIDs attenuate prostaglandin-mediated vasodilatation and may induce an ischemic state within the kidney medulla, leading to papillary necrosis.[207]

Data on the chronic kidney effects of selective cyclooxygenase-2 (COX-2) inhibitors are limited compared to traditional NSAIDs. In a meta-analysis, that of 114 randomized, double-blind clinical trials evaluated the adverse kidney events of COX-2 inhibitors, of the six

agents evaluated, only rofecoxib was associated with adverse kidney effects. In contrast, celecoxib was associated with a lower risk of kidney dysfunction.[207] A cohort study of 19,163 newly diagnosed patients with CKD examined the association between analgesic use and the risk of progression to kidney failure. Among the COX-2 inhibitors, only rofecoxib use was significantly associated with an increased risk of progression to kidney failure.[204] Rofecoxib was voluntarily withdrawn from the U.S. market in 2004 because of the increased risk for serious cardiovascular events, including MI and stroke.[208]

The long-term management of analgesic nephropathy is generally supportive and primarily involves discontinuation of the offending agent and subsequent abstinence from the use of NSAIDs and combination analgesics. For patients requiring analgesics, acetaminophen as a single agent may be safe, although habitual use can contribute to progression of CKD as well as to liver toxicity.[204] Patients with CKD requiring chronic analgesic therapy should use the lowest dose to control pain, avoid combination products when possible, and maintain adequate hydration.

Lithium-Induced Nephropathy

Lithium use has been associated with alterations in kidney function secondary to acute functional and histologic changes and has been associated with the development of chronic pathologic changes to the kidneys (eg, chronic interstitial nephritis). The role of lithium as a causative agent in the development of CKD has been suggested in a variety of epidemiologic, clinical, and histopathologic studies.[209] The concentrating ability within the kidney and GFR have been shown to decline with long-term lithium use.[210] Lithium-induced CKD has a slow progression (average latency between onset of lithium use and kidney failure is 20 years) in which the rate of progression is related to the duration of lithium therapy and the concomitant use of nephrotoxic drugs or other risk factors for CKD.

Patients with lithium-induced kidney disease are generally asymptomatic. They typically present with an insidious decline in kidney function over the course of many years, and proteinuria is usually absent or minimal.[209] In patients taking chronic lithium therapy, close monitoring of serum lithium concentrations is advised, and regular measurements of SCr should be obtained to detect changes in kidney function. Higher lithium concentrations are associated with an increased risk of kidney damage.[210] Current clinical practice guidelines recommend monitoring SCr every 2 to 3 months during the first 6 months of chronic lithium therapy, followed by yearly measurements thereafter.[209] The decision to discontinue lithium and to initiate another mood stabilizer should be a mutual decision made by the psychiatrist, the nephrologist, and the patient. The diuretic amiloride has been suggested to reduce lithium-induced kidney adverse effects in mild cases.[209]

Acute Kidney Injury

Susan A. Krikorian, Oussayma Moukhachen, and Alexander H. Flannery

CORE PRINCIPLES		CHAPTER CASES
1	Acute kidney injury (AKI) is characterized clinically by an abrupt decrease in kidney function over a period of hours to days, resulting in the accumulation of nitrogenous waste products (azotemia) and the inability to maintain and regulate fluid, electrolytes, and acid–base balance.	**Case 29-1(Questions 1, 2), Tables 29-1, 29-2**

	CORE PRINCIPLES	CHAPTER CASES
2	Risk factors for the development of AKI include older age, higher baseline serum creatinine (SCr), chronic kidney disease (CKD), diabetes, chronic respiratory illness, underlying cardiovascular disease, prior heart surgery, dehydration resulting in oliguria, acute infection, and exposure to nephrotoxins.	**Case 29-1 (Questions 1, 2) Case 29-2 (Questions-3) Case 29-3 (Questions 1, 4), Tables 29-5, 29-6 Case 29-5 (Questions 1, 2) Case 29-6 (Question 1)**
3	AKI is classified according to the physiologic event leading to AKI: prerenal azotemia—decreased blood flow to the kidney; functional—impairment of glomerular ultrafiltrate production or intraglomerular hydrostatic pressure; intrinsic—damage to the kidneys; and postrenal—outflow obstruction in the urinary tract. The urinalysis and urine microscopy with sediment examination are important diagnostic tools for differentiating the various AKI types.	**Case 29-1 (Questions 1, 2) Case 29-2 (Questions 1, 3, 4) Case 29-3 (Questions 1, 2) Case 29-5 (Question 1) Case 29-6 (Questions 1, 2) Case 29-7 (Question 1) Case 29-8 (Question 1), Tables 29-2–29-4, Equation 29-1**
4	All medications that are excreted in the kidneys should be dosed according to kidney function and monitored closely in patients with AKI. Nephrotoxic medications should be avoided.	**Case 29-6 (Question 3) Case 29-9 (Question 1)**

	CORE PRINCIPLES	CHAPTER CASES
5	Hydration therapy is useful to increase kidney perfusion and avert the conversion of prerenal azotemia to acute tubular necrosis (ATN), to reduce the risk of contrast-induced acute kidney injury (CI-AKI) in high-risk patients, and to prevent and treat kidney stones.	**Case 29-5 (Question 3)** **Case 29-8 (Question 1), Table 29-5**
6	Few treatment options are available in established AKI; therefore, prevention is key. Supportive therapy is aimed at preventing the morbidity and mortality of AKI: close patient monitoring; strict fluid, electrolytes, and nutritional management; treatment of life-threatening conditions, such as pulmonary edema, hyperkalemia, and metabolic acidosis; avoidance of nephrotoxic drugs; and initiation of kidney replacement therapy (KRT).	**Case 29-1 (Question 3)** **Case 29-2 (Questions 3)** **Case 29-4 (Question 1)** **Case 29-5 (Question 4)** **Case 29-7 (Question 2)** **Case 29-9 (Question 1)**
7	Although diuretics have not been shown to improve patient outcomes in AKI, they can be used to prevent complications from fluid overload. Sodium restriction, daily monitoring of volume status, laboratory chemistries, urine output, and gastrointestinal (GI) losses should be measured during diuretic therapy.	**Case 29-3 (Question 3)** **Case 29-4 (Question 1)** **Case 29-9 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
8	KRT is reserved for patients with severe acid–base disorders, fluid overload, hyperkalemia, or symptomatic uremia as a result of AKI. The benefits to initiate KRT should be assessed by the risk of complications associated with KRT. Dosage adjustments are necessary for drugs that are removed during KRT.	**Case 29-9 (Questions 1, 2), Table 29-7**

INTRODUCTION

Acute kidney injury (AKI) is characterized clinically by an abrupt decrease in kidney function over a period of hours to days, resulting in the accumulation of nitrogenous waste products, urea and creatinine (azotemia), and the inability to maintain and regulate fluid, electrolyte, and acid–base balance.[1] AKI is a devastating syndrome with multiple risk factors or causes. It is associated with multiorgan dysfunction, increased resource utilization, and increased mortality.[2] Not only is underlying chronic kidney disease (CKD) a risk factor for AKI but AKI also contributes to CKD development and may result in dialysis dependency. Minimizing causes of AKI and increasing awareness of the importance of early detection and treatment are associated with improved outcome in AKI. Clinicians recognize that a rapid approach to treatment is essential because the causes and complications of AKI do not allow much time to initiate management and reversal.[3–6]

Many attempts have been made to objectively quantify AKI based on laboratory data, daily urine output, or the need for kidney replacement therapy (KRT). Over the past decade, the working definition of AKI has evolved. Currently, expert opinion and consensus recommend assessing quantitative serum creatinine

(SCr) changes from baseline and/or urinary output as clinical parameters in the detection, diagnosis, and classifying the severity of AKI. Urine production of <400 mL/day is termed *oliguria*, whereas urine production <50–100 mL/day is termed *anuria*.

In 2012, the Kidney Disease: Improving Global Outcomes (KDIGO)[7] guidelines proposed a uniform practical clinical definition of AKI. AKI is defined as an increase in SCr ≥0.3 mg/dL within 48 hours *or* an increase in SCr >1.5 times baseline in 7 days or less *or* a decrease in urine output <0.5 mL/kg/hour for ≥6 hours. The most recent guideline provides a useful staging tool for severity to assist clinicians in managing AKI (**Table 29-1**).

Table 29-1
Kidney Disease: Improving Global Outcomes Classification/Staging System for Acute Kidney Injury

Category	SCr and GFR Criteria	Urine Output Criteria
Stage 1	Increased SCr ≥0.3 mg/dL within 48 hours or increased SCr × 1.5–1.9-fold in ≤7 days	<0.5 mL/kg/hour × 6–12 hours
Stage 2	Increased SCr × 2 to 2.9-fold	<0.5 mL/kg/hour × ≥12 hours
Stage 3	Increased SCr × ≥3-fold or SCr ≥4 mg/dL or need for KRT or eGFR <35 mL/minute/1.73 m^2	<0.3 mL/kg/hour × ≥24 hours or anuria × ≥12 hours

GFR, glomerular filtration rate; SCr, serum creatinine.

EPIDEMIOLOGY

Multivariable models have identified risk factors for the development of AKI, including older age, higher baseline SCr, underlying CKD, diabetes, hypertension, chronic respiratory illness, underlying cardiovascular disease, prior heart surgery, dehydration resulting in oliguria, acute infection, and exposure to nephrotoxins.[8]

According to the KDIGO definition, one in five adults and one in three children worldwide experience AKI during hospitalization.[9] Furthermore, the incidence of hospital-acquired acute kidney injury (HA-AKI) in the intensive care unit (ICU) is ~20% to 50%.[10] Sepsis, a dysregulated immune response to infection resulting in life-threatening organ dysfunction, is the most commonly identified risk factor in 26% to 50% of all cases of AKI.[11–14] Other common causes include cardiac surgery, acute liver failure, hepatorenal syndrome, cardiorenal syndrome, and malignancy.[15]

Community-acquired acute kidney injury (CA-AKI), the development of AKI outside the hospital setting, is also common, and is usually detected in the first hospital assessment when SCr can be measured.[16,17] Data on risk factors are limited, but older age and higher comorbidities, especially diabetes and cardiovascular disease, seem to be more common in patients with CA-AKI.[18,19]

In a meta-analysis, patients with CA-AKI showed less severe clinical manifestations, a better prognosis, a reduced rate of ICU treatment, a shorter hospital stay, and a lower mortality rate compared to patients with HA-AKI. However, the rate of kidney recovery and need for KRT were similar.[20]

PROGNOSIS

Patients with AKI may experience incomplete recovery of kidney function, or worsening CKD or even irreversible loss of kidney function requiring KRT referred to as *kidney failure with replacement therapy* (KFRT). Patients who remain with persistent AKI (from 7 to 90 days following AKI) are classified as having acute kidney disease (AKD). Although many patients with stage 3 AKI or AKD may require KRT in the hospital, some will develop KFRT, requiring long-term dialysis.[6]

AKI is an independent risk factor for death in patients in the ICU. Moreover, a 40% to 55% mortality rate has been reported in patients requiring KRT. The mortality rate has declined minimally during the

past 50 years. The most common causes of death are sepsis, cardiovascular disease as a result of heart failure (HF) and ischemic heart disease, malignancy, and withdrawal of life support.[21] Even stage 1 AKI in patients in the ICU is associated with significantly lower 28-day, 1-year, 5-year, and 10-year survival rates compared to critically ill patients with no AKI at any time.[22]

PATHOGENESIS

The production and elimination of urine requires three basic physiologic events:

- Blood flow to the glomeruli
- The formation and processing of ultrafiltrate by the glomeruli and tubular cells
- Urine excretion through the ureters, bladder, and urethra

Many conditions and drugs can alter these physiologic events leading to AKI. These are classified as prerenal azotemia, and functional, intrinsic, and postrenal AKI (**Table 29-2**). It is possible for more than one of these categories to coexist.[23,24]

Table 29-2
Causes of Acute Kidney Injury

Classification	Common Clinical Disorders
Prerenal azotemia	**Intravascular Volume Depletion**
	Hemorrhage (surgery, trauma) Dehydration (gastrointestinal losses, aggressive diuretic administration) Severe burns Hypovolemic shock Sequestration (peritonitis, pancreatitis)
	Decreased Effective Circulating Volume
	Cirrhosis with ascites Heart failure

Classification	Common Clinical Disorders
	Hypotension, Shock Syndromes
	Antihypertensive vasodilating medications Septic shock Cardiomyopathy
	Increased Renal Vascular Occlusion or Constriction
	Bilateral kidney artery stenosis Unilateral kidney stenosis in solitary kidney Renal artery or vein thrombosis (embolism, atherosclerosis) Vasopressor medications (phenylephrine, norepinephrine)
Functional acute kidney injury	**Afferent Arteriole Vasoconstrictors**
	Cyclosporine NSAIDs
	Efferent Arteriole Vasodilators
	Angiotensin-converting enzyme inhibitors Angiotensin II receptor antagonists
Intrinsic acute kidney injury	**Glomerular Disorders**
	Glomerulonephritis Systemic lupus erythematosus Malignant hypertension Vasculitic disorders (granulomatosis with polyangiitis)
	Acute Tubular Necrosis
	Prolonged prerenal states Drug-induced (iodinated contrast media, cisplatin, aminoglycosides, amphotericin B, vancomycin with or without piperacillin/tazobactam, adefovir, cidofovir, tenofovir, HMG CoA reductase inhibitors, bisphosphonates) Tubular crystal obstruction (eg, ethylene glycol, drugs such as acyclovir, methotrexate, indinavir, atazanavir, sulfonamide antibiotics)
	Acute Interstitial Nephritis
	Drug induced (penicillins, β-lactam antibiotics, fluoroquinolones, proton-pump inhibitors, NSAIDs, sulfonamides)
Postrenal acute kidney injury	**Ureter Obstruction (Bilateral or Unilateral in Solitary Kidney)**

Classification	Common Clinical Disorders
	Malignancy (prostate or cervical cancer) Benign prostate hypertrophy Anticholinergic drugs (affect bladder outlet muscles) Kidney stones

HMG CoA, 3-hydroxy-3-methylglutaryl coenzyme A; NSAIDs, nonsteroidal anti-inflammatory drugs.

Normal kidney function depends on adequate perfusion. The kidneys receive up to 25% of cardiac output, which is >1 L/minute of blood flow. Blood enters the glomerulus via the afferent arteriole. The intraglomerular hydrostatic pressure leads to ultrafiltration across the glomerulus into the proximal tubule. The unfiltered blood leaves the glomerulus via the efferent arteriole. In conditions of decreased kidney perfusion, efferent arteriolar vasoconstriction occurs to increase intraglomerular hydrostatic pressure and maintain ultrafiltrate production. Afferent arteriolar vasodilation also occurs to improve blood flow into the glomerulus.[23,24]

Prerenal azotemia, the most common form of AKI, occurs when blood flow to the kidney is reduced. Major causes include decreased intravascular volume (eg, hemorrhage or dehydration [including overdiuresis]), decreased effective circulating volume states (eg, cirrhosis or HF), hypotensive events (eg, shock or medication-related hypotension), and renovascular occlusion or vasoconstriction. Because no structural damage occurs to the kidney parenchyma per se, correcting the underlying cause rapidly restores glomerular filtration rate (GFR). Sustained prerenal conditions can result, however, in glomerular ischemia causing acute tubular necrosis (ATN).[25]

Functional AKI results when medical conditions or drugs impair glomerular ultrafiltrate production or intraglomerular hydrostatic pressure as a result of impaired autoregulation. Blood travels through the afferent arteriole and enters the glomerulus, where it is filtered, and exits through the efferent arteriole (**Fig. 29-1**). The afferent and efferent arterioles work in concert to maintain adequate glomerular capillary hydrostatic pressure to form ultrafiltrate. Many

medications can drastically reduce intraglomerular hydrostatic pressure and GFR by producing afferent arteriolar vasoconstriction or efferent arteriolar vasodilation.

Figure 29-1 Drugs that alter renal hemodynamics by causing afferent arteriole vasoconstriction or efferent arteriole vasodilation. ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin II receptor blockers; CCBs, calcium channel blockers; COX-2, cyclo-oxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

Intrinsic AKI can occur at the microvascular level of the nephron, glomeruli, kidney tubules, or interstitium. Vasculitic diseases (eg, granulomatosis with polyangiitis, cryoglobulinemic vasculitis) involve the small vessels of the kidney. Glomerulonephritis and systemic lupus erythematosus, although relatively uncommon, result in glomerular damage. ATN is by far the most common cause of intrinsic AKI. ATN occurs in part because the kidney tubules require high oxygen delivery to maintain their metabolic activity. Consequently, any condition that causes ischemia to the tubules (eg, hypotension, decreased blood flow) can induce ATN. Drugs (eg, acyclovir, methotrexate) can cause crystal deposition and also lead to obstruction. Moreover, the tubules may be exposed to exceedingly high concentrations of nephrotoxic drugs (eg, aminoglycosides,

intravenous [IV] contrast). Interstitial nephritis or inflammation within the kidney parenchyma is most often associated with drug administration (eg, penicillins, β-lactam antibiotics).[26,27]

Postrenal AKI occurs when there is an outflow obstruction in the upper or lower urinary tract. Lower tract obstruction is most common, and can be caused by prostatic hypertrophy, prostate or cervical cancer, anticholinergic drugs that cause bladder sphincter spasm, or kidney stones. Upper tract obstruction is less common and occurs when both ureters are obstructed or when one is obstructed in a patient with a single functioning kidney. Postrenal AKI usually resolves rapidly after the obstruction has been removed. Postobstructive diuresis can be dramatic (eg, 3–5 L/day).[24]

CLINICAL EVALUATION

History and Physical Examination

Patients with AKI have a variety of different clinical presentations. Patient symptoms vary, and clinical presentation is largely dependent on the underlying etiology. Symptoms typically include changes in urine output, signs of fluid overload or sudden weight gain, signs of dehydration, or mental status changes. However, many patients are asymptomatic; and are incidentally found to have an elevated SCr concentration, abnormal urine studies (such as proteinuria or microscopic hematuria), or abnormal radiologic imaging of the kidneys.[23]

A detailed history and physical examination often reveal the cause(s) of AKI. The clinician's responsibility is to ask specific, open-ended questions regarding the patient's chief concern; history of present illness; medical history; family, social, and allergy history; and current prescription and nonprescription medication use. Probing for pertinent information regarding recent surgery, nephrotoxin exposure, or concurrent medical conditions can aid in rapidly determining the etiology of AKI. For example, does the

patient have preexisting conditions that point toward prerenal azotemia, such as HF or liver disease? Did the patient receive nephrotoxic medications? Did the patient hemorrhage or have protracted hypotension during surgery? Does the patient report a change in weight, blood pressure (BP), fluid intake, or urine output?

A thorough physical examination, when used in conjunction with the history, can be invaluable in confirming the cause of AKI. The patient's volume status should be evaluated first. Evidence of dehydration (eg, syncope, weight loss, orthostatic hypotension) or decreased effective circulating volume (eg, ascites, pulmonary edema, peripheral edema, jugular venous distension) usually indicates prerenal azotemia. Concurrent rash and AKI associated with recent antibiotic exposure suggest drug-induced allergic interstitial nephritis (AIN). The clinician should suspect rhabdomyolysis in a patient with trauma or crush injuries and AKI. In a patient with suspected AKI, the purpose of kidney ultrasonography early in the diagnostic workup is to rule out obstructive causes of oliguria. An enlarged prostate, painful urination, or wide deviations in urine volume can suggest obstructive AKI causes. Flank and lower abdominal pain suggest upper obstruction, whereas urinary frequency, hesitancy, dribbling, and abdominal fullness indicate lower obstruction.

Laboratory Evaluation

QUANTIFYING GLOMERULAR FILTRATION RATE

GFR is measured with estimating equations that require a steady-state SCr value. No estimating equations can provide an accurate estimate of GFR in AKI because the SCr is fluctuating and not at steady state. Hence, these equations cannot be used during AKI because alterations in SCr may lag several days behind actual changes in GFR.[15] In Chapter 28, Chronic Kidney Disease, the Modification of Diet in Renal Disease (MDRD) equation, the Cockcroft–Gault (CG) equation, and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation are reviewed, and

all three require an SCr value at steady state. The MDRD and CKD-EPI equations are used to quantify baseline GFR, to detect or stage the degree of CKD, and to follow progression. The CG equation is most commonly used to evaluate the appropriate doses of drugs that are eliminated by the kidney.[7] The CG equation may significantly overestimate the kidney function in the early stages of AKI and may underestimate the kidney function when AKI is resolving.[28]An example of this is a patient who develops ATN and anuria. Within the first few days, the SCr level may increase slightly because it takes time for the SCr concentration to achieve a new steady state. In fact, the calculated creatinine clearance (ClCr) may even remain in the normal range, although the true GFR is substantially lower. The converse is true with patients recovering from ATN. As the diuretic phase of ATN begins, urine output can be dramatic, but patients may remain markedly azotemic for several days. Using the CG equation in this setting will produce a falsely low ClCr estimate. The CG equation is also inaccurate in populations that have low muscle mass, such as the elderly, obese, or cachectic patients. Use of SCr to assess kidney function in patients with liver disease may also lead to overestimation of GFR.[29] This may be attributed to decreased production of creatine (the precursor of creatinine) by the liver or increased tubular secretion of creatinine by the kidney.

Therefore, clinicians should be aware that estimating equations have potential limitations and pitfalls. Cystatin C (CysC), a nongylcosylated protein, is an endogenous biomarker of kidney function, produced at a constant rate by all nucleated cells. Its concentration is not influenced by age, gender, and muscle mass. The interindividual variability in CysC production is less than that for SCr. CysC is freely filtered by the glomerulus and then reabsorbed by the proximal tubules, where it is catabolized. Limited evidence suggests that the concentration of CysC is an early AKI biomarker because it peaks earlier than does SCr during AKI, and it may detect AKI earlier than does SCr.[30,31] Even though CysC is not in widespread use, it is a good marker of kidney function and potentially could be used to predict the dose of drugs excreted by the kidneys.

In the past, many clinicians advocated the collection of timed urine specimens to measure urine creatinine excretion and calculate ClCr in AKI. Although this may seem relatively simple, it is susceptible to serious errors, particularly the timing of the collection and ensuring that the patient has not voided urine in the commode, resulting in an incomplete urine collection. For these reasons, the practice of collecting timed urine specimens is not routinely performed. Populations in whom estimation of GFR using a 24-hour urine collection is more reasonable include patients with variation in dietary intake of creatine sources (such as vegetarians) or persons with poor muscle mass (eg, malnourished individuals or amputees).[32] Alternatively, shorter collection times or spot untimed urine samples are sometimes used to determine creatinine excretion.

SERUM AND URINARY TESTS

The lag in SCr rise compared to the decline in kidney function[33] encouraged scientific research on discovering biomarkers that could help with the early identification and diagnosis of AKI. Early AKI identification is extremely important because it could lead to prevention of disease progression or it could help identify patients who may benefit from early interventions. Indeed, various low-molecular weight (MW) molecules, proteins, and enzymes are released by tubular epithelial cells and are secreted in the urine as a response to the AKI constituting the novel biomarkers to identify AKI.[34,35] Examples of such biomarkers include the neutrophil gelatinase associated lipocalin (NGAL), tissue injury metalloproteinase 2 (TIMP-2), and insulin-like growth factor binding protein 7 (IGFBP-7), kidney injury molecule 1 (KIM-1), interleukin 18 (IL-18), and liver-type fatty acid–binding protein (L-FABP). In the near future, some of these novel biomarkers will most likely be incorporated in definitions of AKI; however, these biomarkers are not yet routinely used in most clinical practice sites. The combination product of TIMP-2 and IFGBP-7 is approved by the U.S. Food and Drug Administration (FDA) for the identification of patients at high

risk for developing KDIGO stage 2 or 3 AKI during the next 12 to 24 hours. These two biomarkers are marketed as the Nephrocheck® Test (Astute Medical Inc, San Diego, CA, USA).[36] The Nephrocheck® Test has been validated as the first point-of-care device to detect early AKI. The Nephrocheck® Test is not used as a stand-alone test for the diagnosis of AKI; however, it should be used as an adjunct tool to clinical findings and other diagnostics. The test results are revealed as an AKI risk score, with scores >0.3 $ng/mL^2/1000$ indicating a high risk of developing moderate-to-severe AKI within 12 hours of testing.[36,37] Lastly, real-time noninvasive measurement of GFR using fluorescently labeled markers have been proposed to estimate kinetic GFR, and these tests may be available in the future. Real-time monitoring of GFR in critically ill patients will allow for earlier diagnosis of AKI.[38] Future clinical trials are needed to identify and validate their prognostic role in AKI and estimating GFR.[39]

Assessment of both blood urea nitrogen (BUN) and SCr concentrations is crucial for guiding the diagnosis, treatment, and monitoring of AKI. Measurement of SCr and BUN are discussed in Chapter 2, Interpretation of Clinical Laboratory Tests. The BUN:SCr ratio can delineate prerenal causes from intrinsic and postrenal causes. Urea reabsorption is inversely proportional to the urine flow rate. The normal steady-state BUN:SCr ratio is ~10:1. In prerenal conditions, the BUN:SCr ratio is >20:1 because sodium and water are actively reabsorbed in the kidney tubules to expand the effective circulating volume. Urea, an ineffective osmole, is reabsorbed as a result of increased water reabsorption, whereas creatinine is not reabsorbed. Although SCr may increase owing to decreased glomerular filtration, BUN increases to a greater degree as a result of increased proximal reabsorption.

The presence of hypercalcemia, hyperkalemia, and hyperuricemia could indicate the tumor lysis syndrome (TLS) in patients with malignancy.[40] TLS is a condition that occurs in patients with some cancers particularly after chemotherapy administration. The destruction of cancerous cells results in the release of large quantities of cellular contents (eg, potassium, uric acid) into the

bloodstream, which can overwhelm the kidney's functional ability, especially in dehydrated states.

Other elevated enzymes may also aid in the diagnosis of AKI. An increased level of creatine kinase or myoglobin in the face of AKI usually indicates rhabdomyolysis. Eosinophilia may suggest acute AIN from drug exposure. High levels of circulating immune complexes in the presence of AKI suggest glomerulopathies.[23]

URINALYSIS

The urinalysis is an important diagnostic tool for differentiating AKI into prerenal azotemia, intrinsic AKI, or obstructive AKI (**Table 29-3**).[41] The presence of highly concentrated urine, as determined by elevated urine osmolality and specific gravity, suggests prerenal azotemia. During dehydrated states, vasopressin (antidiuretic hormone) is secreted, and the renin–angiotensin–aldosterone system (RAAS) is activated. These mechanisms promote the reabsorption of water and sodium at the collecting duct of the nephron, which serves to expand the effective circulating volume in an attempt to restore kidney perfusion. As a result of diminished urine volume, the urine osmolality and specific gravity increase dramatically. Patients with prerenal azotemia and oliguria often have a urine osmolality >500 mOsm/kg. The maximal urine osmolality can exceed 1200 mOsm/kg.

Table 29-3

Urinary Indices in Acute Kidney Injury

Component	Prerenal Azotemia	Acute Tubular Necrosis	Postrenal Obstruction
Urine Na^+ (mEq/L)	<20	>40	>40
FE_{Na} (%)	<1	>2	>1
FE_{Urea} (%)	<35	>50	
Urine/plasma creatinine	>40	<20	<20
Specific gravity	>1.010	<1.010	Variable
Urine osmolality (mOsm/kg)	Up to 1200	<300	<300

The presence of proteinuria or hematuria can indicate glomerular damage.[42] Nephrotic syndrome is characterized by urinary protein losses >3.5 g/1.73 m^2/day. Proteinuria can also result from tubular

damage; however, that protein loss is rarely >2 g/day. The protein content can be used to differentiate glomerular versus tubular damage. The low-MW protein β_2-microglobulin is freely filtered at the glomerulus and reabsorbed at the proximal tubule. Therefore, the presence of excessive β_2-microglobulin in the urine suggests a tubular source of AKI, such as ATN. Conversely, albumin is not readily filtered at the glomerulus; hence, the presence of heavy albuminuria suggests a glomerular source of AKI.

Microscopic examination of the urine provides helpful clues for determining the source of AKI (**Table 29-4**). Pigmented granular casts are generally seen with ischemic- or nephrotoxin-induced AKI. White blood cells (WBCs) and WBC casts can indicate an inflammatory process in the glomerulus, such as AIN or pyelonephritis. Red blood cells (RBCs) and RBC casts can result from strenuous exercise or can indicate glomerulonephritis. AIN can be detected by the presence of urinary eosinophils. Obstructive AKI causes, such as kidney stones, can be identified by the presence of crystals in the urine. Cystine, leucine, and tyrosine crystals are considered pathologic. The presence of calcium oxalate crystals may suggest toxic ingestion of ethylene glycol.

Table 29-4

Clinical Significance of Urinary Sediment in Acute Kidney Injury

Cellular Debris	Clinical Significance
Red blood cells	Glomerulonephritis IgA nephropathy Lupus nephritis
White blood cells	Infection (pyelonephritis) Interstitial nephritis Glomerulonephritis Acute tubular necrosis
Eosinophils	Drug-induced acute interstitial nephritis Pyelonephritis Renal transplant rejection

Cellular Debris	Clinical Significance
Hyaline casts	Glomerulonephritis Pyelonephritis Heart failure
Red blood cell casts	Acute tubular necrosis Glomerulonephritis Interstitial nephritis
White blood cell casts	Pyelonephritis Interstitial nephritis
Granular casts	Dehydration Interstitial nephritis Glomerulonephritis Acute tubular necrosis
Tubular cell casts	Acute tubular necrosis
Fatty casts	Nephrotic syndrome
Myoglobin	Rhabdomyolysis
Crystals	Nonspecific, kidney stones

Note: Hyaline casts may also be detected in normal kidney function.

IgA, immunoglobulin A.

URINARY CHEMISTRIES

Analyzing urine electrolyte concentrations and simultaneously comparing them with serum sodium and creatinine concentrations is useful for differentiating between prerenal azotemia and ATN (Table 29-3). The fractional excretion of sodium (FE_{Na}) is a measurement of how actively the kidney is reabsorbing sodium, and it is calculated as the fraction of filtered sodium excreted in the urine using creatinine as a measure of GFR. Under normal conditions, the proximal tubule reabsorbs 99% of filtered sodium. The FE_{Na} formula is listed as follows:

$$FE_{Na^+}(\%) = \frac{(U_{Na})\,(SCr)}{(U_{cr})\,(S_{Na})} \times 100\% \qquad \text{(Eq. 29-1)}$$

where U_{Na} is the urine sodium concentration (mEq/L), SCr is the serum creatinine concentration (mg/dL), U_{Cr} is the urine creatinine concentration (mg/dL), and S_{Na} is the serum sodium concentration (mEq/L).[43,44] In prerenal azotemia, the functional ability of the proximal kidney tubule remains intact. In fact, its sodium-reabsorbing abilities are markedly enhanced because of the effects of circulating vasopressin and activation of the RAAS. Both the FE_{Na} and urine sodium concentration become markedly low (<1% and <20 mEq/L, respectively) in prerenal conditions. In contrast, these indices are elevated in ATN because the kidney tubules lose their ability to reabsorb sodium; the FE_{Na} is >2%, and the urine sodium is >40 mEq/L. FE_{Na} values between 1% and 2% are generally inconclusive. The clinician should ensure that the patient is not receiving scheduled thiazide or loop diuretic therapy when the FE_{Na} is calculated. These diuretics increase natriuresis, thereby making the results difficult to interpret. Urea excretion is not affected by diuretics. The fractional excretion of urea (FE_{Urea}) appears more accurate in detecting prerenal azotemia, particularly in patients taking diuretics. Serum and urine sodium concentrations are replaced by blood urea and urine urea concentrations in the FE_{Na} formula. A FE_{Urea} of <35% and >50% are used to distinguish prerenal azotemia and ATN, respectively.[45]

PRERENAL AND FUNCTIONAL ACUTE KIDNEY INJURY

Chronic Heart Failure and Nonsteroidal Anti-inflammatory Drug Use

CASE 29-1

Question 1: A.W. is a 71-year-old White male, 72 inches (182.88 cm) tall and weighing 194 pounds (87.99 kg) who had an ST-segment elevation myocardial infarction (STEMI) 2 months ago. His ejection fraction is currently 15% (normal, 50%–60%). He presents today for his 2-month follow-up clinic appointment with shortness of breath, dyspnea on exertion, and inability to produce much urine. His medical history is significant for long-standing hypertension, coronary artery disease, osteoarthritis, and recent-onset HF after his MI. His home medications include furosemide 40 mg daily, lisinopril 20 mg daily, metoprolol succinate 100 mg daily, digoxin 0.125 mg daily, atorvastatin 40 mg daily, and naproxen sodium 550 mg twice daily (bid), all of which are taken orally (PO). With the exception of naproxen, A.W. often forgets to take his medications. Physical examination reveals lower leg 3+ pitting edema, pulmonary crackles and wheezes, positive jugular venous distension, and an S_3 heart sound. His vital signs are significant for a BP of 198/97 mm Hg and a weight gain of 8.82 pounds (4 kg) since his last visit 2 months ago. Last week, his BUN and SCr were 23 and 1.2 mg/dL, respectively.

What are A.W.'s risk factors for AKI?

A.W.'s risk factors for AKI are HF with poor cardiac output (ejection fraction, 15%) that resulted from his STEMI and his medication, naproxen sodium. HF is a major cause of prerenal AKI.[46] A.W.'s diminished cardiac output has resulted in decreased effective circulating volume and activation of the RAAS, which are impairing his kidney perfusion. In states of decreased kidney perfusion, prostaglandins E2 and I2 compensate for the afferent arteriole vasoconstriction by stimulating afferent arteriole vasodilation, thereby enhancing kidney blood flow. Prostaglandin synthesis is mediated predominantly by cyclooxygenase-1 (COX-1) and perhaps cyclooxygenase-2 (COX-2). Nonsteroidal anti-inflammatory drugs (NSAIDs), which act by inhibiting COX-1 and COX-2 and selective COX-2 inhibitors, should be considered as causes of AKI in high-risk patients. They exert their pharmacologic effect by inhibiting prostaglandin synthesis, thereby negating compensatory vasodilation. The drugs induce abrupt decreases in GFR in at-risk patient populations, specifically those with HF, liver disease, the elderly, or dehydrated patients. Figure 29-1 illustrates common medications that alter kidney hemodynamics by causing either afferent arteriole vasoconstriction or efferent arteriole vasodilation.

The term *triple whammy* refers to the risk of AKI when an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) is combined with a diuretic and an NSAID. This combination might be seen in a patient with hypertension, HF, or CKD who has arthritis or mild-to-moderate pain.[47,48]

Celecoxib is currently the only COX-2 inhibitor available in the United States. The NSAIDs naproxen, piroxicam, ketorolac, etodolac, indomethacin, sulindac, ibuprofen, and salsalate were associated with a higher risk of AKI, whereas meloxicam, diclofenac, and the selective COX-2 inhibitor, celecoxib, were not associated significantly with AKI.[49] The highest risk was found in those using more than one NSAID, and in those switching from one agent to another. The lowest risk was found in those using the same agent continuously.[50,51] AKI risk was highest in the first 45 days of treatment initiation.[49] Sulindac may offer a "kidney-sparing" effect. Sulindac is a prodrug that is converted to its active sulfide metabolite by the liver and then becomes reversibly oxidized back to its parent compound in the kidney; kidney prostaglandin synthesis is essentially unaltered by sulindac. Cases of sulindac-induced kidney dysfunction have been reported when the drug was administered to patients with cirrhosis and ascites.

Case 29-1, Question 2: A.W.'s cardiologist obtains a stat digoxin level, serum and urine electrolyte panels, and urinalysis. The digoxin level is reported as "not detectable" (target, 0.5–0.8 ng/mL). Other significant serum laboratory values include:

Na+, 140 mEq/L
BUN, 56 mg/dL
SCr, 1.8 mg/dL

The urinalysis is significant for a urinary osmolality of 622 mOsm/kg and specific gravity of 1.092. The urine electrolytes are significant for Na+ of 12 mEq/L and creatinine of 102 mg/dL. What laboratory findings suggest prerenal AKI? Define the criteria used for the detection of AKI and staging of AKI in this patient?

A.W. has classic laboratory findings associated with poor kidney perfusion (Table 29-3). It is important to compare the current and

previous laboratory data to assess acute changes in kidney function. Compared with last week, A.W.'s kidney function has deteriorated based on substantial increases in BUN and SCr concentrations; BUN has increased nearly twofold and creatinine by 50% (SCr increased × 1.5-fold within 7 days). According to the KDIGO criteria, the patient has stage 1 AKI (see Table 29-1). Kidney demise is most likely owing to prerenal AKI because the BUN:SCr ratio is >20:1, suggesting poor kidney blood flow, which is corroborated by other urinary indices such as the urinary Na+ 12 mEq/L; specific gravity, 1.090 (elevated); urine osmolality, 622 mOsm/kg; and the calculated FE_{Na}, 0.1%. These values reflect the ability of the kidney tubules to respond to vasopressin and aldosterone to expand effective circulating volume and restore kidney perfusion.

Another consideration is furosemide-induced volume depletion; however, the nondetectable serum digoxin level indicates likely noncompliance with his medications. A more likely explanation is poor kidney perfusion because of his HF in combination with NSAID therapy.

Case 29-1, Question 3: How should A.W.'s prerenal azotemia be treated?

The presence of volume overload in the face of prerenal azotemia suggests a decreased effective circulating volume, most likely from poorly controlled HF. Restoring and improving A.W.'s cardiac output and kidney perfusion will rapidly correct the prerenal azotemia. This can be achieved by (a) optimizing doses and assuring adherence to his HF medications (furosemide, lisinopril, metoprolol succinate, and digoxin); (b) controlling BP by decreasing both preload and afterload; and (c) modifying any drug therapy that has deleterious effects on the kidney hemodynamics (eg, NSAID). The specific therapies for controlling hypertension and improving cardiac output are presented in Chapter 9, Essential Hypertension, and Chapter 14, Heart Failure. Naproxen should be discontinued and substituted with acetaminophen to treat his osteoarthritis. Normal kidney function should return in a few days after correction of the underlying causes.

Angiotensin-Converting Enzyme Inhibitor and Angiotensin Receptor Blocker–Induced Acute Kidney Injury

CASE 29-2

QUESTION 1: G.B. is a 53-year-old White female, 63 inches (160.02 cm) tall and weighing 170 pounds (77.11 kg) with hypertension, coronary artery disease, peripheral vascular disease, and diabetes, for which she had been taking hydrochlorothiazide 25 mg PO daily, atorvastatin 10 mg PO daily, aspirin 81 mg PO daily, and insulin glargine 30 units subcutaneously once daily every morning. At last week's clinic visit, she had two consecutive BP readings of 187/96 and 193/95 mm Hg, respectively, measured 20 minutes apart. At that time, G.B.'s primary care physician started her on lisinopril 5 mg PO daily. Other notable laboratory values at the time included HgA_{1c} 7.5% and urine albumin to creatinine ratio (ACR) 50 mg/g. The region was in the midst of a protracted heat wave with temperatures >95 °F (35 °C) and she claims she is not drinking enough liquids. She returns to the clinic today for her 1-week follow-up appointment with dizziness, dry mouth, and very little urine production during the past week. Laboratory values and vital signs obtained at this visit include the following:

BP, 98/43 mm Hg
Hg, 15 g/dL
Hct, 45%
Na, 145 mEq/L
K, 5.2 mEq/L
BUN, 62 mg/dL
SCr, 2.7 mg/dL (baseline SCr, 1 mg/dL)

Why is G.B. experiencing AKI?

According to the KDIGO criteria, G.B. is diagnosed with stage 2 AKI most likely because of prerenal azotemia. Inhibition of the RAAS in patients with compromised kidney blood flow is a common cause of functional AKI. A basic understanding of the effects of the RAAS on kidney hemodynamics is necessary in this situation (**Fig. 29-2**). When kidney perfusion is impaired, the juxtaglomerular cells of the kidney secrete renin into the plasma and lymph. Renin cleaves circulating angiotensinogen to form angiotensin I (AT I), which is

further cleaved by ACE and converted to angiotensin II (AT II). AT II induces two physiologic events to improve kidney perfusion. First, it directly causes systemic vasoconstriction, which shunts blood to the major organs, and indirectly increases intravascular volume through aldosterone- and vasopressin-mediated activity. Second, it preferentially vasoconstricts the efferent kidney arteriole to maintain adequate intraglomerular hydrostatic pressure. Under conditions of decreased arterial pressure or effective circulating volume, the RAAS is activated and plasma renin and AT II activity are increased.[52,53]

Figure 29-2 Compensatory hormonal mechanisms of decreased renal perfusion.

CASE 29-2, QUESTION 2: Are there other factors that predispose patients to ACE inhibitor–induced AKI?

G.B. has extensive atherosclerotic disease indicated by the presence of coronary artery and peripheral vascular disease. Atherosclerosis may affect the macro- and microvasculature of the kidney and potentially could cause kidney artery occlusion and decreased kidney perfusion. This activates the RAAS, which causes sodium and water reabsorption and AT II–mediated efferent arteriole

vasoconstriction, to restore normal kidney perfusion and intraglomerular hydrostatic pressure.

The administration of ACE inhibitors directly inhibits the formation of AT II, which is necessary for efferent arteriole vasoconstriction. Consequently, the compensatory physiologic event that maintains G.B.'s kidney blood flow is inhibited, thereby reducing her intraglomerular hydrostatic pressure and GFR. ACE inhibitors are contraindicated in patients with bilateral kidney artery stenosis or unilateral stenosis in patients with a single functioning kidney.[54] In addition to the previous situation, three other general scenarios will result in the development of AKI with ACE inhibitors. First, conditions of sodium and water depletion (eg, dehydration, overdiuresis, poor fluid intake, low-sodium diet) can increase the dependency of the efferent arteriole on AT II. Dehydration from diuretic use and decreased fluid intake during the heat spell may have compromised effective circulating volume and led to decreased kidney blood flow in G.B. When ACE inhibitors are given in these situations, GFR can fall dramatically, and SCr rises. AKI can be averted by withholding the ACE inhibitor (or diuretic, or both) for a day and repleting the intravascular fluid volume with normal saline infusion. The ACE inhibitor can be restarted at the same dose after adequate hydration when SCr returns to baseline. Second, ACE inhibitors can decrease the mean arterial pressure to such a degree that kidney perfusion cannot be sustained. This is more likely to occur with long-acting agents or in situations in which the pharmacologic half-life of the ACE inhibitor is prolonged (eg, preexisting kidney disease). Finally, ACE inhibitors may precipitate AKI in patients who are taking concomitant drugs with kidney afferent arteriole vasoconstricting effects, most notably cyclosporine and NSAIDs.

Case 29-2, Question 3: How should G.B.'s ACE inhibitor–induced AKI be managed?

Patients who are receiving ACE inhibitors should be monitored judiciously regarding their SCr and electrolyte concentrations. Once

an ACE inhibitor is initiated, an increase in SCr of 20% to 30% can be expected.[53] This slight increase should not worry clinicians, because SCr typically normalizes within 2 to 3 months. However, SCr increases greater than this along with reduced urine output signal AKI. AKI related to ACE inhibitors is usually reversible, principally because the AKI is caused by inadequate glomerular capillary pressure, which is restored as soon as sufficient AT II is produced. This normally takes 2 to 3 days to re-equilibrate. AKI appears to develop more commonly in patients with hypotension or in those with intravascular volume depletion (eg, patients with HF receiving high-dose diuretics, inadequate fluid intake with diuretic use). Under these conditions, it is prudent to replete the intravascular fluid volume or temporarily discontinue diuretic therapy until kidney function improves. G.B.'s ACE inhibitor therapy should be temporarily discontinued and reinstituted when she has a normalized intravascular volume and is hemodynamically stable, and kidney function has returned to baseline or stabile kidney function is established. See Chapter 14, Heart Failure, for a discussion on the use of ACE inhibitors and concurrent diuretic therapy in patients with HF.

Case 29-2, Question 4: Do ARBs cause less AKI compared with ACE inhibitors?

The ARBs competitively inhibit the angiotensin II receptor. At least two subtypes of the AT II receptors exist: AT1-R and AT2-R. The ARBs exert their pharmacologic effect at the AT1-R, which is responsible for most, if not all, of the cardiovascular effects of angiotensin II, such as vasoconstriction, aldosterone release, and β-adrenergic stimulation. Few differences are seen in the incidence of AKI between ACE inhibitors and ARBs[54] and one should not be interchanged with the other to decrease AKI risk. See Chapter 14, Heart Failure, for further discussion. After AKI resolves in G.B., an ACE inhibitor is appropriate to consider treating hypertension and delay the progression of CKD.

INTRINSIC ACUTE KIDNEY INJURY

Intrinsic AKI is a general term that connotes damage at the parenchymal level of the kidney. Pragmatically, intrinsic AKI can be subdivided into vascular, microvascular, glomerular, or tubulointerstitial disorders.

Vascular disorders involving the large kidney vessels are relatively uncommon. Acute kidney artery or vein occlusion can be caused by vasculitis, atherothromboembolism, dissection, or clamping of the ascending aorta during surgery. To affect BUN and SCr, occlusion must be bilateral, or it can be unilateral in patients with reduced kidney function or one functioning kidney. Disorders such as thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, disseminated intravascular coagulation, scleroderma, and preeclampsia can cause thrombotic microangiopathies, reducing the blood flow to the kidney microvasculature resulting in AKI. Kidney injury associated with systemic lupus erythematosus, human immunodeficiency virus, multiple myeloma, vasculitis, and rapidly progressing glomerulonephritis (RPGN) are examples of glomerular causes of intrinsic AKI. Tubulointerstitial disorders are commonly caused by medications, crystal precipitation, infections, and rhabdomyolysis. ATN is the most common type of AKI, and it is typically caused by nephrotoxins and any disorder that produces tubular ischemia, such as prolonged hypotension or shock syndromes.[55] In the 2020 COVID-19 pandemic caused by the SARS-CoV-2 virus, AKI was a complication noted in hospitalized patients.[56–59] Future studies are needed to evaluate the impact of COVID-19 on kidney function. Residual kidney dysfunction in patients who have recovered from COVID-19 is concerning and the impact of COVID-19 on glomerular disease is unclear.[60]

Acute Glomerulopathies

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

CASE 29-3

QUESTION 1: B.M. is an 18-year-old white male college freshman 68 inches (172.72 cm) tall and weighing 150 pounds (68.03 kg) in otherwise good health who recently developed strep throat. He received a 10-day course of amoxicillin, which cleared the infection. He returns to the student health center after completing his 10-day course with "puffy eyes," swelling in his legs, a cough productive of clear sputum, and decreased urine output that appears "tea colored." Other than the recent course of amoxicillin, he is not on any other medications. Baseline records from a routine physical examination 2 months ago reveal a BUN and SCr of 10 and 0.8 mg/dL, respectively, and a BP of 120/80 mm Hg. Today, the physical examination is significant for a BP of 176/95 mm Hg, 2+ peripheral edema, and bilateral pulmonary rales. The urinalysis is significant for gross hematuria, nephritic-range proteinuria, RBC and WBC casts, and epithelial cells. B.M.'s BUN and SCr have increased to 85 and 7.1 mg/dL, respectively.

Based on the history, physical examination, and laboratory findings, what is the most likely cause of AKI in this patient?

B.M.'s recent history of a streptococcal infection with the development of AKI suggests poststreptococcal glomerulonephritis (PSGN), which results from the formation of antibodies against streptococcal antigens.[61,62] The streptococcal–antigen immune complexes are deposited in the glomerulus, resulting in complement, cytokine, and clotting cascade activation; neutrophils and monocytes attack the glomerulus causing glomerulonephritis. The onset of PSGN is usually 7 to 21 days after the start of the pharyngeal infection. PSGN is the most common acute-onset, immune-mediated, diffuse glomerulopathy. It primarily affects children, although it can affect any age group and is more prevalent in males than in females. Certain serologic subtypes of group A β-hemolytic streptococci, known as *nephritogenic strains*, cause PSGN. Positive diagnosis of PSGN requires identification of a nephritogenic strain; objective urinalysis findings suggestive of glomerular damage, such as proteinuria, hematuria, and casts; and elevated streptococcal antibody titers.

B.M. exhibits the classic physical and laboratory findings associated with PSGN. The pertinent positive physical findings include periorbital, pulmonary, and peripheral edema; tea-colored

urine; hypertension; and decreased urine output. Edema is a common manifestation, with periorbital edema typically being the first to appear. Reduced GFR, proteinuria, and sodium retention by the kidney all contribute to edema formation. When protein, principally albumin, is lost in the urine, the intravascular oncotic pressure declines, causing a shift of fluid into the extravascular space. The loss of intravascular volume stimulates sodium and water reabsorption by the kidney via aldosterone and vasopressin leading to hypertension.

Pertinent laboratory data in B.M. include elevated SCr, and urinalysis positive for hematuria, proteinuria, WBC casts, and epithelial cells. Hematuria, which is found in almost all patients with PSGN, accounts for the reddish brown, tea-colored urine. Other commonly found urine sediments include cellular casts and hyaline and granular casts. Oliguria is common in PSGN, but anuria is rare.

Case 29-3, Question 2: Are there other tests that can be used to confirm this diagnosis?

Kidney biopsy is rarely needed, but it may be prudent in patients who present with atypical symptoms, such as anuria, prolonged oliguria, marked azotemia, hematuria for >3 weeks, or in those who have no streptococcal antibody titers.

Case 29-3, Question 3: What are the therapeutic goals and treatment options for PSGN?

The therapeutic goals are to minimize further kidney damage and to provide symptomatic relief for B.M. The underlying streptococcal infection should be treated with appropriate antibiotics, but as illustrated by B.M., this has no effect in preventing PSGN. Family members and close contacts of the patient who was infected should receive antibiotic prophylaxis as well. Restriction of protein to 0.8 g/kg/day may be beneficial in patients with marked proteinuria, and antihypertensive drugs can be used on a short-term basis to control

BP. Sodium and water restriction is beneficial in reducing edema, and loop diuretics may be used as needed for symptomatic pulmonary or peripheral edema. Close monitoring of electrolytes is warranted if diuretics are used. KRT is rarely required. Given his age and previous health, B.M.'s prognosis is very good. In general, prognosis is excellent in youth, but significantly worse in the elderly and in patients with other risk factors for CKD, such as diabetes and hypertension.[62]

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

CASE 29-3, QUESTION 4: Are there other glomerulopathies that cause AKI?

Yes; RPGN, also called crescentic glomerulonephritis, is a clinical syndrome of rapid decline in kidney function (from days to weeks) combined with the hallmark findings of gross hematuria, nephritic syndrome with proteinuria, and the presence of extensive glomerular crescents (>50% of glomeruli) on kidney biopsy. It is not uncommon for patients with RPGN to have a 50% decline in GFR in only a few weeks. RPGN is a medical emergency, and treatment success depends on how early therapy is initiated. If left untreated, progression to kidney failure or death is almost certain.

Idiopathic RPGN is divided into three categories based on immunofluorescence microscopy. Type I idiopathic RPGN is characterized by linear deposition of immunoglobulins (Igs), primarily IgG, along the glomerular basement membrane (GBM) indicating anti-GBM antibodies. Type II idiopathic RPGN is identified by granular Ig and complement depositions in the glomerular microvasculature and mesangium, suggesting immune complex deposition. Type III idiopathic RPGN is also called pauci-immune because there are no hallmark Ig or complement findings on immunofluorescence microscopy. Type III idiopathic RPGN is identified by the presence of circulating antineutrophil cytoplasmic antibodies (ANCA). Type IV, known as *double-antibody disease*, is

characterized by anti-GBM antibodies and ANCA seen in types I and III RPGN.[63]

Multisystem vasculitic disorders that result in glomerular capillary inflammation are the most common cause of RPGN.[64] Many of these patients present with nonspecific flulike symptoms such as fever, weight loss, myalgia, and malaise with proteinuria and hematuria.[65] Uremic symptoms can occur with severe disease. The presence of AKI with pulmonary congestion, cough, hemoptysis, or dyspnea suggests granulomatosis with polyangiitis (formerly known as *Wegener's granulomatosis*).[66] The treatment for autoimmune RPGN generally involves various regimens of immunosuppressive agents. Corticosteroid monotherapy (oral or "pulse" IV) or combined with either cyclophosphamide or rituximab, is often used. Plasmapheresis is also a nonpharmacologic treatment option in selected patients.[67] A more detailed discussion of glomerulonephritis is presented in Chapter 28, Chronic Kidney Disease.

Tubulointerstitial Diseases

ACUTE TUBULAR NECROSIS

ATN arises most often from ischemia or drug-induced causes.[26] Prolonged prerenal conditions, such as hypotension, surgery, overwhelming sepsis, or major burns, can lead to ischemic ATN. Unlike prerenal azotemia, tubular cell death occurs in ATN, and immediate volume resuscitation will not reverse the damage. The pathophysiology of ATN is complex and remains unclear. It is currently thought that when tubular cells die, they slough off into the tubule lumen and contribute to cast formation. The casts completely obstruct the tubule lumen and increase intratubular pressure, which causes a back leak of ultrafiltrate across the tubular basement membrane (**Fig. 29-3**). The aforementioned processes are mediated by a variety of substances, including calcium, phospholipases, and, perhaps, growth factors as well as free radical and protease activation.

Figure 29-3 Schematic of acute tubular necrosis (ATN). The process is initiated by ischemia or nephrotoxin exposure that leads to tubular cell death. The cellular debris sloughs off and obstructs the proximal tubule lumen. Once the nephron is obstructed, a back leak of the glomerular ultrafiltrate occurs across the tubular basement membrane and impairment of glomerular filtration is seen. During the recovery phase of ATN, the obstructive cellular casts are released into the urine and filtration begins to normalize. GFR, glomerular filtration rate.

CLINICAL COURSE

There are three distinct phases of ATN: oliguric, diuretic, and recovery.[25] The oliguric phase generally occurs over the course of 1 to 2 days and is characterized by a progressive decrease in urine production. The oliguric stage may last from days to several weeks. Strict fluid and electrolytes monitoring are required during this phase until kidney function normalizes.

After the oliguric phase, a period of increased urine production occurs for several days; this is called the *diuretic phase*. This phase

signals the initial repair of the kidney insult. The diuretic phase can result, in part, from a return to normal GFR before tubular reabsorptive capacity has fully recovered. The elevated osmotic load from uremic toxins and the increased fluid volume retained during the oliguric phase may also contribute to the diuretic phase. Despite the increased urine production, patients may remain markedly azotemic for several days. The increase in urine output may lead to volume depletion and electrolyte loss if patients are not given adequate replacement therapy. Daily modifications in the fluid and electrolyte requirements are necessary based on urine output.

The recovery phase occurs over the course of several weeks to months, depending on the severity of the patient's AKI. This phase signals the return to the patient's baseline kidney function, normalization of urine production, and the return of the diluting and concentrating abilities of the kidneys.

TREATMENT WITH DIURETICS AND DOPAMINE

CASE 29-4

QUESTION 1: V.B. is an 86-year-old White male, 62 inches (157.48 cm) tall and weighing 138 pounds (62.59 kg) who was admitted for elective aortic valve replacement secondary to severe aortic stenosis. He became hypotensive during surgery, requiring aggressive fluid resuscitation. He is now in the ICU and requires vasopressors for hemodynamic support. His BUN is 88 mg/dL and his SCr is 3.5 mg/dL today, stable over the past 3 days. His baseline SCr before surgery was 1.2 mg/dL. Despite IV fluids, V.B. is oliguric with a urine output of 15 mL/hour (350 mL/day).

Do diuretics and dopamine have a role in treating ATN?

It is well documented that patients with nonoliguric kidney failure have significantly better outcomes compared to those with oliguria. This is probably because patients who are nonoliguric have less extensive kidney damage and are better able to maintain fluid and electrolyte balance. Loop diuretics have been used in established ATN to convert patients with oliguria to a nonoliguric state despite the lack of conclusive evidence for their benefits. Numerous clinical

trials, however, have failed to demonstrate improved mortality or duration of azotemia in patients with oliguria who receive loop diuretics, despite improved urine output.[7] Two large systematic reviews of the primary literature convincingly showed that diuretic therapy plays little role in altering the course of AKI, decreasing length of hospitalization, or helping recover kidney function.[68,69] These data suggest that although patients who are nonoliguric generally have better outcomes, converting a patient from oliguria to nonoliguria through pharmacologic intervention does not improve patient outcomes. According to KDIGO, the diuretic administration in patients with established ATN should be limited to managing fluid overload.[7]An interesting approach is the use of loop diuretics as a test to predict the potential subset of patients with ATN who would need KRT. Based on findings from small clinical studies, patients who respond to a loop diuretic challenge are hypothesized to have an intact tubular function and are less likely to need KRT and hence assist with KRT allocation management, particularly if KRT availability is limited. The challenge consists of administering 1 to 1.5 mg/kg furosemide in euvolemic patients and measuring their urine output over the next following 2 hours. A positive response is deemed if the urine output increases significantly (>200 mL/hour).[70]

Another controversy that has been debated extensively in the literature is the use of dopamine in patients with established ATN. Dopamine is a catecholamine that stimulates dopaminergic receptors at low dosages (1–3 μg/kg/minute), and α- and β-receptors at higher dosages (5–20 μg/kg/minute). Animal and human studies have demonstrated that low-dose dopamine improves kidney blood flow by inducing afferent arteriolar vasodilation. A meta-analysis of 61 clinical trials including nearly 3500 patients failed to detect any significant improvement in variables such as occurrence of AKI, need for KRT, or mortality.[71] Unequivocally, dopamine has no role in preventing or treating AKI.

AT II may have beneficial effects on kidney-related outcomes in vasodilatory shock with kidney failure caused by its ability to constrict the efferent arteriole more selectively than does the afferent arteriole, but further research is needed to confirm these findings of

a post hoc analysis.[72] Other modalities such as fenoldopam or atrial natriuretic peptide (ANP) have not been shown to be conclusively beneficial to treat AKI and hence are not recommended to be used.[7] KRT would be the most appropriate to use if life-threatening changes in fluid, electrolytes, or acid–base balance are noted.

Contrast-Induced Acute Kidney Injury

CASE 29-5

Question 1: K.S., a 74-year-old Black male, 69 inches (175.26 cm) tall and weighing 210 pounds (95.25 kg), presents to the emergency department with chest pain. His medical history is significant for advanced type 2 diabetes mellitus with retinopathy, peripheral vascular disease, and advanced coronary artery disease. Based on cardiac enzymes, K.S. is ruled in for STEMI. He is taken to the cardiac catheterization laboratory for a percutaneous coronary intervention. Immediately before the procedure, K.S. is given iopamidol[73] a nonionic, low-osmolar radiocontrast to enhance visualization of his cardiac arteries. His admission BUN is 37 mg/dL and SCr is 1.5 mg/dL. Two days later, pertinent laboratory findings include a BUN and an SCr of 60 and 2.0 mg/dL, respectively, and his urine output is 700 mL/day.

Why did AKI develop in K.S.? How is his diagnosis substantiated by his clinical findings?

Contrast administration is one of the most common causes of drug-induced ATN. Although no set criteria exist for its diagnosis, it is generally considered after contrast exposure when an increase in SCr of 0.5 mg/dL or 25% greater than baseline occurs in 24 to 48 hours, peaks at 3 to 5 days, and returns to baseline in 1 to 3 weeks.[74–76] Contrast-induced acute kidney injury (CI-AKI) usually presents as a nonoliguric ATN, as observed in K.S., whose urine output is >400 mL/day. Oliguria can develop in more severe cases of CI-AKI. It is also differentiated from other forms of ATN in that the FE_{Na} is usually <1% (vs the typical >2%). The degree of creatinine rise and urine output are widely variable. Because of the lack of an accepted CI-AKI definition and differences in both clinical trial design and populations studied, estimating the true prevalence of CI-AKI is

unknown. Nevertheless, patients without risk factors have a relatively minute risk of developing CI-AKI; for those with recognized risk factors, prevalence may approach 50%.[77]

The mechanisms by which contrast agents induce AKI are complex. Initially, the contrast agent produces kidney vasodilation and an osmotic diuresis. This, however, is followed by intense vasoconstriction in the medullary portion of the kidney, which has been demonstrated by significant decreases in medullary oxygen tension (pO_2) after contrast administration.[78] The ischemia is compounded by the increased medullary oxygen consumption because of the osmotic diuresis. Consequently, disequilibrium exists between oxygen supply and demand, creating ischemic ATN. Various vasoactive substances are suspected of decreasing medullary blood flow, including oxygen free radicals, prostaglandins, endothelin, nitric oxide, AT II, and adenosine. Endothelin and adenosine are potent vasoconstrictors that are directly released from endothelial cells on exposure to contrast.

Case 29-5, Question 2: What risk factors did K.S. have for developing CI-AKI?

The documented risk factors for CI-AKI are listed in **Table 29-5**. Any condition that decreases kidney blood flow increases the risk of kidney failure. Patients with diabetes and CKD, estimated glomerular filtration rate (eGFR) <60 mL/minute/1.72 m^2, HF, volume depletion, or those receiving aggressive diuretic regimens are at high risk for developing CI-AKI. Contrast volume administered during the imaging procedure as well as type of contrast remain additional risk factors.[76,79] The use of the ionic high-osmolar or ionic low-osmolar contrast products increases the risk of kidney failure as well as the previously discussed medications that markedly reduce kidney perfusion (eg, diuretics, NSAIDs, COX-2 inhibitors, ACE inhibitors, and ARBs). However, newer nonionic low-osmolar agents may be less nephrotoxic than are older agents, but still can cause

nephrotoxicity in patients at risk. Nonionic iso-osmolar contrast appears to be better tolerated.[80]

Table 29-5
Proven Risk Factors for Developing Contrast-Induced Acute Kidney Injury

Diabetic kidney disease
Chronic kidney disease
Severe heart failure
Diabetes and multiple myeloma
Volume depletion and hypotension
Dosage and frequency of intravenous radiocontrast administration
Ionic radiocontrast agents

Based on the published literature, gadolinium-based contrast agents (GBCAs) are less nephrotoxic than is iodinated radiocontrast; however, when GBCAs are used in high dosage with arterial injection in patients with advanced kidney disease, AKI can occur. More concerning is the development of debilitating nephrogenic systemic fibrosis (NSF), which is sometimes fatal.[81,82] There is no cure for NSF. Patients with AKI or CKD with GFR <30 mL/minute, who have had imaging studies (eg, magnetic resonance angiography) with GBCAs are at high risk for developing NSF. The FDA has issued an advisory Black Box Warning to avoid using these currently approved GBCAs in AKI and CKD stages G4 and G5.[83]

K.S. is at high risk for developing CI-AKI. It is very likely that K.S. has underlying diabetic-associated CKD, as evidenced by his elevated admission SCr. The presence of retinopathy, coronary artery disease, and peripheral vascular disease suggest long-term uncontrolled diabetes mellitus, a risk factor for kidney failure.

PREVENTION

Case 29-5, Question 3: What strategies could have been performed in K.S. to prevent the occurrence of CI-AKI?

Attempts have been made to minimize or prevent CI-AKI using a variety of approaches. Decreasing contact time and the concentration of contrast within the kidney tubule lumen may reduce its direct toxic effects. A higher urine output is associated with a lower incidence of CI-AKI in high-risk patients.[84,85] Volume expansion is a rational approach to prevent kidney dysfunction in this population because human and animal data have revealed dehydration as a major risk factor for developing CI-AKI. IV hydration with normal saline can prevent CI-AKI in high-risk patients. Infusion rates usually start at 1 mL/kg/hour to maintain a goal urine output of 150 mL/hour. Data suggest normal saline should be infused at least 6 hours before and 6 to 12 hours after the imaging study to adequately reduce the risk of developing kidney failure.

Sodium bicarbonate infusion may be of value.[85] Notably, sodium bicarbonate may be beneficial in decreasing the incidence of CI-AKI because it reduces oxygen free radicals in the kidney medulla and, therefore, increases the medullary pH. However, sodium overload is problematic and sodium bicarbonate should be avoided in compromised cardiac states. The antioxidant N-acetylcysteine (NAC) has also been used for its kidney-sparing effects relative to contrast, but its role in preventing CI-AKI remains unclear.[86] NAC is believed to work by protecting kidney tubule cells from apoptosis related to reactive oxygen species.[87] Although much data has been generated with NAC, many of these studies have significant pitfalls, including relatively small sample size; single-center design; heterogeneity of patient populations; differing doses, dosage forms, and schedules of NAC therapy; and differing hydration regimens.

The prevention of serious adverse events following angiography (PRESERVE) trail set out to enroll 8680 high-risk patients undergoing angiography with contrast. Investigators compared the effectiveness of IV sodium bicarbonate infusion versus normal saline infusion and oral NAC versus oral placebo for prevention of CI-AKI.

The sponsor stopped the trial after the interim analysis of 4993 patients. Among patients at high risk for kidney complications who were undergoing angiography, sodium bicarbonate, and oral NAC were not superior to normal saline infusion for the prevention of CI-AKI, need for KRT or persistent decline in kidney function, or death at 90 days. Routine use of sodium bicarbonate infusion and/or oral NAC is no longer recommended to prevent CI-AKI in patients at risk. More studies are needed in patients undergoing diverse procedures requiring imaging with contrast.[88]

When possible, alternative imaging studies that do not require contrast should be attempted. If this is not practical, the lowest effective dose of nonionic low-osmolar or iso-osmolar contrast should be used. Concomitant drug therapy that can impair kidney perfusion, such as diuretics, NSAIDs, COX-2 inhibitors, ACE inhibitors, and ARBs, should be discontinued 1 day before and 1 day after contrast administration. Metformin is also a risk factor. It is not a nephrotoxin; however, its use has been associated with the development of lactic acidosis, systemic complications, and death in rare cases. It is recommended to temporarily discontinue metformin before the administration of contrast to prevent lactic acidosis in patients at risk such as K.S. with underlying CKD.

Case 29-5, Question 4: What treatment options are available for established CI-AKI?

Few data exist regarding treatment of existing CI-AKI. The acute management largely involves supportive care that includes strict fluid and electrolyte management to prevent undue sequelae. Approximately 25% of patients will require temporary KRT. In more severe cases, patients generally require long-term KRT. As already noted, attempts to convert oliguria to nonoliguria with furosemide and mannitol have been largely unsuccessful.

Aminoglycoside-Induced Acute Tubular Necrosis

CASE 29-6

Question 1: T.G. is an 81-year-old, 176.37 pounds (80 kg) White male 70 inches (177.80 cm) tall being treated for *Streptococcus bovis* prosthetic valve endocarditis. T.G. is known to have systolic congestive HF with an ejection fraction of 25%. T.G. has a low BP at 90/50 mm Hg, pulse 110 beats/minute. Since admission, T.G. has received ceftriaxone 2 g IV daily, and gentamicin 80 mg IV every 8 hours. Today, (hospital day 7), significant laboratory values are as follows:

BUN, 67 mg/dL
SCr, 5.4 mg/dL (baseline 0.9 mg/dL)
WBC count, 16,700 cells/μL with continued left shift
FE_{Na}, 3%

During the past 2 days, T.G.'s urine output has steadily declined, and today it is 700 mL/24 hours. A urinalysis revealed many WBCs, 3% RBC casts, brush-border cells, and granular casts with an osmolality of 250 mOsm/kg. A serum trough gentamicin concentration obtained with the last dose is 6 mg/L (target, <1.0 mg/L).

Given the history and laboratory data, what is the likely source of T.G.'s AKI?

The source of AKI in this situation is likely multifactorial (Table 29-2). Low kidney perfusion secondary to low ejection fraction can result in prolonged kidney ischemia. Second, T.G. has received 1 week of gentamicin, a well-known nephrotoxic antibiotic. The risk factors for developing aminoglycoside nephrotoxicity are listed in **Table 29-6**. The latest gentamicin trough concentration of 6 mg/L is far higher than is the target value of <1 mg/L for a traditional three times daily dosing regimen used for synergy for bacterial endocarditis.[89] Given the laboratory data (Table 29-3), the clinical course of prolonged hypotension, and aminoglycoside administration, nonoliguric ATN is the most likely diagnosis.

Cisplatin
Cyclosporine
Foscarnet
Furosemide
Intravenous contrast agents
Vancomycin

PRESENTATION

Case 29-6, Question 2: How does aminoglycoside-induced ATN present, and what are the mechanisms of toxicity?

T.G. illustrates the typical presentation of aminoglycoside-induced nephrotoxicity. Generally, the onset occurs after 5 to 7 days of treatment and presents as a hypo-osmolar, nonoliguric kidney failure with a slow rise in SCr.[90] Because of the tubular necrosis that occurs, the urinalysis is often positive for low-MW proteins, tubular cellular casts, epithelial cells, WBCs, and brush-border cells.[91] T.G.'s plasma and urinary laboratory indices are consistent with those listed for ATN in Table 29-3.

The mechanism of aminoglycoside-induced ATN is complex. Approximately 5% of filtered aminoglycoside is actively reabsorbed by the proximal tubule cells. These agents are polycationic and bind to the negatively charged brush-border cells within the tubule lumen. Once attached, these agents undergo pinocytosis and enter the intracellular space, setting off complex biochemical events that result in the formation of myeloid bodies. With continued formation of myeloid bodies, the brush-border cells swell and burst, releasing large concentrations of aminoglycoside and lysosomal enzymes into the tubule lumen, thereby beginning a cascade of further tubular destruction.[90,92] The following rank order of nephrotoxicity has been collated from human and animal data: neomycin > gentamicin > tobramycin > amikacin > netilmicin > streptomycin.[91]

EXTENDED-INTERVAL DOSING

Case 29-6, Question 3: Is "extended-interval" aminoglycoside dosing less nephrotoxic than are multiple daily dosing regimens?

Extended-interval aminoglycoside dosing entails the administration of one large daily aminoglycoside dose instead of multiple daily dosing. This dosing scheme takes advantage of the concentration-dependent killing activity and postantibiotic effect observed with aminoglycosides while minimizing time-dependent toxicity. The net effect of this dosing scheme, purportedly, is greater efficacy with reduced toxicity. Aminoglycoside nephrotoxicity is a function of drug exposure, and it might be minimized with extended-interval dosing because of saturable uptake kinetics in the proximal tubule. That is, only a maximal amount of aminoglycoside is transported into the tubule cell, no matter how much aminoglycoside is present in the tubule. Consequently, once saturation occurs, the remaining aminoglycoside concentration passes through the proximal tubule without being absorbed and is excreted in the urine. Accumulation is therefore averted.[93] Aminoglycosides, such as gentamicin 1 mg/kg every 8 hours or 3 mg/kg once daily, adjusted for kidney function are

recommended by the American Heart Association for the management of selected cases of bacterial endocarditis for their synergistic activity with the β-lactams. The extended-interval dosing is less well studied for endocarditis.[89] In summary, extended-interval aminoglycoside dosing appears to result in similar or greater efficacy, with similar or reduced toxicity. This dosing schedule is also less costly when considering therapeutic drug monitoring, preparation, and administration costs.

Drug-Induced Acute Interstitial Nephritis

Drug-induced acute interstitial nephritis (DI-AIN) accounts for ~1% to 3% of all AKI cases.[94–98] A variety of antibiotics, such as penicillins, cephalosporins, quinolones, particularly ciprofloxacin, sulfonamides, and rifampin, as well as NSAIDs, loop diuretics, thiazide-like diuretics, and proton-pump inhibitors, have been implicated as common drug causes of AIN. The pathophysiology of this reaction is not well understood; it is suspected that either humoral or cell-mediated immune mechanisms or both are involved.[99] Humoral immune reactions occur within minutes to hours of drug exposure and involve the drug or its metabolite acting as a hapten that binds to host proteins, making them antigenic. The drug–protein antigens become lodged in the kidney tubules, which initiate the inflammatory cascade. Cell-mediated injury can occur days to weeks after drug exposure and is identified by the presence of mononuclear inflammation and the lack of detectable immune complexes. This suggests a delayed hypersensitivity rather than a direct cytotoxic effect from a given drug. Both immune mechanisms probably contribute to the development of DI-AIN.

PENICILLIN-INDUCED ACUTE INTERSTITIAL NEPHRITIS

CASE 29-7

Question 1: J.S. is a 50-year-old Hispanic female, 63 inches (160.02 cm) tall and weighing 160 pounds (72.57 kg), who exhibited cellulitis 3 days after a car

door was closed on her right hand. She was admitted to the hospital, where blood and wound cultures were found to be positive for methicillin-sensitive *Staphylococcus aureus*. She received 2 full days of nafcillin 2 g IV every 4 hours before being discharged to complete a 14-day course with dicloxacillin 500 mg PO four times daily (qid). Ten days after discharge, J.S. returned to the emergency department with weakness, fever, diffuse rash, blood in the urine, and reduced urine output. The following laboratory values were significant:

BUN, 39 mg/dL
SCr, 2.3 mg/dL
WBC count, 18,500 cells/μL with 18% eosinophils
The urinalysis was positive for elevated specific gravity, WBCs, RBCs, eosinophils, and an FE_{Na} of 3%.

What objective data suggest DI-AIN?

J.S.'s onset of symptoms suggests antibiotic-induced AIN. As illustrated by this case, the median onset of penicillin-induced AIN generally occurs 6 to 10 days after drug exposure. Hallmark symptoms of antibiotic-associated AIN include fever, macular rash, and malaise. Fever is present in nearly all patients with antibiotic-induced AIN, and rash occurs in 25% to 50% of patients. In contrast, NSAIDs, proton-pump inhibitors, and rifampin are less commonly associated with rash, fever, eosinophilia, and eosinophiluria, and the onset of AIN may occur several weeks to months or longer following drug exposure.[27,94,98,99] J.S.'s objective laboratory data that suggest AIN include azotemia, elevated SCr, proteinuria, cellular urinary sediment, eosinophilia, and eosinophiluria. Her FE_{Na} of 3% suggests intrinsic kidney disease, and her eosinophiluria and eosinophilia indicate an immune-mediated allergic reaction. DI-AIN is generally nonoliguric, but oliguria can develop in severe cases of AIN.

Case 29-7, Question 2: How should J.S.'s penicillin-induced AIN be treated?

Treatment of AIN includes eliminating the precipitating drug, leading to kidney inflammation from an enhanced immune response. The dicloxacillin should be stopped immediately because most patients recover normal kidney function once the offending agent is

discontinued. A non–penicillin antibiotic, clindamycin or doxycycline, may be chosen to finish the course of treatment for cellulitis. However, J.S. has completed 12 out of 14 days of antibiotic therapy, and alternative agents would be optional. General supportive measures that maintain fluid and electrolyte balance are necessary. Kidney recovery may take weeks to months. Use of steroids to treat AIN has been reported in retrospective trials and case reports, but randomized controlled trials are needed to evaluate their benefits versus risks.

KRT may be needed in patients who are oliguric, but it is usually not required for those who are nonoliguric. The clinician should document J.S.'s allergic reaction to penicillins in her medical record, and not rechallenge the patient to antibiotics with similar chemical structures because repeated exposure is likely to result in similar reactions.

Crystal-Induced AKI

Crystal-induced AKI most commonly occurs as a result of uric acid kidney injury or following the administration of drugs or toxins that are poorly soluble or have metabolites that are poorly soluble in urine. Other drugs or toxins (eg, ascorbic acid, ethylene glycol) may be metabolized to insoluble products such as oxalate, which are associated with precipitation of calcium oxalate crystals in the urine within the tubular lumen resulting in kidney injury.[100,101]

PRESENTATION AND TREATMENT

CASE 29-8

Question 1: T.C., a 45-year-old male with a past medical history of schizophrenia treated with aripiprazole, was seen in an outpatient clinic 7 days before admission where he was started on a 7-day course of oral acyclovir 800 mg five times a day for a diagnosis of herpes zoster. He presents to the emergency department with sharp flank pain, gross hematuria, and dysuria. Serum chemistries are ordered and are significant only for an elevated BUN of 34 mg/dL and an SCr of 1.5 mg/dL, compared to his baseline values of 7 and

0.9 mg/dL, respectively. A urine sample was obtained and visualized with microscopy. Birefringent needle-shaped crystals were seen on polarizing light microscopy. It was consistent with acyclovir-induced kidney injury. On questioning, he admits that he has not been drinking enough fluid during the past week owing to a busy work schedule, and his urine volume has been markedly lower than usual.

Which drugs can crystallize in the urine and cause AKI?

Many commonly prescribed drugs such as acyclovir used in T.C. are insoluble in urine and crystallize in the distal tubule.[102] Some of the risk factors that predispose patients to crystalluria include severe volume contraction, underlying kidney dysfunction, or acidotic or alkalotic urinary pH. In conditions of kidney hypoperfusion, high concentrations of drug become stagnant in the tubule lumen.[102] Drugs that are weak acids (eg, methotrexate, sulfonamide antibiotics) precipitate in acidic urine; drugs that are weak bases (eg, ciprofloxacin, indinavir, and other protease inhibitors) precipitate in alkaline urine. Patients with drug-related crystal-induced AKI are usually asymptomatic, and kidney injury is detected by an increased SCr. Occasionally, as in the case of T.C., patients present within 1 to 7 days after initiation of the offending drug with kidney colic symptoms such as flank or abdominal pain, nausea, or vomiting. Urinalysis often reveals hematuria, pyuria, and crystalluria. The diagnosis is suggested by the appearance of crystals in the urine, the morphology of which depends on the specific causative drug. Prevention of crystal-induced AKI is targeted at dosage adjustment for patients with underlying kidney dysfunction, volume expansion to increase urinary output, and urine alkalization to enhance kidney elimination of drugs that are weak acids or urine acidification to enhance kidney elimination of drugs that are weak bases. KRT may be necessary in a small percentage of patients. With appropriate pharmacotherapy, crystal-induced AKI is usually reversible without long-term complications.[102]

Kidney Stones

Calcium stones constitute ~70% to 80% of all kidney stones,[103] with calcium oxalate and calcium phosphate stones making up most of these. Genetic factors appear to play an important role in the development of kidney stones; the stereotypical patient is a male in his third to fifth decade of life. Other risk factors for developing calcium kidney stones are low urine output, inadequate hydration (eg, living in a hot climate and not drinking adequate fluids), hypercalciuria, hyperoxaluria, hypocitraturia, hyperuricosuria, and distal kidney tubular acidosis. Generally, more than one of these conditions are present simultaneously. The diagnosis and management of kidney stones are beyond the scope of discussion in this chapter. However, pharmacists can be instrumental in providing proper counseling on hydration and preventive measures.

SUPPORTIVE MANAGEMENT OF ACUTE KIDNEY INJURY

CASE 29-9

Question 1: J.W. is a 75-year-old Native American male, 74 inches (187.96 cm) tall and weighing 200 pounds (90.72 kg), who presents to the emergency room with shortness of breath and progressive worsening edema in both lower extremities. His medical history includes nephrotic syndrome secondary to diabetic nephrosclerosis, type 1 diabetes, hypertension, and chronic obstructive pulmonary disease. His surgical history includes a right-sided nephrectomy many years ago. His chronic medications are furosemide 80 mg PO twice a day, metolazone 10 mg PO once a day, lisinopril 5 mg PO once a day, diltiazem extended-release 120 mg PO once a day, albuterol, inhaler as needed, and subcutaneous 20 units of insulin glargine at bedtime, and insulin aspart as directed before meals. Vital signs are temperature 97.34 °F (36.3 °C), pulse 77 beats/minute, respirations 16 breaths/minute, and BP 179/86 mm Hg. Physical examination reveals periorbital edema, jugular venous distension at a 45-degree angle to the jaw, dullness to percussion halfway up the lungs bilaterally, and 4+ pitting edema in the extremities. Admitting laboratory tests reveal the following:

Sodium, 140 mEq/L
Potassium, 5.5 mEq/L

Chloride, 103 mEq/L
Bicarbonate, 19 mEq/L
Glucose, 249 mg/dL
BUN, 67 mg/dL
SCr, 5.2 mg/dL
Serum albumin, 2.0 g/dL
Spot urine albumin:creatinine ratio, 350 mg/g

Baseline kidney function tests 1 month ago are BUN 45 mg/dL and SCr 3 mg/dL. J.W. is oliguric with a urine output of 10 mL/hour. The nephrologist wants to use supportive management of AKI by first optimizing diuretic therapy. If no increase in urine output occurs during the next several hours, then the patient will undergo KRT.

What is the supportive management of AKI?

Despite years of study, no pharmacologic "cure" for AKI exists. Supportive management is therefore directed at preventing its morbidity and mortality. This is achieved by close patient monitoring; strict fluid, electrolyte, and nutritional management; treatment of life-threatening conditions such as pulmonary edema, hyperkalemia, and metabolic acidosis; avoidance of nephrotoxic drugs; and the initiation of dialysis or continuous renal replacement therapy (CRRT).[7]

An assessment of volume status should be performed in all patients who present with AKI, because correction of volume depletion or volume overload may reverse or ameliorate AKI. The underlying cause dictates management of AKI. For example, prerenal AKI because of volume-depleted states, such as the initial phase of septic shock, requires administration of fluids and vasopressors to restore kidney perfusion and increase urine output. On the other hand, diuretic administration for preload reduction to increase cardiac output would be required for prerenal AKI owing to volume-overload states such as HF.

As discussed earlier, diuretics currently have no role in preventing AKI progression or reducing mortality, but they can prevent complications, such as pulmonary edema in patients with fluid overload.[7] For pulmonary edema, IV furosemide (eg, 80–120 mg) is preferred because of its potency and pulmonary vasodilation properties. Oral furosemide therapy should be avoided because gut edema may limit its bioavailability. Torsemide and bumetanide are

two other loop diuretics that have excellent oral bioavailability and are unaffected by gut edema. The dosage of diuretic needed is highly patient specific, especially in those with frank proteinuria, glomerulonephritis, or nephrotic syndrome. Patients who do not respond therapeutically to an effective loop diuretic dose are labeled as diuretic resistant. Many hypotheses have been postulated to explain the lack of response to loop diuretics.[104] For example, low serum albumin could limit drug transport to the kidneys where the loop diuretics exert their action in the ascending loop of Henle to block sodium and water reabsorption. Coadministration of furosemide with albumin (FUR-ALB), to enhance furosemide's effectiveness has been evaluated in a recent meta-analysis[105] and been found to transiently increase the diuresis volume at 8 hours after a FUR-ALB dose. Unfortunately, the effect was not sustained beyond 24 hours questioning the clinical significance of the combination. Albumin is an expensive therapy, and the combination with loop diuretic benefit–risk ratio should be carefully weighed until large randomized clinical trials provide further evidence. In addition, under some conditions such as glomerulonephritis and nephrotic syndrome, furosemide binds to filtered proteins negating its pharmacologic effect.[104] Other tools to overcome loop diuretic resistance include combining the loop diuretic with a thiazide diuretic such as parenteral chlorothiazide or oral metolazone. This combination acts synergistically to block sodium and water reabsorption in both the Henle loop and the distal convoluted tubule.[106] In patients with diuretic resistance, compensatory reabsorption of sodium by the distal tubule is postulated to be the culprit, and to get the optimal benefit of the combination, it is important to administer the thiazide diuretic 30 minutes before the IV loop diuretics. Other alternatives include continuous loop diuretic infusions, such as furosemide 10–40 mg/hour.[106] The infusion rate should not exceed 4 mg/minute because these rates are associated with ototoxicity, especially when given in combination with aminoglycoside antibiotics. Close monitoring of serum bicarbonate, potassium, magnesium, and calcium is necessary when administering large doses of loop diuretics. Diuresis should aim for a

weight loss of 0.5 to 1 kg/day. If diuretics fail to achieve the desired fluid overload reduction, dialysis or KRT can be considered.

Hyperkalemia commonly occurs in patients with AKI because the kidneys regulate potassium homeostasis. It can be life-threatening. It is prevalent in patients with oliguria who are catabolic or have evidence of active cellular breakdown, such as rhabdomyolysis and TLS. J.W. is mildly hyperkalemic, but his serum potassium may decrease after furosemide therapy. Management of hyperkalemia is discussed in Chapter 27, Fluid and Electrolyte Disorders. In cases of severe hyperkalemia in which conventional pharmacologic treatment is not feasible, or not working, emergency KRT should be performed. Medications that can cause hyperkalemia such as ACE inhibitors, ARBs, or trimethoprim should be avoided.

Metabolic acidosis is a common manifestation of AKI because the kidneys are responsible for excreting organic acids. Other factors also contribute to severe acidosis among patients with AKI, who are often critically ill. For example, patients with AKI because of septic shock, trauma, and multiorgan failure often have increased production of lactic acid or ketoacids. J.W.'s serum bicarbonate concentration reveals slight acidemia that does not require correction at this time. Commonly used treatments for metabolic acidosis include bicarbonate administration and KRT. Bicarbonate therapy may be administered as first corrective therapy, in non–life-threatening and non–fluid-overloaded metabolic acidosis. Severe metabolic acidosis (pH <7.1) in the presence of anuria or oliguria and a fluid overload state should be corrected with KRT, because worsening volume overload can occur with the administration of sodium bicarbonate therapy.

Uremia can interfere with platelet aggregation resulting in hemorrhagic diathesis. Patients with uremia display increased bleeding sensitivity to aspirin compared to normal patients taking aspirin. Patients with uremia and major hemorrhagic bleed may benefit from using desmopressin (dDAVP) 0.3 μg/kg intravenously or subcutaneously for one or two doses. Desmopressin produces a dose-related increase in von Willebrand factor VII and tissue-type plasminogen activator (t-PA) levels; this shortens activated

antithromboplastin time (aPTT) as well as bleeding time. The improvement in bleeding time typically begins within about 1 hour to 4 to 8 hours. Tachyphylaxis typically develops after the second dose. Other modalities that can improve platelet function and reduce bleeding in a patient with AKI include KRT, conjugated estrogens, and cryoprecipitate.[107] Severe uremia may also signal buildup of several toxic compounds and contribute to metabolic encephalopathy.

Clinicians should closely monitor the patient's vital signs (eg, weight, temperature, BP, pulse, and respirations) several times per day. The patient's volume status should be assessed daily, and all fluids should be adjusted based on laboratory chemistries to detect fluid and electrolyte abnormalities, urine output, and gastrointestinal (GI) and insensible losses. Pharmacists should pay attention to nutritional support for patients with AKI to provide adequate amounts of energy, protein, and nutrients, while being sensitive to the electrolytes, acidosis, and volume balance issues. The patient's medication profile should be reviewed daily to assess for appropriate dosage adjustment in kidney dysfunction. Preventive measures to reduce the likelihood of AKI should be used, such as monitoring volume status to ensure adequate kidney perfusion, using dosing strategies or products that are associated with less nephrotoxicity, and avoiding drug therapy combinations that enhance nephrotoxicity (eg, NSAID, aminoglycosides, vancomycin and piperacillin/tazobactam).[108,109]

Drug Dosing in Acute Kidney Injury

Many drugs are eliminated at least in part by the kidneys and must be dosed according to kidney function. A more detailed discussion of drug dosing in the presence of compromised kidney function is provided in Chapter 31, Dosing of Drugs in Kidney Failure. Thus, standard doses and dosing intervals of many agents in the presence of AKI may lead to increased drug exposure of the active drug or metabolites. It is important to recommend appropriate drug doses in

the presence of AKI. Some clinicians make dosing recommendations based on eGFR <15 mL/minute as an initial guide for drug therapy in a patient with AKI not receiving CRRT when no other information is available. Drugs not essential for care should be discontinued to avoid potential drug-induced toxicity in the presence of AKI.

Careful monitoring of clinical and biochemical surrogate parameters associated with efficacy and toxicity and therapeutic drug monitoring, especially for drugs with a narrow therapeutic index eliminated by the kidneys, are required. High-risk medications such as aminoglycosides, vancomycin, and piperacillin/tazobactam, and calcineurin inhibitors (eg, cyclosporine, tacrolimus), those with known nephrotoxicity, or other potential toxicities associated with supratherapeutic serum concentrations should be closely monitored. It is also important to note the volume of distribution (V_d) of drugs such as aminoglycosides, vancomycin, β-lactams (eg, most cephalosporins, carbapenems) is dramatically increased in the presence of AKI. Therefore, larger loading doses may need to be administered to avoid subtherapeutic responses from lower than desired serum concentrations.[27,110,111] For most drugs, clinically useful serum drug assays are unavailable. Therefore, trends in kidney function indices (eg, SCr and urine output) along with volume status and response to therapy should be utilized to guide drug dosing. Further dose adjustments may be necessary when KRT is provided.

Kidney Replacement Therapy

INDICATIONS

KRT is not always indicated in AKI. The A-E-I-O-U mnemonic is used to help remember the indications for KRT, where “A” stands for intractable refractory acidosis, “E” refers to electrolyte abnormalities, specifically potassium with EKG changes, “I” refers to ingestion of toxins such as salicylates and ethylene glycol, “O” stands for fluid overload causing pulmonary edema, and “U” refers to symptomatic uremia with confusion, platelet dysfunction and severe bleed, and

seizures. Particularly in the hospitalized patient, these may be considered emergency indications to proceed with KRT.

TIMING

The timing of KRT initiation for AKI without these emergency indications has been more controversial. A landmark trial, the STandard versus accelerated initiation of renal-replacement therapy in acute kidney injury (STARRT-AKI), found no difference in 90-day mortality when comparing an early approach to KRT with a more conservative "watch and wait" approach.[112] KRT also has risks that must be weighed in the decision to initiate KRT, including acute risks such as hypotension, arrhythmias, and vascular access placement complications, as well as long-term considerations including an increased risk of kidney failure and the need for KRT chronically.

MODALITIES

KRT utilized for AKI can be divided into either intermittent hemodialysis (IHD) or CRRT.[3] CRRT runs continuously over 24 hours as opposed to IHD that may last a few hours. Extended daily dialysis (EDD) or sustained low-efficiency dialysis (SLED) or prolonged intermittent KRT are alternatives to both CRRT and IHD. These are typically done daily over 6 to 12 hours using a traditional IHD machine. CRRT may be preferred in patients who are hemodynamically unstable or requiring vasopressor support. Over the years, several CRRT modalities have been developed to treat patients with AKI. Not all CRRT are alike[113]; many variations exist and include modalities such as continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), continuous venovenous hemodiafiltration (CVVHDF), slow continuous ultrafiltration (SCUF), and continuous venovenous high-flux hemodialysis (CVVHFD). The decision to use one modality over another is most often decided by resources available, institutional guidelines, or the nephrologist's experience and comfort level.[37,113]

Refer to Chapter 30, Dialysis Treatment for Chronic Kidney Failure for a complete overview of peritoneal dialysis (PD) and IHD.

PRINCIPLES OF SOLUTES AND WATER REMOVAL IN CONTINUOUS RENAL REPLACEMENT THERAPY

CRRT treatments are currently performed using a double-lumen catheter as vascular access, with a venovenous technique, whereby the blood driven from a vein returns to the same vein after being purified in an external circuit/filter. This process generates an ultrafiltrate or an effluent that is pumped out of the body (**Fig. 29-4**). Solutes and water transport occur through a semipermeable membrane in the external circuit via three different mechanisms: diffusion, convection, and membrane adsorption.[113] The effluent rate in CRRT is often referred to as the *dose* of CRRT. A typical CRRT prescription for AKI will be 20 to 25 mL/kg/hour effluent volume[7] and is important to consider in evaluation of drug dosing.[114]

Continuous venovenous hemodialysis

Continuous venovenous hemofiltration

Figure 29-4 Continuous venovenous hemofiltration (CVVH) and continuous venovenous hemodiafiltration (CVVHD) modalities of continuous renal replacement therapy (CRRT).

Continuous Venovenous Hemofiltration and Convection

CVVH uses convection for solute transport. In convection, water is pushed through the membrane using hydrostatic pressure. As the water passes through the membrane, it drags toxins and other

wastes. This process is referred to as *solvent drag*, and is effective in removing molecules that are <15,000 Da. In addition, solute removal by convection is influenced by ultrafiltration rates, protein binding, and blood solute concentration. The ability of molecules to pass through a membrane by convection is termed *sieving coefficient* (SC). The SC ranges from 0 to 1 with an SC of 1 representing free movement, whereas an SC of 0 represents no movement across the membrane. The effluent rate in CVVH is the ultrafiltration rate.[113–115]

Continuous Venovenous Hemodialysis and Diffusion

CVVHD uses diffusion for solute transport. Diffusion is the movement of solutes from an area of higher solute concentration to an area of lower concentration (dialysate). A concentration gradient is produced by running an electrolyte solution (known as *dialysis fluid* with a flow rate of 17–40 mL/minute) countercurrent to the flow of blood. The rate of diffusion of a solute is also inversely related to its molecular radius. Low-weight molecules (<500 Da) will diffuse faster than do higher MW ones. The effluent rate in CVVHD is the dialysate rate.[113,114]

Continuous Venovenous High-Flux Hemodialysis and Hemodiafiltration

CVVHDF combines convection and diffusion, which can enhance solute and water removal rates. The effluent flow rate is the sum of the ultrafiltrate and dialysate.[113]

Slow Continuous Ultrafiltration

SCUF is another type of KRT used for volume overload in patients needing fluid removal without the need for removal of metabolic waste products such as BUN or other toxins. The removal of fluid occurs via ultrafiltration.[113]

COMPLICATIONS OF CONTINUOUS RENAL REPLACEMENT THERAPY

CRRT has many complications that should be considered in the benefit–risk analysis before initiation of and for continuation of therapy.[3,115] **Table 29-7** lists encountered complications with CRRT. Owing to the slower blood flow rate used in CRRT, blood remains in contact with an exogenous catheter for prolonged periods of time, which predisposes to clotting that would impact functioning of the filter or dialyzer. The preferred anticoagulation in CRRT is often regional citrate (ie, within the extracorporeal circuit only), but systemic unfractionated heparin continuous infusion may also be used.[7] When regional citrate is used, it is important to monitor serum ionized calcium levels to prevent hypocalcemia induced by the formation of the citrate–calcium complex, which is behind the anticoagulant effect of the regional citrate. Ionized calcium is an important cofactor in the anticoagulation cascade. By complexing with calcium, citrate reduced circulating ionized calcium available to form a blood clot.[113,115]

Table 29-7

Complications of Continuous Renal Replacement Therapy

Vascular Access Malfunction	Circuit/Filter Clotting	Venous Thrombosis
Air embolism	Hypothermia	Bleeding
Hemolysis	Thrombocytopenia	Hypotension
Arrhythmias	Infection	Acidemia and electrolytes abnormalities (hypernatremia, hypokalemia, hypophosphatemia, hypocalcemia, hypomagnesemia)
Allergic reactions to hemodialyzer/hemofilter	Suboptimal medications dosing, especially antimicrobials	Nutritional deficiencies

ESTIMATING DRUG REMOVAL

Case 29-9, Question 2: Are there ways to calculate drug removal in CRRT modalities?

Recent reviews provide an excellent background on dosing drugs in patients receiving CRRT.[7,110,114,116–118] The principles for drug removal in hemofiltration are basically identical with those for removal in hemodialysis. Drug removal during CRRT may occur by convection, diffusion, and adsorption. Convection and diffusion have the greatest influence on drug removal. Drug removal is inversely proportional to the percentage of drug that is protein bound. If a drug is >80% plasma protein bound, little will be removed. This principle holds true for convection and diffusion. Ultrafiltration rates and dialysis flow rates (UFRs/DFRs) also affect drug clearance. Because CRRT uses highly permeable membranes, the MW of most drugs has little impact on overall clearance. During convection, clearance of an unbound drug can be dramatic because CVVH can easily remove compounds with MW <15,000 Da. The impact of MW on drug removal during CVVHD is greater than the impact seen during CVVH. Solute clearance during CVVHD is dependent on diffusion, and given that diffusion is inversely proportional to MW, the greatest impact is seen with drugs having an MW <500 Da. Many drugs have low MW, and hence CVVHD can impact their removal significantly. Clearance of unbound drugs during CVVH can be dramatic, and dose adjustments are required to prevent underdosing. Drug dosing can be difficult in patients receiving these therapies, especially in those who are undergoing both dialysis and hemofiltration modalities (ie, CVVHDF).

Given the complexity of dosing in CRRT, pharmacists should use specific CRRT dosing modifications derived from primary or tertiary references. Extrapolating dose adjustments from IHD/PD literature is

not considered appropriate. Drug references such as “Demystifying Drug Dosing in Renal Dysfunction” provide useful guidelines in a concise tabular format.[119]

Dialysis Treatment for Chronic Kidney Failure

Michelle M. Richardson

CORE PRINCIPLES		CHAPTER CASES
1	Chronic kidney failure requiring dialysis occurs when there is progressive loss of kidney function over months to years resulting in the kidneys being unable to remove wastes; concentrate urine; maintain acid–base homeostasis; and regulate fluid, electrolytes, and other important bodily functions.	**Case 30-1 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	Hemodialysis (HD) is a process that attempts to mimic the excretory function of a healthy kidney by facilitating removal of excess water and solutes from the body, both of which accumulate as a result of inadequate kidney function. Solutes from the blood are removed through diffusion and convection. Accumulated water is removed by ultrafiltration.	**Case 30-1 (Questions 1, 6), Figures 30-1, 30-2**
3	HD requires vascular access. Different types of vascular access include arteriovenous (AV) fistula, AV graft, and double-lumen or tunneled central venous catheter (CVC). In most circumstances, an AV fistula is preferred because of its longer survival rates and lower rates of complications.	**Case 30-1 (Question 1), Figures 30-3–30-5**
4	Dialysate is an electrolyte-containing solution that is used to facilitate removal of metabolic end products and excess electrolytes and fluid. The concentration of electrolytes in dialysate can be manipulated to control the diffusion of electrolytes from the blood into the dialysate to maintain homeostasis. Metabolic acidosis is controlled with the addition of a buffering agent such as bicarbonate or lactate to the dialysate.	**Case 30-1 (Question 1), Table 30-1**

CORE PRINCIPLES		CHAPTER CASES
5	The ability of a dialyzer membrane to remove solutes and water is determined by its composition, pore size, surface area, and configuration.	**Case 30-1 (Question 2)**
6	Anticoagulation is necessary during HD to prevent clotting in the extracorporeal circuit. Several methods have been used to provide adequate anticoagulation without increasing the risk of bleeding.	**Case 30-1 (Questions 3–5)**
7	Complications can arise during HD. The most common complications are hypotension and skeletal muscle cramping, along with vascular access thrombosis and infection.	**Case 30-1 (Questions 7–10)** **Case 30-2 (Question 1)**
8	The process of peritoneal dialysis (PD) is similar to that of HD; in this process, however, the peritoneal membrane covering the abdominal contents serves as an endogenous dialysis membrane and the vasculature embedded in the peritoneum serves as the blood supply. Fluid is removed by manipulating the dextrose concentration in dialysate to control the osmotic pressure gradient for fluid and electrolyte removal.	**Case 30-3 (Question 1)**

	CORE PRINCIPLES	CHAPTER CASES
9	Continuous ambulatory peritoneal dialysis (CAPD) is performed by instilling sterile dialysate into the peritoneal cavity through a surgically placed catheter. The dialysate dwells within the peritoneal cavity for a prescribed amount of time (typically 4–8 hours) and is drained and replaced with fresh dialysate. This process of fill, dwell, and drain is performed three to four times during the day, with a longer dwell overnight.	**Case 30-3 (Question 1), Figure 30-6**
10	Preventing PD catheter exit-site infections (and decreasing the risk of peritonitis) is the primary goal of exit-site care. Routine care consists of hand cleansing with antiseptics or antibacterial soap before touching the exit site, washing the exit site daily with antibacterial soap, and using antimicrobial creams around the exit site.	**Case 30-3 (Question 2)**
11	The most significant complication among patients receiving PD is peritonitis. Empiric antibiotics can be administered by the intraperitoneal (IP) route and must cover both gram-positive and gram-negative organisms.	**Case 30-3 (Questions 3–7)**

CORE PRINCIPLES		CHAPTER CASES
12	Other medications can be administered IP. Heparin can be added to dialysate to prevent fibrin clots from forming and obstructing outflow from the peritoneal cavity. Regular insulin can be administered IP to patients with diabetes mellitus.	**Case 30-3 (Questions 5, 6, 8)**

INTRODUCTION

Kidney failure affects all aspects of bodily functioning. Failed kidneys can no longer remove wastes, maintain acid–base homeostasis, regulate fluid and electrolytes, and perform endocrine functions.

Without replacing the excretory function of a healthy kidney, patients with kidney failure will die from metabolic complications. The international organization, Kidney Disease: Improving Global Outcomes (KDIGO) published findings from a consensus conference proposing standardized nomenclature to describe kidney function and disease. Kidney failure is defined as having an estimated glomerular filtration rate (eGFR) <15 mL/minute/1.73 m^2 for ≥3 months or requiring dialysis. Dialysis and kidney transplantation (discussed in Chapter 34, Kidney and Liver Transplantation) as treatments for kidney failure are called *kidney replacement therapy* (KRT).[1] Hemodialysis (HD) and peritoneal dialysis (PD) are the two types of dialysis. Both remove metabolic waste products and water from the blood and use dialysate to create concentration gradients to promote diffusion across a semipermeable membrane. Choosing which type of dialysis to use takes into account many factors including clinical, lifestyle, patient preference, and local availability and expertise.

Despite improved survival over the past two decades, all-cause mortality rates are higher for patients treated with dialysis compared to the general population, and highest in the second and third months after starting dialysis. In 2018, adjusted mortality rates for those 66 to 74 years of age receiving dialysis were >10-fold higher for males and >15-fold higher for females compared to those not receiving dialysis.[2] Annually, the United States Renal Data System (USRDS) publishes an extensive report on KRT using data from the Centers for Medicare and Medicaid Services. In 2017, the most recent year complete data are available, 124,500 incident, or new to KRT, patients started dialysis. The incidence rate has been stable since 2015. In contrast, since 2006 the standardized prevalence rate (ie, the total number of patients treated with dialysis in 1 year), has continued to increase, and in the setting of stable incident patient rates, is likely due to improved care and decreased mortality. In 2017, there were 746,557 prevalent, or the number of existing, patients receiving dialysis in the United States.[2]

According to the USRDS, kidney failure requiring dialysis disproportionally affects patients 45 years of age and older; diabetes and hypertension continue to be the leading causes of kidney failure; and racial and ethnic differences persist. A gap in care also exists. Nearly one-third of patients treated by dialysis receive little or no care for their kidney disease before starting dialysis.[2]

A large percentage (86.9%) of incident, or new, patients choose HD as their initial type of KRT. Only 10.1% of patients start KRT with PD and even fewer patients (2.9%) have preemptive kidney transplantation before starting dialysis. Taking the entire dialysis patient population as a whole (ie, prevalent patients), 62.7% of patients receive HD and 7.1% of patients receive PD. However, the number of patients with functioning kidney transplants increases dramatically to 29.9%.[2] Increasing home dialysis and early kidney transplants is a goal of the Advancing American Kidney Health initiative through the U.S. Department of Health and Human Services. By 2025, the initiative aims for 80% of new patients to receive home dialysis or a kidney transplant.[3] Improved care for patients with chronic kidney disease (CKD) before their needing KRT

may help achieve the goal of more patients treated with home-based therapies and receiving preemptive or early kidney transplants.

The increasing numbers of patients with kidney failure treated with dialysis, racial and ethnic disparities, and the high mortality rate necessitate practitioners who understand the processes and therapies for these patients. This chapter addresses the fundamental clinical aspects of both HD and PD, including principles, common treatment complications, and management. Throughout the chapter, reference is made, when appropriate, to kidney-specific clinical practice guidelines. There are three main sources of KRT-specific clinical guidelines. International clinical practice guidelines and consensus conferences on controversial topics are sponsored by KDIGO. The U.S. National Kidney Foundation supports the Kidney Disease Outcomes Quality Initiative (KDOQI), and the International Society of Peritoneal Dialysis (ISPD) produces clinical guidelines specific to PD.

GENERAL PRINCIPLES OF DIALYSIS

There are no hard and fast rules or specific eGFR for starting dialysis. The decision to begin dialysis is based on the patient's clinical status and symptoms. Severe or intractable hyperkalemia or metabolic acidosis and intolerable uremic symptoms such as nausea, pruritus, malaise, or diuretic-resistant fluid overload are generally considered indications to start dialysis. Once the eGFR is ~10 to 15 mL/minute/1.73 m^2, most patients will exhibit signs and symptoms of kidney failure. However, there is significant variation in the level of eGFR at which patients experience clinical status decline or symptoms.[4,5]

Dialysis is a process that facilitates the removal of wastes, along with excess water, metabolic end products, and electrolytes from the body that accumulate because of inadequate kidney function. The process of dialysis requires three components—a semipermeable membrane, dialysate, and blood flow. The principles of diffusion,

convection, and ultrafiltration interplay with the three components in an attempt to replicate normal kidney excretory function.

Diffusion

Diffusion describes a property of the movement of substances (or solutes) from an environment of higher concentration across a semipermeable membrane to an environment of lower concentration. During dialysis, solutes in the blood component (the area of higher concentrations of electrolytes that have accumulated because of kidney failure) flow along one side of the semipermeable membrane (ie, the dialyzer in HD or the peritoneal lining in PD), into an area of lower electrolyte concentrations, known as the dialysate compartment. Dialysate is a physiologic solution with controlled concentrations of electrolytes and for PD, dextrose. In HD, the semipermeable membrane is a thin layer of synthetic material that contains pores that allow for diffusion to occur. The rate and amount of diffusion is dependent on the difference in solute concentrations between the blood and dialysate compartments, the molecular weight (MW) of the solute (ie, size), and characteristics of the semipermeable membrane including surface area, thickness, and porosity.[6] Regardless of the semipermeable membrane characteristics, the clearance of solutes by diffusion decreases rapidly as the MW of the solute increases. Smaller solutes and fluid pass through, but the semipermeable membrane blocks the passage of larger molecules such as red blood cells and large proteins. This mimics the filtering process that takes place in the kidneys when the blood enters the kidneys, and the larger molecules are separated from the smaller ones in the glomerulus.

Once the concentration of a solute nears equilibrium on both sides of the semipermeable membrane, the net rate of diffusion becomes zero because the rate of movement from the blood to the dialysate compartment is equal to the rate of movement from the dialysate to the blood compartment.[6]

The process of diffusion applies in both directions across the semipermeable membrane. The movement of unwanted electrolytes and metabolic end products in the blood into the dialysate for removal can be promoted by low concentrations of those solutes in the dialysate. Conversely, solutes with higher concentrations in the dialysate can move across the semipermeable membrane into the blood to achieve increased concentrations in the blood compartment.[6]

Convection

Convection also contributes to solute clearance during the process of dialysis. Convection is the mass transport of solutes along with the fluid in which they are dissolved, across a semipermeable membrane. The rate of convection depends on the pressure difference across the semipermeable membrane and the pore size of the membrane. In contrast to diffusion, the process of convection is not dependent on concentration gradient and is relatively independent of solute size. Solute clearance by convection tends to be more constant over a wide range of MWs; and convection contributes more to clearance of larger molecules than it does to smaller molecules, which are preferentially removed by difffusion.[6]

Ultrafiltration

Ultrafiltration is a process that aids in removing excess water only and maintaining extracellular volume at desired levels. The ultrafiltration rate for HD is determined by the transmembrane pressure—the difference in hydrostatic pressure between the blood and dialysate compartments across the dialyzer membrane. It is controlled through settings on the HD machine. The principle of ultrafiltration in PD is discussed in more detail later in the chapter.

Clearance Based on Molecular Weight and Dose of Hemodialysis

The clearance or removal of a substance during dialysis is dependent on its molecular MW, water solubility, and protein binding. To a lesser degree, molecule shape and charge also influence clearance. Historically, the categories of small MW (<500 Da), medium (500–2000 or 3000 Da), or large (>3000 Da) molecules were used to describe MW and the ability of a molecule to be cleared by dialysis.[7] Conventional dialyzer membranes only removed small MW substances. Small MW substances are primarily cleared by diffusion, and the amount of clearance is dependent on blood flow rates. Urea, a 60 Da molecule, is the typical example of a small MW substance and is used to define the dose of dialysis because of its small size, ease of measurement of the blood urea nitrogen (BUN) concentration, and its ability to diffuse readily across dialysis membranes.[6,8]

Advanced dialyzer membrane technology removes larger MW substances, and the traditional categories have been updated. The European Uremic Toxin Work Group kept the small MW classification, but created two new categories: protein-bound solutes and middle molecules. Middle molecules are defined as toxins in the MW range of 500 to 60,000 Da.[9,10]

HD efficiently removes small MW molecules. Molecules such as β_2-microglobulin (11,800 Da), are removed less efficiently by HD, as are low MW compounds that are protein bound, have a large volume of distribution, or are located intracellularly. Larger MW substances (>15,000 Da) are not removed by conventional dialyzer membranes, but newer dialyzer membranes may remove them to a significant degree.[11] Current dialyzer technology does not efficiently remove protein-bound substances.[10,12]

The amount, or dose, of dialysis is determined by calculating the clearance of the small MW molecule urea. The equation used is Kt/V, where K is the clearance of urea in mL/minute; t is the time in minutes of the dialysis treatment; and V is the volume of distribution

of urea. This equation assumes that urea clearance is constant throughout the treatment time. The volume of distribution of urea (V) is equal to total body water, which can be determined by either estimating it from a patient's weight (60% for males or 55% for females) or calculated using the Watson formula.[6,7] The urea reduction ratio (URR), expressed as a percentage, can also be used to assess the removal of urea during dialysis. URR = $(C_{pre} - C_{post})/C_{pre} \times 100$, where C_{pre} is the BUN before the start of dialysis and C_{post} is the BUN at the completion of dialysis.[6] However, KDOQI clinical guidelines state that URR should be phased out because its measurement is error prone, and more precise measures are preferred.[5]

HEMODIALYSIS

During HD, one large-bore needle or catheter is placed into a special vascular access site, an arteriovenous (AV) fistula or graft or central venous catheter (CVC). Tubing connecting the vascular access site to the dialyzer delivers the patient's blood containing metabolic end-products, excessive electrolytes, and water to the dialyzer. This side of the system is referred to as the *arterial line* or *arterial side*. Blood delivered to the arterial side comes into contact with the semipermeable membrane inside the dialyzer cartridge that has dialysate flowing on the other side of the membrane. Inside the dialyzer cartridge is where diffusion, convection, and ultrafiltration occur. The HD machine can be programmed to adjust the rate of ultrafiltration. Cleaned blood exits the dialyzer cartridge and is returned to the patient's access site through tubing attached to a second large-bore needle or catheter, referred to as the *venous line* or *venous side*. The tubing on both sides of the system and the dialyzer is called the *extracorporeal circuit*.[4,6] **Figure 30-1** illustrates a patient receiving HD, and **Figure 30-2** describes the extracorporeal system in HD.

Figure 30-1 Person receiving HD using an arteriovenous (AV) access in an outpatient hemodialysis (HD) facility. Needles, inserted into the AV access in the patient's forearm, are attached to the extracorporeal circuit through which blood flows from the patient to

the HD machine where it is filtered through the dialyzer (vertical cylinder between the machine's right-hand side and the patient) and then returned through venous-side tubing into the patient's AV access. Figure 30-2 Hemodialysis system. A, Blood from an artery is pumped into (B), a dialyzer where it flows through tubes made of semisynthetic polymers, which act as the semipermeable membrane (inset). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows around the

outside of the semisynthetic polymer tubes. The waste products in the blood diffuse through the semipermeable membrane into the dialysate. (Adapted with permission from Smeltzer SC, Bare BG. *Textbook of Medical-Surgical Nursing*. 9th ed. Lippincott Williams & Wilkins; 2000.)

Hemodialysis Vascular Access

CASE 30-1

QUESTION 1: R.W., a 70-year-old male with stage G4 CKD as a result of long-term, poorly controlled hypertension, presents to clinic for reassessment of his kidney function. He is 68 inches (172.72 cm) tall and weighs 154 pounds (69.85 kg). He first saw a nephrologist 6 months ago. He reports feeling tired, but otherwise does not describe any other symptoms. His wife reports that he is not eating very much even when she prepares his favorite foods. On physical examination, his blood pressure is slightly elevated but not different from previous readings, his lungs are clear, and moderate ankle edema is noted. Since his last visit to the kidney clinic 3 months ago, his eGFR has decreased from 17 to 13 mL/minute/1.73 m^2 (now stage G5), and the BUN concentration has increased to 89 mg/dL. The serum potassium is 4.8 mEq/L, and serum bicarbonate (HCO_3) is 17 mEq/L.

R.W. has participated in a dialysis modality patient education program. He informs his nephrologist today that he has selected HD as his choice of dialysis. Given the findings from today's clinic visit, it is anticipated that he will need to begin HD within the next 1 to 3 months.

The next step to prepare for the start of HD is to have a permanent vascular access surgically created. An AV vascular access site is necessary to achieve a sufficient blood flow rate for HD.

What are the options for permanent vascular access in R.W.? Which one is the best option for R.W.?

Ideal vascular access for HD allows high blood flow rates necessary for chronic HD, endures frequent cannulation, and has a low rate of complications (eg, infection, stenosis, thrombosis, aneurysm, and limb ischemia). The typical prescribed blood flow rates of 400 to 500 mL/minute from the patient's venous access through the extracorporeal circuit cannot be achieved through routine venipuncture that uses small-bore needles.[6] The achieved

blood flow rate is dependent on the type of AV vascular access and the cardiovascular status of the patient. Some patients are not able to tolerate high blood flow rates, and a lower blood flow rate may be necessary. Three main types of vascular access that allow for high blood flow rates are available for patients treated with HD: (a) AV fistula, (b) AV graft, and (c) CVC. The access types are illustrated in **Figures 30-3**, **30-4**, and **30-5**, respectively:

1. AV fistula made by surgically joining a patient's native (ie, their own) artery and a vein
2. AV graft, a soft tube made of polytetrafluoroethylene surgically placed as a connection between the patient's artery and a vein
3. CVC, a double-lumen, tunneled, cuffed catheter placed in a large vein, usually in the neck[6,13]

In the 2019 USRDS Annual Data Report, HD was initiated in 80% of patients utilizing a tunneled, double-lumen, or cuffed catheter. Patients of Hispanic ethnicity and those who are Black/African American have the lowest proportion of AV fistulas used at HD initiation. For prevalent patients, the rate of AV fistula use is 63%, and this has grown over the past decade.[2]

ARTERIOVENOUS FISTULA

An AV fistula is created surgically by subcutaneous anastomosis of a patient's native (ie, own) artery to an adjacent vein most often in the nondominant forearm, but it can also be placed in the upper arm. Once created, an AV fistula ideally requires 4 to 8 weeks to mature before it can be used for HD. During this time, the anastomosed vein is subject to arterial pressures and vein hypertrophies. This physiologic change allows the vein to tolerate frequent cannulation. In most circumstances, an AV fistula is the preferred access type because of lower infection and thrombosis rates. However, an AV fistula may be difficult to create in patients with poor vasculature, such as in elderly patients or those with diabetes, atherosclerosis, or small vessels.[4,6,13]

ARTERIOVENOUS GRAFT

An AV graft is considered a suitable alternative to an AV fistula. An AV graft is also created surgically, but the connection between the artery and vein is made by inserting a soft synthetic (eg, polytetrafluoroethylene) tube to create a connection between an artery and a vein. Like AV fistulas, AV grafts are placed in the nondominant forearm, but can also be placed in the upper arm. AV

grafts take less time to mature and can be used soon after surgery, although waiting 2 weeks to use an AV graft allows for healing at the anastomosis sites and prolongs patency. AV fistulas fail to mature at a higher rate than do AV grafts; however, AV grafts may require more interventions per year (eg, elective angioplasty, thrombectomy, or surgical revision) to maintain their long-term patency for HD.[6,13] The AV graft tubing is made of synthetic material, which may predispose patients to infection or thrombosis at higher rates than does an AV fistula. The synthetic tubing acts as a foreign body to which a biofilm created by some bacteria (eg, *Staphylococcus epidermidis, S. aureus*, and *Pseudomonas aeruginosa*) attaches. The presence of the biofilm encapsulates bacteria, allows it to adhere more tightly to the graft, and limits the effectiveness of host defenses and antibiotic therapy.[14,15] The pathophysiology of AV graft thrombosis is complex and includes endothelial and smooth muscle cell injury, proinflammatory mediators, inflammation, oxidative stress, endothelial dysfunction, and genetics.[16]

CENTRAL VENOUS CATHETERS

CVCs are often used at the start of HD either because patients did not have nephrology care before starting dialysis or their AV access is not yet ready to use.[6] The 2019 KDOQI Vascular Access Clinical Guidelines consider short-term catheter use to be reasonable in situations where HD is necessary but permanent access is not available for use (eg, AV fistula or graft did not mature, acute kidney transplant rejection). Long-term use of CVCs is discouraged as permanent vascular access because of much higher rates of infection and occlusion. The KDOQI clinical guidelines only consider long-term catheter use to be reasonable in situations of last resort (eg, multiple prior failed AV accesses with no other available options, limited life expectancy).[13]

Given the options of AV fistula, AV graft, or CVC, R.W.'s best option for permanent HD vascular access is a surgically created AV fistula in the forearm of his nondominant arm. His current symptoms are tolerable. His physical examination and laboratory results do not

suggest an urgent need to start HD. There is ample time for an AV fistula to be surgically created and mature, which will minimize the risk of needing a CVC to begin urgent HD. Also, his past medical history does not suggest he would be likely to have poor vasculature (eg, diabetes), hence an AV fistula is the preferred option for R.W.

Hemodialysis Dialysate

HD dialysate is a physiologic solution typically containing standardized concentrations of electrolytes that can be individualized, if necessary. The dialysate prescription takes into account goals of therapy, expected solute clearance needs, volume removal needs, and logistical concerns. Bicarbonate is added as a buffer to the dialysate to control metabolic acidosis associated with kidney failure that occurs because the daily obligatory load of acid cannot be excreted.[6]

The HD dialysate concentrate is diluted with tap water that is specially treated for HD use. Dialysate water does not require sterilization because the dialyzer membrane separates the blood and dialysate compartments. Nevertheless, pyrogen reactions may occur and a greater risk may exist with certain types of semipermeable membranes such as high-flux membranes because of their increased pore size.[7]

The prescribed dialysate is prepared in the HD machine by proportioning a dialysate concentrate that typically contains those elements listed in **Table 30-1** and mixing with specially treated tap water. Before HD starts, the dialysate is heated to 98.60 °F (37 °C) to maintain the patient's body temperature and avoid hemolysis, which can occur with excessive heating. Dialysate is also deaerated under vacuum to remove dissolved air.[7] The patient-specific dialysate prescription takes into account serum electrolyte concentrations. For example, if the patient is hyperkalemic, the dialysate will contain a lower potassium concentration to facilitate diffusion of potassium from the blood compartment into the dialysate compartment. Conversely, a patient with a normal serum potassium

concentration at the start of HD will have the potassium concentration of the dialysate set at a normal physiologic concentration to minimize movement of potassium across the dialyzer membrane. If the concentration of a solute is higher in the dialysate than in the blood, the net movement will be into the blood, not out.

Table 30-1
Electrolyte Composition of Hemodialysis and CAPD Dialysate

Solute	Hemodialysis (mEq/L)	CAPD (mEq/L)
Sodium	135–145	132
Potassium	0–4	0
Calcium	2.5–3.5	3.5
Magnesium	0.5–1.0	1.5
Chloride	100–124	102
Bicarbonate	30–38	NA
Lactate	NA	35
pH	7.1–7.3	5.5

CAPD, continuous ambulatory peritoneal dialysis; NA, not applicable.

Dialysate flow rates through the dialyzer cartridge are also prescribed and generally range from 500 to 800 mL/minute depending on the type of dialyzer used. Higher dialysate flow rates promote increased clearance of solutes, especially small MW solutes. Dialysate flows in a countercurrent direction to blood flow, which enhances the process of diffusion.[6]

Hemodialysis Dialyzer Membrane Characteristics

The type of semipermeable dialyzer membrane used in HD is also prescribed. Dialyzers are characterized by many factors including membrane composition, size, and ability to clear solutes. The dialyzer membrane can be made of cellulose, substituted cellulose, or synthetic polymer, each of which differs in its degree of

biocompatibility. KDOQI clinical guidelines recommend biocompatible membranes composed of synthetic polymers.[5] Cellulose dialyzers are not recommended in the United States because contact between blood and the dialyzer surface activates the complement pathway, producing proinflammatory cytokines that cause hypotension, fever, and platelet activation.[17]

Dialyzer membranes also differ in fiber configuration, surface area, pore size, and thickness. The most common fiber configuration is the hollow fiber dialyzer in which thousands of hollow fibers run the length of the dialyzer. Blood flows through the hollow fibers and dialysate flows in the space surrounding the fibers within the dialyzer cartridge. The result is an extremely large surface area for diffusion, which is functionally maximized by blood and dialysate moving in opposite directions (ie, countercurrent flow) so that equilibrium is never fully achieved.

The efficiency of a dialyzer membrane is also related to its surface area. High-efficiency membranes have a large surface area and are able to clear larger quantities of small molecules, such as urea.

Most dialyzer membranes have pore sizes that allow small molecules to freely diffuse. Blood flow through the dialyzer is the rate-limiting step in removing small molecules. Large molecules do not easily cross through the pores of conventional dialyzer membranes and their clearance is less dependent on blood flow. Instead, the overall removal of larger molecules depends more on membrane characteristics (ie, thickness and pore size) and the duration of dialysis.[7] Dialyzer membrane pore size and the ability to remove β_2-microglobulin (MW 11,800 Da) is used to characterize membranes as low flux or high flux. High-flux dialyzer membranes have larger pores and are able to clear larger sized molecules (eg, middle molecules such as β_2-microglobulin and leptin) and drugs (eg, vancomycin or vitamin B_{12}) more effectively than do low-flux membranes. High-flux dialysis membranes are defined as providing β_2-microglobulin clearances of at least 20 mL/minute[5] and have a higher rate of water transfer (ultrafiltration coefficient) compared to that of low-flux membranes. In most developed countries, high-flux

membranes are the standard of care. The 2015 update to the KDOQI Clinical Guidelines on Hemodialysis Adequacy recommended either low- or high-flux biocompatible HD membranes, with preference given to high-flux membranes depending on local considerations.[5]

Relative in vitro and in vivo solute clearance rates varying MW substances are typically printed on the outside of the dialyzer or in the dialyzer specification chart (ie, the equivalent of the package insert).

Drug clearance during HD is also influenced by dialyzer membrane surface area and pore size. The amount of drug actually removed by dialysis is dependent on dialyzer and drug characteristics along with blood and dialysate flow rates. Just like with other solutes, larger dialyzer surface area and pore size promote increased removal of drugs. The MW, protein binding (ie, amount of unbound drug available to cross the dialyzer membrane), and volume of distribution (V_d) (ie, a large V_d indicates that a relatively small amount of drug will be available in the blood for dialysis) of a drug will also determine the amount of drug removed.[18] Small MW drugs (ie, MW <500 Da such as aminoglycosides and theophylline) are likely to be significantly cleared by all dialyzer membranes. Drugs with an MW between 500 and 1000 Da (eg, morphine and digoxin) are less well dialyzed by conventional dialyzer membranes, but may be cleared by high-flux membranes. For digoxin, its large V_d and relatively low serum concentrations make it less likely to be significantly removed. Even if digoxin in the blood is effectively removed, tissue-bound drug will quickly redistribute back into the blood as soon as HD is completed, a phenomenon known as *rebound*. Finally, large MW drugs, such as vancomycin, are poorly dialyzed by conventional dialyzer membranes, but are well known to be significantly removed with high-flux dialyzer membranes.[19] Refer to Chapter 31, Dosing of Drugs in Kidney Failure, for a more detailed explanation. Many tertiary resources are available to aid in drug dosing in patients receiving dialysis. One recently published source is “Demystifying

Drug Dosing in Renal Dysfunction"[20] published by the American Society of Health-System Pharmacists, and an older publication by the American College of Physicians is *Drug Prescribing in Renal Failure: Dosing Guidelines for Adults*.[21]

Case 30-1, Question 2: R.W.'s nephrologist is developing an initial outpatient HD plan. Using a polysulfone, high-flux, high-efficiency dialyzer, he will be dialyzed 2 hours on Monday, 3 hours on Wednesday, and 4 hours on Friday for the first week of treatment. Blood flow rates and dialysate flow rates that week will be titrated upward based on R.W.'s tolerance of HD. Assuming a successful first week of HD, his routine schedule will be HD three times a week for 4 hours each treatment, using the same dialyzer with blood flow rate of 400 mL/minute and bicarbonate-containing dialysate with a flow rate of 500 mL/minute. What characteristics of the dialyzer membrane make it a good choice for R.W.? How will the success of R.W.'s HD treatment be determined?

The plan recommended by R.W.'s nephrologist is a typical start to HD to minimize complications discussed later in the chapter and allow patients to become accustomed to longer HD treatments.[8] In accordance with the KDOQI guidelines,[5] R.W.'s nephrologist is prescribing a biocompatible membrane made of polysulfone.

Advances in HD dialyzers have produced semipermeable membranes that have increased clearance of small molecules and also the ability to remove larger MW substances as compared to conventional dialyzers. High-efficiency dialyzers have increased clearance of urea and other small molecules, but their clearance of larger MW substances is variable. High-flux dialyzers, by definition, always have membrane pore sizes that allow clearance of larger MW molecules compared to conventional dialyzer membranes. They also have a higher ultrafiltration coefficient. High-efficiency and high-flux dialyzers are not mutually exclusive, and there is often overlap.[7] R.W. is being prescribed a high-efficiency, high-flux dialyzer, which means the dialyzer membrane has an increased urea clearance, and there are larger pores that will aid in removing larger sized solutes.

Once R.W. is stable on his HD schedule, KDOQI recommends assessing the amount of his dialysis or dose using the Kt/V equation. In accordance with KDOQI guidelines, the target Kt/V for patients

receiving HD three times weekly is 1.4 per HD treatment with a minimum acceptable *Kt*/*V* of 1.2 per treatment.[5] R.W.'s initial treatment goals also include adequately controlling or relieving his symptoms (fatigue and anorexia), achieving adequate fluid balance, and controlling blood pressure. Long-term goals include prolonging survival while achieving good quality of life.[7]

Anticoagulation for Hemodialysis

Case 30-1, Question 3: What is an appropriate anticoagulation regimen for R.W. when he initiates HD? Based on careful review of his past medical history, other than his recent surgery to place his AV fistula, he has no known bleeding risks. What are alternative anticoagulation regimens for patients at high risk for bleeding?

During HD, the patient's blood comes into contact with foreign surfaces in the extracorporeal circuit (ie, tubing, dialyzer) that immediately trigger the coagulation cascade, upregulate proinflammatory and procoagulant pathways, and activate coagulation factor XII and platelets.[17] Anticoagulation during HD is critical to inhibit these pathways and minimize the risk of thrombosis in the dialyzer. Dialyzer membrane clotting reduces surface area for diffusion, and clots in the circuit can cause blood loss because blood in the circuit cannot be returned to the patient via the venous side tubing. Anticoagulation goals in HD are to prevent clotting in the dialyzer, minimize the risk of bleeding, and avoid prolonged bleeding once the large-bore needles are removed from the AV fistula or graft at the end of HD.[22] Most commonly, HD anticoagulation consists of low doses of unfractionated heparin (UFH) by either intermittent bolus injections or an initial bolus followed by a continuous infusion. UFH has a rapid onset of action and short half-life. It is also affordable, reliable, reversible, and requires minimal dialysis staff intervention once an effective dose has been determined.[22] Modern HD delivery systems have incorporated heparin infusion devices that can be programmed to provide the desired infusion rate during HD.

Although not supported by extensive studies or standardized dosing protocols,[23] a common anticoagulation regimen is UFH 40 to 50 units/kg as an initial bolus immediately after vascular access cannulation followed by a continuous infusion of ~10 to 15 units/kg/hour. It is essential to wait 3 to 5 minutes between the initial bolus of UFH and the arrival of blood into the extracorporeal circuit to avoid clotting within the dialyzer.[22] Typically, most U.S. dialysis facilities rely on clinical signs and symptoms to monitor HD anticoagulation. Visual inspection of the circuit and/or the dialyzer and/or prolonged bleeding at the venipuncture sites at the end of HD are clinical clues that the anticoagulation therapy needs to be modified. It is uncommon to use laboratory parameters to monitor UFH during HD.[6,22]

In patients with AV fistulas or grafts, UFH should be discontinued 30 to 60 minutes before the end of HD to prevent excessive bleeding from the vascular access site. Patients with CVCs should receive UFH until the end of HD to minimize the risk of clotting at the tip of the catheter.[6,22]

Heparin-free HD is an alternative for patients who are at a moderate-to-high risk of bleeding or who are actively bleeding. This approach requires priming the HD circuit with UFH 2000 to 5000 units/L in normal saline to coat the extracorporeal surfaces.[22] The UFH-containing priming fluid is drained by filling the circuit with either the patient's blood or normal saline alone at the outset of HD. Next, the blood flow rate is set at 250 to 500 mL/minute if the patient tolerates it. During HD, the dialyzer is flushed with 25 to 30 mL of normal saline every 15 to 30 minutes to rinse away microclots that may have formed. The incidence of clotting with this approach is ~2% to 5%. This anticoagulation approach requires significant dialysis facility staff effort and close observation, which may not be ideal in certain outpatient settings.[22]

The regional administration of trisodium citrate through the arterial line is a potential alternative to UFH. Trisodium citrate binds free calcium, which is necessary for the coagulation process, and the calcium citrate complex is removed by dialysis. Based on serum calcium concentrations, a second infusion containing calcium

chloride is administered on the venous side to prevent hypocalcemia. A portion of the administered citrate is returned to the patient and is metabolized to bicarbonate, potentially leading to metabolic alkalosis. Hypernatremia is also a potential adverse effect. Regional citrate anticoagulation is technically difficult to administer and requires extensive monitoring to safely use. Therefore, it is reserved for patients who are at high risk for bleeding in whom other anticoagulation methods are not an option.[22] Trisodium citrate regional anticoagulation is rarely used in outpatient HD facilities, and is more commonly used in acutely ill, hospitalized patients requiring HD.[22]

Case 30-1, Question 4: R.W. is afraid to start HD, in particular the risk of bleeding has him very concerned. He talked about his fear of receiving UFH during HD with his long-time pharmacist in the outpatient general medicine clinic. As the pharmacist in the outpatient dialysis facility, you call R.W. to conduct a pre-HD medication history. During that call, he tells you that the pharmacist in his outpatient general medical clinic asked if low-molecular-weight heparins (LMWHs) are an alternative to prevent clotting during HD. What should you tell R.W. about the risk of bleeding with UFH and the role of LMWH in HD?

R.W. should be educated about UFH during HD and its risks. Typically, the UFH doses used during HD are relatively low. R.W. will be closely monitored during HD and any signs or symptoms of bleeding will be addressed by the trained dialysis staff. The effect of UFH can be reversed with protamine. In addition, UFH will be stopped 30 to 60 minutes before the end of the HD so that the anticoagulant effect will be gone by the time R.W. leaves the dialysis facility.

LMWHs are considered at least as effective and safe as UFH in HD. However, LMWH use in the United States is very limited because studies haven't shown superiority to UFH in HD-related bleeding. In addition, their effect is not completely reversible with protamine, and LMWHs are significantly more expensive than UFH. These reasons make LMWH a far less desirable alternative to UFH.[22] A meta-analysis comparing the efficacy of LMWH with UFH in patients undergoing either HD or hemofiltration found no

difference in the rate of thrombosis.[24] A second meta-analysis that focused on the safety of LMWH versus UFH found no significant difference in the primary outcome of minor and major bleeding.[25]

If used in patients with kidney failure, dose adjustments along with careful patient monitoring are necessary for LMWHs because they are eliminated by the kidneys. Patients on HD may exhibit greater sensitivity to LMWH effect compared to healthy volunteers.[26] Although LMWHs inhibit several factors (factor X_a, factor XII_a, and kallikrein), antifactor X_a activity is the only available laboratory monitoring parameter. The antifactor X_a test's clinical utility is unclear in this patient population because active heparin metabolites can accumulate and are not detected by the assay.[26–28]

Case 30-1, Question 5: Although it is unlikely that R.W. will develop heparin-induced thrombocytopenia (HIT), which anticoagulants are options for patients on HD who do develop HIT?

Up to 10% of patients on HD who are receiving UFH experience HIT.[29] Antithrombotic treatment guidelines for patients with HIT from the American Society of Hematology[30] and the American College of Chest Physicians[31] recommend immediately discontinuing all forms of UFH, including "heparin-free" dialysis, UFH flush, and LMWH in patients diagnosed with HIT. Both guidelines discuss the lack of high-quality evidence to guide non-UFH anticoagulant use in HD. There are no studies comparing one non-UFH anticoagulant to another in HD patients with HIT. The direct thrombin inhibitors argatroban and bivalirudin are the agents of choice.[32]

Several small studies show that argatroban is safe and effective in HD patients with HIT.[33–35] Argatroban is eliminated by the liver, and hence dosing adjustments are not required for patients receiving HD.[34] Approximately 20% of argatroban is removed during HD, but is not considered clinically significant to suggest dose adjustments.[34] A reported dosing regimen for argatroban is 2 μg/kg/hour continuous infusion with a goal-activated partial thromboplastin time (aPTT) of 1.5 to 3 times baseline.[32] Some regimens include an initial bolus

dose of 250 μg/kg or 20 mg at the start of HD followed by a continuous infusion.[35] In clinical practice, the actual doses needed for anticoagulation may be less than those used in studies.[35,36] Argatroban infusions are discontinued 1 hour before the end of the HD.[33]

Bivalirudin is also a safe and effective HD anticoagulant in patients with HIT.[29,32] Among the direct thrombin inhibitors, in patients without kidney function, it has the shortest half-life of 25 minutes. Appropriate dosing is still being evaluated,[29,37,38] but doses of 0.03 to 0.05 mg/kg/hour have been suggested.[32] Bivalirudin infusion should be stopped before the end of HD to prevent excessive bleeding from the AV site.

Any anticoagulation infusion regimen that requires complicated dosing changes or adjusting doses based on aPTT or other laboratory results may be technically difficult in an outpatient HD facility.

Fondaparinux, a heparinoid, has also been evaluated for HD anticoagulation in patients with HIT but is not recommended for several reasons. Fondaparinux is removed substantially by high-flux dialyzers, resulting in inadequate anticoagulation and increased risk of thrombosis.[39] Also, its half-life is significantly prolonged in patients with kidney failure and is contraindicated in patients with creatinine clearance <30 mL/minute. Lastly, fondaparinux does not have a U.S. Food and Drug Administration (FDA)-approved label for HD anticoagulation.[22,40]

Hemodialysis Process

Case 30-1, Question 6: R.W. visits the outpatient HD facility a week in advance of his expected HD treatment initiation date. What is actually going to happen during HD is among the questions he has about how the dialysis facility works?

Typically, patients receiving chronic, in-center HD are dialyzed for 3 to 4 hours, three times a week on either Monday, Wednesday,

Friday or Tuesday, Thursday, Saturday. Patients have an appointment time during the morning, middle, or evening shift on those set of days. Upon entry to the HD facility, patients are weighed, their blood pressure is taken, and then starts the process of access cannulation and being connected to the HD machine. During the HD treatment, the dialysis unit staff check on the patient routinely and automatic blood pressure measurements are taken at prescribed intervals. As HD ends, the patient's blood is flushed out of the extracorporeal circuit back into the body using normal saline, the large-bore needles are carefully removed, and compression dressings applied to the access site to promote clotting and prevent bleeding. Just before leaving the HD facility, patients are weighed again. The difference in weight from the start and end of HD is an estimate of the amount of fluid removed during HD. In the absence of kidney function, fluids ingested and produced through metabolic processes accumulate. Although patients generally are on fluid restriction, 1 to 5 L of fluid (translating into 2.20–10 pounds [1–5 kg] weight gain) can accumulate between HD treatments. The accumulated fluid must be removed during each HD treatment to avoid the complications of fluid overload.

Hemodialysis Complications

INTRADIALYTIC HYPOTENSION

Case 30-1, Question 7: R.W.'s prescribed target or dry weight at the end of HD is 152.12 pounds (69 kg). During his most recent HD, he complained of nausea and light-headedness 3 hours into his 4-hour treatment. His systolic blood pressure dropped from 135 mm Hg at the start of HD to 80 mm Hg measured shortly after he reported his symptoms. This was the first time R.W. experienced a symptomatic and significant drop in systolic blood pressure during HD. His postdialysis weight was 153.22 pounds (69.5 kg). What are the possible etiologies for his hypotension? How should R.W.'s symptoms and low blood pressure be managed?

In addition to solute removal, HD is used to maintain fluid balance in patients with kidney failure. Most patients will become anuric once

stabilized on HD and will need to limit fluid intake between HD treatments. In patients who are anuric, no appreciable amount of fluid ingested in between HD treatments is eliminated, and HD then becomes the primary way extracellular fluid volume is controlled. Patients on HD have an individualized prescribed target weight to be achieved at the end of HD that is thought to represent appropriate fluid balance. This target weight is referred to as the dry weight. Ending HD below the dry weight may result in the patient becoming symptomatic from extracellular volume depletion. Ending HD too much above the dry weight, the patient may be at risk for extracellular fluid overload. Achieving the desired dry weight is accomplished through the ultrafiltration prescription and adjusting the HD machine transmembrane pressure settings. The prescribed target weight at the end of HD for R.W. was 152.12 pounds (69 kg). R.W.'s signs and symptoms of hypotension 3 hours into today's HD suggest that too much fluid was being removed through ultrafiltration and that his prescribed dry weight is too low.

Although this was the first time R.W. experienced symptomatic hypotension during HD, it is important to monitor for intradialytic hypotension (IDH), which is a common complication related to HD. IDH is associated with increased morbidity such as vascular access thrombosis, inadequate dialysis dose, and mortality. Hypotension impairs end-organ perfusion and can lead to permanent damage. Multiple definitions of IDH exist, but a nadir systolic blood pressure drop <90 mm Hg for >30% of HD treatments strongly correlates with increased mortality.[41] The reported incidence of IDH is 10% to 30%, and even higher in patients with specific risk factors, such as autonomic dysfunction associated with diabetes or cardiac disease.[42] The pathogenesis of IDH is poorly understood. One proposed mechanism is excessive extracellular fluid removal from the vascular compartment at a rate exceeding mobilization of fluid from the interstitial space. As a consequence, patients with an inadequate hemodynamic response to intravascular volume depletion exhibit a decrease in blood pressure and related symptoms.[42] An ultrafiltration rate >10 mL/hour/kg is associated with a statistically significant higher odds of IDH and a statistically significant higher risk of

mortality.[43] Clinical symptoms of IDH include nausea and vomiting, dizziness, muscle cramping, and headache.[42] Increasing the patient's prescribed dry weight may be appropriate if the patient is volume depleted and symptomatic after HD, especially if the patient has lost lean body mass over time. Loss of lean body mass is common in the later stages of CKD, and may not be recognized because total body weight remains the same or increases owing to retained water not being effectively removed by the kidneys.

Other causes of IDH relate to increases in core body temperature. Sympathetic nervous system activity increases in response to ultrafiltration, leading to vasoconstriction of the dermal circulation and impaired heat dissipation. Increased central heat production can occur during the HD procedure. The increase in core body temperature can overcome peripheral vasoconstriction, resulting in hypotension. Excessive heating of dialysate can also produce vasodilation and resultant hypotension. Cooling of the dialysate to slightly below body temperature may correct this problem, although many patients are uncomfortable and do not tolerate the cooling effect. Eating during HD can also cause a fall in blood pressure because of vasodilation of the splanchnic vessels. Although eating is usually prohibited during HD, patients prone to IDH should also avoid eating just before HD. Taking antihypertensive medications before HD may exacerbate hypotensive episodes as well; in some patients, these medications may need to be withheld until after HD has ended. Immediate treatment of IDH can be accomplished by several methods including (a) reclining the patient and raising the level of the lower extremities higher than the head (ie, Trendelenburg position), (b) administering a small (100–250 mL) bolus of normal saline into the venous blood line, and/or (c) reducing the ultrafiltration rate.[42]

In addition to the changes to HD ultrafiltration rates, several pharmacologic agents have been proposed to manage IDH, including ephedrine, fludrocortisone, caffeine, desmopressin, vasopressin, L-carnitine, sertraline, midodrine, and droxidopa with varying degrees of efficacy.[44] Preventing IDH is an area of active

study. Of the pharmacologic options, midodrine, an oral prodrug that is converted to desglymidodrine, a selective α_1-agonist, has shown the most promise. Midodrine studies to treat IDH have been small and of short duration and used hemodynamic end points instead of hard clinical end points. Midodrine 10 to 20 mg given 30 minutes before HD improves hemodynamic parameters in the short term, but negative long-term outcomes have been reported.[45] Droxidopa, a prodrug that is converted to norepinephrine, was studied for treatment of IDH, but neither 400- nor 600-mg doses showed statistically significant benefit compared with placebo, and more patients treated with droxidopa experienced adverse events such as nausea, fatigue, and headache.[46]

R.W.'s symptoms and low blood pressure during HD were managed by placing him in the Trendelenburg position and stopping ultrafiltration, which improved his symptoms and blood pressure. Continuing the last hour of HD without ultrafiltration allows for continued removal of unwanted metabolic end products and electrolytes without appreciable removal of additional water. If his symptoms and blood pressure did not improve with those interventions, a bolus of 100 to 250 mL normal saline could have also been given.

R.W.'s care should also include an accurate assessment of R.W.'s dry weight. Accurate dry weight estimate is essential, but difficult to obtain. Typically, the estimate is made by an experienced dietician in consultation with a physician. There is a potential role for bioimpedance or relative blood volume measurements to guide the process.[6] R.W.'s episode of hypotension could be related to too much fluid being removed during HD, an overestimate of the target weight because of a change in lean body mass or a combination of both. After reviewing his HD records for the presence of fluid balance–related signs and symptoms, the dietitian asks R.W. detailed questions about his diet. R.W. states that he is very careful to follow his HD fluid restrictions. He also reports an improved appetite since starting HD. He thinks it odd that he is eating more yet his clothes seem larger, and he needs to tighten his belt more than

before. Assessing all the information, the dietician concludes that it is likely that since starting HD R.W. has gained muscle mass along with losing excess fluid from his CKD stage 5 kidney failure. It is important to consider "real" weight changes when assessing the patient's dry weight and volume status. Without appropriately increasing the dry weight goal to compensate for his real weight gain perhaps that is more reflective of gained "fat/protein" weight as opposed to "water" weight, R.W. had too much fluid removed, which resulted in volume depletion and hypotension. His dry weight should be adjusted gradually upward over a period of weeks to the point at which he is no longer symptomatic and yet does not show symptoms of fluid overload.

CASE 30-1, QUESTION 8: What other HD-related complications must be monitored in R.W., and if they happen, how can they be treated?

SKELETAL MUSCLE CRAMPS

The pathophysiology of skeletal muscle cramping in patients treated with dialysis is not known. Proposed mechanisms include excessive ultrafiltration resulting in altered perfusion of the affected tissues, electrolyte disturbances, or deranged neurobiologic pathways. Skeletal muscle cramping related to HD is extremely painful, interferes with sleep and activities of daily living, and adversely affects patients' quality of life. A wide range of treatment strategies such as behavioral interventions (eg, exercise, stretching, massage), pharmacologic treatments (eg, hypertonic saline or dextrose in water 10% or 50%), dietary supplements, and changes to the HD treatment (eg, reduced ultrafiltration, changes in treatment time) have been tried with little success.[47]

DIALYSIS DISEQUILIBRIUM

Dialysis disequilibrium is a syndrome that has been recognized since the initiation of HD >40 years ago. Patients new to HD are at greatest risk because urea accumulates over time as the kidneys begin to fail. Urea's V_d is the same as that of body water, and it

distributes in tissues throughout the body. Rapid removal of urea from the extracellular space by HD lowers plasma osmolality, thereby leading to a shift of free water into the brain. Lowering intracellular pH, as can occur during HD, has also been suggested as a cause of dialysis disequilibrium. Clinical manifestations occur during or shortly after HD and include central nervous system effects, such as headache, nausea, altered vision, and, in some rare cases, seizures, and coma. Prevention is the treatment of choice and is accomplished by initiating HD gradually, including shorter treatment times with lower blood flow rates in new patients.[6]

PREVENTING AND TREATING HEMODIALYSIS VASCULAR ACCESS FLOW DYSFUNCTION

Preventing and treating vascular access flow dysfunction is important for both clinical and economic reasons. Maintaining adequate vascular access in HD is extremely important. Complications associated with vascular access flow dysfunction are significant clinical events and are a major cause of hospitalization. Thrombosis is the most common type of vascular access flow dysfunction and is usually the result of venous stenosis.[13] If not treated, thrombosis will result in loss of vascular access.

Routine hemodialysis vascular access function monitoring

Trained dialysis staff prospectively and routinely monitor vascular access function, which is paramount to preventing thrombosis. KDOQI clinical practice guidelines recommend routine inspection, palpation, and auscultation of the AV access. In addition, clinical scenarios such as a decrease in delivered HD dose, difficulty in cannulation, prolonged bleeding after needle removal, or altered character of the pulse or thrill may indicate access malfunction.[13] For routine CVC monitoring, KDOQI considers it reasonable to assess CVC function during each HD treatment by evaluating if the prescribed extracorporeal blood flow to meet the target HD dose can be maintained without lengthening the prescribed HD treatment time.[13]

Preventing hemodialysis vascular access flow dysfunction

Inconsistent definitions and study methodologies make comparing AV fistula and AV graft patency rates difficult. However, stenosis can cause thrombosis and loss of function in both. Stenosis may be corrected by percutaneous transluminal angioplasty, stent placement, or, if necessary, surgical revision of the vascular access site. Correcting stenosis to maintain patency is effective in preventing future thrombosis.[13]

Case 30-1, Question 9: Do fish oil supplements and oral anticoagulant or antiplatelet agents have a role in preventing thrombosis in R.W.'s AV fistula?

A functioning AV fistula is essential to R.W.'s HD treatment, and many studies have attempted to identify a treatment to effectively prevent vascular access thrombosis. Most recently, fish oil, simvastatin-ezetimibe, and clopidogrel-prostacyclin have been evaluated for preventing AV fistula thrombosis.

A study of Fish Oils and Aspirin in Vascular Access Outcomes in Renal Disease (FAVOURED) evaluated fish oil 4 g/day in patients undergoing AV fistula placement. Aspirin 100 mg/day was compared to placebo in a subset of patients. Neither fish oil nor aspirin was better than was placebo for preventing AV fistula failure or thrombosis.[48] Another analysis of the FAVOURED study assessed additional outcomes. This exploratory analysis found that fish oil and aspirin reduced AV fistula intervention rates but had no effect on other outcomes.[49]

A secondary analysis of the Study of Heart and Renal Protection (SHARP) trial found that simvastatin-ezetimibe was no better than was placebo in preventing the need for intervention, access thrombosis, or the rate of any vascular occlusive event in patients with a preexisting AV fistula or graft.[50]

One small, randomized, placebo-controlled trial evaluated clopidogrel-prostacyclin to prevent AV fistula flow dysfunction. At 1 year, the rate of primary AV fistula failure was significantly lower in the clopidogrel-prostacyclin–treated group, and primary patency,

adverse effects, and bleeding were not significantly different between groups.[51] Although this study's results seem promising, because of its sample size and methods, KDOQI does not recommend the clopidogrel-prostacyclin to prevent AV fistula flow dysfunction.[13]

Maintaining R.W.'s vascular access function is of ultimate importance. However, based on the evidence, KDOQI does not recommend the routine use of fish oil or aspirin to prevent AV fistula flow dysfunction and states that there is inadequate evidence to recommend simvastatin-ezetimibe or clopidogrel-prostacyclin.[13] Therefore, none of these agents are appropriate for R.W. In addition to lack of evidence, the risks of bleeding with antiplatelet or oral anticoagulant agents to prevent AV access thrombosis may be increased in the elderly population and those patients with high bleeding risks, such as those with kidney failure.[13]

Preventing thrombosis in other vascular access types (eg, AV graft and CVC) is also important. As with AV fistulas, preventing AV graft thrombosis and maintaining longevity of use is a major consideration. Up to 80% of AV graft failures are due to thrombosis caused by stenosis at the venous anastomosis.[13]

There is no role for low-dose warfarin in achieving a targeted international normalized ratio of 1.4 to 1.9 to prevent AV graft thrombosis or prolong AV graft survival.[52] As with AV fistulas, KDOQI determined that there is inadequate evidence to recommend using simvastatin- ezetimibe to reduce AV graft interventions and thrombosis.[13]

However, unlike with AV fistulas, there may be a role for antiplatelet agents or fish oil in preventing AV graft thrombosis. In one study,[53] the combination of dipyridamole 200 mg and aspirin 25 mg twice daily in HD patients with low bleeding risk showed statistically significant improvement in AV graft primary patency. Despite statistical significance, the difference of essentially 6 weeks in the median time to AV graft failure may not be clinically significant.[53] As a result, KDOQI suggests carefully considering individual patient benefits, risks, and circumstances before using dipyridamole and aspirin to prevent AV graft thrombosis.[13] Fish oil

supplements may have a role in reducing short-term AV graft thrombosis and corrective interventions,[54,55] but there is inadequate evidence to recommend their use for prolonging long-term AV graft patency.[13]

Both systemic and intraluminal agents have been evaluated to prevent CVC thrombosis. Owing to inadequate evidence of benefit and increased risk of harm, KDOQI does not recommend the routine use of prophylactic systemic anticoagulants for the sole purpose of maintaining or improving CVC patency. However, KDOQI suggests that low-dose aspirin 81 mg may be used in patients with low bleeding risk to maintain CVC patency.[13] For intraluminal agents, KDOQI's expert opinion is that either citrate or UFH CVC locking solutions are reasonable options. Available data do not show that one is better than the other. KDOQI does not suggest low-concentration citrate (<5%) or tissue plasminogen activator once per week as prophylactic CVC locking solutions to reduce CVC dysfunction.[13]

Treatment of hemodialysis vascular access flow dysfunction owing to thrombosis

A thrombosed AV fistula or AV graft is considered a medical emergency in patients on HD and requires immediate attention. Once thrombosis occurs in an AV fistula or AV graft, it can be managed by surgical or mechanical thrombectomy with or without stent placement, and/or use of thrombolytic agents. Interventional radiologists typically use alteplase instilled at the vascular access site and allowed to dwell for 1 hour before mechanical intervention. Thrombolytic therapy should be avoided in those patients with an increased risk of bleeding. For CVC occlusion due to thrombosis, KDOQI recommends intraluminal administration of alteplase 2 mg by the dwell or push method in each CVC port.[13]

ARTERIOVENOUS ACCESS INFECTION

Case 30-1, Question 10: HD vascular access sites are assessed by trained dialysis personnel at every treatment to identify any signs and symptoms of infection. In addition to routine assessment, should R.W. be given prophylactic antibiotics (eg, cefazolin with each HD) to avoid HD AV access site infection? Why?

Patients are taught to monitor their own vascular access site, and at each HD treatment, trained staff examine the access site before cannulation. Examination includes signs of infection such as erythema, skin breakdown, purulent discharge, and presence of exposed graft material.[13] In the absence of signs or symptoms of vascular access infection, prophylactic antibiotics offer no benefit. On the contrary, indiscriminate use of antibiotics could lead to colonization with resistant organisms. Thus, R.W. should not receive a prophylactic antibiotic with HD.

Vascular access infections are a serious complication of HD, often leading to hospitalization and increased mortality.[13] If signs and symptoms of infection are present, prompt treatment is necessary to preserve the vascular access and to prevent serious morbidity and mortality. Vascular access infections can range from localized (eg, mild cellulitis) to systemic (eg, bacteremia or sepsis). Vascular access infections are predominantly caused by *S. aureus* or *S. epidermidis*. Infections with gram-negative organisms as well as *Enterococcus* species occur less frequently.[13]

In patients with suspected vascular infections, before starting antibiotics, KDOQI recommends obtaining cultures and sensitivities of the blood and any available infected AV access vessel/material, surrounding tissue, or drainage. Empiric broad-spectrum antibiotics should be initiated quickly along with timely referral to a vascular access surgeon. As with all empiric antibiotic therapy, culture results should be strictly followed up, and the antibiotic regimen adjusted based on microorganism sensitivities. Treatment duration is based on the extent of the vascular access infection. There is a role for surgical incision and resection of infected AV grafts. AV fistula infections are rare, but when they occur, they should be treated as

subacute bacterial endocarditis (Refer to Chapter 66, Endocarditis) with 6 weeks of antibiotic therapy.[13]

CASE 30-2

Question 1: D.B. is a 56-year-old, 168-lb (76.20-kg) female who started HD 3 weeks ago and had no predialysis care. She is dialyzed through a CVC three times a week with 4-hour treatments using a high-flux dialyzer. Upon arrival at the dialysis facility for her routine HD, she reports having chills. Her temperature is 100.40 °F (38 °C), her blood pressure is normal, and her heart rate is slightly elevated. The catheter insertion site appears normal (ie, not red, purulent, or warm to the touch). Blood is drawn both from the catheter and a peripheral vein and sent to the laboratory for white blood cell (WBC) count and cultures. Her WBC count is 22,000 cells/mm^3, and the blood cultures and sensitivities are pending.

What are your recommendations for empiric antibiotic therapy for D.B.'s suspected HD catheter–related bacteremia?

Intravenous empiric antibiotic therapy for suspected CVC bacteremia should cover the predominant pathogens involved (*S. aureus*, *S. epidermidis*, and gram-negative organisms). Usually, the combination of intravenous vancomycin and an agent that covers gram-negative bacilli according to the local antibiogram is prescribed as empiric therapy. Intravenous cefazolin 20 mg/kg after each HD can be used instead of vancomycin in settings with a low prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA).[56] High-flux dialyzer membranes result in greater removal of vancomycin during HD than do conventional dialyzer membranes. Intradialytic dosing of vancomycin is convenient, and it avoids the need for additional intravenous access, longer stays in the HD facility, and home antibiotic administration. For patients such as D.B. receiving high-flux HD, prior guidelines advised a vancomycin loading dose of 20 mg/kg of actual body weight (ie, D.B. weighs 165.35 pounds [75 kg]; therefore, she should receive a vancomycin loading dose of 1500 mg) administered during the last 60 to 90 minutes of HD followed by a dose of 500 mg administered during the last 30 minutes of each subsequent HD.[56] However, more recent dosing guidelines recommend individualized vancomycin dosing along with therapeutic

drug monitoring.[57] In patients on HD, vancomycin dosing should be based on actual weight at the time the dose is given; loading doses range from 25 to 35 mg/kg, and empiric maintenance doses range from 7.5 to 15 mg/kg, depending on dialyzer type and timing of vancomycin administration; a maximum loading dose of 3 g in patients with obesity; and an efficacy target of a 24-hour area under the curve (AUC):mean inhibitory concentration (MIC) of 400 to 600 mg•h/L, assuming an MIC of ≤1 mg/L. The new guidelines acknowledge the lack of evidence in HD, the absence of Bayesian models for dosing in dialysis, and the logistic challenges in implementing the recommendations in an outpatient dialysis facility.[57,58] As an alternative to the goal AUC:MIC, they suggest predialysis vancomycin concentration monitoring, with a goal concentration of 15 to 20 mg/L.

Antibiotic choice for gram-negative bacilli is based on the local antibiogram. Third- or fourth-generation cephalosporins or aminoglycosides can be used. Intravenous gentamicin (or tobramycin) 1 mg/kg, not to exceed 100 mg, infused over 30 minutes after each HD can be used for empiric gram-negative coverage[56] with appropriate serum concentration monitoring. However, aminoglycoside serum concentration monitoring in some outpatient hemodialysis facilities may not be practical, and aminoglycoside use in patients on HD is associated with an increased risk of irreversible vestibular and ototoxicity.[56] Subsequent antibiotic therapy should be tailored based on culture and sensitivity results. D.B. should receive antibiotic treatment for 4 to 6 weeks for uncomplicated *S. aureus* infection or 7 to 14 days for bacteremia caused by gram-negative bacilli or *Enterococcus* species.[13,56] D.B.'s CVC infection treatment will also include assessing if the CVC needs to be removed or replaced.[13,56]

PERITONEAL DIALYSIS

PD, an alternative to HD, relies on principles similar to those described with HD. The peritoneal lining acts as the semipermeable membrane, the peritoneal cavity is the location for dialysate to flow into and remain (ie, dwell) for a prescribed amount of time, and the capillary network in the peritoneum is the blood source. The process of PD differs from that of HD in that there is no external dialyzer membrane, no extracorporeal circuit, and no ability to change transmembrane pressure. PD is performed daily, and the dialysate is exchanged multiple times after each prescribed dwell time. With appropriate training, patients can perform PD in non–health care settings.

Conceptually, the process of PD is similar to that of HD in that uremic toxins and other solutes are removed by diffusion and convective transport down a concentration gradient from the capillary system across a semipermeable membrane, the peritoneal lining, into the dialysate. A primary difference is that blood flow rates and dialysate flow rates cannot be manipulated in PD to improve the removal of water and solutes. The result is a very slow dialysate flow rate of ~7 mL/minute when 10 L of fluid is drained per day. Solute loss occurs by diffusion for small molecules and through convection for middle molecules. Osmosis is the process by which fluid removal takes place in PD.[59]

PD can be performed using different techniques: continuous ambulatory peritoneal dialysis (CAPD) or automated peritoneal dialysis (APD). The most common method is CAPD during which a patient, using sterile technique, instills and withdraws dialysate through a PD catheter placed in the abdomen (**Fig. 30-6**). Scientific advances have resulted in specialized devices or machines (ie, cycler) to perform APD that facilitate the exchange process and improve patient convenience. Types of APD include continuous cycling peritoneal dialysis (CCPD) and nocturnal intermittent peritoneal dialysis (NIPD).[59] APD methods have grown in popularity, especially in children requiring dialysis. Although lower rates of peritonitis are observed in APD compared with that in CAPD,[60] other outcomes measures, such as mortality rates and need for transition to HD, are similar between the two modalities.

Figure 30-6 Person having continuous ambulatory peritoneal dialysis. The fresh dialysate (shown as clean fluid hanging from the intravenous [IV] pole) flows into the person's abdomen through the PD catheter, where it dwells for a prescribed amount of time and then is drained into the drain bag (shown on the floor). The transfer set is the tubing that connects the peritoneal dialysis catheter surgically placed in the patient to the dialysate bags. Peritoneal Dialysis Access

PD access is achieved via an indwelling catheter surgically inserted through the abdominal wall. The most common design is the Tenckhoff® catheter, made of silicone rubber or polyurethane. It consists of a tube, straight or curled, with many holes in the distal end for fluid inflow and outflow. The catheter also has a single or double cuff, which anchors the catheter internally and externally by promoting fibrous tissue growth; the cuff also serves as a barrier to bacterial migration. Maintaining an unobstructed outlet port is essential for successful PD.[59]

Peritoneal Dialysis Dialysate

CASE 30-3

Question 1: K.M., a 27-year-old female, has a 20-year history of type 1 diabetes mellitus (T1DM). She is 64 inches (162.56 cm) tall and weighs 121 pounds (54.88 kg). She has kidney failure requiring dialysis due to her diabetes and has been treated with CAPD for 1 year. Her CAPD prescription is three exchanges with 1.5% dextrose during the day and a fourth, overnight exchange with 4.25% dextrose. She has a double-cuff Tenckhoff® catheter and uses a Y-transfer set for her exchanges. Her blood pressure is controlled, and she shows no evidence of edema. She has no residual kidney function.

What is the purpose of the dextrose in K.M.'s dialysate? Why would the dextrose concentration be different in the overnight dwell compared to the daytime dwell?

The composition of PD dialysate is different from the composition used for HD (refer to Table 30-1). The process of HD has the advantage of adjusting the transmembrane pressure to vary the amount of fluid removed by ultrafiltration. In PD, the amount of fluid removed, or ultrafiltration, is dependent on the hyperosmolality of the dialysate, the length of time the dialysate dwells, and the individual

characteristics of the patient's peritoneal lining.[59] Commercially available PD dialysate has 1.5%, 2.5%, and 4.25% dextrose concentrations, with net fluid losses during a 4-hour dwell period of 200 and 400 mL for the 1.5% and 2.5% solutions, respectively, and ~700 mL for the 4.25% solution after an overnight dwell. In addition to dextrose, CAPD dialysate contains electrolytes (see Table 30-1). Bicarbonate is not compatible with the calcium and magnesium in PD dialysate; therefore, PD dialysate contains lactate. Acid–base balance is achieved through the absorption of lactate from the dialysate, which subsequently is metabolized to bicarbonate in vivo.[59,61]

As dextrose is absorbed through the peritoneal lining into the patient's bloodstream, the osmotic gradient between the dialysate and the blood progressively dissipates, reducing ultrafiltration. Toward the end of the long dwell (typically overnight for CAPD and during the day for APD with a prescribed day dwell), more dialysate fluid may be absorbed than fluid ultrafiltered, resulting in a negative net ultrafiltration volume where the drained volume is less than the infused volume. A negative net ultrafiltration volume is undesirable. Greater ultrafiltration and fluid management are predictors of survival.[59,61]

K.M. is prescribed a very common CAPD regimen that would be expected to achieve fluid removal of ~1300 mL, based on 200 mL of ultrafiltration from each daytime exchange and 700 mL overnight. At this time, K.M. is not showing signs of altered fluid status, her blood pressure is normal, and there is no edema; hence, adjustments to the CAPD are not needed. If adjustments are needed, the dialysate prescription can be changed to achieve fluid balance. Fluid retention is addressed by increasing the dextrose concentration used in the daytime exchanges, beginning with 2.5% in place of one of the 1.5% solutions. This change is expected to result in an additional removal of 200 mL, and therapy can be further adjusted as necessary. For patients with signs and symptoms of excessive fluid removal, the number of exchanges per day may be decreased as long as adequate solute removal is achieved. If four exchanges are needed

to manage solute removal, oral fluid intake can be liberalized to maintain fluid balance.[61]

Icodextrin is an alternative to dextrose as the osmotic agent in the peritoneal dialysate, and is superior to 4.25% dextrose for ultrafiltration.[62] Icodextrin is a starch-derived, water-soluble, nondextrose polymer, and is labeled for use in the United States during the long-dwell period in patients receiving CAPD or APD. Unlike glucose, icodextrin does not readily diffuse across the peritoneal membrane, but it is slowly removed from the peritoneal cavity via convective uptake into the peritoneal lymphatic system.[63] Other advantages of icodextrin compared to glucose-containing PD dialysate include less glucose absorption, carbohydrate exposure, fat accumulation, and weight gain. Its main disadvantage is a higher acquisition cost.[59,61]

Factors to be considered when icodextrin is used for PD include decreased insulin requirements in patients with diabetes and false elevations in glucose concentrations with certain glucose-monitoring devices unable to distinguish glucose from maltose. False readings may result in doses of glucose-lowering medications being increased unnecessarily, resulting in iatrogenic hypoglycemia. Other undesirable effects of icodextrin include skin rash, mild hyponatremia, sterile peritonitis, and false reductions of serum amylase concentrations.[64]

Process of Peritoneal Dialysis Ultrafiltration

Most PD is done in non–health care environments such as the home or the workplace. CAPD exchanges are performed by instilling 2 to 3 L of sterile dialysate into the peritoneal cavity through a surgically placed permanent catheter. Dialysate is delivered and returned through the catheter using Y-sets and double-bag systems. The Y-transfer set uses three limbs of tubing, with fresh dialysate attached to the upper arm of the Y, an empty bag to the lower arm, and the stem connected to the catheter (see Fig. 30-6). One limb of the Y-shaped tubing is the inflow arm, which is used to transfer clean

dialysate into the peritoneal cavity. The other limb of the Y-shaped tubing is the outflow arm and is used to remove spent dialysate from the peritoneal cavity. Clamping the inflow arm and opening the stem and outflow arm allow spent (or used) dialysate to drain from the peritoneum into the empty bag. Reversing the clamps then permits fresh dialysate to enter the peritoneum after a small rinse of the line is performed with the fresh dialysate. Clamping the PD catheter allows the patient to remove the Y-transfer set and bags. The double-bag system uses preattached bags to both limbs and the patient, and makes only a single connection to the catheter.[59] Use of the Y-transfer set has reduced episodes of peritonitis from ~1 for every 9 to 12 patient-months to 1 for every 24 to 36 patient-months. PD performed with the cycler involves only two disconnections of the system, compared with four for CAPD.

In CAPD, the dialysate dwells within the peritoneal cavity for 4 to 8 hours, and then it is drained and replaced with fresh dialysate. The drained, used dialysate is called spent dialysate. This process of fill, dwell, and drain is performed three to four times during the day, with an overnight dwell. The patients can perform any of these exchanges in their normal home or work environment.[59]

In APD, the cycler machine is programmed and automatically cycles dialysate into and out of the peritoneal cavity typically during nighttime hours. Patients receiving CCPD will generally have three to five exchanges at night using the cycler, each lasting ~2 hours. During the daytime hours, the patient maintains a reservoir of dialysate in the peritoneal cavity, resulting in a long dwell. The cycler process then repeats at night. Patients with NIPD have six to eight exchanges performed every night. However, there is no dialysate left to dwell in the peritoneum, and PD is not continued during the day. Nightly dwell times with NIPD are generally 1 to 2 hours for each exchange, resulting in higher small-molecule clearance because of the increased dialysate flow rate. The benefits of APD are that the patient is free from doing exchanges during the day, and the number of connections to the PD catheter is significantly reduced.[59]

PERITONEAL DIALYSIS UREA CLEARANCE

The process of HD maintains a large concentration gradient across the semipermeable membrane throughout the treatment. Unlike HD, during a typical dwell period for CAPD, concentrations of urea and other substances increase in the dialysate dwelling in the peritoneum relative to unbound plasma concentrations. During a 4-hour dwell, dialysate urea concentration achieves near equilibrium with plasma; therefore, the rate of elimination over the dwell time decreases significantly. Instilling fresh dialysate reestablishes the diffusion gradient and increases urea clearance. Urea clearance with PD is substantially lower than is urea clearance achieved with three times a week HD; therefore, multiple CAPD exchanges must be performed daily to achieve adequate urea clearance.[61]

Unlike HD, many patients on peritoneal dialysis have significant residual kidney function that typically lasts longer than that in patients receiving HD. Calculating urea clearance or the dose of PD takes into account both urea and creatinine clearance from PD and residual kidney function (creatinine clearance), reported as a weekly value.[59,61]

The 2006 KDOQI guidelines for PD dose recommend a target minimum Kt/V_{urea} of 1.7 and the target total weekly clearance of 50 L.[65] More recently, the solitary focus of a target dose of PD is being replaced with a comprehensive approach to assess broadly the effectiveness of the entire PD treatment. The newer approach takes into account clinical assessments, solute clearance measurements, prevention or treatment of PD-related complications, nutritional status, fluid removal, and the patient's quality of life.[59,61]

Residual kidney function, especially in patients on peritoneal dialysis, significantly contributes to solute and fluid clearance. Preserving whatever kidney function is present at the start of PD is extremely important; therefore, nephrotoxins such as aminoglycosides, nonsteroidal anti-inflammatory agents, and radiocontrast dye should be avoided if possible.[59,61]

Peritoneal Dialysis Complications

PERITONEAL DIALYSIS EXIT-SITE INFECTION: PROPHYLAXIS

CASE 30-3, QUESTION 2: PD catheter exit-site infections (ESIs) are a significant risk factor for developing peritonitis. Routine retraining on PD technique is recommended to reduce the risk of ESI and peritonitis.[66] K.M. arrives to her retraining clinic visit. What information should be reviewed with K.M. about her routine catheter care to prevent an ESI infection? Recommend an appropriate topical antimicrobial for K.M. to administer around the catheter exit-site.

The primary goal of exit-site care is to prevent PD catheter ESI and thus peritonitis. Preventative measures for initial catheter placement include prophylactic perioperative antibiotics; adequate catheter placement; dedicated postoperative catheter care; and, once healed, routine daily care of the exit site. Prophylactic antibiotics at the time of catheter placement are effective, and either a first-generation cephalosporin or vancomycin, depending on local antibiotic resistance, is recommended.[66] Dialysis nurses use sterile technique to change dressings around a new PD catheter until the exit site is well healed, which can take up to 2 weeks. After that, patients are trained to do routine exit-site care by closely following steps essential to avoid infection. First, K.M. should meticulously clean her hands by rubbing both hands for at least 15 seconds using antibacterial soap or antiseptics that contain at least 70% alcohol. Then, she should wash the exit site daily with antibacterial soap, although use of an antiseptic (eg, povidone iodine or chlorhexidine) is a reasonable option as long as concentrations are noncytotoxic. Hydrogen peroxide should be avoided because of its drying effect. After cleaning her hands and the exit site, K.M. can apply mupirocin or gentamicin cream around the catheter exit site daily using a cotton swab.[68]

Mupirocin 2% cream and gentamicin sulfate 0.1% cream are equally effective in preventing *S. aureus* infections. Mupirocin cream is typically the antimicrobial cream of choice, but gentamicin cream is an acceptable alternative. Unlike mupirocin cream, gentamicin cream is highly effective in reducing *P. aeruginosa* and other gram-

negative catheter infections. However, daily use of gentamicin cream may allow for an emergence of infections caused by other organisms. Mupirocin ointment, not the cream, can cause structural damage to polyurethane PD catheters and should be avoided. The final step in daily PD catheter care is to immobilize the catheter with a small gauze dressing and tape to prevent pulling and trauma to the exit site, which may lead to infection.[68]

Case 30-3, Question 3: During retraining, the PD nurse reminds K.M. that she needs to take prophylactic antibiotics before any extensive dental work. What is the PD nurse concerned about, and why are prophylactic antibiotics necessary?

Preventing peritonitis is critical to avoiding high rates of morbidity and mortality. Antibiotic prophylaxis for colonoscopy, invasive gynecologic procedures, dental procedures, and esophagogastroduodenoscopy have reduced rates of peritonitis.[69] These invasive procedures result in contiguous spread of bacteria or fungi or seeding the peritoneum during bacteremia, which then can cause peritonitis. The ISPD guidelines recommend prophylactic antibiotics for invasive gynecologic procedures and colonoscopy.[66] Although the optimal regimen has not been clinically studied, a systematic review suggests that an intravenous regimen of ampicillin plus an aminoglycoside, with or without metronidazole, may be used.[66,70] The guidelines also state that it would be reasonable for K.M. to receive a single dose of amoxicillin before extensive dental work.[66]

PERITONEAL DIALYSIS EXIT-SITE INFECTION: TREATMENT

Case 30-3, Question 4: If K.M. were to have signs and symptoms of an ESI, would oral antibiotic therapy be appropriate?

ESI is diagnosed when there is purulent drainage, with or without erythema of the skin, at the catheter–epidermal interface. Peritoneal dialysis catheter ESIs are most often caused by *S. aureus* and/or

Pseudomonas species. Exit-site drainage should be sent for Gram stain, culture, and sensitivity to direct antibiotic therapy. Empiric oral antibiotic treatment should start immediately with appropriate coverage for *S. aureus*. A penicillinase-resistant penicillin (eg, dicloxacillin or flucloxacillin) or first-generation cephalosporin is recommended unless there is a prior history of infection or colonization with MRSA or *Pseudomonas* species. Recommendations for those patients include a glycopeptide or clindamycin, or appropriate antipseudomonal antibiotic, respectively.[68]

If the Gram stain demonstrates the presence of gram-positive organisms, continue the empiric coverage for *S. aureus* for at least 2 weeks.[68] Oral antibiotic therapy has been shown to be as effective as intraperitoneal (IP) antibiotic therapy except for documented MRSA infections.[68] If gram-negative pathogens are present, the clinical guidelines recommend prolonged dual therapy including oral fluoroquinolone therapy. Fluoroquinolone monotherapy is not recommended because resistance develops rapidly. Oral fluoroquinolones should be separated by 2 hours from calcium-containing products, iron, multivitamins, antacids, zinc, or sucralfate because of chelation of the antibiotic and the potential for subtherapeutic effect. Antibiotic therapy for pseudomonal ESI should be continued for a minimum of 3 weeks.[68]

PERITONEAL DIALYSIS–ASSOCIATED PERITONITIS

Case 30-3, Question 5: Six months later (18 months of PD), K.M. presents to the PD clinic with moderate abdominal pain and cloudy effluent (ie, spent dialysate). She does not report a fever. K.M. reports an accidental catheter disconnection 2 days ago. On physical examination, her weight today is 143 pounds (64.86 kg), her vital signs are normal, lungs are clear to auscultation, abdominal tenderness is generalized, and the catheter tunnel and exit site appear normal. K.M. brought the cloudy dialysate with her and it is sent to the laboratory for cell count and differential, Gram stain, and cultures. Early laboratory results show an effluent WBC count of 330 cells/μL with 62% neutrophils. The Gram stain and culture results are pending. What is the most likely diagnosis for K.M.? Recommend appropriate treatment and monitoring.

K.M.'s clinical presentation of abdominal pain, recent accidental catheter disconnection, and cloudy dialysate strongly suggest the possibility of peritonitis. The 2022 ISPD Practice Guidelines recommend a diagnosis of peritonitis be made if two of the following are present: dialysate WBC >100/μL with >50% neutrophils after a two hour dwell; clinical features consistent with peritonitis; or positive dialysis effluent culture.[67] Although not present in K.M., peritonitis can also present with nausea and vomiting and fever. Cloudy dialysate effluent is not always present.[66]

Because K.M. has normal vital signs and her abdominal tenderness is not severe, she can be treated as an outpatient with IP antibiotic therapy. K.M. would be hospitalized for treatment if she were showing signs of sepsis or had severe abdominal pain. Peritonitis is a significant complication, and empiric antibiotic therapy should be started as soon as possible. Empiric therapy must cover both gram-positive and gram-negative organisms, and the choice of agents should be based on local microbial sensitivity data.[67]

The ISPD Practice Guidelines recommend empiric antibiotic therapy be started as soon as possible and include vancomycin or a first-generation cephalosporin (eg, cefazolin) to treat gram-positive organisms and an antipseudomonal cephalosporin (eg, ceftazidime, cefepime) or an aminoglycoside (eg, gentamicin) to treat gram-negative organisms.[67] The goal of antibiotic therapy is to rapidly resolve inflammation and preserve peritoneal membrane function.[68]

General principles of treating PD-associated peritonitis include (a) IP antibiotics are the preferred route of administration unless the patient has signs and symptoms of sepsis; (b) daily intermittent IP aminoglycoside and avoid prolonged courses of IP aminoglycoside; (c) intermittent IP vancomycin and serum vancomycin concentrations maintained >15 μg/mL; and (d) IP cephalosporin administered either continuously (in each exchange) or on a daily intermittent basis. Intravenous administration of antibiotics is recommended for patients experiencing signs and symptoms of systemic infection.[68]

The ISPD clinical guidelines list antimicrobial dosing for both intermittent and continuous dosing; however, intermittent dosing is preferred. In CAPD, IP vancomycin dosing for intermittent

administration is 15 to 30 mg/kg added to 1 exchange of dialysate every 5 to 7 days and aminoglycoside (eg, gentamicin) dose 0.6 mg/kg added to 1 exchange of dialysate daily. Antibiotics should be allowed to dwell for at least 6 hours. Both agents can be coadministered IP in the same dialysate, but separate syringes must be used to add the antibiotics to dialysate.[66] If K.M., who weighs 143 pounds (64.86 kg), is prescribed vancomycin and gentamicin, a 1- to 2-g dose of vancomycin IP and 40-mg dose of gentamicin IP would be appropriate. Doses should be rounded to an easily measurable quantity for patients to self-administer. For instance, K.M.'s original vancomycin dose calculation comes to 975 to 1950 mg. Vancomycin for injection is available in 1-g vials, and hence the dosing recommendation of a 1- to 2-g dose. The calculated dose of gentamicin would be 39 mg, but rounding up to 40 mg results in an easier to measure dose because the concentration of gentamicin for injection is 40 mg/mL.

A registry-based study of patients with peritonitis concluded that aminoglycosides did not adversely affect residual kidney function, but there was high systemic absorption across an inflamed peritoneal membrane, and the half-life of gentamicin was prolonged.[71] In this instance, gentamicin can accumulate and cause adverse effects. Short-term use appears to be safe and effective, but there is a potential risk of oto- and/or vestibular toxicity with prolonged therapy. If possible, aminoglycoside use should be limited.[61,67] Subsequent antibiotic therapy should be based on culture and sensitivity results, incorporating specific dosage regimens based on the consensus recommendations.[67]

K.M. is instructed to return to the clinic in 3 days. Her PD catheter site will be reexamined, her clinical signs and symptoms will be reevaluated, and the effluent appearance observed and cell count repeated. When the culture and sensitivity results are available, K.M.'s antimicrobial therapy should be targeted as soon as possible. Assuming clinical improvement, K.M. will receive IP antibiotics as an outpatient for 14 to 21 days depending on the culture results.[66]

Case 30-3, Question 6: In addition to empiric antibiotics, IP UFH is prescribed. What is the indication for UFH? While teaching K.M. how to administer her antibiotics, the pharmacist notices that K.M.'s diabetes has been effectively treated with 10 units of regular insulin IP with each daytime exchange and 15 units in the overnight exchange. What is the best route of administration for insulin administration during her peritonitis episode?

K.M.'s PD effluent was cloudy, and she may benefit from adjunctive IP UFH in addition to empiric antibiotics. Heparin 500 units/L can be added to each dialysate exchange to prevent fibrin clots from forming, which could obstruct dialysate outflow from the peritoneal cavity and occlude the catheter.[66]

During peritonitis, an inflamed peritoneal lining has increased permeability to water, glucose, and proteins, often resulting in hyperglycemia and fluid overload.[66] Insulin absorption will also be increased. As a result, K.M.'s blood glucose concentrations and insulin doses require close attention during the peritonitis.[66] Temporarily switching insulin administration from IP to subcutaneous will simplify treating the variable blood glucose concentrations that are likely to occur as the course of peritonitis resolves. Also see Case 30-3, Question 8, for other considerations regarding insulin dosing.

Case 30-3, Question 7: If K.M. was using APD instead of CAPD, how would the treatment of her presumed peritonitis infection be different?

For patients using APD, the choice of first-line antibiotics is the same as that for CAPD because the likely organisms are similar. Drug dosage regimens, however, can differ because patients having CCPD or NIPD undergo PD only during the nighttime hours, and those treated with NIPD do not have peritoneal dialysate dwelling during the day. The rapid exchanges in APD may lead to inadequate time to achieve therapeutic drug concentrations.[66] The dose of cefazolin in APD is 15 to 20 mg/kg (rounded to the nearest 500 mg) every day, in the long day dwell. If K.M. were treated with APD, she would receive cefazolin 1000 to 1500 mg IP in the long day dwell. A

concern is that patients given a single dose of a cephalosporin during the long day dwell may have IP antibiotic concentrations at night that are below the MIC of most organisms, allowing biofilm-associated organisms to survive, resulting in relapsing peritonitis. A more conservative approach is to add the cephalosporin to each APD exchange. Because of the lack of clinical trials with other antibiotics in APD, extrapolation from the CAPD literature is often necessary.[72,73]

Case 30-3, Question 8: K.M.'s peritonitis resolved with antibiotic therapy, and she has resumed her routine monthly clinic visits. K.M.'s only question today is about an increase in her body weight. Her vital signs and physical examination are normal. K.M.'s body weight has increased 26 pounds (11.79 kg) since starting PD. Fluid retention is possibly the cause of the weight gain, but it is unlikely that K.M. would be asymptomatic (eg, difficulty breathing, swelling) or not have signs of fluid overload (eg, hypertension, crackles on lung examination, edema). What is another cause for K.M.'s weight gain? How might this affect her insulin requirements?

PERITONEAL DIALYSIS–ASSOCIATED WEIGHT GAIN

Dextrose is present in peritoneal dialysate and serves as an osmotic agent for ultrafiltration. Higher dextrose concentrations in peritoneal dialysate result in greater fluid removal. Approximately 500 to 1000 kcal/day are absorbed as glucose from PD dialysate, which, in the absence of decreased oral caloric intake, leads to weight gain.[61] Insulin requirements increased in patients with diabetes because of the additional calories absorbed through the peritoneum. Insulin doses administered IP usually are two to three times the normal subcutaneous dose because of reduced bioavailability of 20% to 50% by this route.[74] Also see Case 30-3, Question 6, for other considerations regarding insulin dosing.

Dosing of Drugs in Kidney Failure

David J. Quan

CORE PRINCIPLES		CHAPTER CASES
1	The pharmacokinetics and pharmacodynamics of many drugs are altered in patients with impaired kidney function (eg, declining glomerular filtration rate) or who are on kidney replacement therapy.	**Case 31-1 (Questions 1, 2)** **Case 31-2 (Question 1)** **Case 31-3 (Questions 1, 3)** **Case 31-4 (Questions 1, 2)** **Case 31-5 (Questions 1)** **Case 31-8 (Questions 1, 3)**
2	Clinicians should be aware of drugs that require dosage adjustment in the setting of kidney dysfunction to avoid adverse drug events and poor patient outcomes.	**Case 31-1 (Questions 1, 2)** **Case 31-3 (Questions 1, 3)** **Case 31-4 (Question 1,2)** **Case 31-5 (Questions 1)**

CORE PRINCIPLES		CHAPTER CASES
3	Dosages of drugs that are cleared by the kidneys should be adjusted according to the patient's kidney function (eg, creatinine clearance or glomerular filtration rate). The initial dose can be determined using the manufacturer's prescribing information, published guidelines, or published literature.	**Case 31-1 (Questions 1, 4)** **Case 31-3 (Question 3)** **Case 31-4 (Question 1)** **Case 31-5 (Questions 1)**
4	Many drugs have a narrow therapeutic window (range of drug concentrations that will achieve the desired effect), for which there may be lack of efficacy with subtherapeutic levels and adverse events associated with elevated levels. Therapeutic drug concentration monitoring should be performed to achieve the desired target concentration.	**Case 31-1 (Questions 2, 3)** **Case 31-5 (Question 2)** **Case 31-7 (Question 1)** **Case 31-8 (Question 3)**
5	Kidney replacement therapy (eg, hemodialysis, continuous venovenous hemofiltration) can have a significant influence on the extracorporeal removal of drug. Clinicians should be aware of the method of kidney replacement therapy and its impact on drug dosing.	**Case 31-1 (Questions 5–8)** **Case 31-2 (Questions 1, 2)** **Case 31-3 (Questions 1, 4)** **Case 31-5 (Question 3)** **Case 31-6 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
6	Biotransformation of drugs may be altered in patients with kidney failure. Active or toxic metabolites may accumulate in patients with kidney failure, leading to adverse effects. Excipients such as diluents can also accumulate in the setting of kidney failure, resulting in toxicity.	**Case 31-3 (Question 2)** **Case 31-8 (Questions 1, 2)**

INTRODUCTION

The kidneys play an important role in the disposition of many drugs. It is important to design specific pharmacotherapeutic regimens for patients with kidney impairment. Without careful dosing and therapeutic drug monitoring for select medications in these patients, accumulation of drugs or toxic metabolites can occur, resulting in serious adverse effects. Many patients are treated with multiple medications, which may require even greater attention to dosage adjustment.

In addition to altered drug elimination, numerous other factors associated with kidney disease predispose patients to potential drug toxicity by altering the pharmacokinetic disposition and the pharmacodynamic effects of drugs. For example, the physiologic changes associated with uremia can change drug absorption, protein binding, distribution, or elimination. These physiologic effects can alter drug concentrations in the plasma or blood, and at the targeted tissue site of activity, thereby affecting drug efficacy and toxicity.

Less is known about the effect of kidney disease on drug pharmacodynamics (ie, the pharmacologic or toxicologic effects produced relative to the drug concentration). Patients with kidney

disease can be more sensitive to some drugs and experience an increased frequency of adverse drug reactions.

Effect of Kidney Failure on Drug Disposition

BIOAVAILABILITY

Several factors can potentially affect drug absorption in patients with kidney disease. Limited data are available describing altered bioavailability. For example, drug absorption could be impaired in uremia because of nausea, vomiting, diarrhea, gastritis, or edema of the gastrointestinal (GI) tract, the latter condition being a complication of nephrotic syndrome. Gastric and intestinal motility, as well as gastric emptying time, can be altered by the neuropathy associated with uremia. Uremia also can increase gastric ammonia, leading to an increased gastric pH, which may affect the bioavailability of drugs that require an acidic environment for absorption such as ferrous sulfate.[1] Similarly, calcium-containing antacids used by patients with kidney failure for GI symptoms and hyperphosphatemia can neutralize hydrochloric acid in the stomach and increase gastric pH. Patients with late-stage chronic kidney disease (CKD) often take oral phosphate binders, such as sevelamer and lanthanum carbonate, which can impair the absorption of other medications.[2,3]

The bioavailability of orally administered drugs also depends on the extent to which the drug is eliminated by first-pass (pre-systemic) metabolism. The first-pass hepatic metabolism of oral propranolol was found to be reduced in patients with kidney disease, leading to increased bioavailability.[4] Subsequent studies have attributed the observed increased concentrations of propranolol in kidney failure to a significant increase in the blood to plasma ratio.[5] Intestinal P-glycoprotein activity may be decreased as well.[6] Other drugs exhibiting increased bioavailability in kidney disease include zidovudine (AZT) and erythromycin.[7]

PROTEIN BINDING AND VOLUME OF DISTRIBUTION

Kidney disease can change the volume of distribution (Vd) of various drugs. The Vd or “apparent volume of distribution” is the “volume” or size of a compartment necessary to account for the total amount of drug in the body if it were present throughout the body at the same concentration as that found in plasma.

The extent to which a drug exerts its pharmacologic effects is related to the amount of free or unbound drug available for distribution to target tissues. Patients with kidney failure often have alterations in plasma protein binding, which can increase the amount of unbound drug. Clinically, this is most important for highly protein-bound (>80%) acidic drugs, whereas the binding of basic drugs is usually unchanged or possibly decreased in kidney disease.[8]

Hypoalbuminemia is a common complication of kidney failure. Because acidic rather than basic drugs are bound to albumin, their protein binding tends to be altered in patients with kidney failure **(Table 31-1)**.[9] Patients with uremia accumulate acidic metabolic byproducts that may inhibit binding or displace acidic drugs from albumin binding sites. This is supported by the observed improvement in protein binding after removal of uremic byproducts by hemodialysis. Finally, the structural conformation of albumin is altered in kidney disease, which may reduce the number or affinity of binding sites for drugs. Studies have demonstrated differences in the amino acid composition of albumin between healthy people and patients with uremia.[10] The anticonvulsant, phenytoin, is an example of a drug whose protein binding is altered in kidney disease.[11] This is discussed in more detail later in this chapter.

Table 31-1

Plasma Protein Binding (%) of Acidic Drugs in Kidney Failure

Drug	Normal	Kidney Failure
Cefazolin	85	69
Clofibrate	97	91
Diazoxide	94	84
Furosemide	96	94

Drug	Normal	Kidney Failure
Pentobarbital	66	59
Phenytoin	88–93	74–84
Salicylate	87–97	74–84
Sulfamethoxazole	66	42
Valproic acid	92	77
Warfarin	99	98

Drugs that are not highly protein bound (eg, gentamicin, isoniazid) have little change in their Vd in kidney disease. Digoxin is a unique exception in that its Vd is decreased in kidney disease. This is attributed to a decrease in myocardial tissue uptake of digoxin, leading to a decrease in the myocardial or tissue to serum concentration ratio.[12]

ELIMINATION

The extent to which kidney disease affects the elimination of a drug depends on the amount of drug normally excreted unchanged in the urine and the degree of kidney impairment. As kidney disease progresses, the kidney's capacity to excrete uremic toxins diminishes. Consequently, the ability to eliminate certain drugs that are excreted by the kidneys also decreases. If the dose of these drugs is not modified for the patient's degree of kidney dysfunction, these drugs will accumulate, potentially leading to an increase in the pharmacologic effect and toxicity.

The kidney eliminates drugs primarily by filtration or active secretion. Characteristics of a drug that determine its ability to be filtered include its affinity for protein binding and its molecular weight (MW). Drugs with low protein binding or those that are displaced from proteins in the setting of kidney disease are filtered more readily. Molecules with a high MW (>20,000 Da) are not readily filtered because of their large size. The reasons for how kidney disease selectively alters the process of glomerular filtration or tubular secretion of specific drugs are not well understood. The

elimination of drugs by the kidneys in patients with kidney disease usually can be estimated by measuring the ability of the kidney to eliminate substances such as creatinine (ie, creatinine clearance [CrCl]) (see Chapter 28, Chronic Kidney Disease).

Organic anion transporters (OATs) are predominantly found in the basolateral membrane of the renal tubules. OATs facilitate the uptake of small organic anions into renal tubular cells. Decreased OAT activity as a result of acute kidney injury can decrease the secretion of various drugs such as methotrexate, nonsteroidal anti-inflammatory drugs, and acetylsalicylic acid.[13]

Kidney disease can also have an important impact on the elimination of drugs that are primarily metabolized by the liver.[14] Metabolic processes, such as hydroxylation and glucuronidation, often produce inactive, more polar compounds that can be eliminated by the kidney. The metabolites of some drugs (eg, meperidine, morphine, procainamide) are pharmacologically active or toxic. In the setting of decreased kidney function, these metabolites may accumulate, leading to an increase in pharmacologic activity and adverse effects.[15] For example, the central nervous system (CNS) toxicity observed in kidney disease has been attributed to accumulation of the morphine metabolite, morphine-6-glucuronide.[16] Therefore, careful dosing modifications or avoidance of these drugs is warranted in patients with kidney impairment. Metabolic enzymes have been found within kidney tissue and may play a role in the metabolism of some drugs.[17] For example, the non-kidney clearance of drugs (eg, acyclovir) decreases in patients with kidney impairment and is believed to be caused by a decrease in “kidney” metabolism.[18]

Excipients used to formulate medications should also be considered. For example, the pharmacokinetics of antifungal agents such as posaconazole and voriconazole are not significantly altered in the setting of kidney dysfunction.[19,20] However, the parenteral formulations of itraconazole, posaconazole, voriconazole, and remdesivir contain the solubilizing agent, β-cyclodextrin, which is normally rapidly eliminated by glomerular filtration but can accumulate in patients with kidney impairment.[21,22] Hemodialysis and

continuous renal replacement therapy (CRRT) removes β-cyclodextrin but not voriconazole or posaconazole, therefore allowing standard intravenous (IV) doses to be given.[23–25]

Drug Removal by Dialysis

The effect of hemodialysis on the removal of a specific drug must be considered when using medications in patients undergoing dialysis. Patients may need supplemental doses of a medication after each hemodialysis session or alteration in their dosage to maintain therapeutic drug concentrations. Hemodialysis can also be initiated to hasten drug removal from the body in some cases of drug overdose.

The primary literature should be used to determine whether any information is available about the ability of hemodialysis to remove the drug. The application of data from the literature to a specific clinical situation often is difficult, as information pertaining to the removal of a specific drug by hemodialysis may be limited.

When applying information from the primary literature to a specific patient, the specifics of the dialyzer (eg, type of machine, membrane surface area, pore size, and blood and dialysis flow rates) must be considered (see Chapter 30, Dialysis Treatment for Chronic Kidney Failure). Furthermore, patient-specific information (eg, time of drug ingestion and liver and kidney function) from case reports in the literature also should be evaluated appropriately. The method used to calculate dialysis clearance also should be considered. In addition, clinical investigators often use predialysis and postdialysis serum drug concentrations for estimating drug dialyzability.[26]

The contributing effects of drug metabolism and excretion on drug elimination should also be taken into account.

DRUG-SPECIFIC PROPERTIES

The physical and chemical characteristics of drugs can be used to predict the effectiveness of dialysis on drug removal.[27–29] Low-MW compounds are more readily dialyzed by conventional hemodialysis

procedures because they can pass with greater ease across the dialysis membrane. Using cuprophane dialysis membranes, compounds with an MW of 500 or less are more likely to be significantly dialyzed than compounds with a high MW (eg, vancomycin, MW ~1400). Newer high-flux dialyzers using polysulfone-based membranes more effectively remove large chemical compounds (see Dialyzer Characteristics section and Chapter 30, Dialysis Treatment for Chronic Kidney Failure). In addition, water-soluble drugs (eg, aminoglycosides, lithium) are removed more readily by dialysis than are lipid-soluble compounds (eg, diazepam) or those that partition into red blood cells (eg, tacrolimus).

Pharmacokinetic characteristics (eg, Vd, protein binding) also can affect drug dialyzability. A drug with a large Vd that distributes widely into the peripheral tissues resides minimally in the plasma and, therefore, is not substantially removed by dialysis. This is particularly true for highly lipid-soluble drugs such as digoxin (Vd 300–500 L) and amiodarone (Vd 60 L/kg). In addition, drugs that are highly protein bound, such as warfarin (99%) and ceftriaxone (83%–96%), are not significantly removed by dialysis because the large protein–drug complex is unable to pass through the dialysis membrane.

Because clearance values are additive, the hepatic and other non-kidney plasma clearance of a drug should be considered in relation to the dialysis clearance. Only when dialysis clearance contributes a substantially additive effect to the patient's own clearance is drug elimination enhanced. For example, AZT has a large non-kidney plasma clearance in patients with severe kidney disease (~1200 mL/minute). Therefore, despite a hemodialysis clearance of 63 mL/minute, the contribution of dialysis to total AZT removal is negligible.

HIGH-FLUX HEMODIALYSIS

High-flux hemodialysis uses higher blood and dialysate flow rates compared with conventional methods. The enhanced efficiency of high-flux dialysis and the larger pore size of membranes made from

a variety of materials, such as polysulfone and polysulfone blends, allow for small- and mid-MW compounds (eg, vancomycin) to be partially removed. Drugs such as gentamicin and foscarnet, which are removed by conventional dialysis, are also efficiently removed by high-flux hemodialysis.[30,31] In many cases, the net amount of drug removed during a high-flux dialysis session is greater than the amount removed during conventional dialysis because of the larger pore size allowing for greater diffusion of solute. The principal difference is the greater efficiency and the ability to clear drugs of larger MW compared with conventional dialysis.

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

Continuous ambulatory peritoneal dialysis (CAPD) uses the patient's peritoneum as the dialysis membrane. Patients maintained with CAPD undergo infusion of a dialysate solution via a catheter inserted into the peritoneal cavity or the solution is allowed to dwell in the cavity for several hours. The accumulated fluid and uremic byproducts diffuse from the blood into the dialysate solution, which is exchanged every 4 to 8 hours (see Chapter 30, Dialysis Treatment for Chronic Kidney Failure).

Some drugs, such as antibiotics, can be administered intraperitoneally (IP) in patients on CAPD by directly adding them to the dialysate solution. This is particularly useful for patients with peritonitis who require high intraperitoneal concentrations of antimicrobial agents to treat this infection. After intraperitoneal administration of drugs, such as the aminoglycosides, plasma and intraperitoneal drug concentrations will eventually reach equilibrium. Despite systemic absorption of these drugs from the peritoneal fluid, peritoneal dialysis (PD) usually is inefficient at removing drugs from the plasma.[32] Because CAPD contributes little to the overall elimination of most drugs, dosage modifications are not always necessary in patients having this procedure.

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous venovenous hemofiltration (CVVH) is a form of continuous renal replacement (CRRT) therapy used in patients who are critically ill with kidney failure. CRRT is typically reserved for patients who are unable to tolerate hemodialysis because of hemodynamic instability. Refer to Chapter 29, Acute Kidney Injury, for a discussion on the indications for and various modalities of kidney replacement therapy.

Data concerning the removal of drugs by hemodialysis cannot be extrapolated to CRRT because of differences in the membranes, blood flow rates, ultrafiltration rate, dialysate flow rate, and the continuous nature of the procedure compared with intermittent hemodialysis. Limited data are available on the effect of CRRT on the removal of drugs. Drugs that have a high sieving coefficient (permeability of a drug through a semipermeable membrane), such as aminoglycosides, ceftazidime, and vancomycin, are readily removed by CVVH.[33–35] CVVH clearance can be estimated to determine the appropriate dosage regimen based on the pharmacologic characteristics of a specific drug (see Case 31-1, Question 8). A literature search should be conducted for estimated drug removal based on modality, flow rates, and the most current recommendations for drug dosing.[27]

HEMOPERFUSION

Hemoperfusion is another method of drug removal that may be used to facilitate the elimination of a drug in the setting of an overdose such as phenytoin.[36,37] During the hemoperfusion procedure, blood is passed through a column of adsorbent material (eg, activated charcoal or resin) to bind toxins and drugs. Hemoperfusion can be particularly useful for removing large MW compounds or highly protein-bound drugs that are not removed efficiently by hemodialysis. Large compounds and drug–protein complexes are adsorbed onto the high-surface-area resin as blood passes through the adsorbent column.

Pharmacodynamics and Kidney Disease

Few studies have investigated the pharmacodynamics of drugs in patients with kidney disease. Clinical observations report that patients with kidney disease are more sensitive to various drugs. For example, morphine has been associated with increased neurologic depression in patients with kidney failure. The ability of morphine to potentiate the CNS-depressant effects of uremia may result from an alteration in the permeability of the blood–brain barrier that results in higher CNS levels of morphine and morphine-6-glucuronide.[38]

Another example of altered drug response in uremia is that of nifedipine, which at similar unbound plasma concentrations has an increased antihypertensive effect in patients with kidney disease.[39] Therefore, the dose of nifedipine may need to be adjusted in patients with kidney disease because of changes in drug effects rather than pharmacokinetic alterations.

The pharmacokinetics of warfarin is not significantly altered in kidney failure. However, patients with kidney failure who are prescribed warfarin have a higher incidence of hemorrhagic complications, likely because of platelet dysfunction from uremia, and drug–drug interactions from concomitant medications.[40,41]

PHARMACOKINETICS AND PHARMACODYNAMICS OF SPECIFIC DRUGS IN KIDNEY FAILURE

DOSAGE MODIFICATION: FACTORS TO CONSIDER

CASE 31-1

QUESTION 1: G.G., a 31-year-old, 154.32-pound (70-kg) female with a 3-year history of systemic lupus erythematosus (SLE) presents to the emergency department (ED) with a 5-day history of fatigue, weakness, and nausea as well as worsening of her facial rash and a fever of 104 °F (40 °C). Her SLE had been

moderately controlled until this acute flare. Her admission laboratory workup now reveals the following pertinent values:

Potassium (K^+), 6.0 mEq/L
Sodium (Na^+), 142 mEq/L
Serum creatinine (SCr), 3.4 mg/dL
Blood urea nitrogen (BUN), 38 mg/dL

Complete blood count (CBC) reveals a hematocrit of 32% and a hemoglobin of 9.2 g/dL. The platelet count is 50,000/μL, and her erythrocyte sedimentation rate is 35 mm/hour. Physical examination is significant for a blood pressure of 136/92 mm Hg and 2+ pedal edema. Prednisone is started at a dose of 1.5 mg/kg/day.

During her hospital course, G.G.'s condition worsens, and signs of sepsis develop. *Pseudomonas aeruginosa* is cultured from her urine. Therapy with ceftazidime is initiated at a dose of 2 g every 8 hours, a dose commonly used for patients with normal kidney function.

Considering that G.G.'s kidney function has remained stable and that she has an estimated CrCl of 27 mL/minute, what factors should be considered before modifying her dose? What would be an appropriate dose of ceftazidime for G.G.?

Before modifying the dose of any drug, its route of elimination should be established. As a general rule, the degree to which kidney impairment affects elimination depends on the percentage of unchanged drug that is excreted by the kidney. Thus, the elimination of most drugs that are primarily cleared by the kidneys will be decreased in the setting of kidney impairment. For many drugs dependent on the kidney for elimination, relationships between some measurements of kidney function (eg, CrCl) and some parameters of drug elimination (eg, plasma clearance or half-life) have been established to help clinicians determine the appropriate dosing modifications in patients with kidney disease.

In contrast, the clearance of drugs that are eliminated primarily by non-kidney mechanisms (eg, hepatic metabolism) may not be altered significantly in patients with kidney disease. However, some drugs have water-soluble metabolites that have either pharmacologic activity or potential toxicity and that may accumulate with kidney dysfunction, warranting dosage adjustment or avoidance of the drug entirely (eg, meperidine; see Case 31-8, Question 1).

Enzymes with metabolic capacity have also been found within kidney tissue, which can result in the kidneys playing a limited role in the metabolism of certain drugs (see Case 31-3, Question 2).

Another important factor to consider is the “therapeutic window” for a given drug (ie, the range of drug concentrations thought to be most effective). Drug concentrations below this range are usually subtherapeutic, whereas concentrations above this range can lead to a greater incidence of adverse effects. For drugs with a wide therapeutic window, the difference between toxic and therapeutic concentrations is large. Although many drugs that are cleared primarily by the kidney may require dosing modifications in patients with kidney dysfunction, aggressive dose reduction may not be necessary for drugs with a large therapeutic window, particularly if the adverse effects of the drug (eg, fluconazole) are relatively mild. This is in contrast to drugs (eg, aminoglycosides, vancomycin, or foscarnet) that are eliminated primarily by the kidney and have narrow therapeutic windows. For these drugs, the toxic plasma concentrations are very close to the therapeutic drug concentrations, with little room for dosing error.

Ceftazidime is a cephalosporin that has excellent activity against most strains of *Pseudomonas* species. As with most cephalosporins, ceftazidime primarily is cleared by the kidneys, with little nonrenal or hepatic elimination.[42] The clearance of ceftazidime correlates with CrCl.

Because her sentinel clearance is approximately one-third of normal, she would require about one-third of the normal daily dose (ie, 2 g every 24 hours). As with other cephalosporins, ceftazidime has a large therapeutic window.[43] Failure to reduce the dose from a normal dose of 2 g every 8 hours, although likely safe, might lead to accumulation of ceftazidime, predisposing G.G. to seizures and other adverse effects associated with toxic β-lactam antibiotic plasma levels.[44,45] This is in contrast to the aminoglycosides, which must be dosed based on specific pharmacokinetic calculations.

Aminoglycosides

Case 31-1, Question 2: G.G.'s medical team decides that the addition of an aminoglycoside antibiotic is necessary to treat her infection. Considering that her kidney function has remained stable, how should gentamicin be dosed in G.G.? Is it best to alter the dose or the dosing interval for this drug?

ALTERATION OF DOSE VERSUS DOSING INTERVAL

The aminoglycosides (eg, tobramycin, gentamicin, amikacin) are effective in the treatment of serious systemic infections caused by gram-negative organisms such as *Pseudomonas* species. Unlike the cephalosporins and penicillins, however, the aminoglycosides have a relatively narrow therapeutic window. Using pharmacokinetic principles, a dose regimen can be designed to produce specific peak and trough serum concentrations. Peak serum concentrations (Cp_{peak}) (eg, gentamicin or tobramycin 5–8 mg/L) correlate best with therapeutic efficacy, whereas toxicity tends to correlate with elevated trough levels (Cp_{trough}), which reflects prolonged exposure to high drug concentrations. To minimize the risk of toxicity, trough levels of <2 mg/L should be maintained. In patients with normal kidney function, these target serum aminoglycoside concentrations are usually obtained after standard doses (eg, 1.5 mg/kg) administered every 8 hours. Peak and trough levels are typically measured once steady state is achieved, which is typically within 24 hours.[46–48]

The discussion regarding aminoglycoside dosing in kidney impairment that follows is based on the traditional every 8 hours dosing regimen.

Aminoglycosides are almost completely eliminated by the kidneys; thus, the clearance of these drugs essentially is equal to the glomerular filtration rate (GFR). The pharmacokinetic properties of gentamicin and tobramycin are similar. A close correlation also exists between CrCl (a surrogate for GFR) and gentamicin total body clearance. As kidney function deteriorates, aminoglycoside doses must be modified to achieve the desired peak and trough plasma concentrations. Failure to appropriately adjust the dosage of aminoglycosides in kidney insufficiency can lead to high drug plasma levels that can result in ototoxicity and nephrotoxicity.

In many cases, the aminoglycoside dose can be modified by extending the dosing interval rather than simply reducing the dose. This permits maintenance of adequate peak plasma concentrations to ensure efficacy while allowing for sufficient elimination between doses to produce trough levels <2 mg/L. The advantages and disadvantages of adjusting the dosing interval versus reducing the dose are summarized in **Table 31-2**. **Figure 31-1** illustrates the effect of increasing the dosing interval in a patient such as G.G. with kidney function that is 30% of normal. Although this is the preferred method for adjusting the dose of aminoglycosides, for many other drugs requiring dose adjustments in kidney disease, simple dosage reduction is sufficient.

Table 31-2

Advantages and Disadvantages of General Approaches to Dosing Adjustments in Kidney Disease

Method	Advantages	Disadvantages
Variable Frequency		
Use the same dose but increase the dosing interval.	Same Cp_{ave}, Cp_{max}, Cp_{min} Normal dose	Levels may remain subtherapeutic for prolonged periods in patients requiring dosing intervals >24 hours.
Variable Dose With Fixed Cp_{ave}		
Decrease dose to maintain a target Cp_{ave}; keep the dosing interval the same.	Same Cp_{ave} Normal dosing interval	Decrease peak levels, which may be subtherapeutic; increase trough levels, which may increase potential for toxicity.

Cp_{ave}, average plasma concentration; Cp_{max}, maximum plasma concentration; Cp_{min}, minimum plasma concentration.

Figure 31-1 Serum concentration versus time profile for a patient with normal kidney function (*dotted line*), and for patient G.G. (Case 31-1) whose estimated creatinine clearance is 27 mL/minute (*solid lines*).

Many clinicians now use extended interval dosing of the aminoglycosides (eg, 7 mg/kg every 24 hours) for patients with normal kidney function in an attempt to minimize aminoglycoside accumulation and nephrotoxicity. The rationale for this regimen is based on the aminoglycosides' concentration-dependent killing and postantibiotic effect. This approach is not recommended for patients with advanced kidney impairment, however. When extended interval dosing is used, peak concentrations are less helpful; however, trough concentrations should be monitored with a target of being below the limit of analytic detection (<1 mg/L).[49,50] Commonly used drug references can be used for dosing guidelines for drugs used in patients with kidney failure.[51,52]

DETERMINATION OF APPROPRIATE DOSE

A number of methods have been developed to determine the appropriate aminoglycoside dose for patients.[53] One method is

Bayesian forecasting, in which pharmacokinetic data obtained in the individual patient are integrated with population parameters. Initially, a dose is used that is based on population parameter values adjusted for characteristics such as increased SCr. Drug concentrations for the individual patient are measured at specific times (eg, peak and trough measurements), and these are compared with the expected values from the population data. Individualized pharmacokinetic parameter estimates are subsequently derived using Bayes theorem to calculate a more patient-specific dosing regimen.[54]

Because of the wide interpatient variability in aminoglycoside pharmacokinetic parameters and the narrow therapeutic index for these drugs, doses should be adjusted based on pharmacokinetic principles (eg, Bayesian calculations or methods described later in this chapter) and plasma concentrations that are specific for this patient.

Patient-specific methods

Sawchuk et al developed a method to derive patient-specific estimates of Vd and clearance based on the patient's size and estimated CrCl.[47] These parameters can be used to calculate a specific dose for G.G. that will produce the desired gentamicin peak and trough concentrations. If steady-state serum concentrations of gentamicin are known, they can be used to calculate patient-specific parameters. To initiate gentamicin therapy, pharmacokinetic parameters should first be estimated from population values.

The clearance of gentamicin (Cl_{gent}) can be calculated based on G.G.'s CrCl. Using the Cockcroft–Gault equation,[55] the CrCl can be estimated as follows:

$$\text{CrCl (males)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SCr})(72)} \qquad \textbf{(Eq. 31-1)}$$

$$\text{CrCl (females)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SCr})(72)}(0.85) \quad \textbf{(Eq. 31-2)}$$

where IBW is ideal body weight in pounds (kilograms), age is measured in years, and SCr is serum creatinine in mg/dL.

With an SCr of 3.4 mg/dL, an ideal body weight of 154.32 lb (70 kg), and an age of 31 years, G.G.'s estimated CrCl is 27 mL/minute.

For practical purposes, Cl_{gent} is usually considered equivalent to CrCl. Therefore, Cl_{gent} also is ~27 mL/minute or 1.6 L/hour. The Vd of gentamicin (Vd_{gent}) is ~0.25 L/kg in patients with normal or impaired kidney function.[47,56]

The Vd_{gent} will be different in patients who are obese or those who have fluid overload. Although G.G. does have some fluid retention, this is minimal and should not affect her Vd_{gent} significantly. Therefore, the Vd_{gent} for G.G. is as follows:

$$\begin{aligned} Vd_{gent} &= (0.25\ \text{L/kg})(\text{body weight}) \quad \textbf{(Eq. 31-3)} \\ &= (0.25\ \text{L/kg})(70\ \text{kg}) \\ &= 17.5\ \text{L} \end{aligned}$$

For treatment of infections caused by *Pseudomonas* species, a peak level of ~6 to 8 mg/L is desired.

The loading dose of gentamicin (LD_{gent}) can be determined using the following equation:

$$LD_{gent} = (Vd_{gent})(\text{desired } Cp_{peak}) \quad \textbf{(Eq. 31-4)}$$

$$\begin{aligned} LD_{gent} &= (17.5\ \text{L})(7\ \text{mg/L}) \\ &= 122.5\ \text{mg or round off to } 120\ \text{mg} \end{aligned}$$

Using Cl_{gent} and Vd_{gent}, the elimination rate constant (Kd) and half-life for gentamicin can be estimated as follows:

$$Kd = \frac{Cl_{gent}}{Vd_{gent}} = \frac{1.6\ L/hour}{17.5\ L} = 0.091\ hour^{-1} \quad \text{(Eq. 31-5)}$$

$$t_{1/2} = \frac{0.693}{Kd} = \frac{0.693}{0.091\ hour^{-1}} = 7.6\ hours \quad \text{(Eq. 31-6)}$$

For the aminoglycosides, the dosing interval (τ) is determined by doubling the half-life, because by the end of two half-lives, 75% of the drug will have been eliminated. This will usually lead to a desired trough level of <2 mg/L. Therefore, gentamicin should be administered at least every 16 hours. For convenience, an interval of 24 hours can be used, which also will achieve the desired trough concentration.

Gentamicin is usually infused over 30 minutes. To determine the peak gentamicin concentration, serum samples are drawn 30 minutes after the infusion has been completed. Because the estimated elimination half-life of gentamicin in G.G. (7.6 hours) is much longer than the infusion time (0.5 hours), the intravenous bolus model can be used to calculate an appropriate maintenance dose.

To achieve the peak concentration of 7 mg/L, the following equation can be used:

$$\text{Dose} = \frac{(Cp_{peak})(1 - e^{-Kd\tau})(Vd_{gent})}{(e^{-Kdt_{sample}})} \quad \text{(Eq. 31-7)}$$

$$= \frac{(7\ \text{mg/L})(1 - e^{-(0.091\ \text{hour}^{-1})(24\ \text{hour})})(17.5\ \text{L})}{(e^{-(0.091\ \text{hour}^{-1})(1\ \text{hour})})}$$

$$= 119.2\ \text{mg}$$

$$= \text{or round off to } 120\ \text{mg}$$

where t_{sample} usually equals 1 hour (30 minutes after a 30-minute infusion).

The expected trough level in G.G. can now be estimated by the following equation:

$$Cp_{trough} = (Cp_{peak})(e^{-Kd\tau_{sample}}) \quad \text{(Eq. 31-8)}$$

$$= (7\ \text{mg/L})(e^{-(0.091\ \text{hour}^{-1})(24\ \text{hours})})$$

$$= 0.8\ \text{mg/L}$$

REVISED PARAMETERS

CASE 31-1, QUESTION 3: After 72 hours of gentamicin therapy, G.G.'s peak and trough levels are 7.6 and 2.6 mg/L, respectively. Her physician attributes this to a gradual decline in kidney function. (Her most recent SCr has increased 4.8 mg/dL.) How would you revise G.G.'s dosing regimen based on these levels?

A gentamicin trough level of >2 mg/L suggests that G.G.'s dosing interval is too short. Although her peak concentration is within the normal range of 5 to 8 mg/L, her trough concentration indicates that she is at a potentially toxic level. Her pharmacokinetic parameters can be revised based on these values, and a new Kd can be estimated from the following equation:

$$Kd = \frac{\ln\left(\frac{CP_1}{CP_2}\right)}{\Delta t} = \frac{\ln\left(\frac{7.6\ mg/L}{2.6\ mg/L}\right)}{23\ hours} = 0.047\ hour^{-1} \quad \text{(Eq. 31-9)}$$

Because little change in G.G.'s Vd_{gent} is expected, a new Cl_{gent} ($Cl_{revised}$) can be estimated from her revised elimination constant (while a revised Vd_{gent} could be calculated, keeping Cl_{gent} constant, the clearance is more likely to change than the volume of distribution):

$$\begin{aligned} Cl_{revised} &= (Vd_{gent})(Kd) \\ &= (17.5\ L)(0.047\ hour^{-1}) \\ &= 0.82\ L/hour \end{aligned} \quad \text{(Eq. 31-10)}$$

These revised values by increasing the dosing interval to 484 for Kd and Cl can now be used to calculate a revised maintenance dose to maintain the Cp_{trough} at <2 mg/L using Equation 31-7:

$$\begin{aligned} Dose &= \frac{(7\ mg/L)(1 - e^{-(0.047\ hour^{-1})(48\ hours)})(17.5\ L)}{e^{-(0.047\ hour^{-1})(1\ hour)}} \\ &= 115\ mg \\ Cp_{trough} &= (7\ mg/L)(e^{-(0.047\ hour^{-1})(48\ hours)}) \\ &= 0.73\ mg/L \end{aligned} \quad \text{(Eq. 31-11)}$$

The revised dose is now 115 mg (or ~110 mg) every 48 hours.

CASE 31-1, QUESTION 4: What are some limitations in calculating G.G.'s CrCl based on her SCr? Can this estimate safely be used to predict gentamicin clearance?

See Chapter 28, Chronic Kidney Disease, for information about equations used to calculate CrCl and estimate GFR. For patients with stable kidney function, CrCl can be estimated from SCr using the Cockcroft–Gault equation (see Equations 31-2 and 31-3). In a patient such as G.G., however, whose kidney function continues to decline during the hospital course, estimation of kidney function based on her increasing SCr becomes more difficult. Because her SCr does not reflect a steady-state level, the previous equations can no longer be used to accurately estimate her kidney function. Because G.G.'s SCr has increased rapidly from 3.4 to 4.8 mg/dL during the past few days, her CrCl is probably much lower than that estimated using the Cockcroft–Gault method. A rising SCr may represent a decline in kidney function manifesting as an accumulation of creatinine.

Although prediction equations such as the Modification of Diet in Renal Disease (MDRD) equations are a good measure of GFR,[57] they were developed in patients with chronic kidney disease, therefore limiting its use in healthy patients. In addition, the MDRD equation has not been validated for the dosing of most drugs in the setting of kidney dysfunction.[58,59] There can be significant differences in drug dosing regimens when the MDRD and Cockcroft–Gault methods are used to estimate kidney function.[60,61] The Cockcroft–Gault equation has been the standard method to estimate kidney function to determine if drug dosage adjustments are necessary. It also should be noted that the units for the Cockcroft–Gault equation for CrCl is mL/minute, whereas the units for the MDRD equation for estimated GFR is mL/minute/1.73 m^2. The manufacturer's prescribing information and available literature should be evaluated to determine the appropriate dosage regimen based on the patient's kidney function.

Effect of Hemodialysis

CONVENTIONAL HEMODIALYSIS

Gentamicin

CASE 31-1, QUESTION 5: G.G.'s kidney function continues to deteriorate to the extent that she requires hemodialysis. What additional alterations in her gentamicin dosing regimen are necessary when she is having hemodialysis?

Gentamicin has an MW of about 500 and a relatively low Vd (averaging 0.25 L/kg) and is about 10% bound to proteins, all favoring effective removal by conventional hemodialysis.[48] For a given patient, the observed dialysis clearance of gentamicin using conventional methods also depends on factors such as the physical properties of the dialysis filter, the blood and dialysate flow rates, and the length of dialysis. Studies indicate that dialysis clearance of gentamicin averages 45 mL/minute compared with an average plasma clearance of 5 mL/minute in patients with CKD.[62,63] Therefore, G.G.'s gentamicin dose must be adjusted to compensate for the amount of drug that will be removed by hemodialysis. Because drug removal represents a combination of drug elimination by the body and hemodialysis, the following equation can be used:

$$Cl_{total} = Cl_{dial} + Cl \qquad \text{(Eq. 31-12)}$$

where Cl_{total} is the total clearance of the drug during dialysis, Cl_{dial} is the clearance by dialysis, and Cl is plasma clearance. If dialysis clearance is high relative to plasma clearance, drug removal will be enhanced by the dialysis procedure. The total clearance of gentamicin in a patient with severe kidney dysfunction during hemodialysis is 50 mL/minute (45 + 5 mL/minute) or 10 times the clearance while off hemodialysis. Plasma clearance and hemodialysis clearance are related to the elimination half-life by the following equation:

$$t_{1/2} = \frac{(0.693)(Vd)}{Cl_{dial} + Cl} \qquad \text{(Eq. 31-13)}$$

Thus, assuming a constant Vd of 17.5 L (ie, 0.25 L/kg × 70 kg), the elimination half-life on hemodialysis is ~4 hours compared with 40 hours off hemodialysis. In addition, the extent (fraction) of drug removal (FD) during a timed dialysis run can be predicted from the following equation:

$$FD = 1 - e^{-(Cl + Cl_{dial})(t/Vd)} \quad \text{(Eq. 31-14)}$$

where t is the duration of dialysis. Therefore, the fraction of gentamicin removed (FD) during a 4-hour conventional hemodialysis procedure is ~50%. If specific data are not available for hemodialysis and plasma clearance, the following equation will predict fraction removed using the elimination half-life data alone obtained during hemodialysis:

$$FD = 1 - e^{-(0.693/t_{1/2on})(t)} \quad \text{(Eq. 31-15)}$$

The estimated value of 50% removal is consistent with literature values indicating that 50% to 70% of a dose of gentamicin is removed during a 4-hour hemodialysis procedure. A limitation of this equation, however, is that it does not consider the redistribution of drug from the tissues back into the plasma after the hemodialysis procedure.

It is generally difficult to calculate an appropriate maintenance dose for patients having hemodialysis that will maintain peak and trough concentrations similar to patients with normal kidney function, in part because of the large variability found in aminoglycoside pharmacokinetic parameters.[63,64] Sustained plasma concentrations >2 mg/L can increase the risk of toxicity; however, dosing gentamicin to achieve trough concentrations of <2 mg/L may lead to prolonged periods of subtherapeutic peak concentrations because one would have to use smaller doses with lower peak concentrations to allow the troughs to decrease before the next dose. Another practical consideration is that unless one expects the patient to recover kidney function in the future, kidney toxicity of the drug is less of a concern. As a compromise in patients receiving hemodialysis,

gentamicin doses are given to achieve a predialysis trough concentration of ~3 mg/L. This can generally be achieved with a loading dose of 2 mg/kg, followed by a maintenance dose of 1 mg/kg after each hemodialysis session.

Ceftazidime

Case 31-1, Question 6: Why does the dose of ceftazidime in G.G. have to be adjusted because of her hemodialysis when this drug has such a large therapeutic window?

Because only 21% is protein bound and its Vd is 0.2 L/kg, ceftazidime should be readily removed by hemodialysis. The mean dialysis clearance of ceftazidime is 55 mL/minute, with 55% of the drug removed during 4 hours of conventional hemodialysis.[65] A supplemental dose of ceftazidime should be given to G.G. after each hemodialysis session to maintain a therapeutic concentration. Alternatively, giving a larger dose (such as 1 g) three times a week (after each hemodialysis session) would be more convenient.

HIGH-FLUX HEMODIALYSIS

Case 31-1, Question 7: G.G.'s physician is considering changing her from a conventional dialysis system to a high-flux system that uses high-efficiency polysulfone membranes. How does the dialyzability of gentamicin and ceftazidime differ with high-flux hemodialysis compared with conventional hemodialysis?

High-flux hemodialysis is more effective than conventional hemodialysis at removing certain pharmacologic agents (see Chapter 30, Dialysis Treatment for Chronic Kidney Failure) because the membranes are more efficient and there is greater blood flow through the dialyzer. Although limited data are available, a greater fraction of drugs, such as aminoglycosides, ceftazidime, and vancomycin, are removed by high-flux versus conventional hemodialysis.[66,67] Approximately 50% to 70% of gentamicin is

removed during a 2.5-hour, high-flux dialysis session.[30] The clearance of ceftazidime by high-flux hemodialysis is 75 to 240 mL/minute compared with 55 mL/minute for conventional hemodialysis.[66] Thus, further dosage adjustments for gentamicin and ceftazidime may be necessary if G.G. is converted from conventional hemodialysis to high-flux hemodialysis.

CONTINUOUS VENOVENOUS HEMOFILTRATION

CASE 31-1, QUESTION 8: What changes would be necessary in G.G.'s gentamicin dosing if she were to start a CRRT such as CVVH?

Because of the continuous nature of CVVH, the extent of drug eliminated will differ from intermittent modes such as hemodialysis. The clearance of a drug in a patient receiving CVVH can be described in a fashion similar to Equation 31-12, where Cl_{dial} is replaced with Cl_{cvvh}.

$$Cl_{total} = Cl + Cl_{cvvh} \quad \text{(Eq. 31-16)}$$

In G.G., the $Cl_{revised}$ from Equation 31-10 can be used for the plasma clearance (Cl). The clearance by CVVH can be described by the following equation:

$$Cl_{cvvh} = Fu + UFR \quad \text{(Eq. 31-17)}$$

where Fu is the fraction of drug unbound and UFR is the ultrafiltration rate. Gentamicin exhibits low plasma protein binding (Fu ~0.95). Typical ultrafiltration rates for CVVH are ~1 L/hour but can vary.

$$\begin{aligned} Cl_{cvvh} &= Fu \times UFR \quad \text{(Eq. 31-18)} \\ &= 0.95 \times 1\ L/hour \\ &= 0.95\ L/hour \end{aligned}$$

$$C1_{total} = C1_{revised} + C1_{cvvh} \quad \text{(Eq. 31-19)}$$
$$= 0.82\ L/hour + 0.95\ L/hour$$
$$= 1.77\ L/hour$$
$$= 29.5\ mL/minute$$

Because the clearance of gentamicin approximates that of CrCl, G.G.'s total clearance is approximately one-third the normal clearance of 100 mL/minute. Therefore, the gentamicin dose should be approximately one-third of the normal dose. G.G. should be given 1.5 mg/kg/day or 100 mg of gentamicin every 24 hours. Gentamicin trough concentrations should be monitored and her dose adjusted to maintain a trough concentration of <2 mg/L.

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

CASE 31-2

QUESTION 1: J.J., a 24-year-old male with CKD, is maintained with CAPD. He presents to the ED with a fever of 100.76 °F (38.2 °C) and severe abdominal pain. He also reports that his peritoneal dialysate has become cloudy in the past few days. All these symptoms are consistent with peritonitis, a frequent complication of CAPD. His culture results reveal *Escherichia coli*, sensitive to gentamicin.

How should gentamicin be dosed in this patient?

Management of dialysis-related peritonitis can vary from one institution to another. Antibiotics often are administered intraperitoneal (IP) with or without systemic antibiotic therapy. For less severe cases, IP administration is often considered sufficient. With IP administration, the goal is to deliver a concentration of drug similar to the desired plasma concentration for the treatment of systemic infections. Therefore, 8 mg of gentamicin into each liter of dialysate (or 16 mg into a 2-L bag of dialysate) is recommended. Once equilibrium or steady state is achieved, the dialysate concentration will be comparable to the concentration of gentamicin

in the plasma. Despite a more rapid transfer of drug into the plasma because of increased permeability of the peritoneal membrane in patients with peritonitis, there will still be a substantial lag time before a steady state is reached. For more serious cases of peritonitis, concomitant systemic antibiotics should be given.

CASE 31-2, QUESTION 2: Is gentamicin removed by CAPD?

In general, most drugs are not well removed via CAPD. This is particularly true for drugs that are highly protein bound or for drugs with a large Vd. Gentamicin and other aminoglycosides, on the other hand, are effectively removed by CAPD because they have low protein binding and a small Vd. It is estimated that 10% to 50% of gentamicin is removed by CAPD.[68]

Acyclovir

KIDNEY CLEARANCE

CASE 31-3

QUESTION 1: D.M., a 28-year-old male with acquired immune deficiency syndrome, presents with a severe herpetic infection requiring IV acyclovir. Because of other complications associated with his human immunodeficiency virus (HIV) infection, D.M. has developed kidney insufficiency during his hospital course prior to initiating acyclovir. His current SCr is 4.5 mg/dL (baseline SCr = 0.9 mg/dL), and his estimated CrCl is <15 mL/minute.

What are important considerations for dosing acyclovir in D.M. now and also if he requires hemodialysis in the future?

Acyclovir is used to prevent or treat a variety of viral infections, such as those caused by herpes simplex and varicella-zoster viruses.[69] It is cleared primarily by the kidneys, with ~70% to 80% excreted unchanged in the urine. Dosage adjustment is necessary in patients with kidney disease.[18,70] Tubular secretion by the kidneys in addition to filtration contributes to the elimination of acyclovir, which

explains why the clearance of acyclovir by the kidneys is about three times greater than the estimated CrCl.

In patients with normal kidney function, the clearance of acyclovir ranges from 210 to 330 mL/minute; however, in patients with CKD, the clearance is 29 to 34 mL/minute. Although this change in clearance primarily results from decreased clearance of the drug by the kidneys. Non-kidney clearance of acyclovir also decreases in these patients.[18,71,72] As a result, the elimination half-life increases significantly from ~3 hours in patients with normal kidney function to 20 hours in patients with CKD. For D.M., with a creatinine clearance of <15 mL/minute, the acyclovir dose should be 5 mg/kg IV every 24 hours.

Acyclovir is moderately removed by conventional hemodialysis, with plasma concentrations decreasing by 60% after 6 hours of hemodialysis.[73] The elimination half-life on-and-off dialysis is 6 and 20 hours, respectively, whereas the dialysis clearance averages 80 mL/minute. Therefore, when giving acyclovir, it is best to administer it after hemodialysis, on hemodialysis days. If D.M. were to start hemodialysis, the dose of acyclovir would be 2.5 mg/kg IV every 24 hours.

EFFECT OF KIDNEY DYSFUNCTION ON METABOLISM

Case 31-3, Question 2: Does D.M.'s kidney dysfunction affect the metabolism of acyclovir? Are other drugs affected similarly?

Approximately 20% of acyclovir is cleared by non-kidney mechanisms.[18,71] The only significant metabolite that has been isolated is 9-carboxymethoxymethylguanine, which accounts for 9% to 14% of an administered dose. It is believed that this metabolite is a product of hepatic metabolism; however, the kidney may also play an important role.[18] Whether kidney dysfunction alters hepatic metabolism or metabolic enzymes present within the kidney is unclear. Kidney tissue contains many of the same metabolic enzymes found in the liver. Mixed-function oxidases have been

found in segments of the proximal tubule, whereas other metabolic processes, such as glucuronidation, acetylation, and hydrolysis, also occur within the kidney.[17,74]

Kidney failure can affect hepatic metabolic enzyme activity and drug transporter function.[75,76] Kidney dysfunction substantially alters the nonrenal clearance of certain antibiotics, such as cefotaxime, and imipenem-cilastatin,[77,78] as well as benzodiazepines such as diazepam and its metabolite, desmethyldiazepam.[79]

Tenofovir

Case 31-3, Question 3: D.M. also is being treated with tenofovir disoproxil as part of antiretroviral regimen for his HIV disease. Will his tenofovir disoproxil dose need to be adjusted?

DOSAGE ADJUSTMENT

Tenofovir is a nucleotide analog of adenosine monophosphate. Tenofovir disoproxil is a prodrug that is converted to tenofovir, which undergoes activation by phosphorylation to the active form, tenofovir diphosphate. Tenofovir diphosphate inactivates HIV reverse transcriptase and hepatitis B virus (HBV) DNA polymerase by causing chain termination.[80] It is used as part of an antiretroviral regimen in the treatment of HIV infection and can also be used for the treatment of chronic hepatitis B infection.[81] Approximately 70% to 80% of tenofovir is excreted unchanged in the urine. The elimination half-life is ~17 hours, and the clearance is significantly reduced in the setting of kidney dysfunction. Nephrotoxicity, including cases of acute kidney injury and Fanconi syndrome (renal tubular injury and hypophosphatemia) have been reported. Organic transporters in the proximal tubule are believed to mediate kidney toxicity.[82] The dose of tenofovir disoproxil must be adjusted in the setting of kidney dysfunction to prevent accumulation, and the potential to worsen kidney dysfunction. For his degree of kidney function, the dose of tenofovir disoproxil is 300 mg by mouth every 72 hours.[81] Tenofovir alafenamide is another prodrug formulation of tenofovir that remains

stable in the plasma and is only converted intracellularly to the active tenofovir diphosphate. Tenofovir alafenamide results in lower circulating plasma tenofovir levels compared to tenofovir disoproxil. The lower plasma levels of tenofovir lead to lower rates of kidney and bone toxicity. Because <1% of tenofovir alafenamide is excreted unchanged in the urine, no dosage adjustment is needed in patients with kidney impairment, including hemodialysis.[83]

Both tenofovir disoproxil and alafenamide are also available in combination with other antiretrovirals in a single-dose formulation for the treatment of HIV infection. The specific dosing recommendation should be consulted in the setting of kidney dysfunction for tenofovir disoproxil or the combination products. It is important to keep in mind that while tenofovir is the same parent compound, however, the different salt forms have their own pharmacokinetic disposition and therefore dosing.

HEMODIALYSIS

CASE 31-3, QUESTION 4: Is tenofovir disoproxil significantly removed by hemodialysis?

Tenofovir disoproxil is effectively removed by hemodialysis, with an extraction coefficient of ~54%. Approximately 10% of a 300-mg tenofovir disoproxil dose is removed after 4 hours of hemodialysis. The recommended dose of tenofovir disoproxil is 300 mg orally every 7 days (after ~12 hours of hemodialysis or three 4-hour sessions).[81] If tenofovir alafenamide is used, the dose is 25 mg once a day (on days of hemodialysis, it should be administered after completion of hemodialysis).[83]

Penicillin

DOSAGE ADJUSTMENT

CASE 31-4

Question 1: T.H., a 57-year-old, 187.39-pounds (85-kg) male with CKD secondary to poorly controlled hypertension, presents to the ED with a 24-hour history of fever 102.20 °F (39 °C), altered mental status, nausea, and vomiting. On physical examination, he is found to have nuchal rigidity and a positive Brudzinski sign. Laboratory analysis reveals the following:

White blood cell (WBC) count, 22,000/μL with 89% neutrophils
BUN, 45 mg/dL
SCr, 4.4 mg/dL

A lumbar puncture yields cerebrospinal fluid (CSF) with a WBC count of 2000/μL (90% polymorphonuclear neutrophils), a glucose concentration of 36 mg/dL, and a protein concentration of 280 mg/dL. Gram-positive diplococci are seen on CSF smear. A diagnosis of meningococcal meningitis is made, and potassium penicillin G is ordered.

What dose should be used?

Meningococcal meningitis can be treated with 24 million units/day (4 million units every 4 hours) of IV penicillin G in patients with normal kidney function. As with many β-lactam antibiotics, penicillin is primarily excreted unchanged in the urine with little or no hepatic metabolism. Thus, the elimination half-life, which averages <1 hour in patients with normal kidney function, increases to 4 to 10 hours in patients with CKD.[84,85]

Using the Cockcroft–Gault method, T.H.'s CrCl is ~20 mL/minute. Therefore, his daily dose of penicillin should be 16 million units. A dose of 4 million units every 6 hours would be appropriate for T.H.[51] Penicillin G is often given as the potassium salt (penicillin G potassium), which contains ~1.7 mEq of potassium per 1 million units of penicillin. Accumulation of potassium because of kidney impairment may lead to hyperkalemia. Penicillin G sodium is an alternative formulation that would be appropriate.

PENICILLIN-INDUCED NEUROTOXICITY

Case 31-4, Question 2: The prescriber fails to consider T.H.'s kidney dysfunction when he orders penicillin and begins a dose of 4 million units every 4 hours. Four days later, T.H. is encephalopathic (confused, disoriented, and difficult to arouse), with some twitching noted on the right side of his face. Are

these toxic symptoms associated with high-dose penicillin? What predisposing factors may contribute to this neurotoxicity?

T.H. is experiencing signs of neurotoxicity that are consistent with elevated penicillin concentrations in the plasma and CSF. Penicillin usually produces few serious adverse effects. When large doses are used in patients with kidney impairment, toxic symptoms such as those exhibited by T.H. can result. Signs and symptoms of penicillin-induced CNS toxicity include myoclonus, complex or generalized seizure activity, and encephalopathy progressing to coma.[44,86]

Predisposing factors

Penicillin neurotoxicity frequently occurs in patients with decreased kidney function.[86] Several possible explanations for this observation exist. Penicillin accumulates in patients with kidney failure. The binding of acidic drugs (such as penicillin) to albumin is decreased, resulting in an increased fraction of free or active drug that can pass into the CSF. Alterations in the blood–brain barrier have been observed in patients with uremia, which can lead to further increases in CSF drug levels. High plasma concentrations of penicillin per se may contribute to changes in the blood–brain barrier permeability of this drug.[44] All these factors, together with the increased sensitivity of patients with kidney failure to centrally acting agents, make CNS toxicity more likely. Previous neurotrauma, history of seizures, elderly age, and concurrent drugs that lower the seizure threshold can also contribute to neurotoxicity. As with penicillin, the carbapenem antibiotic combination, imipenem–cilastatin, is associated with a higher incidence of seizures in patients with kidney dysfunction.[87,88] Other β-lactam antibiotics such as ceftazidime, cefepime, and piperacillin/tazobactam have also been associated with seizures.[89,90]

Antipseudomonal Penicillins

PIPERACILLIN/TAZOBACTAM

CASE 31-5

QUESTION 1: E.R., a 44-year-old, 154.32 pounds (70-kg) female with acute nonlymphocytic leukemia, was admitted to the oncology ward for placement of a Hickman catheter for her chemotherapy. Seven days after treatment with cytarabine and daunorubicin, her temperature spiked to 102.92 °F (39.4 °C). Other physical findings consistent with sepsis included a blood pressure of 102/68 mm Hg, pulse rate of 112 beats/minute, and a respiratory rate of 27 breaths/minute. E.R. is neutropenic with a WBC count of 1400/μL (3% polymorphonuclear leukocytes, 70% lymphocytes, and 22% monocytes). Her platelet count is 16,000/μL. E.R. also has kidney dysfunction as reflected by an SCr of 2.6 mg/dL (baseline = 1.2 mg/dL) and BUN of 38 mg/dL (baseline = 18 mg/dL). Empiric therapy for sepsis is started with tobramycin, piperacillin/tazobactam, and vancomycin.

How should piperacillin/tazobactam be dosed in E.R.?

Doses of piperacillin/tazobactam can be as high as 4.5 g IV every 6 hours for the treatment of serious *Pseudomonas* species infections. In patients with CKD, mean piperacillin clearance and half-life values are 0.7 mL/minute/kg and 3.3 hours, respectively.[91–93] Although these parameters are significantly different, they are less than those expected for a drug primarily cleared by the kidneys, suggesting that some other compensatory mechanism for elimination must be present. Piperacillin is partially cleared by biliary excretion, a route of elimination that is increased in patients with kidney failure.[92,94] Therefore, aggressive dosage reductions in E.R. are unnecessary. An appropriate dose of piperacillin/tazobactam for E.R. would be 3.375 g IV every 8 hours. Widely used drug references can be used for dosing guidelines for drugs commonly used in patients with kidney failure.[51]

Vancomycin

PHARMACOKINETIC DOSAGE CALCULATIONS

CASE 31-5, QUESTION 2: In addition to the aforementioned regimen for E.R., vancomycin therapy is initiated at 500 mg every 24 hours to cover the possibility

of an infection resistant to antistaphylococcal penicillins, such as nafcillin. Is this an appropriate dosing regimen for E.R.?

As with many other antibiotics, vancomycin primarily is cleared by the kidneys.[95] Significant toxicities have been associated with elevated serum concentrations, making careful dosing modification in kidney failure necessary.[96]

As with the aminoglycosides, pharmacokinetic calculations can be used to individualize a dosing regimen to produce the desired plasma levels. For patients with serious methicillin-resistant *Staphylococcus aureus* (MRSA) infections, individualizing the dose to achieve a target AUC/MIC_{BMD} ratio of 400:600 (assuming an MIC_{BMD} of 1 mg/L measured by broth microdilution) is recommended, and trough only monitoring targeting levels of 15 to 20 mg/L should no longer be used.[97] Bayesian forecasting software can be used to optimize the dose by calculating the vancomycin area under the concentration-time-curve (AUC).[98]

Vancomycin has an elimination half-life of 3 to 9 hours in patients with normal kidney function.[99] This increases to 129 to 189 hours in patients with CKD.[100,101] Using pharmacokinetic principles and considering that the plasma clearance of vancomycin is ~60% to 70% of CrCl[102] and the Vd averages 0.7 L/kg,[99,103] the estimated Vd_{vanco} and Cl_{vanco} can be calculated using the following equation:

$$\begin{aligned} Cr_{Cl} &= 30.5 \text{ mL/minute (calculated from Eq. 31-2)} \\ Cl_{vanco} &= (0.65)(CrCl) \\ &= (0.65)(30.5 \text{ mL/minute}) \\ &= 19.8 \text{ mL/minute or rounded off to 1.2 L/hour} \end{aligned} \quad \text{(Eq. 31-20)}$$

$$Vd_{vanco} = (0.7\ L/kg)(\text{body weight}) = (0.7\ L/kg)(70\ kg) = 49\ L \quad \text{(Eq. 31-21)}$$

Based on estimated values for Cl_{vanco} and Vd_{vanco}, the elimination rate constant can be calculated using the following equation:

$$Kd = \frac{Cl_{vanco}}{Vd_{vanco}} = \frac{1.2\ L/hour}{49\ L} = 0.024\ hour^{-1} \quad \text{(Eq. 31-22)}$$

$$Cp = \frac{\frac{Dose}{Vd_{vanco}}}{1 - e^{-Kdt}} = \frac{\frac{500\ mg}{49\ L}}{1 - e^{-(0.024\ hour^{-1})(24\ hours)}} = 23\ mg/L \quad \text{(Eq. 31-23)}$$

$$Cp_{trough} = Cp_{peak}(e^{-Kdt}) = 23\ mg/L\ (e^{-(0.024/hour^{-1})(24\ hours)}) = 13\ mg/L \quad \text{(Eq. 31-24)}$$

Routine monitoring of plasma vancomycin concentrations in patients with normal kidney function is controversial because the

likelihood that toxicity will develop in this group is relatively low. However, in patients with kidney failure, such as E.R., it is advisable to measure vancomycin levels after initiating therapy to ensure that they are within an acceptable range or if toxicity is suspected.[97]

Fluconazole

DOSING

Case 31-5, Question 3: E.R. continues to be febrile despite her triple antimicrobial regimen. One blood culture grew out *Candida albicans*. Fluconazole is started to treat candidemia. How should fluconazole be administered such as E.R. with kidney dysfunction?

Fluconazole is an azole antifungal agent with activity against *C. albicans*.[104] Fluconazole is eliminated primarily by the kidneys, has an MW of 306 Da, and exhibits low protein binding.[105] A loading dose of 800 mg (12 mg/kg) followed by 400 mg (6 mg/kg) daily can be used in patients with normal kidney function.[106] Based on E.R.'s degree of kidney function, the fluconazole dose of 200 mg/day would be reasonable.

FLUCONAZOLE DOSING IN KIDNEY REPLACEMENT THERAPY

Approximately 20%–40% is removed by a single session of hemodialysis.[107,108] In patients receiving hemodialysis, the normal dose is given after each hemodialysis session. Fluconazole is readily removed by continuous venovenous hemofiltration to the degree that regular doses can be given, and doses up to 800 mg/day should be used in patients with serious infections.[109] Fluconazole is a good example of the dose needing to be adjusted based on the degree of kidney dysfunction as well as the mode of kidney replacement therapy.

Cefazolin

PERITONEAL DIALYSIS

CASE 31-6

QUESTION 1: M.J., a 65-year-old female with CKD, is awaiting a kidney transplant. She has been managed with PD for the past 8 years. She presents with a cloudy effluent and abdominal pain. Analysis of the effluent reveals a WBC count of 323/μL and gram-positive cocci in clusters on Gram stain. The patient has a history of *S. aureus* peritonitis that was readily treated with cefazolin previously. The patient has no allergies and weighs 114.64 pounds (52 kg).

How should M.J.'s PD-related infection be managed?

Gram-positive cocci such as *S. aureus* are common causes of PD-related infections. The selection of empiric antibiotics should be made based on the patient's and institution's history of microorganisms and sensitivities. A first-generation cephalosporin such as cefazolin would be a reasonable choice for M.J. At institutions with a high rate of methicillin-resistant organisms, vancomycin should be used.

IP antibiotics can be given with each exchange (continuous dosing). In this situation, a single 500-mg/L loading dose of cefazolin is given followed by a maintenance dose of 125 mg/L with subsequent exchanges. Antibiotics can also be given intermittently (once daily per exchange). With intermittent dosing, the antibiotic-containing dialysis solution should dwell for at least 6 hours to allow for adequate absorption. Cefazolin 15 mg/kg (rounded off to 750 mg) is typically given in one exchange. For patients on automated PD, the dose of cefazolin is 20 mg/kg every day in a long-day dwell. In patients with residual kidney function (eg, >100 mL/day of urine output), empirically, the dose is increased by 25%. The management of PD-related infections and dosing of various antibiotics is discussed in the International Society for Peritoneal Dialysis guidelines.[110]

Phenytoin

PROTEIN BINDING

CASE 31-7

QUESTION 1: R.S., a 24-year-old male with CKD from rapidly progressive glomerulonephritis, is treated by hemodialysis three times weekly. He has a 7-year history of generalized tonic–clonic seizures and has been treated with phenytoin. He presents to the ED after having had a seizure lasting about 5 minutes. His mother states that he ran out of phenytoin 2 weeks ago. Because his plasma phenytoin concentration on admission was <2.5 mg/L, R.S. is given an IV loading dose of fosphenytoin: 15 mg/kg phenytoin sodium equivalents (PE) over 30 minutes. Additional admission laboratory work includes the following:

SCr, 8.6 mg/dL
BUN, 110 mg/dL
Potassium, 5.4 mEq/L
Calcium, 9 mg/dL
Albumin, 2.9 g/dL

Eight hours after administration, his phenytoin level is 5 mg/L.
Is this level subtherapeutic?

R.S. has severe kidney disease, which will affect the total (bound plus free) phenytoin concentration achieved and how this concentration is interpreted. Decreased plasma protein binding will result in lower measured total phenytoin concentrations, and the calculated apparent Vd may increase. In patients with normal kidney function, ~90% of the measured phenytoin is bound to albumin, and 10% is free. The free fraction of phenytoin is increased to about 20% to 25% in patients with uremia.[11,111,112] Because the free fraction for phenytoin is increased in patients with uremia, lower plasma concentrations will produce therapeutic effects that will be equivalent to those produced by higher phenytoin concentrations in patients with normal kidney function.[113–115] Phenytoin is an acidic drug that is bound primarily to albumin. A number of mechanisms have been proposed that account for the decreased binding, including (a) decreased albumin concentration, (b) accumulation of uremic byproducts that displace acidic drugs from their binding sites, and (c) alteration in the conformation or structure of albumin in uremic

patients, resulting in a reduced number of binding sites or decreased affinity for drugs (see Chapter 60, Seizure Disorders). Other acidic drugs with altered protein binding in kidney disease are listed in Table 31-1.

The following equation should be used to correct for R.S.'s altered binding owing to his kidney dysfunction and hypoalbuminemia[116]:

$$Cp_{\text{Normal Binding}} = \frac{Cp'}{(0.48)(1-\alpha)\left(\frac{P'}{P_{NL}}\right)+\alpha} \quad \text{(Eq. 31-25)}$$

where Cp′ is the measured plasma concentration reported by the laboratory, and $Cp_{\text{Normal Binding}}$ is the corrected plasma concentration that would be seen if the patient had normal kidney function and normal albumin. Alpha (α) is the normal free fraction (0.1), P′ is the patient's serum albumin, and P_{NL} is normal albumin (4.4 g/dL). The factor 0.48 was derived from patients on hemodialysis and represents the decreased affinity of phenytoin for albumin.

For R.S., a total plasma phenytoin concentration of 5 mg/L is comparable to 13 mg/L in a patient without kidney failure. Because this falls within the phenytoin's therapeutic range of 10 to 20 mg/L, his measured level is not considered to be subtherapeutic.

The factor 0.48 should be used only to estimate changes in protein binding for patients with CKD receiving hemodialysis. Data for patients with moderate kidney disease are limited, and it is unclear what changes exist in the binding of phenytoin to albumin.[117] For patients with normal or moderate kidney impairment, the following equation should be used only if the serum albumin is low; the factor 0.48 should be omitted:

$$Cp_{\text{Normal Binding}} = \frac{Cp'}{(1-\alpha)\left(\frac{P'}{P_{NL}}\right)+\alpha} \quad \text{(Eq. 31-26)}$$

Fosphenytoin, a prodrug of phenytoin, does not need to be dissolved in propylene glycol, and therefore can be administered more quickly. This offers an important advantage for seizures that must be controlled quickly. In patients with kidney failure, the conversion of fosphenytoin to phenytoin was equally efficient to healthy subjects.[118] Once fosphenytoin is converted to phenytoin, the impact of kidney disease on protein binding is expected to be similar to that seen with phenytoin and thus the same considerations should be made for patients with kidney failure.

EFFECT OF KIDNEY FAILURE ON METABOLIZED DRUGS

Meperidine

CASE 31-8

QUESTION 1: F.G., a 56-year-old female, is admitted for a cervical laminectomy. She has a history of CKD (CrCl 20 mL/minute) and arrhythmias that are treated with amiodarone. Her admission laboratory values are as follows:

SCr, 4.4 mg/dL
BUN, 66 mg/dL
Hematocrit, 34%
Hemoglobin, 12.6 g/dL

After surgery, she reports severe pain and is treated with meperidine 50 to 100 mg intramuscularly every 3 to 4 hours. Three days postoperatively, F.G. experiences a generalized tonic–clonic seizure. She has no history of seizures.

What might be responsible for this sudden event?

Meperidine is a narcotic analgesic that is metabolized by the liver via *N*-demethylation to normeperidine, a metabolite known to accumulate in kidney insufficiency.[15,119] Although meperidine has both CNS excitatory and depressant properties, normeperidine is a very potent CNS stimulant that can cause seizures in patients with

kidney insufficiency who are receiving multiple doses of the parent drug.[120] The kidney clearance of normeperidine correlates with CrCl, and kidney dysfunction can lead to its accumulation, resulting in neurologic toxicity. Because of these safety issues, meperidine is not generally recommended for use as an analgesic. Table 31-3 lists examples of additional drugs that have active or toxic metabolites that may accumulate in kidney disease.

Table 31-3
Drugs With Active or Toxic Metabolites Excreted by the Kidney

Drug	Metabolite
Allopurinol	Oxypurinol
Bupropion	Threo/erythro-hydrobupropion
Cefotaxime	Desacetylcefotaxime
Chlorpropamide	Hydroxy metabolites
Cyclophosphamide	4-Ketocyclophosphamide
Daunorubicin	Daunorubicinol
Meperidine	Normeperidine
Methyldopa	Methyl-*O*-sulfate-α-methyldopamine
Midazolam	α-Hydroxymidazolam
Morphine	Morphine-3-glucuronide
	Morphine-6-glucuronide
Phenylbutazone	Oxyphenbutazone
Primidone	Phenobarbital
Procainamide	*N*-acetylprocainamide (NAPA)
Rifampicin	Deacetylated metabolites
Sodium nitroprusside	Thiocyanate
Sulfonamides	Acetylated metabolites
Tramadol	*O*-Demethyl-*N*-demethyl tramadol

Narcotic Analgesics

MORPHINE

Case 31-8, Question 2: Are the pharmacokinetics or pharmacodynamics of other narcotic analgesics altered in patients with kidney insufficiency?

The pharmacokinetic disposition of morphine does not appear to be altered in patients with kidney failure[121]; however, its active metabolite, morphine-6-glucuronide, as well as its principal metabolite, morphine-3-glucuronide, do accumulate in kidney disease. The elimination half-life of morphine-6-glucuronide increases from 3 to 4 hours in normal subjects to 89 to 136 hours in subjects with kidney failure.[16] This metabolite penetrates the blood–brain barrier more readily, has a greater affinity for CNS receptors, and has analgesic activity that is 3.7 times greater than morphine.[122] Therefore, accumulation of morphine-6-glucuronide may be responsible for the morphine-induced narcosis reported in patients with severe kidney disease.[123,124] Codeine is metabolized to morphine and can cause narcosis in those with kidney dysfunction if the dose is not adjusted for kidney impairment.[125]

HYDROMORPHONE

Hydromorphone is metabolized in the liver to hydromorphone-3-glucuronide, dihydroisomorphone, dihydromorphine, and small amounts of hydromorphone-3-sulfate, norhydromorphone, and nordihydroisomorphone.[126] All metabolites that are eliminated are excreted by the kidneys. Hydromorphone can be used in patients with kidney failure; however, smaller initial doses may be warranted.[127]

Enoxaparin

Case 31-8, Question 3: Because F.G. is not ambulating well after her surgery, her physician would like to initiate deep vein thrombosis prophylaxis with enoxaparin. Are there any dosing considerations for enoxaparin in this patient?

Enoxaparin is a low-MW heparin that is used to prevent and treat various thromboembolic disorders. The kidneys play a major role in the clearance of enoxaparin,[128] and a higher incidence of bleeding complications is associated with the use of enoxaparin in patients with kidney dysfunction.[129] The elimination half-life of enoxaparin is prolonged in patients with CKD, although the other pharmacokinetic parameters are similar to those in healthy subjects.[130] The increased incidence of bleeding complications cannot be completely attributed to pharmacokinetic changes, but may also be related to the effects of enoxaparin on factor IIa and antithrombin III, as well as the effects of uremia on hemostasis.[131]

Enoxaparin should be used cautiously in patients with a CrCl <30 mL/minute. A lower dose of 30 mg subcutaneously once daily for prophylaxis in hip or knee replacement or abdominal surgery is recommended.[132,133] Although monitoring of the anticoagulant effect by anti-Xa activity is not necessary in clinically stable patients, it may be warranted in patients with kidney dysfunction as well as in those who have other factors that may increase the risk of bleeding complications.

ASSESSING KIDNEY FUNCTION IN THE ELDERLY

Kidney function declines physiologically with advancing age and as the result of comorbidities such as hypertension and diabetes.[134] This decrease in kidney function can have significant consequences on drug excretion, metabolism, and the potential for adverse drug reactions, particularly in the elderly population that is often prescribed multiple medications.[135] Antithrombotic and antidiabetic drugs are high-risk medications that are often implicated as a cause for hospitalizations because of adverse drug events in elderly patients. CKD is a risk factor for hypoglycemia in patients with diabetes.[136] Glycemic control in patients with CKD is challenging

because of physiologic changes and alterations in the disposition medications to treat diabetes. Sulfonylurea antidiabetic agents such as glyburide that are eliminated primarily by the kidneys can lead to prolonged hypoglycemia in patients with decreased kidney function.[137] Dipeptidyl peptidase-4 (DPP-4) inhibitors have a similar mechanism of action but differ in their pharmacokinetic disposition. For example, sitagliptin is 80% excreted by the kidneys, and its dose should be adjusted in the setting of kidney dysfunction, whereas only 5% of linagliptin is excreted in the urine and does not need any dose adjustment.[138–140]

Formulas that estimate kidney function use serum creatinine. In elderly adults, a low serum creatinine may not always be indicative of normal kidney function. Older adults tend to have lower muscle mass than younger people, and a low serum creatinine may not be indicative of normal kidney function, but rather reduced muscle mass. Differences in the estimated GFR between the MDRD and Cockcroft–Gault formulas may result in discordant dosing recommendations in an elderly population[141] (see Chapter 28, Chronic Kidney Disease).

This highlights the importance of obtaining a comprehensive medication history, assessment of the patient's kidney function, and evaluation of the available drug-information resources for appropriate dosing recommendations for each patient.

SUMMARY

The kidneys play a vital role in maintaining homeostasis by regulating the excretion of water, electrolytes, and metabolic byproducts. In addition, the kidneys are the primary route of elimination for many drugs. Pharmacokinetic changes, such as altered bioavailability, protein binding, drug distribution, and elimination, can occur with many drugs in patients with kidney failure. Pharmacodynamic changes, such as altered sensitivity or response to medications, can also occur in this patient population.

Kidney replacement therapies, such as hemodialysis, CAPD, and CRRT, will aid in the removal of fluid, electrolytes, metabolic byproducts, and drugs as well. Data from clinical trials provide valuable information about the disposition of drugs in patients with kidney failure. Pharmacokinetic principles should be applied when appropriate to determine the optimal dose of drugs for patients with kidney failure.

Drug Hypersensitivity Reactions

Mariana C. Castells, Kathleen Marquis, and Kylie Marie Besz

CORE PRINCIPLES		CHAPTER CASES
1	Drug allergies are a subset of adverse drug reactions that are usually mediated by the immune system. Although typically unpredictable, there are several factors known to influence the frequency of allergic reactions including age, sex, genetics, prior drug exposure, and drug dose and route. A detailed drug history is key to assisting in the diagnosis of a drug allergy.	**Case 32-1 (Questions 1, 2), Table 32-1**

CORE PRINCIPLES		CHAPTER CASES
2	Skin testing for allergy to penicillin is an important diagnostic tool that assists in determining whether a patient is truly allergic to this class of drug. Patients presenting with a history of penicillin allergy but who have a negative penicillin scratch test and a negative intradermal test should be challenged with penicillin and if no reaction can be safely given β-lactam antibiotics.	**Case 32-1 (Question 3), Table 32-4**
3	There are varying degrees of cross-reactivity between various β-lactam antibiotics. Understanding the frequency of cross-reactivity is important in making treatment decisions if skin testing is not available. The frequency of cross-reaction between penicillins and cephalosporins appears to be very low except for aztreonam and ceftazidime. The risk of a cephalosporin reaction in a patient with a penicillin allergy decreases with increasing cephalosporin generation, being lowest with the third- and fourth-generation drugs. The frequency of cross-reaction between penicillins and carbapenems or monobactams appears to be very low (~1%).	**Case 32-1 (Question 4)**

ANAPHYLAXIS

CORE PRINCIPLES		CHAPTER CASES
1	Anaphylaxis is a serious allergic reaction that has a rapid onset and might cause death. It is caused by the rapid release of immune mediators from tissue mast cells and peripheral blood basophils. Symptoms such as pruritus of the hands, feet, and groin; flushing; light-headedness; hypotension; tachycardia; and difficulty breathing can begin within minutes of exposure to the precipitating agent, which is most commonly foods, insect stings, and drugs. Prompt recognition and treatment are critical to ensure a favorable outcome.	**Case 32-2 (Questions 1, 2), Table 32-2**

CORE PRINCIPLES		CHAPTER CASES
2	Epinephrine is the drug of choice for treatment of anaphylaxis and should be given immediately upon suspicion of an anaphylactic reaction. Epinephrine should be given intramuscularly into the lateral thigh as often as every 5 minutes to treat symptoms. Intramuscular injection is preferred over the subcutaneous and intravenous (IV) routes because of rapid absorption and ease of administration. The patient should be placed in the Trendelenburg position and second-line treatments including oxygen, IV fluids, and a nebulized β-agonist initiated as needed. Antihistamines and corticosteroids are also commonly used to treat anaphylaxis, although there are no data showing an impact on outcome from these therapies.	**Case 32-2 (Question 3), Table 32-5**
GENERALIZED REACTIONS		
1	Generalized hypersensitivity reactions can manifest in a number of ways including drug fever, serum sickness, hemolytic anemia, vasculitis, and autoimmune disorders. Specific organ systems such as the lungs, liver, kidneys, and the hematopoietic system can also be the target of allergic drug reactions.	**Case 32-3 (Questions 1-3)** **Case 32-4 (Questions 1-3)** **Case 32-5 (Questions 1-4), Tables 32-6 to 32-8**

CORE PRINCIPLES		CHAPTER CASES
NON-IGE HYPERSENSITIVITY REACTIONS		
1	Non–IgE hypersensitivity reactions are drug reactions that exhibit clinical signs and symptoms of an allergic response but are not immunologically mediated. Non–IgE mediated reactions can be relatively benign (such as red man syndrome from vancomycin) or potentially life-threatening, clinically resembling immune-mediated anaphylaxis as from radiocontrast media. Several drugs are associated with non-IgE reactions including aspirin and nonsteroidal anti-inflammatory drugs, opiates, angiotensin-converting enzyme inhibitors, and injectable iron products.	**Case 32-6 (Questions 1, 2, 5)** **Case 32-7 (Questions 1-3), Table 32-9**
2	The management of non–IgE mediated reactions is the same as for true allergic reactions.	**Case 32-6 (Questions 3, 4)** **Case 32-7 (Question 2)**
PREVENTION AND MANAGEMENT OF ALLERGIC REACTIONS		
1	The keys to preventing an allergic reaction in a patient with a history of allergy are a good description of the reaction and its causes, distinguishing between drug allergy and drug intolerance, and good documentation and communication of the reaction.	**Case 32-1 (Questions 1, 2)** **Case 32-8 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	In some cases, it is necessary to treat a patient with a drug to which they have a significant allergic reaction. To accomplish this, the process of tolerance induction and desensitization should be used for acute IgE and non-IgE reactions and for nonsevere delayed reactions but not for hepatitis, hemolytic anemia, Stevens–Johnson syndrome, or toxic epidermal necrolysis. Tolerance induction starts with administration of a suballergenic dose of the drug to which a patient is allergic and the progressive administration of larger doses with the goal of modifying the patient's response. Once tolerance has been successfully induced, the patient must remain on the drug to maintain the state of tolerance.	**Case 32-9 (Questions 1-5)**
3	All routes can be used for desensitization including oral, IV, and SQ. The oral route of tolerance induction is preferred over the IV route. Patients may experience a mild reaction during desensitization, although severe reactions are rare. Even after successful desensitization, patients may experience an allergic reaction during full-dose therapy.	**Case 32-9 (Questions 2, 3)**

CORE PRINCIPLES		CHAPTER CASES
4	A graded drug challenge (also called test dosing) is a process of giving subtherapeutic doses of a drug to a patient to determine whether they are allergic. A graded drug challenge generally uses larger starting doses than tolerance induction and involves fewer steps. The graded drug challenge may be appropriate in patients with a distant or unclear history of drug allergy, when the reaction seems minor or when diagnostic testing is unavailable, or in cases where cross-reactivity is expected to be low. It should not be used in patients with a history of a severe non–IgE-mediated reaction such as hepatitis, hemolytic anemia, Stevens–Johnson syndrome, or toxic epidermal necrolysis.	**Case 32-9 (Question 1)**

INTRODUCTION

Adverse drug reactions occur in up to 20% of hospitalized patients and in up to 25% of ambulatory patients. Studies have found that up to 6% of all hospitalizations are caused by an adverse drug event. Immunologically mediated adverse drug reactions (also commonly referred to as drug allergy or hypersensitivity) account for about one-third of all adverse drug reactions and may affect 10% to 15% of hospitalized patients.[1–4] In one study of >36,000 hospitalized patients, 731 adverse events were identified, with 1% being severe, life-threatening, allergic reactions.[5] The potential morbidity and mortality associated with allergic drug reactions can be significant.

DEFINITION

Adverse drug reactions resembling an immune response are called drug hypersensitivity reactions (DHRs). True drug allergies show evidence of either drug-specific antibodies or T cells.[1] Clinically, DHRs are commonly classified as immediate or delayed depending on their onset during treatment. Immediate reactions occur within a few hours of exposure and usually are mediated by IgE. Delayed reactions will occur a few days after starting therapy and are typically mediated by T cells. New reactions have been recently described such as infusion reactions, cytokine release reactions (CRR), and mixed reactions (IgE and CRR).[6] See **Table 32-1**.

Table 32-1

Immunologic Classification of Allergic Drug Reactions

Type	Type of Immune Response	Pathophysiology	Clinical Symptoms	Typical Chronology of the Reaction
I	IgE	Mast cell and basophil degranulation	Anaphylactic shock Angioedema Urticaria Bronchospasm	Within 1–6 hours of the last intake of the drug
II	IgG and complement	IgG- and complement-dependent cytotoxicity	Cytopenia	5–15 days after the start of the eliciting drug
III	IgM or IgG and complement or FcR	Deposition of immune complexes	Serum sickness Urticaria Vasculitis	7–8 days for serum sickness/urticaria 7–21 days after the start of the eliciting drug for vasculitis
IVa	Th1 (IFN-γ)	Monocytic inflammation	Eczema	1–21 days after the start of the eliciting drug
IVb	Th2 (IL-4 and IL-5)	Eosinophilic inflammation	MPE, DRESS	1 to several days after the start of the eliciting drug for MPE 2–6 weeks after the start of the eliciting drug for DRESS
IVc	Cytotoxic T cells (perforin, granzyme B FasL)	Keratinocyte death mediated by CD4 or CD8	MPE, pustular exanthema, SJS/TEN	1–2 days after the start of the eliciting drug for fixed drug eruption 4–28 days after the start of the eliciting drug for SJS/TEN
IVd	T cells (IL-8/CXCL8)	Neutrophilic inflammation	Acute generalized exanthematous pustulosis	Typically 1–2 days after the start of the eliciting drug (but could be longer)

DRESS, drug rash with eosinophilia and systemic symptoms; FasL, Fas ligand; FcR, Fc receptor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; MPE, maculopapular exanthema; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

PATHOGENESIS

DHRs cannot be attributed to a single immunopathologic mechanism. Traditionally, an allergic drug reaction was thought to occur in two phases, initial sensitization and subsequent elicitation.[7] Most drugs are small molecules (<1000 Da) and are unable to stimulate an immune response. Sensitization occurs as a result of covalent binding of a drug or a metabolite to a carrier protein in a process referred to as *haptenation*.[1,8] This drug–protein (or drug metabolite–protein) complex is sufficiently large to induce the production of drug-specific T or B lymphocytes and IgM, IgG, and IgE. On reexposure to the drug, the patient is likely to present with allergic symptoms.[8] Allergic reactions to β-lactam antibiotics occur by this mechanism. This theory, however, cannot explain several allergic phenomena. For instance, some chemically inert drugs (ie, drugs that cannot form stable covalent bonds and do not have reactive metabolites) can still elicit an allergic response. Lidocaine and mepivacaine are examples. Furthermore, some patients have a strong allergic reaction to a drug on initial exposure, and some allergic reactions rapidly occur after drug exposure, a time period shorter than expected for the development of new antibodies. For example, infusion reactions causes by the release of cytokines, namely IL-6, during infusion of platins (oxaliplatin) and monoclonal antibodies.[9-11] To account for some of these observations, other models for explaining allergic reactions have been proposed. The direct pharmacologic interaction concept offers one explanation for these observations. This model suggests that some drugs are able to bind directly to T-cell receptors in a reversible, noncovalent manner.[12] The drug–T-cell receptor complex interacts with major histocompatibility complex (MHC) molecules, leading to activation and expansion of T cells that are directed against the drug.[13]

Recent studies have demonstrated an additional mechanism whereby abacavir and carbamazepine can alter the shape and chemistry of the antigen-binding cleft via noncovalent interactions in patents with specific human leucocyte antigen (HLA) variants. These

alterations cause endogenous peptide to be viewed as foreign and lead to the activation of T cells. This process is referred to as the *altered repertoire model*.[14,15] Undoubtedly, the processes involved in allergic reactions are complex and might include some combination of each theory. The three models of hapten sensitization, direct pharmacologic interaction, and altered repertoire are not mutually exclusive. Interested readers are referred to more in-depth reviews.[16]

PREDISPOSING FACTORS

Factors known to affect the incidence of allergic reactions can be categorized as being drug-related or patient-related ones.[3] Patients with histories of allergic rhinitis, asthma, or atopic dermatitis who experience a systemic drug reaction tend to react more severely than do others.[3,17,18]

Age and Sex

Children are less likely to become sensitized than are adults, presumably because children typically have less cumulative drug exposure.[1,17] More female than male patients experience allergic reactions (up to 2.3:1), although this may vary by type of reaction, drug, patient age, and setting.[3,18]

Genetic Factors

Familial occurrences of allergic reactions, although rare, have been reported.[19] A patient's ability to metabolize a drug is influenced by his or her genetic makeup and may affect the incidence of DHRs.[16,20–22] In humans, the MHC is encoded by a group of genes on chromosome 6 called the *HLA system*. Variations in HLA are probably the most important genetic determinant of drug allergies.[16]

Genetic differences in drug-metabolizing enzymes can explain the predisposition to drug allergy and hypersensitivity of some

individuals.[16] Examples of the phenotypic expression of these polymorphisms include poor metabolizers (who possess nonfunctional alleles and have reduced metabolic activity) and ultrarapid metabolizers (who have multiple copies of functional genes and have enhanced metabolic activity).[22,23]

Slow acetylators are at risk for sulfonamide hypersensitivity and are also more likely to develop antinuclear antibodies (ANAs) and symptoms of systemic lupus erythematosus (SLE) when treated with procainamide or hydralazine.[24] Anticonvulsant hypersensitivity syndrome, characterized by fever, generalized rash, lymphadenopathy, and internal organ involvement, is most associated with aromatic anticonvulsants (eg, phenytoin, phenobarbital, and carbamazepine). Oxidation of these compounds by cytochrome P-450 enzymes results in arene oxides that are antigenic. Patients with a heritable deficiency in epoxide hydrolase cannot clear the formed antigen and are at increased risk for a drug sensitivity syndrome, also known as DRESS (drug rash with eosinophilia and systemic symptoms).[25] A polymorphism might also be responsible for a serum sickness–like reaction to cefaclor.[23]

Although polymorphism in drug-metabolizing enzymes is responsible for some allergic reactions, variation in MHC appears to be more important.[16,20] HLA polymorphisms mostly map to the antigen-binding cleft, thereby diversifying the repertoire of peptide antigens selected by different HLA allotypes. Several important DHRs are associated with specific HLA alleles.[16] For example, HLA-B*1502 is associated with increased risk (odds ratio [OR] 17.6) of Stevens–Johnson syndrome (SJS) with carbamazepine (CBZ), phenytoin, and lamotrigine.[20] HLA-B*1502 occurs in 10% to 15% of individuals from southern China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan and has a prevalence rate of 2% to 4%, or higher, in other southern Asian groups, including Indians. It is uncommon in Japan and Korea (<1%) and in European Caucasians (0%–0.1%).[21]

The potentially life-threatening hypersensitivity syndrome seen with abacavir is strongly associated with the HLA-B*5701 haplotype.[16,26–29] HLA-B*5701 in patients predicted abacavir

hypersensitivity 100% of the time, and its absence had a 97% negative predictive value.[29] This haplotype appears more commonly in White patients than in other ethnic groups and explains the predisposition of White patients to this severe reaction. Genetic screening of patients for this haplotype before initiating abacavir therapy has significantly reduced the occurrence of hypersensitivity reactions.[29] In the future, it is hoped that screening tests for HLA haplotypes associated with a variety of allergic reactions will become widely available.

A more comprehensive and up-to-date listing of alleles associated with immunologically mediated adverse drug reactions can be found at https://www.pharmgkb.org/.

Associated Illness

Although genes clearly play a role in hypersensitivity reactions, environmental factors (eg, concomitant illness) also are implicated. For example, the incidence of maculopapular rash with ampicillin therapy is significantly higher in patients with Epstein–Barr virus infections (eg, infectious mononucleosis), lymphocytic leukemia, or gout.[30] Infection with herpes virus or Epstein–Barr virus has also been linked to DRESS syndrome,[30] and the occurrence of reactions to trimethoprim–sulfamethoxazole in patients who are human immunodeficiency virus (HIV) positive is about 10-fold higher than in the HIV-negative population.[26] Liver or kidney disease may alter the metabolism or elimination of reactive drug metabolites, increasing the risk of an allergic response.

Previous Drug Administration

A history of an allergic reaction to a drug being considered for treatment, or one that is immunochemically similar, is the most reliable risk factor for the development of a subsequent allergic reaction.[1,30] A commonly encountered example is the patient with a history of a severe allergic reaction to penicillin, in whom all

structurally related penicillin compounds should be avoided, and in whom the possibility of a hypersensitivity reaction should be considered when using other β-lactam antibiotics.[1,30]

Drug-Related Factors

The dose, frequency of exposure, and route of administration can influence the incidence of drug allergy. For example, penicillin-induced hemolytic anemia requires high and sustained drug concentrations.[31] In β-lactam antibiotic IgE sensitivity, frequent intermittent courses, rather than continuous therapy, are more likely to result in drug sensitization.[25] The route of administration is important in terms of the risk of both sensitization and allergic reaction in a previously sensitized person. Topical administration carries the greatest risk of sensitization, followed by subcutaneous, intramuscular (IM), and oral routes. The intravenous (IV) route is the least sensitizing route of administration.[32] However, in a patient who is already sensitized to a specific medication, the risk of an allergic reaction to that medication is greatest when it is given IV and least when given orally. This is thought to be a function of the rate of drug delivery.[32] Multiple drug therapy is associated with a greater risk of allergic reactions. This may be related to increased demands on metabolic pathways from multiple drugs, leading to the accumulation of reactive metabolites.[32]

Drugs as Allergens and Immunologic Classification

Although there are proposed changes to the nomenclature and classification of drug allergies,[33] the Gel and Coombs classification is the most common. In this system, allergic drug reactions can be classified into one of four types (Table 32-1).[1]

TYPE I: IMMEDIATE HYPERSENSITIVITY REACTIONS

Type I reactions are typically mediated by IgE. Initial exposure to an antigen results in the production of specific IgE antibodies that are expressed on the surface of mast cells in the tissue and basophils in the blood. On reexposure, the antigen cross-links with two or more surface-bound IgE antibodies, causing the release of several chemical mediators including histamine, tryptase, leukotrienes, prostaglandins, and cyotkines.[32]

A period of several weeks is required after initial exposure and sensitization before a type I reaction can be elicited; once sensitized, however, a type I response can be elicited within minutes as a result of existing antibodies. In addition, a type I reaction can occur on reexposure to small amounts of drug administered by any route.[32,34] Immune-mediated anaphylaxis is a classic example of a type I reaction. Acute non–IgE mediated reactions involve direct activation of mast cells and basophils through the recently discovered mast cell-specific receptor called Mas-related G protein-coupled receptor X2 (MGRPRX2 receptor), CRR, mixed reactions, and COX-1 inhibition induced reactions.[35] Reactions that clinically resemble anaphylaxis, but do not involve immunologic mediators (antibodies), are termed *anaphylactoid* or *pseudoallergic* reactions (see Case 32-6, Question 1).

TYPE II: CYTOTOXIC REACTIONS

Cytotoxic reactions involve the interaction of IgG or IgM and can occur by three different mechanisms (Table 32-1). Common clinical manifestations of cytotoxic reactions include hemolytic anemia, thrombocytopenia, and granulocytopenia. Penicillin-induced hemolytic anemia is the best-known example of a cytotoxic drug reaction. This reaction typically appears after 7 days of high-dose therapy.[31]

TYPE III: IMMUNE COMPLEX–MEDIATED REACTIONS

Immune complex–mediated reactions result from the formation of drug–antibody complexes in serum, which often deposit in blood vessel walls, resulting in activation of complement and endothelial

cell injury.[34] Also referred to as serum sickness, these reactions typically manifest as fever, urticaria, arthralgia, and lymphadenopathy 7 to 21 days after exposure.[30,34]

TYPE IV: CELL-MEDIATED (DELAYED) REACTIONS

In cell-mediated (delayed) reactions, an antigen binds with sensitized T cells. Contact dermatitis is the most common manifestation of cell-mediated reactions, although systemic reactions can occur. The variety of clinical manifestations of delayed hypersensitivity has been attributed to distinct patterns of cytokine release and effector-cell recruitment, based on the type of T cells stimulated. Each pattern of cytokine release recruits specific effector cells, such as macrophages, neutrophils, or other T cells, and is responsible for the unique clinical manifestations of the reaction. Based on this understanding, type IV reactions have been further subclassified as types IVa, IVb, IVc, and IVd, corresponding to four unique patterns of T-cell and effector-cell involvement.[36]

An understanding of the immunologic mechanism can be helpful in the diagnosis and treatment of an allergic reaction; however, the exact immunologic mechanism is unknown for many allergic reactions to drugs.[30] In addition, patients often present with several symptoms characteristic of more than one of the reactions described herein. The use of many drugs concurrently also makes it difficult to identify the drug responsible for the reaction. Therefore, a careful drug history and diagnostic tests are often necessary for an appropriate diagnosis and treatment of a patient.

DIAGNOSIS

Distinctive Features of Allergic Reactions

The first step in the diagnosis of an allergic drug reaction is to recognize and differentiate it from other adverse drug reactions. This

can be accomplished by having a good understanding of the distinctive features of allergic drug reactions (**Table 32-2**).[30]

Table 32-2
Clinical Features of Allergic Drug Reactions

- Are unpredictable
- Occur only in susceptible individuals
- Have no correlation with known pharmacologic properties of the drug
- Reactions can occur at first exposure or may need a sensitization period.
- Can occur with doses far below therapeutic range
- Can affect most organs, but commonly involves the skin
- Most commonly manifests as an erythematous or maculopapular rash, but includes angioedema, serum sickness syndrome, anaphylaxis, and asthma
- Occur in a small proportion of the population (10%–15%)
- Disappear on cessation of therapy and reappear after readministration of a small dose of the suspected drug(s) of similar chemical structure . Many patients are labeled as penicillin allergic while once tested they are able to tolerate penicillin. Delabeling patients with a history of penicillin allergy is recommended to avoid usage of more expensive and complication prone medications and the generation of antibiotic resistance.
- Desensitization may be possible.

Sources: Schnyder B. Approach to the patient with drug allergy. *Immunol Allergy Clin North Am*. 2009;29:405–418; Demoly P, Adkinson NF, Brockow K, et al. International consensus on drug allergy. *Allergy*. 2014;69:420.

CASE 32-1

Question 1: J.A., a 73-year-old female, is admitted with an infected decubitus ulcer. Cultures reveal *Staphylococcus aureus*, which is sensitive to oxacillin, cefazolin, and vancomycin. On questioning, J.A. reports having experienced a rash to penicillin in the past. Her current medications include oral docusate 100 mg twice daily, oral enalapril 5 mg every morning, oral prednisone 20 mg daily, and oral ibuprofen 800 mg three times daily.

What information should be obtained to determine whether J.A.'s rash represents an allergic drug reaction?

The single most informative diagnostic procedure for allergic drug reactions is a detailed drug history (**Table 32-3**), which is helpful in obtaining the information necessary to determine whether a reaction represents a drug allergy and in identifying the culprit drug. In inquiring about prior allergic and medication encounters, it is important to document the drugs to which the patient has or has not previously reacted. This can alert the clinician about certain types of compounds to which the patient is likely to react. The acquired information allows the clinician to characterize the drug reaction and to appreciate how such a reaction might be manifested in the patient on exposure to the same, or an immunologically similar, compound in the future.

Table 32-3

Detailed Drug History

- Name of the medication
- Route of administration
- Reason medication was prescribed
- Nature and severity of reaction
- Temporal relationships between drugs and reaction (dose, date initiated, duration, when during the course of treatment did the reaction occur)
- Prior allergy history
- When did the reaction occur (days to weeks vs months to years)?
- Similar reactions in family members
- Prior exposure to the same or structurally related medications
- Concurrent medications
- Management of the reaction (effect of drug discontinuation; therapies required to treat the reaction)

- Response to treatment
- Prior diagnostic testing or rechallenge
- Other medical problems (if any)

Sources: Khan DA, Solensky R. Drug allergy. *J Allergy Clin Immunol*. 2010;125(2 Suppl 2):S126–S137; Celik G. Drug allergy. In: Adkinson NF, ed. *Middleton's Allergy: Principles and Practice*. 7th ed. Mosby; 2008:1205.

The temporal relationship between drugs and reactions is often the strongest piece of evidence implicating an allergic reaction to a particular agent. Drugs that the patient has received for long continuous periods before the onset of a reaction are less likely to be implicated than are drugs that have been recently initiated or restarted.[30] Equally important is to determine when an adverse reaction has occurred. Many compounds have been reformulated over the years, resulting in removal of sensitizing impurities (eg, penicillin and vancomycin). Therefore, it is possible that reexposure to the agent will not result in an adverse event. Inquiring about whether the patient has received the drug since the first episode by asking the patient about other brands or names of other drugs in the same class (eg, amoxicillin and ampicillin) will assist in determining whether the patient is likely to react to the drug on reexposure. It is usually helpful to chart all the drugs the patient is currently taking, their dose, and start and stop dates of use. This can be compared with the onset and disappearance of the reaction.

Case 32-1, Question 2: On further questioning, J.A. reports having experienced an urticarial rash in the past when given ampicillin for a kidney infection ~2 years ago. The rash developed over her entire body less than a day after starting the antibiotic and disappeared 2 days after discontinuation. Her treatment course was completed with ciprofloxacin. She denies having had a viral infection at the time of the rash to ampicillin. She does not recall having experienced any adverse effects when she received penicillin before this reaction. No other recent changes in her treatment regimen were made before the occurrence of the rash. Why is it likely that J.A. is allergic to penicillin?

Several pieces of information in the drug history obtained from J.A. can be used to determine the likelihood of an allergic reaction to penicillin. J.A.'s rash appeared less than a day after initiation of ampicillin and other drugs had not been added; therefore, the rash probably was caused by ampicillin. Additionally, since the reaction occurred 2 years prior, it is likely that the patient may still be allergic. Time is important, and patients with a history of penicillin allergy over 20 years are unlikely to be allergic because the rate of penicillin allergy decreases every 10 years.[37]

Another important method of identifying a potential drug-induced allergic reaction is to examine the patient's medication list to determine whether the patient is receiving an agent that commonly is implicated in causing the exhibited allergic manifestation. For example, amoxicillin and ampicillin are two of the top three drugs implicated in drug-induced rash.[31]

J.A. received penicillin previously without experiencing any adverse effects until an urticarial rash (a relatively common allergic manifestation) developed on subsequent exposure. This sequence of events follows the typical pattern of an allergic reaction. Allergic reactions commonly require an induction period to sensitize the person to the antigen; however, once sensitized, allergic symptoms typically occur immediately on reexposure.[30] Therefore, a prior exposure to the same or structurally related compounds needs to be documented.

Finally, it is important to evaluate other medical problems that can elicit or mimic a reaction resembling drug allergy (see the section on "Associated Illness"). Rashes to ampicillin commonly occur in patients with concurrent Epstein–Barr virus infection.[38] J.A. denies having a viral infection at the time of her rash, thereby strengthening the case that the rash was likely a manifestation of an allergic reaction.

Skin Testing

Case 32-1, Question 3: Would skin testing for penicillin allergy be appropriate for J.A.?

Although J.A.'s medication history strongly suggests that she is allergic to penicillin, a skin test and a drug rechallenge would more firmly establish her drug allergy. Penicillin degrades to major determinants (95%) and minor determinants (5%). Penicilloyl, the primary metabolite of penicillin, is referred to as the *major determinant*. The other derivatives are referred to as *minor determinants*. Of these, the parent compound (penicillin), penicilloate, and penilloate are the minor determinants most associated with allergic reactions. The terms *major determinant* and *minor determinant* refer to the frequency of antibody formation to these antigenic penicillin metabolite–protein complexes. These terms do not describe the severity of the allergic reaction. Indeed, the major determinant is thought to be responsible for accelerated reactions, but not anaphylaxis. The minor determinants are responsible for anaphylaxis and immediate systemic reactions.

Skin testing with these determinants is used to identify which patients have IgE antibodies to penicillin and which do not. The skin testing antigen for the major determinant of penicillin is commercially available as penicilloyl polylysine (PPL; Pre-Pen®), which was recently reintroduced into the United States after several years of absence.[39] Skin testing using Pre-Pen® is a safe and effective procedure (**Table 32-4**), with <1% of positive responders developing systemic reactions.[40] In those in whom a false-negative response occurred, reactions were mild after penicillin administration and, in most cases, did not require drug discontinuation.[30,40] Skin testing with PPL identifies 80% of patients allergic to penicillin. When PPL is supplemented with skin tests for the minor determinants of penicillin, 99.5% of patients with allergy to penicillin can be identified.[30] Of the minor determinants, only penicillin G is available in the United States, although a minor determinant mixture is marketed in Europe and Australia.[41]

Table 32-4

Overview of Penicillin Allergy Skin Testing

Skin Testing Reagents	Epicutaneous/Puncture	Testing Intradermal Testing
Controls		
Positive: Histamine		
Negative: Normal saline	1 mg/mL 0.9%	0.9%
Major Determinanta		
Benzylpenicilloyl polylysine (Pre-Pen®)	6 x 10-5 M	6 x 10-5 M
Minor Determinants[a]		
Benzylpenicillin (Penicillin G)	10,000 units/mL	10,000 units/mL
Benzylpenicilloate	0.01-0.02 M	0.01-0.02 M
Benzylpenilloate	0.01-0.02 M	0.01-0.02 M

Penicillin Skin Testing Procedure	Interpretation
Epicutaneous/puncture testing	Histamine test site must measure at least 5 mm
▪ Apply a drop of the following and then prick/puncture the skin using a skin prick/puncture device. ▪ Histamine (positive control) ▪ Normal Saline (negative control) ▪ Pre-PenR ▪ Diluted penicillin G (10,000 units/mL) ▪ Wait 15.20 minutes to read, measure, and record	▪ If not, do not proceed with skin testing Criteria for negative prick/puncture skin test: ▪ No reaction at testing site or no reaction greater than control site ▪ Proceed with intradermal testing Criteria for positive prick/puncture skin test: ▪ Induration 3 mm greater than diluent control ▪ Do not proceed to intradermal testing ▪ Choose alternative agent, consider desensitization if no other alternatives exist

Skin Testing Reagents	Epicutaneous/Puncture	Testing Intradermal Testing
Intradermal testing ▪ Inject sufficient volume of the following to create a bleb of 2.3 mm under skin: ▪ Test in duplicate Pre-PenR ▪ Test in duplicate penicillin G (10,000 units/mL) ▪ Diluent control ▪ Mark perimeter of bleb at placement ▪ Wait 15.20 minutes to read, measure, and record	Criteria for positive intradermal skin test: ▪ Increase in size of original bleb of 3 mm or more; itching and flare are commonly present Criteria for negative intradermal skin test: ▪ No increase in size of original bleb and no reaction greater than control site Equivocal intradermal skin test: ▪ Weal only slightly larger than initial injection bleb and control site, with or without erythematous flare or duplicates are discordant	

[a]Approximately 95% of penicillin degrades to form a penicilloyl complex, which is called the major determinant. The remaining penicillin remains in its native form (benzylpenicillin) or degrades further to form minor determinants, which include benzylpenicilloate and benzylpenilloate.

The negative predictive value of skin testing was demonstrated when 34 patients purportedly allergic to penicillin needed β-lactam antibiotics during hospitalization. Each subsequently tested negative to penicillin skin testing and no allergic drug reactions occurred.[42]

Penicillin and its metabolites become antigenic when combined with proteins and can precipitate a hypersensitivity reaction in a patient on reexposure. In patients with a history of penicillin hypersensitivity, skin test reactivity is affected by the length of time since the allergic reaction and by the nature of the past reaction. Skin test positivity is greatest 6 to 12 months after a reaction and decreases with time. Skin test positivity in one study was found to be only 40% of patients with a history of anaphylaxis, 17% with urticaria,

and 7% for maculopapular rashes.[43] Skin testing should not be performed in patients receiving antihistamines because they block the response to the antigen and can result in misinterpretation. In patients receiving antihistamines (ie, H_1- or H_2-receptor antagonists) or when skin testing is not possible because of severe skin disease, in vitro assays to detect drug-specific IgE antibodies have been developed for the major and minor determinants of penicillin.

To determine whether skin testing is appropriate for J.A., the risks and benefits must be weighed. Because the time of the last reaction was ~2 years ago, J.A. may still retain some skin test positivity if the previous reaction was truly an allergic response to ampicillin. Testing with PPL (major determinant) and penicillin G (minor determinant) could be useful in determining whether J.A. is likely to experience an urticarial or anaphylactic reaction to penicillin or its derivatives. That J.A. is currently receiving prednisone should not alter the interpretation of the skin test results because the corticosteroids minimally affect the IgE-mediated immediate hypersensitivity reactions. The risks of developing serious systemic reactions to penicillin skin testing are minimal.

In patients with demonstrated penicillin allergy in need of penicillin, desensitization should be the first treatment choice. Avoidance with usage of alternative second-line antibiotics will generate antibiotic resistance, provide more complications, increase resource utilization, and increase hospital stay.[44]

Cross-Reactivity

Case 32-1, Question 4: J.A. received a scratch test with PPL, the result of which was negative; however, an intradermal test result was positive. What treatment options are available to J.A. for her infection?

All penicillin derivatives should be avoided because J.A. had a positive skin test reaction. Skin tests are not commercially available for cephalosporins and other β-lactam antibiotics. Although cephalosporin skin testing (ie, prick followed by intradermal

instillation) has been proposed, no prospective studies have evaluated this approach and this practice is not without risk.[45,46] Therefore, clinicians must rely on cross-reactivity data to determine whether a non-penicillin β-lactam antibiotic (eg, a cephalosporin) can be used in a patient with allergy to penicillin.

Cross-reactivity (ie, cross-antigenicity) between penicillin and cephalosporins has been reported in 5% to 15% of patients[40,43]; however, the true incidence of cross-reactivity is considerably less because these initial percentages were based on the recollection of patients about an allergic history rather than by objective skin tests.

The risk of a cephalosporin reaction in a patient with a penicillin allergy decreases with increasing cephalosporin generation: 5% to 16.5% for first-generation, 4% for second-generation, and 1% to 3% for third-generation and fourth-generation cephalosporins.[47] The risk of a serious allergic reaction with the use of an advanced-generation cephalosporin in a patient with allergy to penicillin might be no greater than the risk of any alternative antibiotic.[48] The cross-reactivity between penicillins and cephalosporins formerly was attributed primarily to their common β-lactam chemical-ring structure; however, side-chain–specific reactions are now recognized to be responsible for a significant portion of allergic reactions within and between the penicillin and cephalosporins families.[45,48,49] In a study of 30 patients with immediate allergic reactions to cephalosporins, <20% reacted to penicillin determinants (ie, skin test positivity, radioallergosorbent testing positivity, or both).[49] (Radioallergosorbent testing is a radioimmune test to detect IgE antibodies responsible for hypersensitivity.) This cross-reactivity between penicillin and cephalosporins is significantly less than earlier reports (up to 50%); however, the results of this study could be attributable to the greater use of third-generation, rather than the first-generation cephalosporins, which share more chemical structure similarities with the penicillins. Additional support for the importance of side-chain–specific reactions of β-lactams comes from observational data noting that 30% of patients with immediate reactions to penicillins were selective for amoxicillin.[50] In patients with allergy to amoxicillin, studies have found 2% to 38% cross-reactivity with the

cephalosporin cefadroxil; both drugs share the same side chain.[34] Patients allergic to ampicillin may also have a greater risk of allergic reaction to cephalosporins that share the same side chain, such as cephalexin, cefaclor, cephradine, and loracarbef. Some patients also have multiple drug allergies and could manifest an allergic reaction to these drugs (and others that are not β-lactams) in a manner similar to their penicillin reaction.[43]

Cross-reactivity between penicillins and carbapenems (imipenem, meropenem, ertapenem, doripenem), and monobactams (eg, aztreonam) has also been studied. One hundred and twelve patients with a history of immediate reactions to penicillin and a positive skin test result to penicillin underwent skin testing with imipenem–cilastatin. One patient (0.9%) had a positive skin test result. One hundred and ten of the remaining 111 patients received gradually increasing IM doses of imipenem–cilastatin with no reactions observed.[51] Similarly, 108 children with a history of an immediate hypersensitivity reaction to a penicillin and a positive skin test underwent intradermal skin testing to meropenem. One child (0.9%) had a positive skin test. The remaining 107 subjects received increasing doses of IM meropenem with no reactions reported.[52] There also does not appear to be significant cross-reactivity between penicillins and the monobactam aztreonam.[53] Ceftazidime and aztreonam have an identical side chain, however, and there is evidence of cross-reactivity between these two antibiotics.[54]

Although desensitization with an appropriate cephalosporin is a potential option for J.A. (see Case 32-9, Question 1), her infection is not life-threatening, and the organism is probably sensitive to another antimicrobial agent. In this case, it would be prudent to treat J.A. with a non–β-lactam antibiotic. If J.A.'s skin tests to cephalosporin were undertaken, and results had been negative, she could receive a cephalosporin despite her positive history beginning with a cautiously administered small (ie, "test") initial dose.[43]

GENERALIZED REACTIONS

Drug allergies can be grouped into three categories: generalized reactions, organ-specific reactions, and non–IgE mediated hypersensitivity reactions. Generalized reactions involve multiple organ systems and variable clinical manifestations. Anaphylactic reactions, serum sickness reactions, drug-induced fever, hypersensitivity vasculitis, drug-induced vasculitis, and autoimmune drug reactions are the generalized drug reactions presented in this chapter.

Anaphylaxis

CASE 32-2

Question 1: L.P., a 187.39-pound (85-kg), 29-year-old male, presents to the emergency department with a cat bite to the forearm 2 days prior. Physical examination reveals a male in moderate distress with multiple puncture wounds on the volar aspect of the right arm. The area surrounding the wounds is swollen, erythematous, and tender to the touch. L.P.'s history is notable for exercise-induced asthma, controlled with an albuterol metered-dose inhaler as needed, and a history of a laparoscopic appendectomy 3 years prior. He has no known allergies. The wound is cleansed with a germicidal soap and 3 g ampicillin/sulbactam is started via IV route. Three minutes after starting the ampicillin/sulbactam, L.P. notes tingling and pruritus of both his hands and feet, and appears flushed. One minute later he reports feeling light-headedness, difficulty breathing, and a lump in his throat. His vital signs at this time are blood pressure (BP) 100/60 mm Hg (normal, 125/85), heart rate 70 beats/minute (normal, 60), and respiratory rate 27 breaths/minute (normal, 12). Chest auscultation reveals restricted airflow and stridor. Anaphylaxis is the diagnosis and emergency treatment is started.

What subjective and objective evidence support the diagnosis of anaphylaxis in L.P.?

Anaphylaxis is a serious allergic reaction that has a rapid onset and can cause death.[55] The diagnosis is considered probable if one of three clinical criteria are met[56]:

1. An acute onset of a reaction (minutes to hours) with involvement of the skin, mucosal tissue, or both, and at least one of the following:
   - **a.** Respiratory compromise

b. Reduced BP or symptoms of end-organ dysfunction

2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient:

a. Involvement of the skin/mucosal tissue

b. Respiratory compromise

c. Reduced BP or associated symptoms

d. Persistent gastrointestinal (GI) symptoms

3. Reduced BP, after exposure to a known allergen

Anaphylaxis results from the rapid release of immunologic mediators from tissue mast cells and peripheral blood basophils.

The symptoms of anaphylaxis vary widely, depending on the route of exposure, rate of exposure, and dose of allergen.[34] Symptoms often begin within minutes of exposure, as in L.P., and most reactions occur within 1 hour. On rare occasions, anaphylaxis can appear several hours after exposure, and late phase or biphasic attacks have occurred 1 to 72 hours after the initial attack (most commonly within 8 hours). In general, the severity of the anaphylaxis is directly proportional to the speed of onset. L.P. displays symptoms in many of the organs commonly involved in anaphylaxis. Although almost any organ system can be affected, the cutaneous, GI, respiratory, and cardiovascular systems are involved most frequently, either singly or in combination.[34] These “shock organs” contain the largest number of mast cells and are the most highly affected.

L.P. exhibits erythema (flushed appearance) and pruritus of his hands and feet, both common initial symptoms of anaphylaxis; the groin is also commonly affected. These symptoms can progress to urticaria and angioedema, especially of the palms, soles, periorbital tissue, and mucous membranes. L.P. describes the early manifestations of angioedema (laryngeal edema) with a feeling of a lump in his throat (this may also be described as throat tightness or constriction by some patients).

The upper and lower respiratory tracts can also be involved during an anaphylactic event. L.P. exhibits stridor, indicating upper airway

involvement. Hoarseness is another sign of upper respiratory tract involvement. In addition, L.P. is tachypneic with poor airflow, suggesting his lower airway also is affected. L.P. does not display wheezing or acute emphysema, which are further clues of lower airway involvement. Respiratory symptoms can lead to suffocation and death. In one autopsy series, laryngeal edema accounted for 25% of the fatalities and acute emphysema for another 25% of the deaths.[57] Cardiovascular symptoms also are ominous. Cardiovascular collapse and hypotensive shock (anaphylactic shock) are caused by peripheral vasodilation, enhanced vascular permeability, leakage of plasma, low cardiac output, and intravascular volume depletion. Thus, hypotension, as seen with L.P., is a common cardiac manifestation. Tachycardia also commonly occurs in patients with cardiac complications of anaphylaxis. L.P. does not show a significant increase in heart rate; however, he is taking the β-blocker atenolol. Other cardiac manifestations of anaphylaxis include a direct cardiodepressant effect and various electrocardiographic changes, including arrhythmias and ischemia.

Although not demonstrated by L.P., common GI manifestations such as abdominal cramping, diarrhea (which can be bloody), nausea, and vomiting are also manifested during an anaphylactic reaction.[34] In summary, L.P.'s rapid onset and progression of symptoms involving multiple organ systems (ie, cutaneous, respiratory, and cardiovascular systems) are consistent with an anaphylactic reaction. L.P.'s anaphylaxis is a severe reaction given its speed of onset, the number of organ systems involved, and the degree of involvement. In particular, his respiratory and cardiovascular symptoms indicate a potentially life-threatening reaction.

Case 32-2, Question 2: What is the mechanism behind anaphylaxis, and what is the likely cause of L.P.'s anaphylactic event?

Anaphylaxis occurs through one of three mechanisms.[34] In the first type of reaction, exposure to a foreign protein, either in its native

state or as a hapten conjugated to a carrier protein, causes IgE antibody formation. The IgE antibodies then bind to receptors on mast cells and basophils. On reexposure, the antigen stimulates cellular degranulation through both antigen-IgE antibody formation and cross-linking, which result in massive release of preformed immunologic mediators from the mast cells and basophils. Tryptase is the major biomarker of anaphylaxis and is released into the peripheral blood within 30 minutes of the start of the symptoms. Measuring tryptase during an anaphylactic reaction and at baseline provides evidence of mast cell/basophil activation can rule out clonal and non-clonal mast cell activation disorders associated with an increased frequency of anaphylaxis, such as systemic mastocytosis and hereditary α-tryptasemia (HαT).[58] Whether drugs that activate MRGPRX2 receptors on mast cells such as general anesthetics, rocuronium, atracurium quinolones, and others can induce anaphylaxis has not been demonstrated. Histamine is the major mediator of anaphylaxis and the primary preformed cellular constituent. Histamine has multiple effects and is likely responsible for vasodilation, urticaria, angioedema, hypotension, vomiting, abdominal cramping, and changes in coronary flow.[34] Leukotrienes (eg, leukotrienes C_4 and D, also known as slow-reacting substance of anaphylaxis), platelet activating factor, and prostaglandins are generated rapidly as a result of cellular degranulation, and other mediators of anaphylaxis (eg, tryptase, chymase, carboxypeptidase A, tumor necrosis factor, and other cytokines and chemokines) are released as well.[34] Anaphylactic reactions to *Hymenoptera* venom (eg, bee stings), insulin, streptokinase, penicillins, cephalosporins, local anesthetics, and sulfonamides occur through this IgE-mediated mechanism.

Anaphylaxis also can occur via the formation of immune complexes that activate the complement system and the subsequent formation of anaphylatoxins C3a, C4a, and C5a. Such anaphylatoxins can directly stimulate mast cell and basophil degranulation and mediator release. In 2008, cases resembling anaphylaxis in patients receiving heparin, particularly those also

undergoing dialysis, were reported, with almost 100 deaths occurring internationally. The culprit was found to be a contaminant (oversulfated chondroitin sulfate) that caused symptoms by this mechanism.[59,60]

The third mechanism by which substances, such as radiocontrast media and other hyperosmolar agents, can cause anaphylaxis is by the direct stimulation of mediator release (primarily histamine). The pathway by which this occurs is as yet unknown, but it is independent of IgE and complement.

In addition, when no distinct mechanism can be associated with an anaphylactic event, the term idiopathic anaphylaxis is applied.[34]

Foods, insect stings, and drugs are the most common causes of anaphylaxis.[61] Antibiotics (particularly β-lactams and fluoroquinolones), nonsteroidal anti-inflammatory drugs (NSAIDs), neuromuscular blocking agents, radiocontrast media, chemotherapeutic agents, and monoclonal antibodies are the most common causes of drug-induced anaphylaxis. L.P.'s anaphylactic episode most likely is related to the first mechanism (ie, IgE antibody formation). L.P. is receiving a drug from a class of antibiotics well known to cause anaphylaxis. Specifically, L.P. may have received a prophylactic β-lactam antibiotic before his appendectomy, a standard of practice. Exposure to the antibiotic at that time stimulated IgE antibody formation. After exposure to the β-lactam ampicillin/sulbactam in the emergency department, antibody–antigen complexes were formed, resulting in cellular degranulation and anaphylaxis. The temporal relationship of L.P.'s anaphylactic reaction to the administration of the antibiotic also strongly implicates ampicillin/sulbactam as the precipitating agent. Furthermore, L.P. was not exposed to agents known to cause anaphylaxis by one of the other known mechanisms. A review of L.P.'s surgical records is necessary to confirm his prior exposure to a sensitizing antibiotic.

Case 32-2, Question 3: Given L.P.'s signs and symptoms and the presumed cause of his anaphylactic reaction, how should he be treated?

Effective management of anaphylaxis requires quick recognition and aggressive therapeutic intervention because of the immediate life-threatening nature of the reaction, as illustrated by L.P. The severity of the anaphylactic reaction must be assessed quickly, the probable causative agent determined, the administration of the offending substance discontinued, and the absorption of the offending agent minimized if possible. Recent guidelines on the management of anaphylaxis list the following treatments in order of importance: epinephrine, patient position, oxygen, IV fluids, nebulized therapy, vasopressors, antihistamines, corticosteroids, and other agents.[56] All of these interventions must be undertaken promptly and the clinical status of the patient closely monitored. Vital signs, cardiac and pulmonary function, oxygenation, cardiac output, and tissue perfusion in particular must be immediately and continuously assessed.[34,56]

Although not definitively known to be the cause, the infusion of ampicillin/sulbactam should be stopped to prevent further exposure to the presumed precipitating agent. In addition, the forearm wounds should be flushed with normal saline to remove any residual cleansing agent in the event that this is the cause of the reaction.

Pharmacologic treatment of anaphylaxis has traditionally involved several drugs and drug classes such as epinephrine, antihistamines, and corticosteroids aimed at reversing the clinical manifestations of anaphylaxis and interrupting the biologic pathways involved. Recent literature reviews, however, failed to find well-designed and well-conducted randomized controlled trials to support the use of these drugs.[62–64] Recommendations for use are based on tradition, case reports, case series, and expert opinion.

L.P. is showing early signs of anaphylactic shock that must be managed immediately. Epinephrine is the drug of choice for the pharmacologic management of anaphylaxis, and all national and international anaphylaxis guidelines recommend epinephrine as first-line treatment.[34,56,65] Studies have shown that failure to use epinephrine early in anaphylaxis is a risk factor for a poor outcome. Use of standard order sets and autoinjectors by emergency

departments has been shown to increase epinephrine utilization for patients experiencing anaphylaxis.[66]

The α-adrenergic effects of epinephrine increase systemic vascular resistance and increase BP while decreasing mucosal edema and relieving upper airway obstruction, angioedema, and hives. These actions counter the vasodilating and hypotensive effects of histamine and the other mediators of anaphylaxis. In addition, the β-adrenergic effects of epinephrine promote bronchodilation and increase cardiac rate and contractility. Epinephrine also inhibits the release of mediators from basophils and mast cells.

The route of epinephrine administration is important. Most guidelines recommend IM epinephrine, 0.01 mg/kg of a 1 mg/mL (1:1000) solution to a maximum dose of 0.5 mg in an adult or 0.3 mg in a child injected into the lateral aspect of the thigh every 5 to 10 minutes as needed.[66,67] Epinephrine doses should be expressed in mass concentration (eg, 1 mg in 1 mL) instead of ratios such as 1:1000, which have been confused with epinephrine concentrations used in cardiac arrest (1:10,000) and caused dosing errors.[65] Epinephrine is vasodilatory in skeletal muscle, and because the skeletal muscle is highly vascular, absorption is rapid. Although some guidelines propose the subcutaneous route for epinephrine administration, subcutaneous tissue is less vascular than is skeletal muscle; thus, there is less rapid absorption of epinephrine. In addition, epinephrine causes vasoconstriction in subcutaneous tissue, thereby slowing its own absorption. Studies have shown that IM epinephrine injections into the thigh achieve higher blood concentrations more rapidly than do subcutaneous or IM injections into the arm in healthy subjects.[56] The rate and extent of absorption from IM and subcutaneous routes of epinephrine administration, however, have not been studied in patients experiencing anaphylaxis, and there is no evidence that epinephrine is ineffective when given IM or subcutaneously into the arm.[56] Epinephrine should be administered via the IV route in cases of anaphylaxis that have not responded to repeated doses of IM epinephrine and/or are progressing to shock, or in cases where cardiorespiratory arrest

appears imminent. Low cardiac output and intravascular volume depletion from shock decrease tissue perfusion and, possibly, the absorption of subcutaneous or IM injections. In animal studies, the benefits of intermittent IV boluses of epinephrine are short-lived and a continuous infusion of epinephrine provides optimal results.[67] In L.P.'s case, an initial dose of 0.5 mg of 1 mg/1 mL epinephrine solution should be injected IM into his lateral thigh. This should be repeated every 5 minutes until symptoms improve.

Some evidence suggests poor outcomes in patients who are in an upright position during anaphylactic shock.[68] Placing L.P. in the Trendelenburg position (patient supine, inclined ~45 degrees with head at the lower end and legs at the upper end) might improve survival by enhancing perfusion to vital organs. After repositioning, oxygen should be started and normal saline infused at a rate sufficient to maintain perfusion to vital organs. Normal saline is the preferred crystalloid because it stays in the intravascular space longer than does dextrose and does not contain lactate (eg, lactated Ringer solution), which could worsen metabolic acidosis. Circulating blood volume can decrease by as much as 35% in the first 10 minutes of anaphylactic shock because of vasodilation and fluid shifting from the intravascular to the extravascular space.[56] Therefore, vigorous fluid resuscitation might be necessary (eg, 1–2 L of normal saline at a rate of 5–10 mL/kg in the first 5 minutes). Cerebral perfusion, as evidenced by adequate mentation, must always take precedence over BP readings when managing shock.

The effect of L.P.'s atenolol must also be considered. Patients taking a β-blocker, whether cardioselective or not cardioselective, could experience more severe episodes and more refractory episodes of anaphylaxis than do patients not taking a β-blocker. This effect might be caused by a blunted response to epinephrine when given to treat anaphylaxis, resulting in refractory hypotension, bradycardia, and bronchospasm.[56] If L.P.'s BP and heart rate do not substantially improve shortly after initiating epinephrine, IV glucagon, which can stimulate heart rate and cardiac contractility independent of β-adrenergic blockade, should be given (**Table 32-5**). Airway protection is important because glucagon may cause emesis and

there is a risk of aspiration, especially in drowsy or obtunded patients. Methylene blue, through its ability to reduce nitric oxide production (a known potent vasodilator), has been found to be effective in a small number of cases of anaphylaxis with refractory hypotension.[61,68] Other vasopressors such as dopamine (2–20 μg/kg/minute) may be needed to maintain BP if there is a poor response to epinephrine and glucagon. Second-line treatment for anaphylaxis includes inhaled β-agonists, H_1 and H_2 antihistamines, and corticosteroids. In light of L.P.'s severe pulmonary reaction, he should receive a nebulized β-agonist (eg, albuterol). If L.P.'s respiratory status fails to improve after pharmacologic intervention, intubation must be considered. Atenolol would not be expected to diminish the effect of albuterol because atenolol is a β_1 cardioselective β-blocker and the dose is low. Because histamine is the primary mediator of anaphylaxis, IV administration of an H_1 antihistamine such as diphenhydramine (50 mg every 6 hours until the reaction resolves) should be considered. Similarly, giving an H_2 antihistamine is a common practice. Both therapies present little acute risk to the patient, but as already noted, there are few data supporting their efficacy in treating anaphylaxis.[63]

Table 32-5
Drug Therapy of Anaphylaxis

Drug	Indication	Adult Dosage	Complications
First-Une Therapy			
Epinephrine	Hypotension, bronchospasm, laryngeal edema, urticaria, angioedema	0.01 mg/kg to a maximum of 0.5 mg of a 1 mg/I mL solution IM every 5 minutes prn: if progressing to cardlorespiratory arrest 1–3 mLof 1:10,000 (0.1–0.3 mg) IV for 3 minutes	Arrhythmias, hypertension, nervousness, tnemor
		I mLof I mg/mL (1:1000) In 250 mLof normal saline IV at a rate of 4–10 pg/minute	
		3–5 mL of 0 1 mg/mL (1:10.000) Intratracheally every 10–20 minutes prn	
Oxygen	Hypoxemia	40%–100%	None
Albuterol		0.5 mL of 0.5% solution In 2.5 mL of saline via nebulizer (Ie, 2.5 mg)	Arrhythmias, hypertension, nervousness, tremor
IV flulds	Hypotension	1 L of normal saline every 20–30 minutes prn (rates as high as 1–2 mL/kg/minute may be necessary)	Pulmonary edema, CHF
Second-Line Therapy			
Antihlstamines	Hypotension, urticaria		
H_1 receptor antagonists[1]		Diphenhydramine 25–50 mg IV over 10–15 minutes Oral H_1 antagonists may be used in less severe cases.	Drowsiness, dry mouth, urlnary retention; may obscure symptoms of continuing reactlon
H_2 receptor antagonists*		Famotidine 20 mg IV over 10–15 minutes	
Corticosteroids'	Bronchospasm; patlents undergoing prolonged resuscitation or severe reaction	Hydrocortisone sodium succinate 100 mg IV every 3–6 hours for two to four doses or Methylprednisolone sodium succinate 40-125 mg IV every 6 hours for two to four doses	Hyperglycemla, fluid retention
Dopamine	Hypotension refractory to epinephrine	400 mg in 500 mL dextrose 5% at 2–20 pg/kg/minute	Hypertension, tachycardia, palpitations, arrhythmias
Norepinephrine	Hypotension refractory to epinephrine	4 mg In 1 L dextrose 5% IV at a rate of 2-12 pg/minute	Arrhythmias, hypertension, nervousness, tremor
Glucagon[b]	Refractory hypotension	1 mg IV for 5 minutes, followed by 5–15 pg/minute in fusion	Nausea, vomiting

CHF, congestive heart failure; IM, intramuscularly; IV, intravenously; prn, as needed.

[a]Agents in these classes may be used as adjuncts to epinephrine. Controlled studies demonstrating a clear benefit in anaphylaxis are lacking. Do not delay the administration of epinephrine, supplemental oxygen, or IV fluid resuscitation by taking time to draw up and administer a second-line medication.

[b]Glucagon may be particularly useful in patients taking β-adrenergic blockers, because it can increase both cardiac rate and contractility regardless of β-adrenergic blockade. Choice of agent and starting doses should be patient specific, weighing safety and efficacy.

Lastly, given the severity of his reaction and his pulmonary involvement, L.P. is a candidate for IV corticosteroids. Methylprednisolone, 125 mg every 6 hours for four doses, might be beneficial and is associated with minimal risk. Although commonly

used, corticosteroids will not affect the acute course of the reaction because of their delayed onset of action (typically 4–6 hours after administration). Corticosteroids may impact a prolonged episode of anaphylaxis and could prevent or minimize the occurrence of a biphasic reaction, although this has not been proved in well-controlled trials. The effect of methylprednisolone on L.P.'s diabetes is not a factor because his condition is potentially life-threatening. Once stabilized, L.P. should be transferred to a critical care setting and monitored for a minimum of 24 hours because relapses of the anaphylactic reaction can occur.[34,56] Complications of anaphylaxis include Kounis syndrome with chest pain and coronary spasm with clean coronary arteries, which typically resolved after the resolution of symptoms but can lead to elevated troponins. Takotsubo is a severe complication that can lead to death and associates with inefficient cardiac output during hypotension and epinephrine treatment.

Serum Sickness

Serum sickness is a type III hypersensitivity reaction that results from the production of antibodies directed against heterologous protein or drug haptens with subsequent tissue deposition. The typical presentation of serum sickness includes fever, cutaneous eruptions (95%), lymphadenopathy, and joint symptoms (10%–50%).[69-72] Symptoms usually occur 1 to 2 weeks after exposure, but accelerated reactions can occur within 2 to 4 days in previously sensitized persons. Laboratory data are relatively nonspecific and are of little diagnostic value. For example, the erythrocyte sedimentation rate (ESR) and the serum concentration of circulating immune complexes usually are increased. Complements C3 and C4 are often low, whereas activation products C3a and C3a desarginine are elevated. Urinalysis might reveal proteinuria, hematuria, or an occasional cast.[69-72]

In most cases, serum sickness reactions are mild and self-limiting and resolve within a few days to weeks after withdrawal of the

inciting agent. Antihistamines and aspirin can be used to relieve pruritus and arthralgias. In severe cases, corticosteroids might be used and can be tapered during 10 to 14 days.[69-72] At one time, heterologous serum (eg, anti-thymocyte globulin made from rabbit or equine serum) was a leading cause of serum sickness. With the decline in the use of these products, however, the most common causes of serum sickness today are penicillins and cephalosporins, although biologic agents such as rituximab, infliximab, and natalizumab are increasingly associated with serum sickness.[73,74]

CASE 32-3

Question 1: M.M., a 57-year-old ill-appearing female, is hospitalized with a 3-day history of difficulty breathing, left-sided chest pain on inspiration, fever, chills, and a productive cough. Her medical history is significant only for hypertension, well controlled on hydrochlorothiazide; she has no known drug allergies. M.M.'s physical findings on admission are temperature, 100.4 °F (38 °C); respirations, 20 breaths/minute; left-sided crackles heard on auscultation; oxygen saturation 85% on room air; and heart rate, 85 beats/minute. A chest radiograph reveals an infiltrate in her left lower lobe. Her white blood cell (WBC) count is 17,500 cells/μL with the following differential:

Polymorphonuclear neutrophil leukocytes (PMN), 83% (normal, 45%–79%)
Bands, 12% (normal, 0%–5%)
Lymphocytes, 10% (normal, 16%–47%)
Basophils, 0% (normal, 0%–1%)
Eosinophils, 1% (normal, 1%–2%)

Community-acquired pneumonia is the diagnosis, and M.M. is empirically started on ceftriaxone 1 g IV daily, azithromycin 500 mg IV daily, and oxygen at 2 L/minute. Other medications include oral acetaminophen 325 mg every 4 to 6 hours as needed for temperature >100.4 °F (38 °C), oral famotidine 20 mg bid, and oral hydrochlorothiazide 12.5 mg daily. Seventy-two hours later, M.M. is breathing without pain at a respiratory rate of 12 breaths/minute, her lungs are clear to auscultation, and her oxygen saturation is 98% on room air. She appears much better and offers no new symptoms. Her temperature during the previous 48 hours has ranged from 101.48 °F (38.6 °C) to 104 °F (40 °C), her pulse has ranged from 90 to 100 beats/minute, and her WBC count is 22,000 with the following differential: PMN, 89%; bands, 5%; lymphocytes, 12%; basophils, 0%; and eosinophils, 7%. Drug-induced fever is considered.

What evidence supports this diagnosis? What is the mechanism for drug fever?

Drug Fever

Drug fever is described as a febrile reaction to a drug without cutaneous symptoms and is estimated to occur in 3% to 5% of inpatients.[75] Drug fever can be challenging to identify and can be misinterpreted as a new infectious process or failure of an existing infection to respond to treatment. Such failure to recognize a drug fever can lead to prolonged hospitalization and unnecessary tests or medications.[76] **Table 32-6** lists the characteristics of hypersensitivity drug-induced fever. The most important finding in the case of M.M. is her clinical improvement with respect to her pulmonary status despite a high-grade fever and persistent leukocytosis; she also appears healthier than expected if she had an untreated infection. Although a drop in her WBC count would be anticipated given her improving respiratory function, her WBC count remains elevated, consistent with hypersensitivity drug fever. Notably, her eosinophil count is increased, a frequent sign of hypersensitivity reactions. Despite her high-grade fever, she has a relative bradycardia; that is, her heart rate is not as elevated as expected if an infectious process were ongoing. Further, the timing of the symptoms favors a drug-induced fever (ie, within days of starting a new medication). A definitive diagnosis can be made only by stopping the suspected offending agent, however, because fever generally resolves within 48 to 72 hours if a rash is not present. When a rash is present, on the other hand, the fever may persist for several days after stopping the implicated drug.

Table 32-6

Hypersensitivity Reactions to Drugs: Drug-Induced Fever

Frequency	True frequency is unknown because fever is a common manifestation and almost any drug can cause fever. Estimate is that 3%–5% of hospitalized patients experiencing adverse drug reaction suffer from drug fever alone or as part of multiple symptoms.
Clinical manifestations	Temperatures may be ≥100.4 °F (38 °C) and do not follow a consistent pattern. Although patients may have high fevers with shaking chills, patients generally have few symptoms or

	serious systemic illness. Skin rash (18%), eosinophilia (22%), chills (53%), headache (16%), myalgias (25%), and bradycardia (11%) can occur in patients with drug fever. Onset of fever after exposure to the offending agent is highly variable, ranging from an average of 6 days for antineoplastics to 45 days for cardiovascular agents. Occurrence of fever is independent of the dose of the offending agent.
Treatment	Although drug fever can be treated symptomatically (eg, with antipyretics, cooling blankets), stopping the offending agent is the only therapy that will eliminate fevers. Patients generally defervesce within 48–72 hours of stopping the suspect drug.
Prognosis	Drug fever is usually benign, although one review[57] found a mean increased length of hospitalization of 9 days per episode of drug fever. Rechallenge with the offending drug usually results in rapid return of the fever. Although reexposure to the suspect drug was previously thought to be potentially hazardous, there is little risk of serious sequelae.

Sources: Patel RA, Gallagher JC. Drug fever. *Pharmacotherapy*. 2010;30:57–69; Mackowiak PA, LeMaistre CF. Drug fever: a critical appraisal of conventional concepts. An analysis of 51 episodes in two Dallas hospitals and 97 episodes reported in the English literature. *Ann Intern Med*. 1987;106:728–733; Cunha BA, Shea KW. Fever in the intensive care unit. *Infect Dis Clin North Am*. 1996;10:185–209.

Drug fever can be caused by various mechanisms, although it is ascribed most commonly to a hypersensitivity reaction. Other mechanisms include the pharmacologic action of the drug (eg, cell destruction from antineoplastic agents releases endogenous pyrogens); altered thermoregulatory function (eg, increased metabolic rate from thyroid hormone); decreased sweating from drugs with anticholinergic properties (eg, atropine, tricyclic antidepressants, and phenothiazines); drug administration–related fever (eg, amphotericin B and bleomycin); and idiosyncratic reactions (eg, neuroleptic malignant syndrome from haloperidol, malignant hyperthermia from inhaled anesthetics).[75]

Case 32-3, Question 2: What agent is the most likely cause of drug fever in M.M.?

Most of the information available on drug fever is based on case reports or small case series and reviews of the literature.[76,77] Unfortunately, the literature is inconsistent with regard to the frequency of drug fever (eg, very common, common, uncommon) and such descriptions are not supported by good clinical data. Nevertheless, some drugs are more commonly associated with drug fever than are others. These include anti-infectives as a class (especially β-lactam antibiotics), antiepileptics, and antineoplastics. Drug fever has also been reported frequently with amphotericin B, azathioprine, hydroxyurea, methyldopa, procainamide, quinidine, and quinine.[76–78]

In M.M.'s case, ceftriaxone or azithromycin is the most likely cause of her ongoing fever, given the timing of the reaction relative to beginning the antibiotics and the frequency of febrile reactions attributed to them, especially to β-lactam antibiotics. Febrile reactions have not been associated with acetaminophen, and famotidine is rarely a cause of fever without other symptoms of an allergic reaction. Although diuretics such as hydrochlorothiazide can cause fever, M.M. was taking this medication before admission without any ill effects, making this drug an unlikely culprit.

Case 32-3, Question 3: How should M.M.'s drug fever be treated? Can M.M. receive cephalosporins in the future?

Because M.M. has responded clinically, her antibiotics should be discontinued and her fever curve, WBC count, heart rate, and respiratory status followed up. An oral antibiotic from another drug class (eg, a fluoroquinolone) should be started to complete a 7- to 10-day antibiotic course of therapy. Acetaminophen and other antipyretics should be avoided unless M.M. becomes uncomfortable from the fever because they can mask the response to the discontinuation of her antibiotics.

As with any hypersensitivity reaction, rechallenge with the offending drug can cause a similar, or sometimes greater, response.

In M.M.'s case, reexposure to ceftriaxone (or another β-lactam antibiotic) or a macrolide might cause a febrile reaction. It is unclear, however, how large the risk of reexposure truly is. Although drug fever sometimes precedes more serious hypersensitivity reactions, evidence suggests that there may be little risk of reexposure. Should M.M. require ceftriaxone (or another β-lactam or macrolide antibiotic) in the future, it would be prudent to administer the drug in a setting where M.M. can be monitored, at least initially, to ensure prompt treatment if an immediate hypersensitivity reaction develops.

Hypersensitivity Vasculitis

CASE 32-4

QUESTION 1: M.G., a 26-year-old female with cystic fibrosis, is admitted for treatment of pneumonia. Sputum cultures obtained before admission reveal *Alcaligenes xylosoxidans* sensitive only to minocycline and chloramphenicol. M.G. is initiated on appropriate doses of these two antibiotics for a 2-week course. On day 8 of therapy, M.G. begins to develop a rash on her legs. Physical examination reveals palpable purpura and a maculopapular rash on both lower extremities. Laboratory data reveal an elevated ESR and leukocytosis.

What is the likely cause of M.G.'s rash and laboratory abnormalities?

M.G.'s presentation is suggestive of a diagnosis of hypersensitivity vasculitis.

Hypersensitivity vasculitis, also called cutaneous leukocytoclastic angiitis, is characterized by inflammation of the small blood vessel walls. These reactions occur when immune complex deposition within the small veins and arterioles activates complement, causing the release of chemotactic factors. These factors attract polymorphonuclear cells that cause vessel damage.[79–82]

Drug-Induced Vasculitis

Approximately 10% of cases of cutaneous vasculitis are believed to be drug related.[81] Approximately 100 drugs have been identified as causing vasculitis, including β-lactams, fluoroquinolones, NSAIDs, antiepileptics, and tumor necrosis factor blockers.[80–83] Interested readers are referred to more in-depth reviews.[82–84] The diagnosis of hypersensitivity vasculitis is based on five clinical criteria (**Table 32-7**), three of which must be present.[84] M.G. meets three of the five criteria, including age older than 16 years, palpable purpura, and a maculopapular rash. In addition, minocycline, a medication that she was taking at the onset of the rash, has been associated with serum sickness and vasculitic-type reactions. Onset of symptoms typically occurs 7 to 10 days after initiation of drug therapy but can occur sooner on reexposure. Purpuric papules and macular eruptions, the most commonly observed findings, are usually symmetric and occur on the extremities (**Table 32-8**).[79] Hypersensitivity vasculitis can involve multiple organ systems. Renal damage, ranging from microscopic hematuria to nephrotic syndrome and acute renal failure, is common in patients with disseminated disease.[84] An enlarged liver with elevated enzymes is indicative of hepatocellular involvement. Although the lungs and ears can be involved as well, clinical manifestations are usually mild.[79] Arthralgia is also commonly observed. Laboratory examinations usually show nonspecific abnormalities of inflammation such as an elevated ESR and leukocytosis. In patients with cystic fibrosis experiencing acute pneumonia, these laboratory abnormalities could already be present and, therefore, will not be helpful in establishing the diagnosis of hypersensitivity vasculitis in M.G.

Table 32-7

Criteria for the Classification of Hypersensitivity Vasculitis

Development of symptoms after age 16
Medication at disease onset that may have been a precipitating factor
Slightly elevated purpuric (hemorrhagic) rash over one or more areas of the skin that does not blanch with pressure and is not related to thrombocytopenia
Maculopapular rash over one or more areas of the skin

Biopsy showing granulocytes around an arteriole or venule

The diagnosis of hypersensitivity vasculitis can be made if a patient exhibits at least three of these criteria.

Table 32-8
Hypersensitivity Reactions to Drugs: Clinical Manifestations of Drug-Induced Vasculitis

- Palpable purpura and maculopapular rash occurring symmetrically predominantly on the lower extremities
- Multiple organ systems may be involved:
- *Renal:* microscopic hematuria to nephrotic syndrome and acute renal failure
- *Liver:* enlarged liver, elevated enzymes
- *Joints:* arthritis
- *Gastrointestinal:* abdominal pain
- Laboratory data usually show nonspecific abnormalities of inflammation: elevated erythrocyte sedimentation rate and leukocytosis. Peripheral eosinophilia may be present and serum complement concentrations can be low. Histologic findings on biopsy reveal small blood vessels with leukocytoclastic or necrotizing vasculitis
- Onset typically 7–21 days after initiation of therapy

Source: Valeyrie-Allanore L, Sassolas B, Roujeau JC. Drug-induced skin, nail and hair disorders. *Drug Saf*. 2007;30:1011–1030.

Case 32-4, Question 2: What additional workup could be performed to confirm the diagnosis of drug-induced vasculitis in M.G.?

In addition to the previous workup, other laboratory and diagnostic procedures might demonstrate peripheral eosinophilia and low serum complement concentrations. A biopsy, which typically reveals

granulocytes in the wall of a venule or arteriole and eosinophils at any location, would provide more definitive information.

Case 32-4, Question 3: How should M.G.'s hypersensitivity vasculitis be treated?

The first step is to discontinue the minocycline therapy. Drug-induced vasculitic reactions typically resolve on their own without additional interventions. If the reaction is severe, corticosteroids can be used.

Autoimmune Drug Reactions

CASE 32-5

Question 1: R.F., a 24-year-old White male medical student, has been treated for 5 months with isoniazid because of a positive skin test result for tuberculosis. He now is in the clinic presenting with new-onset myalgias and arthralgias. Laboratory values obtained the morning of the visit are within normal limits except for a positive ANA titer and an elevated ESR.

What is the likely cause of R.F.'s symptoms and laboratory abnormalities?

Some drugs can induce an autoimmune process characterized by the presence of autoantibodies and, in some instances, clinical features of an autoimmune disorder. A drug-induced syndrome resembling SLE is usually characterized by myalgias, arthralgias, positive ANA titer results, and an elevated ESR (see Chapter 33, Systemic Lupus Erythematosus). All of these characteristics are manifested by R.F.

The first case of drug-induced lupus erythematosus (DILE) was recognized >60 years ago and was associated with sulfadiazine.[85] Subsequently, >80 drugs have been associated with DILE including isoniazid, chlorpromazine, quinidine, methyldopa, and minocycline; however, hydralazine and procainamide are the drugs most frequently associated with this syndrome.[86–88] As with idiopathic SLE, DILE can be separated into systemic, subacute cutaneous, and

chronic cutaneous lupus. An exact incidence of DILE is difficult to ascertain because of changing patterns of drug use; however, it is estimated that 10% of SLE cases are drug induced, with 15,000 to 30,000 cases in the United States annually.[81]

Case 32-5, Question 2: How can the diagnosis of drug-induced lupus be differentiated from SLE in R.F.?

In contrast to idiopathic SLE, DILE is less likely to affect females and Black patients.[87] On average, patients with DILE are twice as old as those with idiopathic SLE at the time of diagnosis. Individuals with a slow acetylator phenotype have a greater tendency to exhibit DILE; ANA after exposure to lupus-inducing drugs also appears more rapidly.[89] In general, DILE is a milder disease than is idiopathic SLE. Many patients with DILE, however, could fulfill the diagnostic criteria for SLE according to the American Rheumatism Association.[89–91] Arthralgias or myalgias accompanied by a positive ANA test result can be the only clinical features for some patients with drug-induced lupus. Symptoms usually appear abruptly after several months to years of continuous therapy with the offending drug. Common symptoms include fever, malaise, arthralgias, myalgias, pleurisy, and slight weight loss. Mild splenomegaly and lymphadenopathy have been reported occasionally. The skin is affected in about 25% of cases, manifesting as photosensitivity on light-exposed surfaces. The classic butterfly malar rash, discoid lesions, oral mucosal ulcers, Raynaud phenomenon, and alopecia are unusual features in DILE in contrast to idiopathic SLE. In addition, the central nervous system and kidneys rarely are affected.[92] Laboratory abnormalities commonly include anemia and an elevated ESR. The evidence supporting a diagnosis of drug-induced lupus in R.F. includes White male predominance, abrupt onset and relatively mild symptomatology, and lack of the classic butterfly malar rash. More definitive tests include determining whether antibodies to single-stranded (indicative of drug-induced lupus) or double-stranded DNA (indicative of SLE) are present.

Case 32-5, Question 3: Should ANA have been monitored in an effort to detect drug-induced lupus at an earlier stage in this patient?

No. Although all patients with symptomatic drug-induced lupus test positive for ANA (which consists predominantly of single-stranded DNA and antihistone antibodies),[92] many patients taking lupus-inducing drugs become ANA positive without going on to experience lupus. In patients treated with procainamide, about 50% to 75% are positive for ANA after 12 months and 90% after 2 years or more of continuous therapy; only 10% to 20% of those patients actually experience lupus symptoms.[92–94] Similarly, up to 44% of patients are ANA positive after 3 years of hydralazine therapy, but DILE occurs in only 6.7% of patients after 3 years of treatment.[92] It is not necessary to discontinue therapy in asymptomatic patients with positive ANA because most of them will never exhibit clinical symptoms.[87]

Case 32-5, Question 4: How should R.F.'s drug-induced lupus be treated?

Musculoskeletal symptoms can be treated with aspirin or an NSAID. More severe symptoms from pleuropulmonary or pericardial involvement may require the use of corticosteroids. Clinical features of DILE usually subside and disappear in days to weeks with discontinuation of the offending drug. Occasionally, these symptoms linger or recur over a course of several months before eventually disappearing. Serologic tests tend to resolve more slowly: ANA may persist for a year or longer.[87,95] Drug-induced lupus does not predispose patients to the subsequent development of idiopathic SLE.[96] In most instances, lupus-inducing drugs do not increase the risk of exacerbation of idiopathic SLE[97]; however, long-term treatment with isoniazid may worsen preexisting SLE.[98] Because R.F. has not yet completed his 6- to 9-month course of isoniazid therapy, an alternative agent should be prescribed for R.F. with appropriate monitoring (see Chapter 68, Tuberculosis).

ORGAN-SPECIFIC REACTIONS

The drug allergies in this chapter have been grouped into categories of generalized reactions, organ-specific reactions, and non–IgE mediated reactions. The generalized reactions have been described first, the organ-specific hypersensitivity drug reactions affecting the blood, liver, lung, kidney, and skin are described next, and non–IgE reactions follow.

Blood: Immune Cytopenias

Drug-induced immune cytopenias (eg, granulocytopenia, thrombocytopenia, and hemolytic anemia) result from type II–mediated allergic reactions (Table 32-1). A drug or drug metabolite binds to the surface of blood elements such as granulocytes, platelets, and red blood cells. IgG or IgM antibodies are formed and are directed against the drug or drug metabolite bound to the cell (ie, hapten–cell reaction).[31] Typical symptoms associated with immune thrombocytopenia include chills, fever, petechiae, and mucous membrane bleeding. Granulocytopenia generally manifests with chills, fever, arthralgias, and a precipitous drop in the leukocyte count. Symptoms of hemolytic anemia can be subacute or acute and can be sufficiently severe to cause renal failure. The Coombs test is useful in identifying antibodies bound to red cells or circulating immune complexes directed against red cells. Antibiotics are the most commonly implicated class of drugs causing either neutropenia or hemolytic anemia.

Liver

Hypersensitivity reactions involving the liver can be classified as cholestatic or cytotoxic. Jaundice is usually the first sign of a cholestatic reaction, in addition to pruritus, pale stools, and dark urine. Cholestatic reactions usually are reversible on discontinuation

of the offending agent. Cytotoxic reactions can involve hepatocellular necrosis or steatosis and can result in irreversible damage if not recognized early.

Lung

Pulmonary manifestations of drug hypersensitivity include asthma and infiltrative reactions. Asthma typically occurs as part of a generalized systemic reaction. Most reactions to drugs that involve asthma alone represent a pharmacologic side effect rather than a true allergic reaction.

Infiltrative reactions typically develop 2 to 10 days after exposure and manifest with cough, dyspnea, fever, chills, and malaise.[30] Infiltrative reactions vary in presentation from eosinophilic pneumonitis to acute pulmonary edema.

Kidney

The most common hypersensitivity reaction involving the kidney is interstitial nephritis. Typical findings include fever, rash, and eosinophilia. Methicillin is the drug most commonly associated with interstitial nephritis, although penicillins, sulfonamides, and cimetidine also have been implicated in renal hypersensitivity reactions.[31] (See Chapter 29, Acute Kidney Injury, for hypersensitivity reactions to specific drugs that adversely affect the kidney.)

Skin

Adverse reactions involving the skin are the most common clinical manifestation of drug allergy. Although several different types of cutaneous reactions are possible, most drug-induced skin eruptions can be classified as erythematous, morbilliform, or maculopapular in appearance.[31] In a surveillance study of drug-induced skin reactions, amoxicillin was the most common cause, followed by trimethoprim–

sulfamethoxazole and ampicillin. Overall, allergic skin reactions were identified in 2% of hospitalized patients.[18]

Treatment of skin reactions includes discontinuation of the offending drug and general supportive care (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders).

NON-IGE REACTIONS

CASE 32-6

QUESTION 1: C.C., a 37-year-old male with no known allergies, is hospitalized for treatment of methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremia associated with an infected central line. His medical history is significant for short bowel syndrome requiring parenteral nutrition and one previous episode of MRSA line infection successfully treated with vancomycin. Similar to his last admission, vancomycin 750 mg IV for 60 minutes every 12 hours is begun. A trough level taken after the fifth dose, however, is 8 mg/L and the vancomycin dose is doubled to 1500 mg IV every 12 hours, to be administered at the same rate. Fifteen minutes after the new dose of vancomycin is begun, C.C. experienced hypotension (100/70 mm Hg), tachycardia (85 beats/minute), generalized pruritus, and facial flushing. C.C. is diagnosed as having a non–IgE mediated hypersensitivity reaction to vancomycin.

What subjective and objective data in C.C. are important in differentiating vancomycin non-IgE reaction from a true allergic reaction?

Non–IgE mediated reactions (also called nonallergic hypersensitivity reactions) are drug reactions that exhibit clinical signs and symptoms of an allergic response but are not immunologically mediated.[99] They can manifest as relatively benign symptoms or as severe, life-threatening events indistinguishable from anaphylaxis (**Table 32-9**).[99] The latter response is described as an anaphylactoid reaction because it resembles true anaphylaxis, but it does not involve IgE antibody formation.[31,99] The risk of such potentially severe reactions needs to be considered when prescribing agents known to be associated with anaphylactoid reactions. For example, the prophylactic use of antibiotics such as

ciprofloxacin to prevent meningococcal infections during an outbreak was associated with a relatively high rate (1:1000) of serious anaphylactoid reactions.[100] This would be of potentially greater importance in the setting of a mass prophylaxis program to combat exposure to anthrax. Unlike true allergic reactions, which require an induction period during which a patient becomes sensitized to an antigen, non–IgE mediated hypersensitivity reactions can occur on the first exposure to a drug. The development of non-IgE reactions can be dose related, manifesting when large doses of the drug are administered, when the dose is increased, or when the rate of IV administration is increased.[30]

Table 32-9

Hypersensitivity Reactions to Drugs: Acute Non-IgE Mediated Reactions

Frequency	Highly variable, depending on the agent involved. For example, up to 30% of patients taking aspirin exhibit a cutaneous non-IgE response. On the other hand, non–IgE mediated reactions to other agents, such as phytonadione and thiamine, are rare.
Clinical manifestations	Range from benign reactions (eg, pruritus and flushing) to a life-threatening clinical syndrome indistinguishable from anaphylaxis. Commonly require a higher drug dose to elicit the response than a true IgE-mediated reaction. May arise less quickly (>15 minutes after exposure) than a true allergic reaction.
Diagnostic workup	Skin test results and identification of specific antibodies are negative.
Treatment	Non–IgE mediated reactions are treated the same as true allergic reactions (ie, according to the clinical presentations of the patient). Thus, some reactions simply may require removal of the suspect agent, whereas some reactions may require aggressive therapy (eg, epinephrine, antihistamines, and corticosteroids).
Prognosis	As with true allergic reactions, patients who have experienced a non-IgE mediated drug reaction may have a similar reaction to reexposure. The severity of response may lessen, however, with repeated administration. Furthermore, for some drugs, the frequency and severity of the reaction also

	may be influenced by the dose or rate of intravenous administration. Pretreatment regimens to reduce the frequency and the severity of responses have been developed for some drugs well known to cause non–IgE mediated reactions (eg, radiocontrast media).

IgE, immunoglobulin E.

Sources: Pichler WJ, Adam J, Daubner B, Gentinetta T, Keller M, Yerly D. Drug hypersensitivity reactions: pathomechanism and clinical symptoms. *Med Clin North Am*. 2010;94:645–664; Schnyder B. Approach to the patient with drug allergy. *Immunol Allergy Clin North Am*. 2009;29:405–418; Sanchez-Borges M. NSAID hypersensitivity (respiratory, cutaneous, and generalized anaphylactic symptoms). *Med Clin North Am*. 2010;94:853–864.

C.C. has experienced a common non–IgE mediated hypersensitivity reaction to vancomycin, usually referred to as the *red man syndrome* or *red neck syndrome*, which primarily occurs when large doses of vancomycin are administered rapidly. Differentiating between a true allergic response (IgE mediated) and a non–IgE mediated response can be difficult because the signs and symptoms can be indistinguishable. For example, each of the symptoms experienced by C.C. (flushing, tachycardia, pruritus, and hypotension) is caused by histamine release and can occur during an anaphylactic episode (see Case 32-2, Question 2). To conclusively determine the cause of the reaction would require immunologic testing for antibodies to the suspect drug or agent, which is not always possible or practical. In this case, C.C. had uneventfully received vancomycin previously and has tolerated five doses during this hospitalization; therefore, it is unlikely that the reaction is immunologically mediated (ie, a true allergic reaction). Furthermore, the reaction occurred after an increase in his vancomycin dose, which further supports the diagnosis of non–IgE mediated reaction.

Case 32-6, Question 2: Why did vancomycin cause a non-IgE hypersensitivity reaction in C.C.?

Non-IgE reactions from vancomycin occur because of a drug-induced histamine release that occurs through an as-yet-unknown pathway. Direct drug-induced release of histamine does not involve complement activation or IgE antibody formation. Several other drugs (eg, deferoxamine, opiates, pentamidine, phytonadione protamine, radiocontrast media) are known to directly stimulate histamine release.[17,99]

Some drugs (eg, radiocontrast media and protamine) cause non–IgE mediated reactions via both complement activation and direct-histamine release mechanisms. Furthermore, some drugs (eg, vancomycin, quaternary ammonium muscle relaxants, and ciprofloxacin) can cause both true allergic reactions (IgE mediated) and non–IgE mediated reactions.[8]

Case 32-6, Question 3: How should C.C.'s non-IgE reaction be treated? Does treatment of non–IgE mediated reactions differ from that of true allergic reactions?

The first step in treating C.C.'s reaction is to eliminate the underlying cause. Thus, his vancomycin infusion should be held until the reaction resolves. Because the reaction is histamine mediated, administration of an antihistamine such as diphenhydramine 50 mg IV is warranted. Observation of his BP and heart rate is mandatory. IV fluids should be administered if his BP continues to fall or fails to stabilize. Patients with allergic reactions should be treated based on their clinical signs and symptoms, regardless of the mechanism behind the reaction. Thus, for all intents and purposes, non–IgE mediated reactions are treated in the same manner as true allergic reactions.

Case 32-6, Question 4: Can C.C. continue to receive vancomycin? How can future reactions be prevented?

The patient should be diagnosed with red man syndrome, a non–IgE mediated hypersensitivity reaction. It is not necessary to

discontinue vancomycin therapy in C.C. This reaction can be prevented by administering smaller doses of the drug more frequently (eg, 1000 mg every 8 hours rather than 1500 mg every 12 hours) or infusing the dose for a longer interval, typically 2 hours. Alternatively, pretreatment with an antihistamine 1 hour before vancomycin administration is effective. In addition, tachyphylaxis to vancomycin-induced red man syndrome is independent of pretreatment with antihistamine and is another characteristic that differentiates a non–IgE mediated hypsersentivity reaction from a true allergic reaction. Pretreatment regimens to prevent non–IgE mediated hypersensitvity reactions to various other drugs (eg, radiocontrast media) are also well described and can be effective.

Case 32-6, Question 5: What other drugs are commonly associated with non–IgE mediated hypersensitivity reactions?

Many other agents have been associated with non–IgE mediated reactions.[8] Some of the agents more commonly associated with non-IgE reactions are described next.

Aspirin/Nonsteroidal Anti-inflammatory Drugs

After penicillins, aspirin is the drug most commonly reported as causing “allergic” reactions. Reactions to aspirin can be divided into three broad categories: respiratory reactions, cutaneous manifestations, and anaphylaxis. None of these reactions has been consistently associated with IgE and are thus non-IgE mediated reactions.[26,101]

RESPIRATORY

The prevalence of bronchospasm with rhinoconjunctivitis is 0% to 28% in children with aspirin sensitivity. In adult asthmatics, the prevalence of aspirin sensitivity ranges from 5% to 20%. The prevalence of aspirin sensitivity during aspirin challenge in adult asthmatics with a history of aspirin-induced respiratory reaction

ranges from 66% to 97%.[102] Symptoms usually occur within 30 minutes to 3 hours of ingestion. The triad seen in many sensitive patients is aspirin sensitivity, nasal polyps, and asthma. All potent inhibitors of cyclo-oxygenase (COX) can cause respiratory symptoms in patients with aspirin sensitivity. Thus, patients who react to aspirin should be considered sensitive to NSAIDs, and vice versa. Weak COX inhibitors, such as acetaminophen, choline magnesium salicylate, salicylamide, salsalate, and sodium salicylate, are generally well tolerated in patients with aspirin sensitivity.[101]

CUTANEOUS

The prevalence of cutaneous reactions to aspirin depends on the type of reaction and the population studied. For example, urticaria/angioedema occurs in 0.5% of children, 3.8% of the general adult population, and in 21% to 30% of patients with a history of chronic urticaria. Disease activity at the time of aspirin challenge plays an important role in those with a history of chronic urticaria. In one study, 70% of patients whose urticaria was active at the time of challenge reacted to aspirin, compared with only 6.6% of patients whose urticaria was not active at the time of challenge. Furthermore, aspirin or NSAIDs may aggravate preexisting urticaria.[101–103] Other dermatologic reactions to aspirin occur with less frequency; for example, eczema, purpura, and erythema multiforme occur in 2.4%, 1.5%, and 1% of the population, respectively.

ANAPHYLAXIS

The true prevalence of aspirin-induced or NSAID-induced anaphylaxis is unknown, but it may range from 0.07% of the general population to 10% of patients with anaphylactic symptoms. Although IgE is not consistently associated with aspirin or NSAID-related reactions (including anaphylaxis), aspirin-induced or NSAID-induced anaphylaxis shares three characteristics with immune-mediated anaphylaxis that point to IgE as a cause. First, the reaction occurs after two or more exposures to the offending agent, suggesting that preformed IgE antibodies are responsible. Second, patients do not

have underlying nasal polyposis, asthma, or urticaria. Third, the patient who reacts to aspirin or a single NSAID can tolerate a chemically unrelated NSAID, suggesting that a drug-specific IgE antibody has been formed.[101,104]

The NSAIDs that selectively inhibit COX-2 while sparing COX-1 include celecoxib, rofecoxib, and valdecoxib, among others. Celecoxib is the only COX-2 inhibitor currently marketed in the United States. Selective inhibition of COX-2 provides anti-inflammatory effects while minimizing the renal effects, GI toxicity, and antiplatelet effects seen with inhibition of COX-1. Aspirin and older NSAIDs are nonselective inhibitors of cyclo-oxygenase, inhibiting both COX-1 and COX-2. Anaphylactoid or hypersensitivity reactions have been reported with celecoxib, and it appears that the rate of hypersensitivity is comparable to that of traditional NSAIDs.[104] Notably, celecoxib prescribing information states that, as with any NSAID, use is contraindicated in patients who have experienced asthma, urticaria, or allergic-type reactions after taking aspirin or other NSAIDs. Several reports, however, describe successful administration of celecoxib and other COX-2 selective agents to patients with aspirin-sensitive asthma or a history of hypersensitivity reactions to traditional NSAIDs, and evidence suggests that inhibition of COX-1 rather than COX-2 is key to initiating these events.[105–108] Nevertheless, COX-2 selective agents can still elicit allergic responses by other means (eg, IgE-mediated hypersensitivity). Thus, appropriate precautions and monitoring should be followed when initiating therapy in any patient with a history of allergic reactions to aspirin or other NSAIDs.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

CASE 32-7

Question 1: K.J., a 48-year-old female, seeks care at an urgent care center. She presents with impaired speech but is able to swallow; she has red and

swollen lips and tongue, and puffy eyes. Her medical history includes hypertension, atrial fibrillation, and a new diagnosis of hypercholesterolemia (plasma cholesterol, 290 mg/dL). Although her BP had been well controlled on hydrochlorothiazide, her diuretic was discontinued about 3 weeks ago because of its effect on cholesterol, and enalapril 5 mg daily was started. K.J. also takes a multivitamin (one tablet each day) and warfarin (5 mg daily). Her physical examination shows BP, 130/87 mm Hg; heart rate, 70 beats/minute; lungs clear to auscultation and percussion; respirations, 12 breaths/minute; and skin without rash or urticaria. Her condition is attributed to angioedema induced by enalapril.

What is angioedema, and what evidence supports this diagnosis? What is the mechanism behind angioedema?

Angioedema refers to a localized, transient swelling of the deep skin layers or the upper respiratory or GI mucosa. Angioedema commonly manifests as localized erythematous edema, involving the tongue, lips, eyelids, and mucous membranes of the mouth, nose, and throat. However, in rare cases, it can occur in the lower GI tract. Angioedema can be caused by a variety of mechanisms involving complement, histamine, substance P, and bradykinin that can be hereditary, immunologically acquired, or pharmacologic. Angiotensin-converting enzyme (ACE) inhibitors are the most common pharmacologic cause and have been associated with this adverse effect in about 0.1% to 0.7% of individuals treated with this drug class and account for up to 60% of cases of angioedema that present to emergency departments.[109] The reaction is not dose related and occurs with all ACE inhibitors. ACE inhibition causes accumulation of excess bradykinin leading to capillary leakage. Bradykinin receptor B2 is a G protein–coupled receptor found in blood vessels and encoded by the *BDKRB2* gene in humans.[110]

K.J. presents with classic symptoms of angioedema and does not have symptoms of a true anaphylactic reaction, further strengthening the diagnosis of drug-induced angioedema. Symptoms of angioedema usually occur within the first week of starting therapy, although they can occur at any time, even years later. Thus, although angioedema developed 3 weeks after K.J. began enalapril, the temporal relationship is reasonable.

Case 32-7, Question 2: How should K.J. be treated? Would an angiotensin receptor blocker (ARB) be an appropriate substitute for her ACE inhibitor?

Although angioedema can be life-threatening, symptoms are usually mild and resolve within hours to days of stopping the offending drug. The most common life-threatening complication of angioedema is airway obstructions. More severe reactions affecting the upper airway must be treated emergently with appropriate measures to maintain airway patency. A small clinical trial of ACE-induced angioedema comparing treatment with corticosteroid and antihistamine (prednisolone 500 mg IV and clemastine 2 mg IV) to treatment with icatibant (30 mg subcutaneous injection) found that the time to initial relief and complete symptom resolution were significantly shorter with icatibant.[110] Additional trials are currently evaluating icatibant and hopefully will help define which patients will be most likely to benefit from this drug.

K.J. does not need to be hospitalized because her respirations are not compromised and she is not experiencing swallowing difficulty; however, she should be kept under observation at the urgent care center to ensure that her angioedema does not worsen. She can be treated with icatibant 30 mg subcutaneously or she can be observed and later sent home with instructions to seek emergent help if her breathing or swallowing becomes difficult. She should be instructed to discontinue her enalapril, follow up with her primary physician as soon as possible, and to request her community pharmacist to record this adverse reaction to enalapril into her drug profile at the pharmacy. Because angioedema occurs with all ACE inhibitors, K.J. must avoid all drugs in this class.

Angioedema with ARBs has also been reported,[111,112] although with less frequency than with ACE inhibitors. Many of the cases of ARB-induced angioedema involved patients with a history of ACE inhibitor–induced angioedema, but this is not consistently the case. Similar to the ACE inhibitors, angioedema to ARBs can occur at any time during treatment. In K.J.'s case, it would be best to avoid ARBs and ACE inhibitors. Instead, other antihypertensive agents that have

little effect on cholesterol (eg, calcium channel blockers) should be used.

Several other drugs have been associated with angioedema including aspirin, NSAIDs, antibiotics, radiocontrast media, and dipeptidyl peptidase (DPP)-4 inhibitors (eg, sitagliptin and saxagliptin).[109] The causes of angioedema with these drugs are less well understood but often occur after having ACE inhibitor–induced angioedema. These drugs should be used with caution if K.J. needs them in the future.

Case 32-7, Question 3: Are there other non-IgE reactions that occur with ACE inhibitors and ARBs?

Besides angioedema, cough is a non-IgE reaction caused by ACE inhibitors. It may occur in up to 39% of patients after 1 week to 6 months of therapy. Interestingly, it is more common in nonsmokers than in smokers; the incidence does not increase in patients with chronic airway disease or asthma. Cough is more common in females than in males, is not dose related, and, as with angioedema, occurs with all ACE inhibitors.[101,109,113] Several mechanisms appear to be responsible, including inhibition of the breakdown of bradykinin in the lung and increases in local mediators of inflammation such as prostaglandins and substance P. Although many approaches to the management of ACE-induced cough have been proposed,[113] angiotensin II receptor blocking agents are the most promising alternative. Cough can occur with an ARB, but the frequency appears to be no more than that of placebo. Furthermore, most direct comparative trials between ARBs and ACE inhibitors demonstrate that the frequency of cough with ARBs is much lower than that with ACE inhibitors.[113]

Radiocontrast Media

Radiocontrast media are widely used diagnostic agents, exceeding 75 million administrations annually.[114] Adverse reactions to

radiocontrast media can be divided into immediate reactions (occurring within 1 hour of administration and include nausea, flushing, BP changes, bronchospasm, urticaria, angioedema, cardiac arrhythmias, convulsions, angina, and symptoms indistinguishable from true anaphylaxis) and nonimmediate reactions (occurring 1 hour to 10 days after administration and include pruritus, maculopapular drug eruption, Stevens–Johnson syndrome, toxic epidermal necrolysis, and vasculitis). The cause of radiocontrast media reactions remains unknown, although histamine release, complement activation, and direct toxic effects on end organs might all play a role. Many of the adverse effects to radiocontrast media have historically been classified as non–IgE mediated reactions because the evidence did not support IgE mediation of these reactions. Recently, however, skin tests and laboratory evidence suggest an immunologic mechanism for radiocontrast media reactions.[114] The overall incidence of reaction to radiocontrast media is 0.7% to 13%, depending on the type of agent selected and whether the patient was pretreated before administration.[115] Conventional, ionic, high-osmolality contrast media produce reactions in 4% to 13% of recipients, whereas nonionic, low-osmolality agents produce fewer reactions (0.7%–3.1%). The mortality rate from radiocontrast media is 1 to 2 cases per 100,000 procedures and is the same for ionic and nonionic agents.[116]

Female sex, a history of asthma, and a history of reaction to contrast media are risk factors for reactions to radiocontrast media. Of these, a history of reaction is the most important; 21% to 60% of patients with a history of reaction to radiocontrast media will have a reaction on reexposure.[114] Several pretreatment regimens have been developed to minimize such occurrences. For example, 32 mg of oral methylprednisolone given 12 hours and 2 hours before a procedure involving a high-osmolality contrast medium can reduce the reaction rate by up to 45%.[115] Another pretreatment regimen uses oral prednisone 50 mg taken 13 hours, 7 hours, and 1 hour before the procedure, plus diphenhydramine 50 mg orally or IM 1 hour before the examination.[117] This latter regimen lowers the occurrence of non–IgE mediated reactions to high-osmolality

contrast media, even in high-risk patients (ie, those with a history of severe anaphylactoid reactions). Note that a “seafood allergy” is not a risk factor for a reaction to radiocontrast media. Patients with food allergies do not require special pretreatment before procedures involving these agents.[116,118]

Narcotic Analgesics

Some opiates stimulate histamine release and, thereby, cause hypotension, tachycardia, facial flushing, increased sweating, or pruritus. However, severe reactions are uncommon. In many cases, the opiate can be continued with the administration of an antihistamine to treat the symptoms. If the reaction is significant, a nonnarcotic alternative analgesic may be considered, or an opiate that does not cause histamine release can be substituted. Morphine and meperidine cause the greatest histamine release in both in vitro and in vivo studies. Codeine, hydromorphone, oxycodone, and butorphanol stimulate histamine release less commonly; and levorphanol, fentanyl, sufentanil, methadone, and oxymorphone have little to no effect on histamine levels. One of the more frequent reactions to epidurally or intrathecally administered opiates is pruritus, which does not appear to be mediated by histamine because narcotics that do not release histamine (eg, fentanyl and sufentanil) still cause pruritus after spinal administration. Furthermore, pruritus tends to develop several hours after the opiate has been administered, when serum levels of histamine are insignificant. The cause of pruritus from spinal opiates remains unclear. The reaction can be managed with antihistamines and low-dose naloxone or nalbuphine while continuing with the spinal narcotic.[99]

Iron-Dextran Injection

Parenteral iron is used in the treatment of iron deficiency when oral iron preparations cannot be used or are ineffective. This is most

commonly seen in patients with anemia of chronic renal failure, particularly those treated with epoetin alfa or darbepoetin and undergoing hemodialysis (Chapter 28, Chronic Kidney Disease). Iron preparations are associated with a wide spectrum of adverse events (eg, chest pain, hypotension, hypertension, abdominal pain, nausea, vomiting, weakness, syncope, backache, arthralgias, myalgias, and hypersensitivity reactions). Hypersensitivity reactions can manifest as urticaria, sweating, dyspnea, rash, fever, and as anaphylactoid reactions, which can be fatal. Consistent with a nonimmunologic mechanism, hypersensitivity reactions to iron are not dose related and can occur with the first drug exposure.[119]

Iron preparations differ in regard to the salt or carbohydrate carrier used, molecular weight, and rate of hypersensitivity reactions. The first commonly used iron preparations were iron dextran, available as a high-molecular-weight ferric oxyhydroxide and dextran solution (Dexferrum®) and later as a low-molecular-weight ferric hydroxide and dextran solution (INFeD). Adverse events occur more often with iron dextran preparations compared to non-dextran preparations and are highest with high-molecular-weight iron dextran. Data reported to the FDA MedWatch program between 2001 and 2003 were used to determine the odds of adverse events between iron dextran products and two non-dextran products: sodium ferric gluconate and iron sucrose (also known as iron saccharate). Relative to the INFeD brand of iron dextran, patients receiving sodium ferric gluconate or iron sucrose were half as likely to experience an allergic reaction or any adverse reaction. An equal risk existed of experiencing an allergic reaction, or any adverse reaction, between sodium ferric gluconate and iron sucrose. Although sodium ferric gluconate and iron sucrose were safer than was iron dextran, at least one death and five life-threatening reactions were reported with each of the four agents studied.[120] Ferumoxytol, an agent approved in 2009, was designed with a modified dextrose shell to reduce hypersensitivity reactions. In a comparison trial, there was a comparable safety profile but it did include one anaphylactoid reaction, although no deaths compared to iron sucrose.[121] Since approval, postmarketing FDA surveillance has demonstrated several reports of life-

threatening and serious anaphylactoid reactions, including six deaths in a 10-month reporting period.[122] The prescribing information has been updated to include a black box warning for fatal and serious hypersensitivity reactions.[123] The newest iron product is ferric carboxymaltose complex, which releases iron from a carbohydrate polymer. Hypersensitivity reactions are expected to be lower because it does not contain a dextran or modified dextran component. In comparison to iron sucrose, no significant difference was found in the rate of hypersensitivity reactions or anaphylactoid reactions.[124,125] Although FDA approval was initially delayed because of a potential safety imbalance in the risk of death, subsequent pooled analysis has not validated the early findings, and the product was approved with only a warning for hypersensitivity reactions.[126,127]

All patients receiving iron dextran should receive a test dose to assess tolerance; the other iron preparations do not require a test dose per their prescribing information. It appears that patients tolerant toward iron dextran have little risk of experiencing a serious hypersensitivity or anaphylactoid reaction to sodium ferric gluconate or iron sucrose injection and can safely be given one of these products without a prior test dose. Similarly, patients who have never received any parenteral iron product can be administered sodium ferric gluconate or iron sucrose for injection without a prior test dose. Although studies support the safety of both sodium ferric gluconate and iron sucrose for injection in patients with sensitivity to iron dextran, such patients may be at increased risk for an anaphylactoid reaction or other serious hypersensitivity response, and test dosing in this population may be reasonable. Because of the risks associated with any of the parenteral iron products, close monitoring of the patient for at least 30 minutes after drug administration is necessary and the availability of resuscitative medication and personnel trained to evaluate and address anaphylaxis is prudent.

PREVENTION AND MANAGEMENT OF ALLERGIC REACTIONS

CASE 32-8

QUESTION 1: A.M., a 40-year-old female, is hospitalized with a diagnosis of community-acquired pneumonia. Her medical history is noncontributory except for an uneventful course of ampicillin 6 months before admission for an ear infection. A.M. is empirically treated with cefuroxime 0.75 g IV every 8 hours. On day 2 of therapy, she develops a raised pruritic maculopapular rash on her back, abdomen, and upper extremities. Antacid, docusate sodium, albuterol by metered-dose inhaler, and multivitamins were initiated on the same day as the cefuroxime.

How should A.M.'s allergic reaction be managed? How might her allergic reaction have been prevented?

When examining methods to prevent allergic reactions, three possibilities exist: (a) the patient has unknowingly been sensitized to a drug and experiences an allergic reaction on receiving the same or a similar drug again; (b) the patient has a history of an allergic reaction to a medication and mistakenly receives the same or a similar medication a second time and again develops an allergic reaction; and (c) the patient has a history of an allergic reaction to a medication and intentionally receives the same or similar medication again. As in the first situation, A.M.'s allergic reaction was unpredictable and, therefore, could not be prevented. To prevent future allergic reactions (ie, the second situation), however, A.M.'s reaction should be well-documented in the medical chart and pharmacy records. In addition, all patients should undergo a thorough drug history on hospitalization. Careful attention should be paid to differentiating drug intolerance (eg, stomach upset) from true allergic reactions, and any allergic reactions elicited during an interview should be documented appropriately. Adequate communication of allergic reactions is the single most important method of preventing their occurrence.

As described earlier, the first step in managing an allergic reaction is to determine its cause. Given A.M.'s history of exposure to ampicillin, the timing of the reaction, and the low frequency of allergic reactions to her other medications, cefuroxime is the most likely candidate. Second, a decision regarding whether to stop the suspect drug should be made. This decision must be based on the severity of the reaction, the condition being treated, and the availability of suitable alternatives. When possible, an equally effective alternative drug should be substituted for the suspect agent, preferably one that is immunologically distinct to avoid cross-sensitivity (see Case 32-1, Question 4, for a discussion of cross-reactivity).[128] If a suitable alternative exists, the offending agent should be stopped and the reaction treated symptomatically if necessary. In the case of A.M., another antimicrobial (eg, azithromycin, clarithromycin, trimethoprim–sulfamethoxazole) could be substituted for cefuroxime (Chapter 67, Respiratory Tract Infections) and her symptoms treated with an oral or a parenteral antihistamine, as well as a low-potency topical corticosteroid if necessary.

Some cases are described by the third situation: a patient develops an allergic reaction (or has a well-documented history of drug allergy), and it is inappropriate or not possible to change to an alternative drug. If the sensitivity reaction is severe or life-threatening, desensitization should be considered (Case 32-9, Questions 1 and 2); premedication to prevent or minimize anaphylaxis is not effective.[33] If the reaction is minor (eg, pruritus, rash, or GI symptoms), premedication or management of the reaction with antiallergy medications (eg, antihistamines) might be sufficient to allow completion of therapy. It is rare in such cases for the reaction to progress to more serious allergic symptoms such as anaphylaxis[128]; however, suppression of allergic symptoms should be undertaken cautiously because many immunologic reactions are not IgE mediated and may progress to serious reactions, despite treatment. In general, allergy suppression should be reserved for the prevention of mild reactions that are known or strongly suspected to be IgE mediated.[8,128]

Desensitization

β-LACTAMS

CASE 32-9

QUESTION 1: K.A. is a 24-year-old primigravida in her eighth week of pregnancy with a history of angioedema secondary to penicillin. Her initial pregnancy screening revealed a positive Venereal Disease Research Laboratory reaction and a fluorescent treponemal antibody absorption titer of 1:64. K.A. denies a history of genital lesions, currently does not exhibit clinical signs or symptoms of syphilis, and denies previous treatment for syphilis. Based on the serologic evidence and her history, a diagnosis of early latent syphilis is made. Current treatment guidelines indicate that penicillin is the drug of choice for K.A.

How can a possible reaction to penicillin be prevented in K.A.? Is premedication an alternative to preventing a reaction?

There are situations where a drug is medically necessary in a patient with a known or suspected allergy to the drug, alternative therapy is not available, and diagnostic testing does not exist. In such cases, there are two options: induction of tolerance (also called desensitization) or a graded challenge. Desensitization is the process of administering gradually increasing doses of a drug in an effort to modify a patient's response to the drug so that it can then be safely administered.[116] This process has been used successfully to manage both immune-mediated and non–immune-mediated reactions. A graded challenge (also called incremental test dosing) is the process of careful administration of subtherapeutic doses of drug to determine whether a patient is truly allergic. Although similar sounding, there are distinct differences between the two processes.[116] For example, unlike induction of tolerance, a graded challenge does not alter a patient's response to the drug. The initial drug doses used for inducing tolerance are suballergenic—as low as 1/10,000th of the final dose and the process can take several hours involving multiple doses, each slightly larger than the preceding dose. Starting doses for a graded challenge may be 1/100th of the final dose. The process generally involves fewer steps (as few as two) and can be typically accomplished more rapidly. If the graded

challenge is completed and a therapeutic course of drug tolerated, a graded challenge is not required before future courses of the drug. Tolerance induction, on the other hand, is only maintained as long as the patient receives the suspect drug; any interruption of therapy will require the desensitization procedure to be repeated (see Case 32-9, Question 4).

The choice of drug desensitization or using a graded challenge depends on the likelihood of the patient having a true allergic reaction. A graded challenge may be appropriate in patients with a distant or an unclear history of drug allergy; when the reaction seems minor or for which diagnostic testing is unavailable; or in cases where cross-reactivity is expected to be low. For example, a patient with a maculopapular rash to ceftriaxone may undergo a graded challenge to imipenem–cilastatin to assess tolerance. On the other hand, a patient with a well-described, severe IgE-mediated reaction to a drug may be better suited for tolerance induction. Importantly, graded challenge or tolerance induction should not be used in patients with a history of a severe non–IgE-mediated reaction such as hepatitis, hemolytic anemia, Stevens–Johnson syndrome, toxic epidermal necrolysis, or DRESS syndrome because of the risk of provoking a potentially life-threatening reaction.[116] Because K.A.'s reaction to penicillin may be potentially severe, premedication is not an option and desensitization to penicillin should be started. (See Chapter 72, Sexually Transmitted Diseases, for alternative therapy.)

Case 32-9, Question 2: How should K.A. be desensitized? Why should she be skin tested before desensitization?

If possible, before tolerance induction is begun, K.A. should be skin tested (see Case 32-1, Questions 3 and 4) to confirm her penicillin allergy.[8,40,128] Patients who have a positive history of penicillin allergy, but whose skin test results are negative, can receive full therapeutic doses without desensitization with little risk of developing an allergic reaction. One author, for example, reported

only one case of acute anaphylaxis in a patient whose skin test result was negative and was given full therapeutic doses of penicillin in >1500 skin tests; similar results have been reported by other investigators.[40,128] If skin testing cannot be performed or if K.A.'s skin test result is positive, desensitization should be initiated. Acute oral desensitization to penicillin and other β-lactam antibiotics is well established.[129]

The oral route for β-lactam desensitization is preferred to the parenteral route because (a) exposure by the oral route is less likely to cause a systemic allergic reaction than is parenteral exposure; (b) fatal anaphylaxis from oral β-lactam drug therapy is rare; (c) preformed polymers and conjugates of penicillin major and minor determinants to *Penicillium* proteins are not well absorbed after oral administration; (d) blood levels rise gradually, favoring univalent haptenation; and (e) fatal or life-endangering reactions have not occurred using current methods. In addition, oral desensitization can be accomplished over several hours.[8] If oral desensitization is not possible (eg, if oral absorption is questionable), parenteral desensitization can be instituted. Although the subcutaneous and IM routes have been used, the IV route is quicker and allows better control over the rate and concentration of drug administered, and any untoward reaction can be detected promptly and treated rapidly.[8,130] However, oral and parenteral desensitization methods have not been compared formally. Patients should not be premedicated before desensitization, because this may prevent detection of minor allergic responses that may precede more serious reactions. In addition, only experienced personnel should undertake desensitization in an appropriate setting where emergency resuscitative equipment is readily available because severe reactions can develop.[128] Thus, K.A. should undergo oral desensitization if her skin test result is positive or if skin testing cannot be performed.

Case 32-9, Question 3: Is K.A. at risk for an allergic reaction during tolerance induction? If tolerance induction is successful, is she at risk for a reaction during full-dose penicillin therapy?

Acute β-lactam desensitization, regardless of the route or protocol chosen, is not without risk. Approximately 5% of patients experience mild cutaneous reactions during desensitization, although one study reported reactions in 20% of patients during oral desensitization.[8,131] If a reaction occurs during the desensitization procedure itself, the reaction may be treated and desensitization continued using lower doses, increased intervals between doses, or both, after the reaction has abated. Severe, fatal reactions during desensitization are rare.[130]

Uneventful β-lactam desensitization, however, does not guarantee that patients will be without reaction during full-dose therapy. Approximately 25% to 30% of patients experience a mild reaction during therapy, and 5% experience more severe reactions, including drug-induced serum sickness, hemolytic anemia, or urticaria.[8] Reaction rates are no different in severely ill or pregnant patients compared with stable or nonpregnant patients, although those with cystic fibrosis may be more difficult to desensitize because of their high frequency of allergic reactions.[131,132] Despite the occurrence of reactions, full-dose therapy is possible for most tolerance induction procedures, but suppression of the reaction (eg, by diphenhydramine) may be required.[130] Tolerance induction is also dose dependent because allergic symptoms can appear after a substantial increase in the dose after tolerance has been achieved.[8]

Case 32-9, Question 4: If K.A. requires penicillin at a later date, will she need to undergo desensitization again? What is chronic desensitization?

The desensitized state, once achieved, will persist for ~48 hours after the last full dose of antibiotic; after this time, drug sensitivity will return.[8,130] Thus, if K.A. requires future courses of penicillin, she will need to undergo desensitization once again. In some cases, those requiring long-term antibiotic therapy (eg, for endocarditis), those who may require β-lactams at a future date (eg, those with cystic fibrosis), or those who have occupational exposure to β-lactams, maintenance of the desensitized state can be considered. Chronic

twice-daily dosing of oral penicillin has safely resulted in "chronic desensitization." Similar to acute desensitization, once therapy is interrupted, the allergic state returns.[8,31]

OTHER DRUGS

CASE 32-9, QUESTION 5: Have patients allergic to drugs besides β-lactams been desensitized successfully?

Although most experience with desensitization is with penicillin and other β-lactams, desensitization also has been accomplished with numerous other drugs, including allopurinol, vancomycin, antineoplastic agents, aspirin, and monoclonal antibodies.[74,131,132] Interestingly, not all of these cases represent IgE-mediated hypersensitivity reactions. For example, reactions to trimethoprim–sulfamethoxazole commonly occur in patients infected with HIV and may not be IgE mediated. Yet, given its role in treating and preventing *Pneumocystis jiroveci* pneumonia, successful desensitization to trimethoprim–sulfamethoxazole is commonly used.[132]

Systemic Lupus Erythematosus

Jerika T. Lam, Ann M. Lynch, and Mary A. Gutierrez

CORE PRINCIPLES		CHAPTER CASES
1	Systemic lupus erythematosus (SLE) affects multiple organ systems with diagnoses based on clinical findings and objective criteria from the American College of Rheumatology (ACR) and Systemic Lupus International Collaborating Clinics (SLICC) guidelines.	**Case 33-1 (Questions 1–4)** **Case 33-2 (Question 1), Table 33-1, Figure 33-1**
2	Management of SLE is complex, and involves many specialists, including cardiologists and rheumatologists.	**Case 33-2 (Question 2)**

CORE PRINCIPLES		CHAPTER CASES
3	SLE treatment includes nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, antimalarials, and immunosuppressants. The goals of SLE treatment should be considered when devising a treatment plan.	**Case 33-2 (Question 3)** **Case 33-3 (Questions 1–3, 5, 6), Table 33-3**
4	Pregnancy considerations should be applied when selecting drug treatments for female patients with SLE.	**Case 33-3 (Questions 7, 8)**
5	Hydroxychloroquine and cyclophosphamide could cause bothersome side effects. Monitoring parameters and management of hydroxychloroquine and cyclophosphamide side effects should be considered for patients with SLE.	**Case 33-3 (Questions 4, 9–11), Table 33-3**
6	Belimumab is the first U.S. Food and Drug Administration (FDA)-approved biologic treatment for SLE. The appropriate use and monitoring parameters should be considered to optimize its efficacy.	**Case 33-3 (Questions 12–17), Tables 33-2, 33-3**
7	There are several drug–drug interactions pertaining to the treatments for SLE. Concomitant use of hydroxychloroquine and antacids could have a potential adverse effect.	**Case 33-4 (Questions 1, 2), Table 33-4**

CORE PRINCIPLES		CHAPTER CASES
8	Pharmacists can play an important role in the education regarding SLE, management of side effects, and monitoring of drug–drug interactions.	**Case 33-3 (Questions 2, 3, 5–9, 13)** **Case 33-4 (Questions 2, 3), Tables 33-3–33-5**

INTRODUCTION

Systemic lupus erythematosus (SLE) is a chronic, autoimmune, inflammatory disease that affects multiple organ systems and primarily the connective tissue. Its presentation and disease progression are unpredictable and highly variable. This multiorgan disease is characterized by inflammation, autoantibody production, the deposition of complement-fixing immune complexes, and a clinical pattern alternating between disease flares and periods of remission.[1] In essence, the immune system attacks the body's own cells and tissue, resulting in a continuous inflammatory response and tissue and/or organ damage over time. Although SLE can eventually affect any organ such as the lungs and the nervous and cardiovascular systems, it mainly affects the skin, joints, and kidneys.[2] The 10-year survival rate is ~70% for patients with SLE.[3]

EPIDEMIOLOGY

SLE is more common among females than males (9:1), and generally occurs during childbearing age, with a peak age of onset between 15 and 45 years.[4,5] It is estimated that >16,000 new cases of SLE are reported annually in the United States, with an average prevalence of 1.5 million Americans. Approximately 5 million people are afflicted with SLE globally, and 90% are females.[6] Progression of

SLE is usually slow. It typically begins as a benign disease without signs or symptoms (preclinical phase) to disease with mild-to-moderate symptoms with exacerbations or flares, resulting in the involvement of additional organs and sustained damage (clinical phase). Over time the disease will progress, continually relapsing and remitting until eventually reaching severe potentially fatal disease (comorbidities phase).[7] Isolated skin and musculoskeletal involvement are associated with a milder course of disease and a higher survival rate over patients with renal and central nervous system (CNS) involvement, which indicate more severe and progressive disease conditions.

PATHOPHYSIOLOGY

The specific cause of SLE is unknown. Many genetic, ethnic, environmental, and hormonal factors are identified as potential causative risk factors. As part of the genetic component involved in the development of SLE, there is no clear Mendelian pattern of inheritance. Siblings of patients with SLE have a risk of disease of ~2%.[8] Identical twins have an ~10-fold higher risk of SLE than do dizygotic twins.[4] First-degree relatives of patients with SLE have a 20-fold increased risk of developing SLE when compared to the healthy population.[9,10] The genetic risk for the disease is more likely associated with multiple genes than with the deficiency of a single gene. Interestingly, genome-wide association studies have identified risk alleles shared between SLE and other autoimmune disorders such as rheumatoid arthritis, Graves disease, multiple sclerosis, type 1 diabetes, and psoriasis.[11] SLE is more likely to develop in females of color, at a rate two to three times higher than the rate for Caucasian females.[6] Furthermore, the symptoms are found to be more severe in African American, Asian, Native American, and Hispanic females.[4,12] However, individuals of all ages, genders, and ancestral backgrounds are susceptible to having the disease.

The association of environmental factors to SLE remains unclear. Some of the exposure-related factors that have been implicated for causing SLE include smoking and ultraviolet (UV) radiation.[13] The proposed hypothesis behind cigarette smoke is that it is associated with the indirect generation of anti-double-stranded DNA (anti-dsDNA) and related to immunoregulatory effects of tobacco exposure. Thus, in genetically predisposed individuals with a smoking-related decreased ability to clear apoptotic cells, the excess levels of intracellular antigens may lead to the production of autoantibodies such as anti-dsDNA.[14]

Ultraviolet Radiation

Exposure to sunlight may cause the occurrence of SLE, and could exacerbate preexisting symptoms. UV radiation has been implicated in cutaneous manifestations of SLE, such as macular, papular, or bullous lesions, and erythema.[15] Systemic disease is rarely induced by UV radiation. Possible mechanisms that may link the pathogenesis of UV radiation and SLE include circulating antibodies to the Ro/Sjögren syndrome type A (anti-Ro/SSA) and anti-La Sjögren syndrome type B (anti-La/SSB) antigen particles that result in an autoimmune response.[2,15] Nevertheless, both anti-Ro/SSA and anti-La/SSB are more commonly associated with Sjögren syndrome than with SLE.

Viral Infection

It has been considered for many years that viruses, particularly the Herpesvirus family and the Epstein–Barr virus (EBV) may trigger SLE via polyclonal immune activation, resulting in an activation of the autoimmune system.[16] EBV may reside in and interact with B cells, promoting interferon (IFN)-α production and contributing to the inflammatory process.

Female Hormones

The increased prevalence in the female gender proposes that hormones such as estrogen or progesterone may play a role in aggravating the disease. Both estrogen and progesterone levels are increased during pregnancy and at conception. These hormones can lead to an increase in mature, high-affinity autoreactive B cells, resulting in an autoimmune reaction.[17] Evidence that SLE worsens during pregnancy ironically does not contribute to this theory because levels of estrogen and progesterone are lower in second- and third-trimester pregnant patients with SLE compared to healthy pregnant individuals.[17] Interestingly, hormone replacement therapy is linked to worsening SLE symptoms in postmenopausal females.[18] The X chromosome may also independently contribute to the incidence of SLE, where the combination of two X chromosomes increases the severity of SLE over an X,Y combination.[19] The gene *CD40* is located on the X chromosome and has been known to contribute to the pathogenesis of the disease.[13]

Immunologic Abnormalities

SLE is a disease of an overall dysregulated, aberrant immune function, indicated by a large number of autoantibodies involved. Abnormalities of the immune system include immune complexes, T lymphocytes, cytokines, and antibodies.[13] Antigen receptor–mediated activation is changed in T and B cells for patients with SLE. B cells play a pivotal role in the disease. They produce autoantibodies, which amplify inflammation and mediate tissue damage. The autoantibodies are immunoglobulin (Ig)G mediated, and T lymphocytes help stimulate B cells to produce antibodies. Moreover, B cells process and present antigen and autoantigen to T cells and contribute to disease manifestation.[20] The innate immune system (ie, toll receptors, plasmacytoid dendritic cells, and IFN-α) and the adaptive immune network also contribute to the production of autoreactive B cells and autoantibodies.[21] Similarly, cellular debris from apoptosis further stimulate activation of the immune system. The decreased clearance of cellular debris may be related to low-

complement levels, such as C1q, C2, and C4, which normally function to help phagocytes and macrophages eliminate apoptotic material and self-reactive B cells. As a result, deposits of immune complexes can lead to organ damage, systemic inflammation, and pain.[5,13]

CLASSIFICATION CRITERIA

In 1971, the Diagnostic and Therapeutic Criteria Committee of the American College of Rheumatology (ACR) developed a disease classification criteria system. Because there is no single test to diagnose SLE, the classification criteria have been used for the diagnosis of SLE. The original classification criteria system and definitions were revised in 1982, 1997, 2012, and, most recently, in 2019 (**Table 33-1**).[22–24] In 2019, the European League Against Rheumatism (EULAR) and the ACR together revised and validated the SLE classification criteria to improve its sensitivity and specificity. SLE classification comprises of one entry criterion followed by scoring of weighted additive criteria.

Table 33-1

American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) Revised Criteria for Classification of Systemic Lupus Erythematosus (SLE), 2019 Updates

Entry Criterion	■ Antlnuclear antibodies (ANA) at a titer of al 80 on HEp-2 cells or an equivalent positive test at least once. Testing by immunofluorescence on HEp-2 cells ot a solid-phase ANA screening immunoassay wlth at least equivalent performance is highly recommended ■ If absent, do NOT classify as SLE ■ If present, apply additive criteria		
Additive Criteria	■ Do not count a criterion if there is a more likely explananon than SLE ■ Occurrence of a criterion on at least one occasion is sufficient ■ SLE classifrcation requires at least one clinical criterion and a10 points ■ Criteria need not occur simulianeously ■ Withiri each domain, only the highest weighted criterion is counted toward the total score		
Clinical Domains		**Definition**	**Weight**
Constitutional			
	Fever	Temperature >100.9A T (>38.3 "Q	2
Hematologic			
	Leukopenia	White blood celi count <A000/mm^3	2
	Thrombocytopema	Platelet count <100.000/mm^3	A
	Autoimmune hemolysis	Evidence of hemolysis, such as reticulocytosts, Iow haptogiobln, elevated Indirect bilirubin, elevated LDH, and positive Coombs (direct antiglobulin) test	A
Neuropsychiacrlc			
	Delirium	Characterized by (1) change in consciousness or level of arousal with reduced ability to focus, (2) symptom development over hours to <2 days, (3) symptom fluctuatlon throughout the day, (A) either (Aa) acute/subacute change in cognitlon (eg, memory deficit or disorlentatlon), or (Ab) change In behavior, mood, or affect (eg, restlessness, reversal of sleep/wake cycle)	**2**
	Psychosis	Characterized by (1) delusions and/or halluonations without insight and (2) absence of delirium	3
	Seizure	Primary generallzed seizure or partial/focal seizure	5
Mucocutaneous			
	Nonscarrmg alopecia	Nonscarring alopecia observed by a cllnician	**2**
	Oral ulcers	Oral ulcers observed by a clinician"	2
	Subacute cutaneous or discoid lupus	Subacute cutaneous lupus erythematosus observed by a clinician: *Annular or papulosquamous (psoriasiform) cutaneous eruption, usually photodistributed If skin biopsy is performed, typical changes must be present (interface vacuolar dermatitis consisting of a perivascular lymphohlstiocytic infiltrate, often with dermai mucin noted) *or* Discoid lupus erythematosus observed by a clinician: Erythematous-violaceous cutaneous lestons with secondary changes of atrophic scarring, dyspigmentation, often follicular hyperkeratosis/plugging (scalp), leading to scarring alopecia on the scalp If skin biopsy is performed, typical changes must be present (interface vacuolar dermatitis consisting of a perivascular and/or periappendageal lymphohistiocytic infiltrate, in the scalp, follicular keratin plugs may be seen; in long-standing lesions, mucin deposition may be noted)	A

	Acute cutaneous lupus	Malar rash or generalized maculopapulat rash observed by a clinictarr' if skin biopsy is performed. typical changes must be present (interface vac-uolar dermatitis consisting of a penvascular lymphohistiocytic infiltrate. often witn dermal mucin noted, penvascular neutrophilic inriltrate may be present early in the course).	6
Serosal	Pleural or pericardial effusion	Imaging evidence (such as ultrasound. x-ray, CT scan, MRI) of pleural or pericardial effusion. or both	5
	Acute pericarditis	*&2* of (I) pericardial chest pain (typically sharp, worse with Inspiratlon. im-proved by leaning forward). (2) pericardial mb. (3) ECG with new wide-spread ST elevation or PR depression. (4) new or worsened pericardial effusion on imaging (such as ultrasound. x-ray. CT scan. MRI)	6
Musculoskeletal			
	Joint involvement	*Either* (I) synovitis involving two or more joints characterized by swelling or effusion *or* (2) tenderness in two or more |olnts and at least 30 min-utes of morning stiffness	**6**
Renal			
	Proteinuria >0.5 gf2A hours	Protdnuria >0.5 g/2A hours by 2A-hour unne or equivalent spot urine proteln-to-creatlnine ratio	A
	Renal biopsy Class II or V lupus nephritis	***Closs II:*** Mesangial proliferative lupus nephritis purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial Immune deposit. A few isolated subeplthellat or subendothellal deposits may be visible by immunofluorescence or electron microscopy. but not by light microscopy **Class V:** Membranous lupus nephritis: global or segmental subepirhelial immune deposits or their morphologic sequeiae by light microscopy and by Im-munofluorescence or electron microscopy. with or without mesangial alterations	B
	Renal biopsy Class III or IV lupus nephritis	***Class III:*** Focal lupus nephritis active or inactive focal. segmental. or global en-docapillary or extracapillary glomerulonephritls involving <50% of all glomeruli. typically with focal subendothelial immune deposits. with or without mesangial alterations ***Class IV:*** Diffuse lupus nephritis: active or inactive diffuse. segmental. or global endocaplllary or extracapillary glomerulonephritls Involving a50% of all glomeruli. typically with diffuse subendothelial immune deposits. with or without mesangial alterations. This class includes cases with diffuse wire loop deposits but with little or no glomerular prollferation	10
Immunology Domains and Criteria			
Antiphospholipld Antlbodles			
	Anti-cardiollpin antt-bodies *or* Anti p2GP1 antibod-ies *or* Lupus anticoagulant	Anticardiolipin antibodies (IgA. IgG. or IgM) at medium or high titer (>AO APL GPL, *nr* MPL. or > rhe 9Sth percentile) or posinve ann (β-GPI anti-bodies (IgA. IgG. or IgM) or positive lupus anticoagulam	*2*
Complement Protelns			
	Low C3 *or* low CA	C3 *or* CA below the lower limit of notmal	3
	Low C3 *and* low CA	Both C3 *and* CA below their lower limits of normal	A
SLE-Specific Antibodies			
	Anti-dsDNA antibody *or* anti-Sm antibody	Anti-dsDNA antibodies in an immunoassay with demonstrated a90% specificity for SLE against relevant disease Controls or anti-Sm antibodies	6
Total Score:			
Classify as SLE with a score of 10 or more if entry criterion is fulfilled.			

Anti-DNA, anti-deoxyribonucleic acid; anti-Sm, anti-Smith antibodies; IgG and IgM, immunoglobulins G and M.

[a]This may include physical examination or review of a photograph.

CLINICAL PRESENTATION

The clinical features of the disease are diverse and vary among patients. Signs and symptoms may be subtle early in the course of the disease; and the spectrum of mild-to-severe symptoms may fluctuate, with periods of remission, throughout the disease process.[25] Clinical patterns of the disease can be categorized as constitutional, musculoskeletal, and mucocutaneous.

Constitutional symptoms usually include fatigue, general malaise, fever, and weight loss. These may occur in the early stages of the disease. Fatigue is the most common and can be a debilitating symptom early on.[26,27] Musculoskeletal symptoms include arthritis, arthralgia, and myalgia. Early in the course of the disease, the symptoms may be confused with rheumatoid arthritis, especially with intermittent symmetric arthritic and joint pain. Arthritis associated with SLE is nonerosive and does not damage the joint even though it affects the joints of the hands, wrist, knees, and feet. Myopathy may also be present during periods of active disease, or secondary to treatment of hydroxychloroquine and corticosteroids.[28]

Mucocutaneous manifestations occur frequently in patients with SLE. The malar or butterfly rash across the face is one of the classic cutaneous signs; however, it may not be present in all patients with SLE. It is an erythematous skin rash distributing over the cheeks and

the bridge of the nose, but spares the nasolabial folds. It can persist for weeks and resolves without scarring. The malar rash should be differentiated from flushing, glucocorticoid-induced dermal atrophy, rosacea, and seborrheic, atopic, and contact dermatitis.[2] Other cutaneous signs may include alopecia, discoid lesions, photosensitivity reactions, periungual erythema, nail fold infarcts, and splinter hemorrhages.[29,30] In comparison, mucosal symptoms can include vasculitis and painful, recurrent ulcers in the mouth, nose, and genital cavity.[28] Raynaud phenomenon may also occur in patients with SLE. It is described as a vasospastic disorder of the extremities, commonly affecting the hands, and is characterized by color changes as a result of decreased temperature or intense stress.[18] It can also lead to avascular bone necrosis, which is a major cause of disability in patients with SLE.[2]

Additional clinical presentation of SLE may include the development of antiphospholipid antibodies (eg, lupus anti-β_2-glycoprotein, IgG and IgM anticardiolipin antibodies, and IgG and IgM anti-β_2- glycoprotein I) in the blood, and places patients with SLE at increased risk for developing blood clots.[31] Livedo reticularis is a common feature of antiphospholipid syndrome (APS), which is further discussed in the section Hematologic System. Common symptoms of SLE are described in **Figure 33-1**. Other major organ systems may also be affected by SLE, including the nervous, cardiovascular, pulmonary, gastrointestinal (GI), renal, and hematologic systems.

Figure 33-1 Common symptoms of systemic lupus erythematosus. (Modified from Häggström, Mikael/Wikipedia Commons/Public Domain.)

Nervous System

SLE affects both the CNS and peripheral nervous system. The CNS manifestations affect approximately two-thirds of patients with SLE.[31] Collectively, both have been described as neuropsychiatric syndromes. The pathology of the syndromes is not well understood. The syndromes may be ascribed to the autoimmune nature of SLE, where the immune antineuronal antibodies attack the neurons, causing neuronal damage and leading to cognitive dysfunction, or the production of antiphospholipid antibodies that damage blood vessels and may cause clots in the brain.[29] Neuropsychiatric manifestations are nonspecific and variable. They may occur in <40% of patients with SLE, whereas the remaining events represent complications of the disease, therapies and therapy-related side effects, infections, and metabolic abnormalities.[32] Patients with SLE can present with higher rates of anxiety and depression. Depression is more common in those experiencing changes in appearance and limitations from complications and medication-related side effects.[33] Other manifestations include migraine headaches, memory loss, and seizures. Less common symptoms may also occur, such as psychosis, confusion, peripheral neuropathy, mood disorders, autonomic dysfunction, movement disorders, Guillain–Barré syndrome, and cerebrovascular disease.[28] Diagnosis and laboratory tests for neuropsychiatric events related to SLE continue to be challenging, as well as the therapies used for them.[34]

Cardiovascular System

Patients with SLE are at increased risk for morbidity and mortality from cardiovascular disease, especially associated with atherosclerosis. Premature atherosclerosis is associated with longer lupus disease duration, more damage, and less aggressive immunosuppressive therapy.[35,36] They are at higher risk for myocardial infarction or stroke compared to the healthy population. In addition, pericarditis and pericardial effusion are the most common cardiac complications associated with SLE, occurring in

~45% of patients.[29–31,37] They range from mild-to-severe symptomatology. Patients may present with fever, dyspnea, tachycardia, and congestive heart failure. Other clinical features that may occur in >80% of patients with SLE include left ventricular dysfunction, segmental wall motion abnormalities, nonspecific ST-T wave changes, and decreased ejection fraction.[2] Valvular abnormalities can also be common and are linked to antiphospholipid antibodies. The most common abnormality is diffuse thickening of the mitral and aortic valves followed by the presence or absence of nonbacterial vegetations (Libman–Sacks), valvular regurgitation, and stenosis.[2] Modifiable risk factors, in addition to comorbid disease screening, include reducing long-term steroid use because it is linked to the development of hypertension, smoking cessation, reducing homocysteine levels with folate supplementation, and preventing thrombosis with aspirin or anticoagulation in patients with APS.[28] These will help reduce cardiovascular risk and control disease activity by reducing the inflammatory atherogenic effects.

CASE 33-1

Question 1: T.C. is a 45-year-old Hispanic female with hypertension, hypercholesterolemia, and an 18-year history of SLE. For the first 10 years after the diagnosis of SLE, she had frequent SLE flares, and was treated with high doses of prednisone. As a result, she developed steroid-induced diabetes and osteoporosis. Although her SLE has been relatively stable over the past 2 years, she has not been feeling well for 1 month. T.C. denies symptoms consistent with her usual SLE flares, but she reports a sharp chest pain that worsens when lying down and improves when leaning forward, significant fatigue, and shortness of breath with minor activity. She feels better after resting, but has not returned to her previous energy level. She reports good adherence with her medications, which include the following:

Alendronate 70 mg weekly
Hydrochlorothiazide 25 mg every morning
Hydroxychloroquine 400 mg daily
Lisinopril 40 mg daily
Metformin 1000 mg twice daily
Simvastatin 40 mg daily
Acetaminophen 650 mg prn for pain

Findings from an examination of the patient are unremarkable, except for elevated blood pressure. Lupus anticoagulant antibodies are within normal limits.

What is the most likely cause of T.C.'s fatigue and positional chest pain?

Patients with long-standing SLE are at increased risk for cardiovascular disease. Given that T.C.'s SLE is stable, cardiovascular disease is the most likely cause of her current symptoms.

Case 33-1, Question 2: What tests would best confirm your suspicion?

Electrocardiograms (ECGs), exercise stress tests, and echocardiograms. Cardiac stress test is also considered the best way to determine the presence and extent of her cardiovascular disease, especially for symptomatic patients.

Case 33-1, Question 3: Along with a referral to a cardiologist, which of the following treatments would you recommend that T.C. initiate at this time?

Aspirin is recommended because her most likely diagnosis is cardiovascular disease. She has no evidence of active SLE, so aspirin would be the most appropriate treatment at this time to prevent risk of thrombosis. Premature atherosclerosis with cardiovascular events tends to manifest as a late complication for patients with SLE. Oral anticoagulants may be considered for T.C. if she has developed antiphospholipid antibodies and APS.

Case 33-1, Question 4: Late in the disease course of SLE, what is the most common cause of high mortality rates?

Early in the disease course, mortality is primarily from inflammation affecting organ systems. Over time, mortality tends to be mostly from coronary artery disease and complications of chronic steroid therapy and immunosuppression. SLE disease could elevate

the low-density lipoprotein (LDL) and reduce the high-density lipoprotein (HDL) levels in addition to treatment with systemic steroids that could worsen the cholesterol profile.

Pulmonary System

Pulmonary involvement occurs in 30% of patients with SLE.[31] Pleuritis or pleural inflammation is the most common pulmonary manifestation of SLE. It is associated with chest pain, cough, and dyspnea. Pleural effusions are typical findings and are usually linked with antinuclear antibody (ANA)-positive exudates with low complement.[38] Alveolar hemorrhage is a common occurrence in patients with SLE, particularly in those with high titers of anti-dsDNA antibodies and active extrapulmonary disease.[31] Another respiratory complication is identified as the “shrinking lung syndrome,” which can occur in 25% of patients with SLE.[2] It is characterized as progressive dyspnea (worse in the supine position) and weakness of the diaphragm and respiratory muscles. Acute lupus pneumonitis and pulmonary hypertension, although rare, could also develop as pulmonary complications.

Gastrointestinal System

Nonspecific GI symptoms include abdominal pain, nausea, vomiting, diarrhea, and stomach upset. These are reported in 25% to 40% of patients with SLE, which could be disease related or from medication side effects.[2] Other clinical manifestations include dyspepsia and peptic ulcers.

Renal System

Up to 70% of all patients with SLE will develop some form of renal complication, which is a poor prognostic indicator. Approximately 60% will have kidney involvement in the first 10 years of the disease.[18] Thirty-five percent of patients will develop nephrotic

syndrome or lupus nephritis (LN) by the time of SLE diagnosis.[39] It is a serious kidney complication, which increases the risk of renal failure, cardiovascular disease, and mortality.[40] LN is caused by inflammation and deposits of immune complexes consisting of anti-dsDNA in the glomeruli. It includes proteinuria (>0.5 g/24 hours) and/or hematuria, described as active urinary sediment (>5 red blood cells [RBCs] per high-power field, pyuria, or cell casts), in addition to a significant creatinine clearance reduction. For patients with an inactive sediment and >500 mg/day of proteinuria, monitoring is recommended with urinalysis every 3 to 6 months for 3 years. More frequent monitoring, such as every 3 months, is preferred for patients with anti-dsDNA antibodies and/or hypocomplementemia.[41]

Aside from performing a urinalysis, a renal biopsy is required in all patients with lupus with evidence of kidney involvement to determine the histologic subtype of LN and the extent of disease severity.[42,43] Pathology reports can elucidate the extent of inflammatory (reversible) and chronic (irreversible scarring) changes. LN can be an ongoing disease, with flares often requiring repeat biopsy and repeat treatment (refer to Chapter 28, Chronic Kidney Disease, for Lupus Nephritis, Case 28-4).

Hematologic System

Hematologic disorders can occur in patients with SLE. The most common hematologic manifestation is normochromic, normocytic anemia, which is often overlooked in young menstruating females. Iron deficiency may also develop. A common cause of anemia is suppressed erythropoiesis from chronic inflammation. Patients may have a positive Coombs test finding without apparent hemolysis.[43] Leukopenia and thrombocytopenia are also common manifestations that can develop as part of the disease process, or may be a side effect of the pharmacologic treatment for SLE. Oftentimes, leukopenia consists of lymphopenia, not granulocytopenia.[44] Patients with SLE may also develop a thrombotic disorder known as

antiphospholipid syndrome (APS). APS is characterized by the development of autoantibodies to phospholipids present in the serum. Antiphospholipid antibodies interfere with the coagulation system, particularly protein C and the function of endothelial cells.[13] APS features are described as venous or arterial thrombosis, miscarriages or spontaneous abortions, and thrombocytopenia from antiphospholipid antibodies.[28] The EULAR recommends low-dose aspirin in individuals with SLE and antiphospholipid antibodies as primary prevention of thrombosis and pregnancy loss.[7] Long-term use of oral anticoagulants is considered as secondary prevention of thrombosis in nonpregnant patients with SLE and thrombosis associated with APS. On the other hand, unfractionated or low-molecular-weight heparin and aspirin should be used in pregnant patients with SLE and APS.

Lymphadenopathy could be a common presentation in SLE, where it may occur in 15% to 26% in patients. Diffuse lymphadenopathy, however, is a very rare occurrence.[45,46] Lymph node biopsy may be considered to exclude alternative diagnoses.

DIAGNOSIS

Based on the 2019 EULAR/ACR updated criteria classification system, diagnosis of SLE is based on the presence of 1 or more of the entry criteria in conjunction with ≥1 additional clinical criterion and scoring of the weighted additive criteria equaling ≥10. Entry criterion should not be counted in the event there is a more likely explanation other than SLE. Occurrence of criterion on at least one occasion is sufficient to consider SLE as a diagnosis. Criteria do not require simultaneous occurrence. If multiple criteria within one domain are met, only the highest scoring criterion should be counted toward the total score. For instance, many patients with biopsy-proven LN do not meet the criteria. However, the classification can be made from a biopsy confirming LN and presence of ANA, or anti-dsDNA antibodies. Both anti-Smith (anti-Sm) and anti-dsDNA

antibodies are highly specific for SLE, but anti-Sm antibodies lack sensitivity.[1] Anti-dsDNA and anti-Sm antibodies are found in ~70% and 30% of patients with SLE, respectively.[47] Other markers, such as the lupus anticoagulant and IgG and IgM antibodies to anticardiolipin, are specific for APS. Their presence may increase the risk of thrombosis or miscarriages. When compared to the 2012 SLICC, the EULAR/ACR 2019 criteria have slightly lower sensitivity (96% vs 97%), but a much higher specificity (93.4% vs 84%) (**Table 33-1**).[18,22]

The diagnostic workup can be challenging because of the complexity of the disease and overlapping features of many other autoimmune diseases, such as polymyositis, rheumatoid arthritis, and scleroderma. The workup includes an assessment of the clinical presentation, physical examination, and diagnostic and laboratory tests. Approximately 80% of patients have skin involvement manifesting as photosensitivity, alopecia, malar and discoid rash (thick, red, scaly patches on the skin), and ulcers in the oral and nasal cavities or in the vagina, all of which are part of the ACR criteria.[22]

CASE 33-2

Question 1: D.S., a 30-year-old, obese African American female, weighing 176.37 pounds (80 kg) and 60 inches (152.40 cm) tall, presents to the emergency department with chest pain. It is a sharp and substernal pain, but with a component that is diffuse and aggravated by deep aspiration. Two months ago, she presented to the emergency department with a 6-week history of fatigue, low-grade fevers, hair loss, joint pain, and oral ulcers. Her laboratory tests showed a positive ANA test result. Blood culture findings were negative for infection. The urinalysis study result was negative for blood, and the urine culture was negative for infection. A chest x-ray showed nonpulmonary infiltrates. Her symptoms improved after a 10-day tapering course of prednisone. Feeling better, D.S. decided not to follow up with her physician's appointment last week. Today, the medical resident's examination reveals an ill-appearing female, with a temperature of 100.5 °F (38.06 °C), oral ulcers, alopecia, and tachycardia with distant heart sounds.

What signs and symptoms exhibited by D.S. are consistent with SLE?

According to the "2019 EULAR/ACR Classification Criteria for Systemic Lupus Erythematosus," the diagnosis of SLE is satisfied when 1 entry criterion and at least 1 clinical criterion with a weighted score of at least 10 are met. The criteria contain one constitutional, three hematologic, three neuropsychiatric, four cutaneous, two serosal, one musculoskeletal, three renal, and three immunologic components (**Table 33-1**). D.S. meets criteria with the presence of a positive ANA test result, oral ulcers, presumed pericarditis, and presumed arthritis (joint pain). Furthermore, her clinical features are consistent with SLE including fatigue, alopecia, and low-grade fevers (infection ruled out).

Case 33-2, Question 2: After D.S. has started treatment and further laboratory tests are performed, what other specialists would you involve in her care at this time?

A rheumatologist and cardiologist because of D.S.'s pericarditis. The cardiologist could evaluate the patient's modifiable cardiovascular risk factors, such as hypertension, dyslipidemia, and obesity. Pericarditis with pericardial effusion is most commonly associated with cardiovascular involvement and SLE. Symptoms could include sharp chest pain and fluid around the heart, worsened with deep breathing and certain body positions. Endocarditis, myocarditis, and valvular disease are less common. Over time, other specialists including gastroenterologist, neurologist, pulmonologist, and nephrologist may be considered as part of D.S.'s multidisciplinary team.

PHARMACOLOGIC AND NONPHARMACOLOGIC TREATMENTS

The management approach for SLE will depend on the severity of the disease and organ involvement. A therapeutic plan is created

based on clinical guidelines for the management, treatment, and monitoring of SLE. It should include considerations for pharmacologic and nonpharmacologic approaches with clearly defined goals. Because there is currently no cure for SLE, the goals of therapy are to prevent flares, treat active symptoms of disease, minimize drug toxicity, and reduce risk of complications and organ damage. An effective and successful therapeutic plan is individualized based on the patient's needs, symptoms, lifestyle, and disease complications. Patients should be regularly monitored by their providers every 3 to 6 months.

Nonsteroidal Anti-inflammatory Drugs and Selective Cyclooxygenase-2 Inhibitor

Treatment options will differ depending on the level of severity of SLE. For mild disease, nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase (COX)-2 inhibitor, such as celecoxib, are used. Because of their ability to inhibit the release of prostaglandins and leukotrienes, NSAIDs and the COX-2 inhibitor possess anti-inflammatory, analgesic, and antipyretic properties. They are effective in reducing swelling, relieving muscle and joint pain, fever, and pleuritic chest pain.[27,48] Patients with antiphospholipid antibodies are at increased risk for thrombosis or atherosclerotic disease, and may benefit from low-dose aspirin for primary prevention or long-term anticoagulation therapy for secondary prevention.[7] Long-term use of NSAIDs is encumbered with GI, cardiovascular, and renal issues. Common GI side effects include dyspepsia, heartburn, and nausea. More serious GI symptoms such as stomach bleeding and mucosal lesions may occur. Cardiovascular side effects associated with NSAIDs may include hypertension and the risk of myocardial infarction. Fluid retention and acute tubular necrosis with kidney failure may also occur with long-term use, especially in elderly patients.

As a class, NSAIDs work in the same manner; however, not every agent has the same effect on every patient. When an NSAID is used,

it needs to be titrated to its maximal dose over 1 to 2 weeks. The agent should not be discontinued until the patient has been on the maximal dose for at least 2 weeks, which is the amount of time NSAIDs reach maximal efficacy.[28] Although all NSAIDs appear to work in the same way, not every agent has the same effect on every person. In addition, patients may do well with one NSAID for a period of time, and then may not derive further benefit from it for some unknown reason. Switching the patient to a different NSAID could produce the desired effects. NSAIDs may be appropriate for chronic pain management in aspirin users provided that appropriate GI prophylactic measures are used in high-risk patients. Patients should use only one NSAID at any given time to really know its benefits.

Celecoxib, a COX-2 inhibitor, is more selective in the inhibition of COX, which is involved in the transformation of arachidonic acid to prostaglandin precursors. Celecoxib has the same efficacy as NSAIDs; however, it possesses a milder GI side effect profile. It does not have a direct effect on platelets.[49] Therefore, it is preferred over NSAIDs in patients with thrombocytopenia. There have been many studies and case reports correlating COX-2 inhibitors with cardiovascular risks (eg, stroke and heart attack), especially with rofecoxib (Vioxx), which was removed from the U.S. market.[49–51]

Case 33-2, Question 3: Which of the following treatments would D.S. benefit from using at this time?

D.S. could benefit from high-dose NSAIDs. Traditionally, the initial treatment for SLE pericarditis (inflammation of the lining of the heart or pericardium) is high-dose NSAIDs such as ibuprofen. Patients with SLE are at increased risk for coronary heart disease from increased cardiovascular risk factors (ie, chronic inflammation, dyslipidemia, obesity, and physical inactivity). Patients with SLE with recurrent pericarditis will need to be on immunosuppressive medications.

Antimalarials

Antimalarials are currently the mainstay systemic therapy for SLE, in particular hydroxychloroquine sulfate (Plaquenil) and chloroquine. Both are 4-aminoquinoline antimalarial drugs and function through immunomodulation by downregulating the production of tumor necrosis factor (TNF)-α and other pro-inflammatory cytokines.[52] Chloroquine is not used in the United States for treatment of SLE. Hydroxychloroquine is preferred over chloroquine because it has a better safety profile. It is associated with less corneal deposition (opacities) and retinopathy risks.[34] Ocular side effects occur in a dose-dependent manner, where the risk is low when hydroxychloroquine's dose is <400 mg daily and <6.5 mg/kg/day based on total body weight. It has anti-inflammatory effects, and is used to reduce the time to flare-ups, constitutional (ie, fever and rashes), skin, fatigue, and joint symptoms.[53] In addition, hydroxychloroquine has antithrombotic and lipid-lowering effects, which can help patients with SLE.[54] Other ocular symptoms may include blurred vision, night blindness, missing or blanched out areas in the central or peripheral fields, light flashes and streaks, and photophobia. Hydroxychloroquine-related side effects may also include a bull's eye appearance in the macular region.[34] The manufacturer recommends that eye exams should be performed at baseline and subsequently every 3 months with long-term hydroxychloroquine treatment. In contrast, the American Academy of Ophthalmology (AAO) proposes more flexible eye exam criteria. The AAO recommends that patients who are at low risk (those taking hydroxychloroquine <6.5 mg/kg/day dose for a treatment duration of <5 years) be checked at baseline and then, if normal, every 5 years. Patients who are at high risk (those taking hydroxychloroquine >6.5 mg/kg/day dose for >5 years, age older than 60 years or pediatric patients, or those with existing retinal disease and kidney or liver disease) should be evaluated at baseline and then annually.[55] Patients should be screened for the presence of "premaculopathy" antimalarial retinopathy, or retinal toxicity during scheduled eye exams because it is a reversible stage as long as hydroxychloroquine is discontinued.

A rare, but severe adverse effect associated with hydroxychloroquine is cardiomyopathy and/or conduction abnormalities (eg, atrioventricular block, sick sinus syndrome, bundle branch block). The risk factors for hydroxychloroquine-associated cardiac adverse effects could include longer duration of hydroxychloroquine therapy, higher cumulative doses, preexisting cardiac condition, older age, female sex, and renal impairment.[56] Monitoring of certain laboratory biomarkers and imaging may be necessary for those at highest risk.

Patients may need to take hydroxychloroquine for months to experience the maximal effect. For SLE, the initial oral hydroxychloroquine dose is 400 mg given daily for 3 to 6 months depending on patient response, and then tapered to 200 mg daily for maintenance therapy. If the patient does not have any benefit from hydroxychloroquine after 6 months, the drug should be discontinued.

CASE 33-3

QUESTION 1: J.B., a 49-year-old Caucasian female with a 30-year history of SLE, returns to her rheumatologist for evaluation. She has received prednisone, hydroxychloroquine, and azathioprine in the past. Her SLE has been stable for 2 years. Feeling well, J.B. discontinued all of her medications >1 year ago. She recently returns from a family vacation in the Caribbean. Having been out in the sun for a few hours on the first day, she developed an erythematous eruption over photoexposed areas of her face, ears, and legs despite the application of sunscreen. J.B. returns home, and the lesions are healing. Although she is fatigued, she feels well enough to return to work. You determine that her rash is because of photosensitivity.

What would be the best next step in the management of J.B.?

The next appropriate step is to initiate a short course of low-dose prednisone because it can be used to treat a photosensitive rash from SLE. The rash may occur because, with SLE, the body's immune system does not function properly, and the inflammatory response works to damage the patient's own tissues. Prednisone is a corticosteroid that helps reduce the inflammation and immune response, thereby preventing further damage to the tissues in the body.

Case 33-3, Question 2: The rash resolves, however, J.B. continues to have fatigue and arthralgia. No other clinical signs or symptoms consistent with SLE flare emerge. Laboratory test results reveal continued elevation of anti-dsDNA antibody titers and suppressed complement levels. What is your next step in managing J.B.?

Hydroxychloroquine should be initiated because it is effective for long-term treatment of SLE with rash, fatigue, and arthralgias. Hydroxychloroquine is often prescribed in combination with steroids to reduce the dose of the steroids required. It is prescribed for skin rashes, mouth ulcers, and joint pain. Hydroxychloroquine improves SLE by decreasing autoantibody production, protecting against the damaging effects of UV light from the sun and other sources, and improving skin lesions. Several studies have reported the benefits of hydroxychloroquine in treating symptoms of SLE, preventing disease flares, and its association with less organ damage.[57]

Case 33-3, Question 3: J.B. is initiated on hydroxychloroquine 400 mg orally daily. How long should she be on the initial treatment dose?

Three to 6 months of the initial treatment dose of hydroxychloroquine is recommended unless J.B. does not tolerate the side effects or does not benefit from the medication. After J.B. has responded to the initial dose, hydroxychloroquine can be tapered to 200 mg daily for maintenance therapy.

Case 33-3, Question 4: How often should eye exams be performed for J.B.?

At high doses and over time, hydroxychloroquine may damage the retina of the eye (retinal toxicity), causing vision problems. Eye exams should be performed at baseline before initiating hydroxychloroquine and every 3 months based on the manufacturer's recommendation. If based on the AAO, an eye exam should be performed at baseline and then every 5 years. If low doses of hydroxychloroquine are used in the treatment of SLE, the

risk of retinal toxicity is low. Long-term users of high-dose hydroxychloroquine will need to monitor their eye health regularly to prevent retinal toxicity.

Case 33-3, Question 5: What are the goals of SLE treatment?

Because there is no cure for SLE, the goals of treatment are to reset the patient's immune system to a state of remission, reduce the incidence of drug toxicity, and prevent multiorgan damage.

Corticosteroids

Systemic corticosteroid treatment is considered for patients with SLE who have not responded to NSAIDs and hydroxychloroquine. Corticosteroids possess anti-inflammatory effects and work by inhibiting T- and B-cell responses.[58] They provide immediate relief for mild-to-moderate symptoms compared to immunosuppressant treatments. Low-dose corticosteroids, such as prednisone, may be effective for mild-to-moderate symptoms. For instance, low-dose oral prednisone (6–10 mg daily) over a duration of 4 to 6 weeks is recommended for mild disease activity. Short-term use of tapered courses of prednisone will help reduce acute flares with or without systemic symptoms starting at adult doses of 0.5 to 1 mg/kg/day, up to 60 mg daily, and tapered over 8 weeks with the aim of discontinuing treatment.[59] Short-term treatment can minimize risks of developing side effects associated with long-term corticosteroid use, such as weight gain, decreased bone mineral density, muscle wasting, hypercholesterolemia, and hyperglycemia. More severe adverse effects associated with long-term use of high-dose corticosteroids may include diabetes, osteoporosis, mood changes (eg, anxiety, insomnia, depression, and delirium), Cushing syndrome, and risks of cardiovascular events. Topical corticosteroids are recommended for cutaneous SLE manifestations, such as 1% hydrocortisone and 0.05% fluocinonide. Treatment with topical corticosteroids should be intermittent and not exceed a treatment

duration of a few weeks.[59] Adjunctive treatments with NSAIDs or celecoxib may be combined with prednisone to reduce its dose and side effects, or allow it to be administered as an every other day therapy. High-dose oral corticosteroids (eg, prednisone 40–60 mg daily) or intravenous (IV) corticosteroids (eg, methylprednisolone 0.5–1.0 g daily) are considered for more severe disease.[28]

Case 33-3, Question 6: If J.B. is to be initiated on chronic, high-dose corticosteroid therapy for management of her SLE symptoms, what should she be monitored for?

With the use of high-dose corticosteroids, it is important to monitor for weight gain, hyperglycemia, osteoporosis, glaucoma, cataracts, hypercholesterolemia, mood changes, and premature atherosclerosis. Steroid medications can have serious long-term side effects, and the risk of the side effects increases with higher doses and chronic therapy.

Disease-Modifying Antirheumatic Drugs

Disease-modifying antirheumatic drugs (DMARDs) are immunosuppressive medications that are used to treat pain and swelling of the arthritis that could accompany SLE. They could also reduce the long-term damage to the joints. Methotrexate ([MTX], Rheumatrex®, Trexall®) is an antimetabolite or folate antagonist that inhibits dihydrofolate reductase, an essential enzyme for DNA synthesis. MTX induces apoptosis of inflammatory cells and reduces levels of inflammatory cytokines, particularly interleukin (IL)-1, IL-6, and TNF-α.[60,61] Moreover, MTX increases IL-10 and IL-4 levels, which promote T helper type 2 (Th2) cytokine effects that may be protective against autoimmune manifestations.[61] MTX is usually considered for treatment of rheumatoid arthritis, particularly for arthritis and skin manifestations. It is an effective alternative agent to hydroxychloroquine and corticosteroids for patients with SLE with arthritis, rash, or serositis.[53,62,63] When used with or without

corticosteroids, MTX is dosed between 7.5 and 15 mg weekly, orally or subcutaneously, not to exceed 25 mg/week. Subcutaneous injection is recommended for patients who experience drug-induced nausea. Side effects are dose dependent and can range from mild to severe. Mild side effects include GI effects (eg, nausea and vomiting) versus mucosal ulcerations, leukopenia, thrombocytopenia, and infections that are more severe side effects. Concomitant use of folic acid is recommended with MTX to reduce the side effects, especially nausea and vomiting. Hepatotoxicity could occur from MTX use. Patients should receive baseline liver function tests, and this should continue periodically throughout therapy. They should also be screened for preexisting liver disease, excessive alcohol use, or diabetes. Patients with liver disease (eg, hepatitis B or C) should avoid MTX because of liver toxicity risk. Similarly, MTX should be used cautiously in patients with renal disease because of increased risk of renal toxicity. Other adverse effects may include lung toxicities, such as cough, shortness of breath, and pulmonary infiltrates.[53,62] MTX is teratogenic and contraindicated in pregnant females (pregnancy category X). Adequate contraception should be used while on MTX treatment. Males and females who take MTX should stop 1 to 3 months before trying to conceive. The 3-month period allows the complete elimination of MTX from the body.

Leflunomide (Arava®) is a pyrimidine synthesis inhibitor that inhibits the formation of DNA in the cells of the body, particularly the immune cells that contribute to the inflammation, swelling, stiffness, and joint pain. Leflunomide can be used as a steroid-sparing treatment for patients with SLE with photosensitive rashes and arthritis. It is also administered either as monotherapy or in combination with MTX. Treatment may be initiated with or without a loading dose, depending on the balance between the patient's tolerability of the medication and rapid efficacy associated with a loading dose and their risk for leflunomide-associated hepatotoxicity and myelosuppression.[64] Of note, the serum half-life of teriflunomide, the active metabolite of leflunomide, is between 18 and 19 days.[65] Therefore, a loading dose of leflunomide may be needed for eligible patients because it will take a long time for leflunomide to reach

steady-state plasma concentrations. For patients who are at a low risk for leflunomide-associated hepatotoxicity and myelosuppression, the oral loading dose is 100 mg daily for the first 3 days, followed by a maintenance oral dose of 20 mg daily. Alternatively, an oral loading dose of 100 mg once a week for 3 weeks, in addition to the maintenance dose have been used to reduce the increased incidence of diarrhea and other GI adverse effects. If diarrhea persists to be a bothersome side effect, in spite of the use of antidiarrheal medication, then the dose can be reduced to 10 mg daily. In contrast, patients who are at a high risk for leflunomide-associated hepatotoxicity (ie, concomitant MTX use) or leflunomide-associated myelosuppression (ie, concomitant immunosuppressant use) should receive an oral dose of 20 mg daily without a loading dose.[64] Similar to MTX screening, patients initiated on leflunomide should receive baseline liver function tests and complete blood count tests every 3 to 4 months. Furthermore, they should also be screened for preexisting liver disease and excessive alcohol use. Leflunomide is teratogenic and contraindicated in pregnant females (pregnancy category X). Females should use oral contraceptives or other forms of effective birth control methods while taking the drug. More importantly, they should continue to do so until 2 years after discontinuation of leflunomide because teriflunomide remains in the plasma. Cholestyramine (Questran®) can be used to accelerate the elimination of leflunomide and reduce the plasma levels of teriflunomide.[65]

Immunosuppressants

Azathioprine (Imuran®, Azasan®) is a derivative of 6-mercaptopurine that acts as an antimetabolite agent by inhibiting DNA synthesis and blocking cell proliferation.[62] It is used to treat LN and nonrenal SLE manifestations, such as photosensitive rashes and cutaneous lupus erythematosus. Before starting azathioprine treatment, genotyping or phenotyping of the thiopurine S-methyltransferase (TPMT) is strongly recommended.[66] Caution is recommended for patients with

reduced TPMT activity because they may be at increased risk for bone marrow suppression.[58,67] Patients who are homozygous, or carry two nonfunctional TPMT alleles, will experience life-threatening myelosuppression when treated with azathioprine because of high concentrations of thioguanine nucleotides. Bone marrow suppression can occur in any patient, is dose dependent, and reversible by reducing the dose of azathioprine.[68] Taking azathioprine with food could help reduce the GI side effects (eg, nausea, vomiting, diarrhea, and stomach pain). Leukopenia, anemia, and thrombocytopenia may result from high doses of azathioprine or from poor metabolizers of the drug. The dosage of azathioprine ranges between 1 and 3 mg/kg/day given orally and in two to three divided doses. Azathioprine has an acceptable benefit-to-risk profile in controlling SLE symptoms during pregnancy.[69]

Mycophenolate mofetil ([MMF] Cellcept®, Myfortic®) inhibits inosine monophosphate dehydrogenase, an essential enzyme for DNA synthesis in lymphocytes. Its active metabolite inhibits the proliferation of T and B cells.[58] Similar to methotrexate, MMF treatment could be used to treat patients with SLE with arthritis. It is also used for patients with SLE with renal symptoms. It has been demonstrated to be superior to azathioprine as maintenance therapy of LN.[70] Patients with SLE and nephritis have a much better response with a 6-month induction trial of mycophenolate versus azathioprine for prolonging time to treatment failure, time to renal flare, and time to rescue therapy. MMF belongs to the Risk Evaluation and Mitigation Strategy (REMS) drug safety program and cannot be prescribed by those who are not REMS certified. MMF is teratogenic (pregnancy category D) and should not be used in pregnant females or in those who plan to become pregnant. It could cause birth defects and reduces the effectiveness of oral contraceptives. Females who take this drug should wait at least 1 to 3 months after stopping the drug before trying to conceive. Common side effects are dose dependent and may include GI symptoms (eg, nausea, vomiting, and diarrhea), risk of infection, hepatotoxicity, and decreased white blood cell counts.[53] Monthly laboratory monitoring

for hematologic, hepatic, and renal toxicities is mandatory for patients taking MMF.

Case 33-3, Question 7: J.B.'s daughter has also been diagnosed with SLE. She is 25 years old and is married. She and her husband want to start a family. J.B. heard about MMF as one of the treatment options for SLE. She asks you if her daughter can benefit from taking MMF.

MMF is not an option because it is teratogenic and has been associated with infertility even though it is classified as pregnancy category D. Furthermore, MMF has risk of causing birth defects if taken during pregnancy (ie, cleft lip/palate or ear malformations). Females who take this drug should wait at least 1 to 3 months after stopping the drug before trying to conceive.

Cytotoxic Drug

Cyclophosphamide (Cytoxan®) is an alkylating agent. Its active metabolite, aldophosphamide, interferes with DNA links and causes cell death.[52] It is the agent of choice for treatment of LN, severe CNS, lung, or hematologic manifestations.[53,71] It is teratogenic (pregnancy category D) and should not be used in pregnant females or in those who plan to become pregnant. Cyclophosphamide has been reported to cause birth defects, especially if taken during the first trimester. Birth defects may include growth restriction, ear and facial abnormalities, hypoplastic limbs, and absence of digits.[72] Cyclophosphamide has a serious adverse effect profile that includes hemorrhagic cystitis, bacterial and viral (herpes zoster) infections, and infertility. Its metabolite, acrolein, is toxic to the bladder. Hemorrhagic cystitis and bladder cancer risks can be minimized by hydrating the patient (orally and via IV), frequent bladder emptying, and using mesna (sodium 2-mercaptoethane sulfonate) as a protectant before IV use.[53] Mesna is a sulfhydryl donor that binds and detoxifies acrolein.[73] Urinalysis testing and monitoring for hematuria should be performed regularly. If the patient develops hemorrhagic cystitis, cyclophosphamide therapy should be

discontinued. The risk of bladder cancer is increased after receiving a total dose of 30 g.[62]

Because immunosuppressants and cyclophosphamide can increase the prevalence of secondary malignancies, such as cervical cancer in female patients with SLE, the ACR recommends annual Papanicolaou (Pap) exams as part of laboratory monitoring.[53,74] Infertility, from ovarian failure in females or azoospermia in males, can occur in patients with SLE and of childbearing age.[7] Gonadotropin-releasing hormone analogs may preserve gonadal protection and can be considered for patients who are concerned with infertility associated with cyclophosphamide.

Case 33-3, Question 8: J.B. asks you what other commonly used drugs for SLE treatment should her daughter avoid taking if she wanted to become pregnant?

Other than MMF, her daughter should avoid taking leflunomide (pregnancy category X), MTX (pregnancy category X), and cyclophosphamide (pregnancy category D) for treatment of her SLE if she plans to get pregnant. Females should use oral contraceptives or other forms of effective birth control methods while taking leflunomide. More importantly, they should continue to do so until 2 years after discontinuation of leflunomide because its active metabolite, teriflunomide, remains in the plasma. Cholestyramine (Questran®) can be used to accelerate the elimination of leflunomide and reduce the plasma levels of teriflunomide.[65] Males and females who take MTX should stop 1 to 3 months before trying to conceive. The 3-month period allows the complete elimination of MTX from the body. Cyclophosphamide has been reported to cause birth defects, especially if taken during the first trimester. Birth defects may include growth restriction, ear and facial abnormalities, hypoplastic limbs, and absence of digits.[70]

Case 33-3, Question 9: Over the next couple of months, J.B. continues to have mild-to-moderate flares of her skin and joints because of SLE, despite

hydroxychloroquine therapy. Her primary care physician is considering cyclophosphamide for her. What common toxicity should J.B. be monitored for?

J.B. should be monitored for bladder toxicity. Acrolein, a compound of one of cyclophosphamide's active metabolite aldophosphamide, is toxic to the bladder epithelium and could cause hemorrhagic cystitis.[75] Hemorrhagic cystitis is associated with hematuria and occasional dysuria.

Case 33-3, Question 10: How is the risk of bladder toxicity reduced?

By administering mesna and plenty of fluids (orally and via IV), the risk of bladder toxicity is reduced. Pulsed or intermittent dosing of cyclophosphamide can decrease the cumulative drug dose and reduce bladder exposure to acrolein.

Case 33-3, Question 11: Considering her present symptoms, should J.B. be initiated on cyclophosphamide?

Because her symptoms are still mild to moderate without signs of CNS, lung, or renal complications, cyclophosphamide is not recommended. Cyclophosphamide is primarily reserved for treatment of LN and severe CNS associated with SLE, lung, or hematologic manifestations.

Biologic Therapies

Rituximab (Rituxan®) is a chimeric monoclonal antibody that has activity against protein CD20. CD20 is expressed from early pre-B cells to those later in differentiation; however, it is absent in terminally differentiated plasma cells. The proposed mechanism of action of rituximab includes its Fc portion that mediates antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity, resulting in apoptosis of $CD20^+$ cells.[76] Efficacy of rituximab against SLE was studied in two phase III randomized

placebo-controlled trials, The Lupus Nephritis Assessment with Rituximab (LUNAR) and The Exploratory Phase II/III SLE Evaluation of Rituximab"(EXPLORER), which did not meet the studies' primary end point.[77,78] Data regarding the use of rituximab in managing SLE manifestations, particularly cutaneous lupus erythematosus, are limited. Rituximab is currently used by international expert groups for the off-label management of severe renal disease, CNS involvement, or severe autoimmune thrombocytopenia associated with SLE.[79]

Belimumab (Benylsta®) is the first biologic agent approved for adjunctive treatment of SLE in patients with active, autoantibody-positive SLE. It is a human IgG1 lambda monoclonal antibody against the B lymphocyte stimulator (BLyS). Belimumab is also referred to as a B-cell–activating factor (BAFF)-specific inhibitor. B cells have three membrane receptors: B-cell maturation antigen, transmembrane activator and calcium modulator and cyclophilin ligand interactor, and the BAFF receptor.[18] BAFF is involved in B-cell survival, activation, and differentiation. It is elevated in patients with B-cell–mediated autoimmune diseases, such as SLE.[80] Belimumab is hypothesized to decrease the amount of abnormal B cells ($CD20^+$ B cells).

Phase II clinical trials reported that belimumab combined with standard therapy offered a better response to patients with active SLE versus standard therapy alone.[80,81] Belimumab's efficacy was further demonstrated in two phase III randomized placebo-controlled clinical trials Belimumab in Subjects with Systemic Lupus Erythematosus (BLISS-52 and BLISS-76). A total of 1684 patients were randomized to receive either belimumab or placebo in combination with standard therapy.[82,83] The combination of belimumab and standard therapy was found to be superior to placebo plus standard therapy. Furthermore, the combination of belimumab and standard therapy was well tolerated, improved SLE Responder Index response rates, and reduced disease activity and severe flares.[82,83] Belimumab has not been studied in patients with severe active LN or severe active CNS lupus; therefore, it cannot be recommended for use in patients with these symptoms. More importantly, it is not recommended to be administered in combination

with other biologics or IV cyclophosphamide because it has not been studied in these settings.

Possible side effects (≥5%) of belimumab may include diarrhea, nausea, fever, insomnia, nasopharyngitis, pharyngitis, bronchitis, extremity pain, migraine, and depression.[84,85] More common side effects reported from the belimumab study group were serious infections, primarily upper respiratory tract infections.[84] Therefore, patients being treated for chronic infections should not start belimumab therapy. If an infection develops while receiving belimumab, temporary discontinuation of the drug is recommended. From clinical trials, mortality (resulting from infection, cardiovascular disease, and suicide) was increased in patients receiving belimumab versus those on placebo therapy.[80–83] Hypersensitivity reactions, including infusion reactions and anaphylaxis, may occur. Patients should be closely monitored for potential side effects and reactions.

Belimumab is administered parenterally as an IV infusion over 1 hour (**Table 33-2**). Premedication with an antihistamine for prophylaxis against infusion-related reactions and hypersensitivity reactions is recommended as part of the therapy. No dosage adjustments are required for patients with hepatic and renal impairment.

Table 33-2

Preparation and Administration Instructions of Belimumab

Reconstitution

Reconstitution
Remove belimumab vial from refrigerator and allow it to stand for 10–15 minutes to reach room temperature. Reconstitute belimumab powder with Sterile Water for Injection, USP, as follows, with reconstituted solution to make a concentration of 80 mg/mL belimumab. Reconstitute 120-mg vial with 1.5-mL sterile water. Reconstitute 400-mg vial with 4.8-mL sterile water. Direct the stream of sterile water to the side of the vial to minimize foaming. Gently swirl the vial for 60 seconds. Allow vial to sit at room temperature during reconstitution, gently swirling the vial every 5 minutes until powder is dissolved. *Do not shake.* It usually takes 10–15 minutes, but it may take up to 30 minutes. Protect solution from light. If a mechanical reconstitution device (swirler) is used to reconstitute belimumab, it should not exceed 500 rpm, and the vial should not be swirled for longer than 30 minutes. Once reconstitution is complete, the solution should be opalescent and colorless to pale yellow and without particles. Small bubbles can occur and are acceptable.
Dilution Instructions
Belimumab should only be diluted with 0.9% sodium chloride injection, USP (normal saline). Dextrose IV solutions are incompatible with belimumab. Dilute the reconstituted product to 250 mL in normal saline for IV infusion. From a 250-mL infusion bag or bottle of normal saline, withdraw and discard a volume equal to the volume of the reconstituted solution of belimumab required for the patient's dose. Then add the required volume of reconstituted solution into the infusion bag or bottle. Discard any unused solution. Inspect visually for any particular matter and discoloration before administration. Discard if present. Use reconstituted solution immediately, otherwise it should be stored protected from sunlight and refrigerated at 36–46 °F (2–8 °C). Solutions of belimumab diluted in normal saline may be stored at 36–46 °F (2–8 °C) or room temperature. The time from reconstitution to completion of infusion should not exceed 8 hours. No incompatibilities exist between belimumab and polyvinyl chloride or polyolefin bags.
Administration Instructions
Administer the diluted solution of belimumab by IV infusion only, over a period of 1 hour. Belimumab should be administered by health care professionals prepared to manage anaphylaxis. Do not infuse belimumab concomitantly in the same IV line with other agents.

IV, intravenous; USP, US Pharmacopoeia.

Case 33-3, Question 12: Over the next year, J.B. continues to have bothersome symptoms associated with her SLE, despite hydroxychloroquine therapy. She resists the recommendation to use steroids because of risks of weight gain, osteoporosis, and vision problems. She is excited to hear about a recently approved drug for SLE, belimumab. J.B. asks you, "What is the mechanism of action of belimumab?"

Belimumab is a monoclonal antibody that inhibits the B-cell survival factor, BLyS. As a BLyS-specific inhibitor, belimumab blocks the binding of BLyS to receptors on B cells, thus inhibiting the survival of B cells including autoreactive B cells. It also reduces the differentiation of B cells into immunoglobulin-producing plasma cells. Belimumab reduces disease activity and, possibly, a number of severe flares and steroid use when administered in combination with standard therapy. It is approved for treatment of patients with active, autoantibody-positive lupus in combination with standard therapies (ie, hydroxychloroquine, azathioprine, and MTX).

Case 33-3, Question 13: How is belimumab dosed and administered?

Belimumab is given at a recommended dose of 10 mg/kg that is administered via IV as an infusion over 1 hour, 2 weeks apart for the first three doses, and 4 weeks apart thereafter.

Case 33-3, Question 14: What are the necessary precautions taken before administration of belimumab?

Antihistamine premedication is recommended as a prophylaxis to prevent infusion reactions and hypersensitivity reactions. Patients should be monitored before and after drug administration. Belimumab should be used with caution in patients with chronic infections. Infections were the most common adverse events

associated with belimumab in BLISS-52 and BLISS-76 clinical trials. Upper respiratory tract infections were the most common type, occurring in >5% of patients taking belimumab.

Case 33-3, Question 15: When is belimumab not recommended for use in patients with SLE?

Belimumab is not recommended in patients with severe active LN, or in those with severe active CNS lupus because its efficacy has not been evaluated in these types of patients. Furthermore, depression and suicidality have been reported in clinical trials; therefore, it is not recommended for patients with uncontrolled psychiatric disorders. Belimumab is not recommended in combination with other biologics or IV cyclophosphamide because it has not been studied with these drugs.

Case 33-3, Question 16: Are there drug–drug interactions between belimumab and other combination treatments for SLE?

No clinically significant drug–drug interactions have been identified with belimumab in the clinical trials. It was administered concomitantly with corticosteroids, antimalarial drugs, statins, NSAIDs, angiotensin-converting enzyme inhibitors, and immunomodulatory and immunosuppressive agents.

Case 33-3, Question 17: Can J.B. receive immunizations while receiving belimumab treatment?

Live vaccines should not be administered in the 30 days before treatment starts or during treatment. Belimumab may interfere with J.B.'s response to immunizations.

Table 33-3 summarizes the current medications used for treating SLE.[53,58,74,84,85] There are drug interactions with the medications used for treating SLE symptoms. **Table 33-4** summarizes the possible significant drug–drug interactions.[86,87]

Table 33-3

Medications Used for the Treatment of Systemic Lupus Erythematosus (SLE)

Medication	FDA-Approved for SLE	Dose	Side Effects/Toxicities	Monitoring Parameters
Anifrolumab	Yes	300 mg given IV over 30 minutes every 4 weeks	Upper respiratory tract infection, bronchitis, infusion-related reactions, herpes zoster, cough, and serious infections (rare)	Signs and symptoms of infections and hypersensitivity reactions, including anaphylaxis
Azathioprine	No; off label	1–3 mg/kg/day	Bone marrow suppression, liver toxicity, elevated lymphocytes	Clinical: symptoms of infection Laboratory: CBC and platelet count every 1–2 weeks with initiation and dosage changes, then every 1–3 months; monitor LFTs and Scr; Pap test at regular intervals
Belimumab	Yes	IV: 10 mg/kg every 2 weeks for the first three doses and then administer monthly	Serious infusion and anaphylactic reactions; depression with suicidal ideation	Clinical: symptoms of allergic reaction, including hypotension, angioedema, rash, urticarial, pruritus, and difficulty breathing Symptoms of common infusion reactions, including headache, nausea, and skin reactions Symptoms of infection, including fever, nausea, diarrhea; chest pain or shortness of breath Laboratory: CBC monthly
Corticosteroids	No; off label	Prednisone (or equivalent) 0.125–1 mg/kg/day	Elevated blood pressure, glucose and cholesterol levels; low potassium or reduced potassium levels; reduced bone density; cataracts; weight gain; infections; and fluid retention	Clinical: symptoms of high blood sugar, edema, shortness of breath, high blood pressure, visual changes, bone pain. CNS symptoms of depression, suicidal ideation, insomnia, or other mood changes can occur at higher doses (eg, prednisone >60 mg). Laboratory: glucose every 3–6 months, cholesterol annually, BP at each visit, bone density

Cyclophosphamide	No. off label	IV: 0.5–1 g/rrr' monthly; Oral: 1–2 mg/kg/day	Bone marrow suppression, mallgnancy, immunosuppression. hemorrhagic cystltis, secondary Infertllity	Cllnical: symptoms of infection and presence of blood in urlne Laboratory: CBC and urinalysis monthly, urlne cytology and Pap test annually for life
HydroKychloroquine	Yes	200–400 mg twice daily	Ophthalmic damage, conduction abnormalities, cardiomyopathy	Cllnical: visual changes Laboratory: funduscoplc and visual fieid examlnation, frequency determined by risk, creatine kinase, lactate dehydrogenase, and/or troponins
Leflunomide	No: ofI label	Loadlng dose: 100 mg daily × 3 days, followed by 20 mg daily. *or* 100 mg weekly × 3 weeks, then 20 mg daily Leflunomide-associated hepatotoxicityor leflunomide-associated myelosuppression: 20 mg daily without a loading dose	Diarrbea, nausea, rash, liver toxicity, myelosuppression	Cllnical: frequency and severlty of dlarrhea Laboratory: LFts, CBC
Methotrexate	No. off label	Oral: 5–15 mg as a single weekly dose a can be given as three divided doses/week given every 12 hours (ie, 2.5 mg × 3 doses wlth 12 hours apart)	Bone marrow suppression, lung and liver toxicity, infection	Clinical: symptoms of infection, shortness of breath, nausea, vomiting Laboratory: Initial chest x-ray, CBC and platelet count monthly, LFTs, albumin, Scr every 4–8 weeks
Mycophenolate mofetil	No. off label	1000–3000 mg daily	Bone marrow suppression, liver toxicity and Infection	Cllnical: symptoms of infection Laboratory: CBC and platelet count every 1–2 weeks with initlation and changes In dosage (then every 1–3 months), monitor LFTs and Scr, monitor changes in BP
NSAIDs	No. off-labef	Product dependent	GastroIntestinal bleeding, liver and kidney toxicity, elevated biood pressure	Clinical: dark/black stool, upset stomach, nausea, vomiting, abdominal pain, edema Laboratory: CBC, LFTs and Scr annually, BP at each visit

BP, blood pressure; CBC, complete blood count; CNS, central nervous system; IV, intravenous; LFTs, liver function tests; NSAIDs, nonsteroidal anti-inflammatory drugs; SCr, serum creatinine.

[a]Aspirin is approved for treatment of SLE.

Table 33-4

Summary of Drug Interactions With Medications for Systemic Lupus Erythematosus

Medication	Possible Interaction With Concomitant Drugs
Azathioprine	Allopurinol, ACE inhibitors, cyclosporine, etanercept, everolimus, febuxostat, infliximab, leflunomide, mycophenolate sodium, mercaptopurine, ribavirin, sulfamethoxazole/trimethoprim
Belimumab	Tofacitinib
Corticosteroids	Erythromycin, ketoconazole, mifepristone, hormonal contraceptives, NSAIDs, protease inhibitors, rifampin, tacrolimus
Cyclophosphamide	Carbamazepine, ceritinib, cyclosporine, doxorubicin, etanercept, fosphenytoin, nevirapine, nilotinib, protease inhibitors, St John's wort, phenytoin, tamoxifen, tofacitinib, warfarin
Hydroxychloroquine	Antacids, cyclosporine, digoxin, haloperidol, quinidine, other QT-prolonging drugs, tacrolimus
Leflunomide	Acyclovir, atorvastatin, baricitinib, bosentan, ciprofloxacin, elagolix, furosemide, glyburide, grazoprevir, irinotecan, methotrexate, montelukast, paclitaxel, pitavastatin, rosuvastatin, simvastatin, sulfasalazine, tenofovir alafenamide, topotecan, valacyclovir, warfarin
Methotrexate	Amoxicillin, aspirin, diclofenac, doxycycline, fosphenytoin, indomethacin, leflunomide, levetiracetam, NSAIDs, penicillin, phenytoin, piperacillin, probenecid, proton-pump inhibitors, sulfamethoxazole/trimethoprim, sulindac, tamoxifen, warfarin
Mycophenolate mofetil and mycophenolate sodium	Antacids, amoxicillin/clavulanate, azathioprine, colestipol, cholestyramine, colesevelam, ciprofloxacin, isavuconazonium, metronidazole, oral contraceptives, proton-pump inhibitors, tofacitinib
NSAIDs	ACE inhibitors, angiotensin receptor blockers, β blockers, diuretics, other antihypertensives, lithium

Anifrolumab (Saphnelo™) is the latest human IgG1κ monoclonal antibody approved for the treatment of SLE. It binds to type 1 IFN receptor subunit 1 and inhibits the signaling activity of all type 1 IFNs.[76] Between 60% and 80% of adults with SLE show increased IFN-induced genes, which reflect an overproduction of the immune protein type 1 IFN. Anifrolumab's efficacy was investigated in a phase III, randomized, double-blind, placebo-controlled, parallel-group clinical trial Treatment of Uncontrolled Lupus via Interferon Pathway-2 (TULIP-2).[88] TULIP-2 followed the Treatment of Uncontrolled Lupus via Interferon Pathway-1 (TULIP-1) trial, which failed to meet its primary end point. The second trial used a different end point, the British Isles Lupus Assessment Group (BILAG)-based Composite Lupus Assessment (BICLA) response that measures both partial and complete improvement within an organ system. TULIP-2 was completed at the end of 2019 and involved 362 patients with moderate-to-severe disease who received a fixed dose of anifrolumab 300 mg by IV administration or a placebo once every 4 weeks for 48 weeks. TULIP-2 demonstrated that the anifrolumab group was superior to the placebo group in achieving the primary end point and disease–activity response. There was a significant percentage of patients in the anifrolumab group who had a reduction in overall disease activity in all active organs, improvement in lupus skin disease, a reduction in glucocorticoid drug doses, and a reduced annual rate of flare-ups over a period of 52 weeks.[88] Regarding the adverse events from the trial, there was one death from pneumonia in the anifrolumab group. Adverse events that occurred in at least 10% of the patients in the anifrolumab group included bronchitis and upper respiratory infection. Herpes zoster was reported to be more frequent in patients receiving anifrolumab than did placebo.

Nonpharmacologic Therapy

Both the ACR and EULAR recommend nonpharmacologic treatments as part of the management of SLE.[22,89] Sunscreens with a

sun protective factor of ≥15 should be used daily, preferably with a high protection factor (SPF 60) to prevent UV-induced skin lesions.[90] There are patients who are sensitive to UVA light and may require broader spectrum sunscreens (UVA and UVB). Patients are advised to apply broad-spectrum sunscreen each morning and before sun exposure. Vitamin D supplementation may be included in photoprotective methods. A randomized controlled trial of healthy adults showed that vitamin D supplementation helped reduce the expression of pro-inflammatory mediators, such as TNF-α and increased skin expression of the anti-inflammatory mediator arginase-1 and other genes related to skin barrier repair.[91] In short, photoprotection of patients with SLE includes wearing protective clothing, minimizing sun exposure, applying broad-spectrum sunscreen, and supplementing with vitamin D. Sunbathing and the use of sunbeds in tanning parlors are discouraged. Patients with SLE should also be educated about lifestyle modifications, such as smoking cessation, weight control, and regular exercise to reduce comorbidities of atherosclerosis, hypertension, and diabetes.[7] A meta-analysis showed an increased risk of developing SLE among patients who smoke as compared with nonsmokers.[92] Furthermore, smoking is found to be associated with reduced efficacy among patients with SLE receiving belimumab.[93] Psychosocial support is also an important aspect of management because the disease and several of the medications may cause depression and anxiety. The medications' side effects can also affect a patient's adherence to treatment and medical office visits.

DRUG-INDUCED LUPUS ERYTHEMATOSUS

Drugs can cause subacute cutaneous lupus erythematosus or drug-induced lupus (DIL) (<1%) by inducing autoantibodies.[4] For as many patients who develop these antibodies, a surprisingly low number of them do not develop signs of an autoantibody-associated condition.[2] Over 38 drugs have been implicated with causing the disease (**Table**

33-5).[43,94–96] However, most DIL cases have been associated with the following medications: hydralazine, procainamide, and quinidine.

Table 33-5

Drugs That May Cause Systemic Lupus Erythematosus

Drug Class	Very Low Risk	Low-to-Moderate Risk	High Risk
Antiarrhythmics	Disopyramide, propafenone	Quinidine	Procainamide
Antimicrobials/antibiotics	Nitrofurantoin	Isoniazid, minocycline	
Anticonvulsants	Phenytoin, primidone, ethosuximide	Carbamazepine	
Antihypertensives	Enalapril, clonidine, atenolol, labetalol, pindolol, minoxidil, prazosin, chlorthalidone, hydrochlorothiazide	Captopril, methyldopa, acebutolol	Hydralazine
Anti-inflammatories	Phenylbutazone	Sulfasalazine, D-penicillamine	
Antipsychotics	Perphenazine, phenelzine, chlorprothixene, lithium	Chlorpromazine	
Anti-thyroids		Propylthiouracil	
Miscellaneous	Lovastatin, levodopa, interferon-α, timolol eye drops		

Sources: Vedove CD, Giglio MD, Schena D, Girolomoni G. Drug-induced lupus erythematosus. *Arch Dermatol Res*. 2009;301:99–105; Marzano A, Vezzoli P, Crosti C. Drug-induced lupus: an update on its dermatologic aspects. *Lupus*. 2009;18:935–940; Hussaini MA, Hammouda EI, Hammouda AE. Optimizing pharmacotherapy of systemic lupus erythematosus: the pharmacist role. *Int J Clin Pharm*. 2014;36:684–692.

The symptoms of DIL may present as arthralgia or myalgias, fatigue, malar rash, erythema multiforme-like, and the presence of anti-histone antibodies. The symptoms are similar to those of SLE; however, they are generally not as severe. Typically, the symptoms are self-limiting and resolve after discontinuing the offending drug. NSAIDs may be used to help speed up the healing process. Corticosteroids may also be used if more severe symptoms of DIL are present. The development of DIL occurs over the long term and from chronic use of medications that have high risk for causing lupus.

The mechanism by which these drugs exert their effect is not well understood. However, it may be attributed to a patient's genetic predisposition as a slow acetylator, which decreases the metabolism of some drugs such as procainamide and hydralazine. Gene expression is regulated by DNA methylation and histone modifications.[95,96] Procainamide and, particularly, hydralazine are hypothesized to inhibit DNA methylation, which alters gene expression in T lymphocytes. Subsequently, this process induces an

overexpression of lymphocyte function-associated antigen 1 (LFA-1 antigen), thereby resulting in autoreactivity.[29,94]

INVESTIGATIONAL AGENTS

Aside from the current therapies used for the treatment and management of SLE symptoms, newer therapeutic agents are being investigated for their activities against the immune system, such as the B cells, T cells, IFN, and cytokines that are involved in patients with SLE. Investigational biologic agents are being developed and undergoing phase I, II, and III clinical trials. These newer biologic agents specifically target different phases of the pathogenesis of SLE, have different mechanisms of action, and possess milder adverse effect profiles. The investigational drug classes include immune cell–targeted therapies, anti-cytokine therapy, therapies targeting costimulatory signaling pathways, and neutralizing monoclonal antibody against IFN-α.[58]

TREATMENT APPROACHES

The primary goal of treatment for SLE is to control acute flares, and maintenance strategies are used to suppress symptoms and to prevent further organ damage. NSAIDs, hydroxychloroquine, and low-dose corticosteroids are considered maintenance therapy to control mild-to-moderate symptoms of arthritis, dermatitis, and constitutional symptoms. High-dose systemic corticosteroids, DMARDs, immunosuppressants, belimumab, and anifrolumab are used for patients with more serious active disease, including those with more life-threatening forms such as LN.[71] Certain DMARDs and immunosuppressants (ie, leflunomide, MTX, cyclophosphamide, and MMF) should be used with extreme caution in females of childbearing age and in those who are planning to get pregnant

because of teratogenic effects.[7] MMF is the preferred maintenance therapy for LN in patients who can tolerate the medication, who are not pregnant, and who respond to it. It can reduce the effectiveness of oral contraceptives and, thus, additional or alternative nonhormonal methods of birth control should be considered. Currently, only hydroxychloroquine, belimumab, and anifrolumab are FDA approved for the treatment of SLE. Immunosuppressants and DMARDs (ie, azathioprine, cyclophosphamide, leflunomide, MTX, and MMF) have been used off label for managing SLE symptoms for years. Prophylaxis with aspirin or long-term anticoagulation should be considered in patients with antiphospholipid antibodies and who are at an increased risk for thrombosis.[18] Patients with mild disease require frequent medical evaluations every 3 to 6 months. On the contrary, patients with inactive disease may benefit from being monitored every 6 to 12 months.

ROLE OF PHARMACISTS

SLE disease is very complex, and the symptoms are variable. Successful and effective management of SLE requires the involvement of a multidisciplinary health care team comprising many specialists (eg, rheumatology, cardiology, nephrology, dermatology, psychology, and ophthalmology) and pharmacists. Pharmacists have an important role in caring for patients with SLE, especially with education, management of their medications, and the monitoring of drug–drug or drug–herbal interactions. As part of the health care team, pharmacists can provide drug education and counseling to patients with respect to proper administration of the medications, common side effects, management of the side effects, and reinforcement of adherence to their medications and office visits. Education and counseling of the teratogenic effects of certain DMARDs and immunosuppressants should be offered, as well as the information that the disease should remain inactive for at least 6 months before attempting to conceive.[53] More importantly,

pharmacists can provide education to help patients with SLE maintain a healthy lifestyle and better quality of life (eg, regular weight-bearing exercise, sufficient dietary vitamin intake, smoking cessation, and limited alcohol intake to a minimum of two drinks daily).[97,98]

CASE 33-4

QUESTION 1: S.P., a 35-year-old Asian female with a 10-year history of SLE, sees you for follow-up management of her medications. She currently takes hydroxychloroquine 200 mg orally (PO) daily as part of her maintenance regimen. S.P. reports experiencing some heartburn and bloating symptoms over the past several days and purchases an over-the-counter antacid, calcium carbonate. Calcium carbonate has helped alleviate her GI symptoms; however, she notices feeling more fatigued lately.

What is the potential drug interaction between hydroxychloroquine and calcium carbonate?

Antacids that contain calcium carbonate, magnesium, or aluminum (ie, Tums®, Maalox®) can interfere with the absorption of hydroxychloroquine and reduce its effectiveness when taken at the same time.

CASE 33-4, QUESTION 2: As her pharmacist, what advice would you provide to S.P. regarding the appropriate administration of hydroxychloroquine and calcium carbonate?

S.P. should be advised to separate the administration of hydroxychloroquine and calcium carbonate by at least 4 hours to reduce the risk of a drug interaction. No clinically significant drug–drug interactions have been reported for concomitant use of hydroxychloroquine and histamine (H_2) receptor antagonists.

CASE 33-4, QUESTION 3: What other counseling points could you offer to S.P. about her health?

S.P. should be advised to incorporate a heart-healthy exercise regimen (low-impact aerobic exercise, such as walking, swimming, or Pilates) and diet (a low-sodium, low-fat, and low-carbohydrate regimen) to reduce modifiable cardiovascular risk factors and on approaches to maintain adequate rest. Counseling should also be provided regarding the use of sunscreen, vitamin D supplementation and adequate calcium intake, smoking cessation, maintenance of schedule immunizations, and prompt management of infections.

Kidney and Liver Transplantation

David J. Taber, Robert E. Dupuis, Nicole A. Pilch, and Kristen Szempruch

CORE PRINCIPLES		CHAPTER CASES
1	Successful kidney transplantation involves rigorous evaluation of both donor and recipient. This results in immunologic categorization as either a high-risk or low-risk transplant and determines the immunosuppressive regimen an individual recipient should receive. The majority of these patients will receive combination therapy, which includes a calcineurin inhibitor, an antiproliferative agent, and a corticosteroid.	**Case 34-1 (Question 1), Table 34-1**

CORE PRINCIPLES		CHAPTER CASES
2	Induction therapy is used in most kidney transplant cases. Rabbit antithymocyte globulin (rATG), alemtuzumab, and basiliximab are common agents. Differences among these agents include dosing regimen and side effect profile. rATG and alemtuzumab are often used in high-risk patients, including those with delayed graft function, whereas basiliximab is frequently used in low-risk recipients.	**Case 34-1 (Questions 2–6)**
3	Immunosuppressive combination therapy is directed at prevention of rejection. Acute rejection can be either T-cell mediated or B-cell mediated. T-cell–mediated rejection can be successfully treated, whereas B-cell–mediated rejection is much more resistant. Despite success in reducing acute rejections, chronic rejection and chronic graft dysfunction are major causes of graft loss.	**Case 34-1 (Questions 7–9)**

CORE PRINCIPLES		CHAPTER CASES
4	The calcineurin inhibitors cyclosporine and tacrolimus and steroids have significant toxicity profiles, particularly with chronic long-term use. Tacrolimus and cyclosporine are calcineurin inhibitors with a complex pharmacokinetic profile associated with multiple adverse effects and requires therapeutic drug monitoring (TDM). Calcineurin inhibitor–induced nephrotoxicity is a major problem. Steroids have a negative impact on the cardiovascular, bone, and endocrine systems. Several strategies have been developed in an attempt to either avoid or minimize these adverse effects.	**Case 34-2 (Questions 1, 2)** **Case 34-3 (Question 1)** **Case 34-5 (Question 2)**
5	The mammalian target of rapamycin (mTOR) inhibitors, sirolimus and everolimus, have complex pharmacokinetic profiles, significant adverse effects, and require TDM. These agents appear to be most useful in minimizing or avoiding the use of calcineurin inhibitors or other agents.	**Case 34-4 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
6	Liver transplantation is considered the treatment of choice for patients with end-stage liver disease. Common early posttransplant complications include surgical (biliary leaks and bleeding), neurologic (continued hepatic encephalopathy, drug toxicity), and infectious complications.	**Case 34-5 (Question 1)**
7	Acute rejection of the transplanted liver is a common, but usually reversible, consequence after this surgery. It is usually asymptomatic, but can be identified early through serial monitoring of serum transaminases and bilirubin, and definitively diagnosed only through liver biopsy. Treatment usually consists of pulse-dose corticosteroids, followed by a taper, or the use of rATG for more severe rejections or those refractory to steroid therapy.	**Case 34-5 (Questions 3–5)**

CORE PRINCIPLES		CHAPTER CASES
8	Mycophenolate is considered the adjuvant agent of choice in solid organ transplantation and is used to reduce calcineurin inhibitor exposure or augment immunosuppressant regimen potency. TDM is not common and has yet to prove effective in optimizing therapy. Common side effects of this agent include gastrointestinal issues (nausea, vomiting, and diarrhea) and cytopenias (leukopenia and thrombocytopenia).	**Case 34-6 (Question 1)**
9	Drug interactions with immunosuppressants are numerous and are commonly encountered clinical dilemmas in the transplant recipient. Pharmacists should prospectively screen for these interactions and, depending on their magnitude, may need to prospectively adjust medication regimens. Closer TDM or clinical monitoring is warranted when adding or removing an interacting medication to a patient on immunosuppression.	**Case 34-6 (Question 2), Table 34-2**

CORE PRINCIPLES		CHAPTER CASES
10	Cardiovascular complications, including hypertension, hyperlipidemia, and diabetes, are prevalent among kidney transplant recipients. These contribute to poor patient survival and graft loss. Other complications such as osteoporosis are frequently observed. Monitoring and treatment of these complications, which may be drug induced, are an important part of the posttransplant care plan.	**Case 34-7 (Questions 1–3)**
11	Posttransplant lymphoproliferative disorder (PTLD), which is usually a B-cell lymphoma, is the most common cancer encountered after organ transplant. Early PTLD is generally responsive to reductions in immunosuppression; advanced PTLD is usually not responsive to this nor to traditional chemotherapy. The use of rituximab, a monoclonal antibody directed against B cells, has shown promise in the treatment of this disease.	**Case 34-8 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
12	Infections, including opportunistic infections, are common complications after transplant. Prophylaxis with antimicrobial agents is critical for the most common and severe pathogens. Hepatitis B and hepatitis C are problematic after liver transplant and require immunoprophylaxis or treatment in certain circumstances.	**Case 34-9 (Question 1), Table 34-3**
13	Cytomegalovirus is the most common and debilitating opportunistic infection after solid organ transplantation. Reactivation or new infection with this virus can lead to severe tissue-invasive disease and, potentially, death. Indirect effects include acute rejection, chronic rejection, graft loss, and, potentially, lymphoma. Prophylaxis with potent antivirals (ganciclovir or valganciclovir) is the cornerstone of prevention. Treatment involves a long course of antiviral therapy, usually in conjunction with reductions in immunosuppression.	**Case 34-10 (Questions 1–3)**
14	BK polyomavirus is almost exclusively seen in kidney transplantation and is associated with graft loss. The best approach to reducing its occurrence is viral surveillance. If it is present, then reduction of immunosuppression appears to be the most effective treatment.	**Case 34-11 (Questions 1–3)**

INTRODUCTION

Solid organ transplantation, adult and pediatric, is an established therapeutic option for patients with end-stage kidney, liver, heart, and lung disease. For many of these patients, it is the only option. Pancreas or combined pancreas–kidney transplantation is available as a treatment for patients with diabetes with or without end-stage renal failure.

Unfortunately, many more patients are in need of transplantation than there are organs available. In 2021, about 30,000 organ transplants were performed by August 2021, whereas 117,260 people were waiting for all organs and over 97,000 for kidneys as of September 29, 2021 (UNOS.org). The donor pool has been expanded beyond traditional contraindications. Specifically, now hepatitis C–positive donors are frequently used for non-hepatitis C–positive recipients because of the potency of the new direct-acting antivirals (DAAs). Despite expansion of the donor pool and the focus on getting more living donors, about 6000 patients annually will die while on the waiting list.

Immunosuppression strategies continue to evolve. During the 1960s, azathioprine, prednisone, antilymphocyte serum, and antilymphocyte globulin made the success of kidney transplantation possible. In the 1980s, the introduction of cyclosporine had a remarkable impact on solid organ transplantation, and the first monoclonal antibody approved for human use, OKT3, was introduced, but is no longer available.

Since the 1990s, a number of other agents have been approved. These include tacrolimus, mycophenolate mofetil (MMF), enteric-coated mycophenolate sodium (EC-MPS), sirolimus (formerly rapamycin), and everolimus; monoclonal antibodies, such as basiliximab; a polyclonal antibody, antithymocyte globulin (ATG) (eg, rabbit antithymocyte globulin [rATG]); and belatacept. More recently, several agents, such as alemtuzumab, intravenous immunoglobulins (IVIGs), rituximab, eculizumab, and bortezomib, have been

incorporated into transplant protocols. Several new agents are undergoing investigation.

Although transplantation has a significant positive impact on the quality of life in most patients, rehospitalizations, retransplantation because of graft failure or disease recurrence, donation source (living-related and -unrelated organs), and costs to individuals, insurers, and society are major issues. For example, the average Medicare cost during the first year after kidney transplantation is $83,000 and during the second year is $25,000. After liver transplantation, first-year average Medicare cost is $190,000 (adjusted for inflation in 2021, this would convert to $219,299) and second year $30,000 (adjusted for inflation in 2021, this would convert to $34,626).[1,2] The ability of transplant recipients to pay for their medications or insurance denial or termination of coverage is another major issue.

The goal of immunosuppressive therapy is to prevent organ rejection, prolong graft and patient survival, and improve quality of life by helping to maintain graft function. Short-term (ie, 1- to 2-year) survival after transplantation has improved dramatically. Long-term survival also has improved, but not to the same degree.[3] As patients live longer after transplantation, the focus of therapy has shifted to survival and management of long-term complications. Immunosuppressive agents are associated with significant long-term complications. These include nephrotoxicity, hypertension, hyperlipidemia, osteoporosis, diabetes, infection, and malignancy. Many patients also have several pre- and posttransplant comorbidities and complicated drug regimens, which must be evaluated and managed. Pharmacists play an important role in these patient care activities.[4] Although acute rejection rates are significantly lower, this remains a problem, along with chronic rejection and/or chronic allograft injury (CAI) and long-term outcomes. The search for safer and more effective immunosuppressive regimens continues, along with a better understanding of optimal long-term immunosuppression to promote improved outcomes after 1 year posttransplant.[5] This chapter addresses the immunology of transplantation and rejection,

indications for kidney and liver transplantation, appropriate use of immunosuppressive agents, and the management of postoperative and long-term complications in these patients. Many of these issues are similar for the various types of solid organ transplantations, but there can also be significant differences. This chapter addresses some of these issues because they relate to kidney and liver transplantation.

TRANSPLANTATION IMMUNOLOGY

Successful organ transplantation has evolved from a greater understanding and application of pharmacology, microbiology, molecular and cellular biochemistry and biology, genetics, and immunology. Suppression of the host's immune system and prevention of rejection are vital for host acceptance of the transplanted organ. The ultimate goal is permanent acceptance or tolerance, a situation in which the new organ is seen as "self" by the host's immune system. In general, the currently used immunosuppressive drugs provide a nonpermanent form of tolerance and lifelong immunosuppression is required. A basic understanding of the immune system and the mechanisms of rejection is key to the effective use of immunosuppressive drugs in organ transplantation.

Major Histocompatibility Complex and Human Leukocyte Antigen

The degree to which allogeneic grafting (eg, donor and recipient from same species) is successful depends on the genetic similarities or differences between the donor organ and the recipient's immune system. The recipient recognizes the transplanted graft as either self or foreign. This recognition is based on the recipient's reaction to alloantigens or antigens (ie, substances that initiate an immune

response that can lead to rejection of the transplanted organ). These substances, also known as histocompatibility antigens, play a very important role in organ transplantation. The ABO blood group system of red blood cells is also important, and, in most cases, the donor and recipient should be ABO compatible; otherwise, immediate graft destruction can occur because of antibodies directed against the ABO antigens.

Histocompatibility antigens are glycoproteins that are located on the surface of cell membranes. These are encoded by the major histocompatibility complex (MHC) genes located on the short arm of chromosome 6. In humans, the MHC is called the human leukocyte antigen (HLA). The gene products encoded on the HLA are divided into classes I, II, and III based on their tissue distribution, antigen structure, and function. Class I antigens (HLA-A, HLA-B, and HLA-C) are present on all nucleated cell surfaces and are the primary targets for cytotoxic T-lymphocyte reactions against transplanted cells and tissues. The three class II antigens (HLA-DR, HLA-DQ, and HLA-DP) have a more limited distribution and are found on macrophages, B lymphocytes (B cells), monocytes, activated T lymphocytes (T cells), dendritic cells, and some endothelial cells, all of which can act as antigen-presenting cells (APCs). Individual HLA loci are extensively polymorphic. Each transplant recipient possesses two A, B, and DR antigens, one from each parent. This is called a haplotype. Recognition of these polymorphic loci by recipient T cells appears to account for rejection events. Class III antigens (C4, C2, and Bf) are part of the complement system.

Rejection of a transplanted organ is the outcome of the natural response of the immune system, innate and adaptive immunity, to a foreign substance, or an antigen, and is a complex process, the understanding of which continues to evolve. This process involves an array of interactions between antigens, T cells, macrophages, cytokines (soluble mediators secreted by lymphocytes, also called lymphokines [the interleukins or ILs]), adhesion molecules (also referred to as costimulatory molecules), and membrane proteins expressed on a wide variety of cells that enhance binding of T and B cells. This process of organ rejection ultimately can involve all

elements of the immune response, but it is predominantly T-cell mediated. This process can be divided into several important steps, which include antigen presentation, T-cell recognition, activation, proliferation, and differentiation of the various components of the immune response. For foreign antigens to interact with recipient T cells and B cells, they must be prepared for presentation by APCs. These APCs usually are recipient macrophages or dendritic cells (indirect pathway of allorecognition), although initially donor cells—dendritic cells or passenger leukocytes and graft endothelial cells—also can serve as APCs (direct pathway of allorecognition). This phase takes place within the blood, lymph nodes, spleen, and the transplanted organ.

Once antigens are prepared and presented, the next step (signal one) involves T-lymphocyte cell recognition of the antigen presented on the surface of the APC. The primary site for this to occur is at the CD3 (clusters of differentiation)–T-cell receptor (TCR) complex on recipient T cells. This step involves the binding of the antigen, MHC, and TCR for T-cell activation. These T cells also express other molecules on their surfaces that, along with CD3, recognize and respond to different types of antigens. These T cells are known as $CD4^+$ cells (T_H, helper or inducer T cells) and $CD8^+$ cells (T cells, cytotoxic or suppressor T cells). $CD4^+$ cells interact with class II antigens. $CD8^+$ cells interact with class I antigens.

In addition (signal two), proteins known as adhesion molecules or costimulatory molecules promote T-cell signaling and activation. For T-cell activation to occur, binding of these costimulatory molecules as well as binding of the TCR with the presented antigen and MHC is required. Examples of these molecules include intercellular adhesion molecule (ICAM)-1 found on APCs, which bind with the lymphocyte function–associated antigen expressed on the surface of T cells; ICAM-1 and ICAM-3 on APCs with CD2 on T cells; B7 (now called CD80 and CD86) on APCs with either CD28 or CTLA4 on T cells; and CD40 on APC with CD40 ligand (now called CD154) on T cells. The binding of costimulatory molecules is critical to T-cell activation.

Without this costimulation, T cells undergo abortive activation or programmed T-cell death (apoptosis).

Once recognition and costimulatory binding occur, T-cell activation and proliferation are initiated. After interacting with class II antigens and stimulation from IL-1 secreted from macrophages, T_H cells produce and secrete cytokines IL-2 and interferon (IFN)-γ. T_H cells are classified, according to their cytokine secretion pattern, into either T_{H1} or T_{H2} cells. T_{H1} cells secrete IL-2, IFN, and tumor necrosis factor (TNF), which stimulate cytotoxic T cells. T_{H2} cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13, which stimulate B cells. T_H cells, along with cytotoxic T cells, are stimulated to express cell-surface IL-2 receptors (IL-2R) and other cytokines. Once these T cells express IL-2R, they bind to IL-2 and other cytokines, which leads to signal transduction that results in proliferation, division, and stimulation of more T cells (signal 3). These committed cytotoxic T cells bind directly to allogeneic cells and produce cell lysis. T_H-secreted cytokines recruit other T cells, which results in further cytotoxicity. During this process, T_H cells also produce cytokines that trigger a cascade of events involving B cells and antibody production, complement fixation, increased macrophage infiltration, neutrophil involvement, fibrin deposition, platelet activation and release, prostaglandin release, and inflammatory response at the graft site. These delayed-type hypersensitivity and humoral responses occur in conjunction with one another and are not mutually exclusive. This results in cellular and tissue injury and graft destruction.

The antibodies produced by plasma cells, which are transformed B cells under the influence of cytokines, bind to the target antigenic cells. This leads to local deposition of complement and results in immune complexation and injury to the graft (complement-mediated cell lysis). The newly formed antibodies cause a series of interactions to occur with T cells, which lead to cytotoxicity (antibody-dependent, cell-mediated cytotoxicity). These cell-mediated and humoral immunologic events can impair organ function so significantly that without therapeutic intervention, complete organ

graft dysfunction may occur. Under certain circumstances, which are not clear, certain T cells cells, known as suppressor T cells, downregulate the immune response to alloantigen.[6]

Human Leukocyte Antigen Typing

The genetic compatibility between donor and recipient can have a major impact on acute rejection, graft function, graft survival, and patient survival. The liver is unique; however, blood type matching is the only immunologic matching that is done pretransplant currently. The liver has the unique ability to promote tolerance, allowing many patients to be on minimal immunosuppression long term.[7] However, in kidney transplantation, the closer the HLA matching is between recipient and donor, the better the outcome, particularly over the long term. To determine this compatibility, a number of laboratory tests, including serologic, flow cytometric, genetic-DNA based, and cellular assessments of donor and recipient serum and lymphocytes, are performed before organ transplantation. This process is referred to as *tissue typing*. Lymphocytes are typed for HLA-A, HLA-B, and HLA-DR. Typing for HLA is performed using the donor and recipient lymphocytes for serology-based techniques or tissue- or fluid-containing nucleated cells.[8]

The panel-reactive antibody (PRA) test is commonly used to assess organ compatibility because recipients may have HLA antibodies from previous exposure to antigenic stimuli (eg, blood transfusions, previous transplantation, and pregnancy). In this test, the recipient's serum is tested against a cell panel of known HLA specificities that are representative of possible donors in the general population. The percentage of cell reactions (recipient with potential donor) determines a recipient's PRA. It is done periodically on patients in the waiting list to determine their immunologic reactivity. The potential recipient with a higher percentage of PRA (>99%) is at higher risk for rejection and will generally a have longer wait time for a kidney than do patients with lower PRAs. In December 2014, that kidney allocation system was changed to provide additional priority

points to those patients with a PRA >99% to ensure they would be included in more offers with the intent of reducing their wait times.

A cytotoxic and/or flow cytometry lymphocyte cross-match is also performed before transplantation. In this case, the potential recipient's serum is cross-matched to determine whether preformed antibodies to the donor's lymphocytes are present. A positive cross-match indicates the presence of recipient cytotoxic IgG antibodies to the donor. In kidney transplantation, a positive cross-match is usually considered a contraindication. Recently, a number of transplant programs have utilized desensitization strategies to reduce the level of HLA antibodies present in potential recipients as a mechanism to reduce the likelihood of a positive cross-match with either identified living donors or future potential deceased donors. Common strategies to reduce these preformed HLA antibodies include serial delivery of plasmapheresis coupled with IVIG, rituximab, and bortezomib.[9] In liver transplantation, a positive cross-match is not an absolute contraindication because the need is urgent and because the liver appears to be more resistant immunologically to this type of reaction. These liver transplant recipients can, however, experience significant complications and early graft dysfunction. In kidney transplantation, organ allocation and matching now utilize a virtual cross-match in which potential recipients are listed with known unacceptable HLA antigens (those that have been preidentified in the patient). If a potential donor is identified with a specific HLA antigen that the recipient has known antibodies directed against, they will be skipped on the list.

ABO blood typing is one of the most critical of all evaluations when determining the genetic compatibility for all solid organ transplants. Transplantation of an organ with ABO incompatibility typically results in a hyperacute rejection and destruction of the graft, although in kidney transplant, newer therapeutic approaches to overcome ABO incompatibility have been successful.[8]

IMMUNOSUPPRESSIVE AGENTS AND MECHANISM OF ACTION

Immunosuppressives, based on an improved understanding of their mechanisms of action and the mechanisms of rejection, have had the most significant impact on patient and graft survival. The currently used immunosuppressives are shown in **Table 34-1**. These agents can be categorized as induction or maintenance therapy.[10] Sites of action and the role of the currently used agents are discussed here.

Table 34-1
Currently Used Immunosuppressive Agents

Drug (Brand Name)	Usual Dose/Route (How Supplied)	TherapeuCic Use(s)	Major Adverse Effects
Alemtuzumab (Campath-H1)	IV ot SC 0.3 mg/kg or 30 mg × I dose (30-mg vtal for Injection)	Prevention and treatment of acute cellular and antibody-mediated reiection; steroid-free protocols	Lymphopenia, leukopenia, Infectlon
Azathloprlne (Imuran)[1]	IV ot oral 1–3 mg/kg/day (50-mg tablet; 100-mg vial for injection)	As maintenance agent to prevent acute rejection	Leukopenia, thrombocytopenia, hepatotoxicity, nausea and vomitlng, diarrhea, pancreatitis, infection
Antithymocyte globulln, equine (Atgam)	IV 10–20 mg/kg/day (250 mg/5-mL ampoule for Injection)	Treat acute rejection (including severe or steroid-resistant forms), as induction agent in high-risk patient to prevent acute rejection	Anemia, leukopenia, thrombocytopenia, arthralgia, myalgias, nausea and vomiting, diarrhea, fevers, chilis, hypotension, tachycardia, anaphylaxis, infection
Antithymocyte globulin, rabbit (Thymoglobulin)	IV I 5 mg/kg/day given daily fot 4–10 days (25 mg/5-ml vial for injection)	Treat acute rejection (including severe or steroid-resistant forms), as Induction agent in high-risk patient to prevent acute rejection	Fever, chilis, nausea and vomit Ing, hypotension, neurropenia, flushtng, rash, itching, joint pain, myalgias, thrombocytopenia, infection
Basiliximab (Simulect)	IV 20 mg × 2 doses 10 mg, 2 doses for children if <35 kg (10- and 20-mg vial for injection)	As induction agent to prevent acute rejectlon	Abdominal pain, dizziness, msomnla, hypersensitivity reaction (rare)
Elelatacept (Nulojix)	IV Initial maintenance 10 mg/kg on days 0, 4, 14, and 28: and weeks 8 and 12 and monthly thereafter Conversion from CNI 5 mg/kg q 2 weeks for five doses, then q 4 weeks thereafter	As maintenance agent to pie vent acute rejection, converslon agent from CNIs in patients with Intolerances	Anemia, neutropema, diarrhea, UTIs, headaches, penpheral edema, PTLD
Cyclosporine[1] (Sandimmune)	Oiai 5–10 mg/kg/dose bid IV 1.5–2.5 mg/kg/dose (100 mg/mL oral solution; 25- and 100-mg cap sule: 250 mg/5-ml ampoule for injection)	As maintenance agent to prevent acute rejection	Nephrotoxlcity, hypertension, neurotoxicity, hair growth, glngival hyperplasia, hyfierglycemia, hyperkalemia, dyslipidemia, hypomagnesemia, Infection, neoplasm
Cyclosporine (Neoral, Gengraf, various others)[1]	Oral 4–8 mg/kg/day bid (100-mg solution: 25-, 50-, and 100-mg capsuies)	As maintenance agent to prevent acute rejection, converslon agent from tacroilmus in patients with intolerance	Same as given earlier
Everolimus (Zortress)	Oral 0.5–1.5 mg bid (0.25-, 0 5-, 0.75-mg tablets)	As maintenance agent to prevent acute rejection: converslon agent from CNI In patients with intolerance or poor response	Dyslipidemia, thrombocytopenia, neutropenia, impaned healing, mouth uicers, proteinuria, pneumonitis (rare)
Methyiprednisolone[1] sodium succlnate (Solu-Medrol, various others)	10–1000 mg/dose (40-, 125-, 250-, 500-, 1000-, and 2000-mg vial for injection)	As induction and maintenance agent to prevent acute rejection; to treat acute rejection	Hyperglycemia, psychosis, euphoria, Imfaired wound healing, osteoporosls, acne, peptic uicers, gastritis, fluid, electrolyte disturbances, hypertension, dyslipidemia, leukocytosis, cataracts, cushingoid state, infection, Insomnia, irritabillty

Mycophenolate* mofetll (CellCept)	1.5–3 0 g/day bid IV/PO (250-mg capsule: 500-mg tablet: 200 mg/mL oral suspension: 500-mg vial for injectlon)	As maintenance agent to prevent acute rejection; conversion agent from azathioprine and sirolimus In patients with intolerance or poor response	Diarrhea. nausea and vomlting. neutropenia. dyspepsia. ulcers. Infection. thrombocytopenla. anemla
Mycophenolate' sodium (Myfortic)	360–720 mg PO bid (180- and 360-mg tablets)	As maintenance agent to prevent acute rejection Alternative to MMF	Simllar side effect profile as MMF
Prednisone" (Deltasone)	Oral 5–20 mg/day (1-, 2.5-. 5-, 10 . 2 0 . 5 0 . and 100-mg tablet)	As maintenance agent to prevent acute rejection	See methylprednisolone
Sirolimus" (Rapamune)	Oral 2–10 mg/day (0.5-, 1-, and 2-mg tablet; 1 mg/mL oral solution)	As maintenance agent to prevent acute rejection; conversion agent from CNI or mycophenolate or azathioprine in patients with Intolerance or poor response	Dyslipidemia. thrombocytopenia. neutropenia. anemia. diarrhea. impaired healing. moutti ulcers. proteinuria. pneumonltis (rare)
Tacrolimus (Prograf. Astagraf XL. Envarsus XR)*	Oral 0 15–0.3 mg/kg/day bid IV 0.025–0.05 mg/kg/day as continuous infuslon (0.5-. 1-, and 5-mg capsule; 5 mg/mL ampoule for injection) Astagraf XL oral 0 1–0.2 mg/kg/day once daily (0.5-. 1-. and 5-mg capsules) Envarsus XR: oral 0 1–0.2 mg/kg/day once daily 80% of total daily dose of tacrolimus when converting from Immediate-release formulation (0.75 . 1-. and 4-mg tablets)	As maintenance agent to prevent acute rejection; conversion agent from cyclosporine in patients with Intolerance or poor response	Nephrotoxicity. hypertension. neurotoxicity. alopecia. hyperglycemia. hyperkalemia. dyslipidemia. hypomagnesemia. infection. neoplasm
Bortezomib (Velcade)	1.3 mg/m' on days 1. A. 8. and 11 IV bolus or SC (3 5-mg single-use vial)	Inhiblts plasma cells	Bone marrow suppression. thrombocytopenia. neuropathy. hypotension. gastrointestinal
Eculizumab (Sollris)	600- to 1200-mg IV infusion (300-mg single-use vial |30 mL of 10 mg/mL soiution|)	Inhibits complement	Infuslon reaction. headache. hypertension. leukopenia. Infections
Rituximab (Rituxan)	375 mg/m² x 1–5 doses or 500 mg/m² single-dose IV infusion (100- and 500-mg single-use vial. in 10-mg/mL concentration)	Inhiblts B-cell production	Infuslon reactions (fever. chills. rigors); pain at mfusion site. infections
Intravenous Immunoglobulin (Carimune NF. Flebogamma. Gammagard S/D. Gamunex. Iveegam EN. Octagam, Polygam)	100 mg/kg to 2-gfkg IV infusion (vial size varies based on manufacturer. ranglng from 1.2.5. 5. 6. 10. 12. 20. 30. and 40 g: usually concentrations are 5% and 10%)	Immonomodulation of T and B cells and/or immunoglobulin replacement	Infusion reactions (fever. chills. rigors); pain at infusion site. thrombosis. hemolytic anemia, acute renal failure, septic meningitis

bid, twice daily; CNI, calcineurin inhibitor; IV, intravenous; MMF, mycophenolate mofetil; PO, orally; PTLD, posttransplant lymphoproliferative disorder; q, every; SC, subcutaneous; UTI, urinary tract infection.

[a]Generic products available.

Maintenance

AZATHIOPRINE

Azathioprine is a prodrug of 6-mercaptopurine (6-MP). Azathioprine and 6-MP are purine antagonist antimetabolites. The introduction of cyclosporine, tacrolimus, mycophenolate, and sirolimus has led to a significant reduction in azathioprine use or its elimination altogether in immunosuppressive protocols. It can be useful in some cases, because it is inexpensive, or in patients who cannot tolerate other agents. It continues to be used in other countries.[10]

Azathioprine, a nonspecific antimetabolite immunosuppressive agent, affects both cell-mediated (ie, T cell) and antibody-mediated (ie, B cell) immune responses. Because it inhibits the early stages of cell differentiation and proliferation, azathioprine is useful for preventing rejection, but it is ineffective for the treatment of acute rejection. 6-MP, an active metabolite, is incorporated into DNA and RNA, thereby interfering with the intracellular formation of thioguanine nucleotides (TGNs). 6-MP is intracellularly converted by hypoxanthine phosphoribosyltransferase to thioinosinic acid and then to TGNs. 6-MP may have two separate immunosuppressive effects: inhibition of cellular proliferation and cytotoxicity. A decrease in the levels of intracellular purine ribonucleotides decreases cellular proliferation, and incorporation of TGN into DNA mediates cytotoxicity.

The major metabolic conversion of azathioprine to 6-MP is via nucleophilic attack by glutathione. The liver and red blood cells are thought to be major tissue sites for this metabolic conversion. The 6-MP formed by this reaction can be metabolized further to thiopurine ribonucleosides and ribonucleotides such as 6-TGN. These active metabolites, which have longer half-lives, are responsible for immunosuppressive activity. Azathioprine pharmacokinetics are not affected by renal dysfunction, but 6-TGN metabolite concentrations can accumulate in this situation.[11]

The most common adverse effect of azathioprine is bone marrow suppression. Bone marrow suppression may be related to a genetic deficiency of the enzyme, thiopurine methyltransferase. Low activity of this enzyme is rare, but, in some individuals, it leads to greater

availability of 6-MP, elevated 6-thioguanine levels, and susceptibility to myelosuppression. Low levels of thiopurine methyltransferase and specific genetic polymorphisms of this enzyme have been associated with severe azathioprine myelotoxicity and reduced efficacy.[11,12] Testing for this polymorphism has been advocated. However, few transplant centers perform genetic testing before use.

MYCOPHENOLIC ACID DERIVATIVES (MYCOPHENOLATE MOFETIL AND MYCOPHENOLATE SODIUM)

As a result of several multicenter comparative registry trials in kidney transplant recipients, MMF and EC-MPS have replaced azathioprine in many transplant protocols. MPA derivatives are used as adjunctive therapy in combination with cyclosporine or tacrolimus, prednisone, mammalian target of rapamycin (mTOR) inhibitors, and monoclonal and polyclonal antibodies to prevent acute rejection and are also used for calcineurin inhibitor (CNI) withdrawal and minimization. It is also used as rescue therapy when patients have not responded to, or cannot tolerate, the side effects of other immunosuppressive agents.

MPA derivatives are antiproliferative antimetabolites that inhibit purine synthesis, but in a more selective manner than does azathioprine. Unlike azathioprine, MPA derivatives interfere with the de novo pathway for purine synthesis. MMF is the morpholinoethyl ester prodrug of MPA, which is the active component. MPA selectively, noncompetitively, and reversibly blocks an enzyme known as inosine monophosphate dehydrogenase (IMPDH) found primarily in actively proliferating T and B cells. T and B cells rely on this enzyme and the de novo purine pathway to produce purine nucleotides for DNA and RNA synthesis. Thus, MPA interferes with T-cell and B-cell proliferation. It is more selective than is azathioprine. MPA also may affect cytokine production. Other secondary effects include inhibition of B-lymphocyte antibody production, decreased adhesion molecule expression, decreased smooth muscle proliferation and recruitment, and infiltration of neutrophils.[13]

Another oral formulation of MPA, EC-MPS, is also approved by the U.S. Food and Drug Administration (FDA) to prevent rejection in kidney transplantation, when used in combination with a CNI and corticosteroids. The original purpose of designing the enteric-coated formulation was to reduce or prevent the gastrointestinal (GI) side effects commonly seen with MMF. However, most data suggest that the efficacy rates and side effect profiles of MMF and EC-MPS are nearly identical. These two agents are not bioequivalent.[13]

CORTICOSTEROIDS

Prednisone, methylprednisolone, and prednisolone—all synthetic analogs of hydrocortisone—are the primary corticosteroids used to prevent and treat rejection of transplanted organs. These agents usually are given in fixed doses or dosing is based on body weight (milligram/kilogram) despite the pharmacokinetic differences. Although they are an important part of immunosuppression, a goal of most transplantation programs is to minimize, eliminate, or avoid corticosteroid use because of their numerous and significant side effects.

Corticosteroids have multiple effects on most cells and tissues of the body, but it is their anti-inflammatory and, more importantly, their immunosuppressive properties that serve as the basis for their use in organ transplant recipients. The corticosteroids bind with specific intracellular glucocorticoid receptors and interfere with RNA and DNA synthesis as well as transcription of specific genes. Cell function is altered, resulting in suppression or activation of gene transcription. Corticosteroids also affect RNA translation, protein synthesis, cytokine production and secretion, and protein and cytokine receptor expression.

Even after a single dose, corticosteroids cause marked lymphocytopenia by redistribution of circulating lymphocytes to other lymphoid tissues, such as the bone marrow, rather than by cell lysis; however, they also transiently increase the number of peripherally circulating neutrophils. Corticosteroids inhibit IL-1 and IL-6 production from APC, a number of events associated with T-cell

activation, and IL-2 and IFN-γ production. They interfere with the action of IL-2 and IL-2R on activated T cells, resulting in the inhibition of T_{H1} function. They can enhance IL-10 regulatory function and enhance T_{H2} cell function. Moderate-dose to high-dose corticosteroids also inhibit cytotoxic T-cell function by inhibiting cytokine production and lysis of T cells. They can inhibit early proliferation of B cells but have a minimal effect on activated B cells and immunoglobulin (Ig)-secreting plasma cells. The corticosteroids affect most cells and substances associated with acute allograft rejection and inflammatory reactions. They inhibit accumulation of leukocytes at sites of inflammation; inhibit macrophage functions, including migration and phagocytosis; inhibit expression of class II MHC antigens induced by INF-γ; block the release of IL-1, IL-6, and TNF; inhibit the upregulation and expression of costimulatory molecules and neutrophil adhesion to endothelial cells; inhibit secretion of complement protein C3; inhibit phospholipase A_2 activity; and decrease production of prostaglandins.[14]

CALCINEURIN INHIBITORS

Cyclosporine

The activity of cyclosporine is mediated through a reversible inhibition of T-cell function, particularly T_H cells. Its major effect is inhibiting the production of IL-2 and other cytokines, including INF-γ. These actions result in an inhibition of the early events of T-cell activation, sensitization, and proliferation. Cyclosporine has little effect on activated mature cytotoxic T cells. Therefore, it has little usefulness in the treatment of acute rejection. Its site of action is within the cytoplasm of T cells after antigenic recognition and signaling occurs. Cyclosporine binds to an intracellular protein (immunophilin) called *cyclophilin*. Although binding to cyclophilin is required, it alone is not sufficient for immunosuppression. This cyclosporine–cyclophilin complex then binds to a protein phosphatase, calcineurin. This is thought to prevent activation of nuclear factors involved in the gene transcription for IL-2 and other cytokines, including IFN. Also, because of this inhibition,

cyclosporine indirectly impairs the activity of other cells, macrophages, monocytes, and B cells in the immune response. Cyclosporine has no effect on hematopoietic cells or neutrophils. Cyclosporine is metabolized extensively in the liver to >25 metabolites. Two of these metabolites elicit a lower immunosuppressive effect in vitro. The role of these metabolites in the development of toxicity with cyclosporine is unclear.[15]

Tacrolimus

Tacrolimus is a macrolide with a molecular structure different from that of cyclosporine. Tacrolimus is more effective than cyclosporine in liver and kidney transplant recipients as the primary immunosuppressant in combination with corticosteroids or mycophenolate, azathioprine, mTOR inhibitors, and antibodies. It also is effective in some patients as rescue treatment in liver and kidney recipients experiencing acute or chronic rejection resulting from failure of standard immunosuppressive therapy. Tacrolimus is the preferred CNI over cyclosporine in most transplant centers.[2]

The activity of tacrolimus is similar to that of cyclosporine, but the concentrations of tacrolimus needed to inhibit the production of IL-2 are 10 to 100 times lower than those of cyclosporine. Tacrolimus also inhibits production of other cytokines, including IL-3, IL-4, INF-γ, TNF, and granulocyte-macrophage colony-stimulating factor. It has variable effects on B-cell response and also has anti-inflammatory effects. As with cyclosporine, tacrolimus binds to an intracellular, although different, protein: FK binding protein 12. This protein, which interacts with calcineurin, inhibits gene transcription of cytokines and interferes with T-cell activation.[16]

MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

Sirolimus, formerly known as rapamycin, is an FDA-approved agent for the prevention of acute rejection and for withdrawal of cyclosporine in kidney transplantation. Positive results for sirolimus also have been observed in other transplant populations; in situations in which it is used in combination with other agents,

including antibodies, tacrolimus, mycophenolate, and prednisone; and when it has been used for rescue therapy. Its major use, as has been traditionally published, is in CNI avoidance, withdrawal, or minimization protocols but more recently is used in patients with solid tumors or other indications such as resistant CMV.

Unlike CNIs, which work earlier in the T-cell activation cycle and inhibit cytokine production, sirolimus is an inhibitor of late T-cell activation. It does not block cytokine production; rather, it inhibits signal transduction, which blocks the response of T cells and B cells to cytokines, such as IL-2. Sirolimus binds to the same immunophilin bound by tacrolimus, FK binding protein. This complex interferes with the action of certain enzymes or proteins involved in cell proliferation signaling. Both cyclosporine and tacrolimus inhibit calcineurin, whereas sirolimus influences a protein called the mTOR. Sirolimus also inhibits an enzyme called P7056 protein kinase, which is involved in microsomal protein synthesis. These effects result in cell-cycle arrest, blockage of messenger RNA production, and blockage of cell proliferation. Sirolimus also inhibits the proliferation of smooth muscle cells and may, although it is too early to tell, reduce the development of chronic rejection and cancer.

Sirolimus exhibits significant pharmacokinetic variability. Its average bioavailability is 15%; C_{max} and area under the curve (AUC) are linear over a wide range of doses. Sirolimus is extensively distributed. It distributes primarily into red blood cells and is highly plasma protein bound, ~92%. It also binds to lipoproteins. Sirolimus is extensively metabolized in the gut and liver by cytochrome P450 (CYP) 3A4 and 3A5 isoenzymes, and it is a substrate for P-glycoprotein. Its drug interaction profile is similar to that of cyclosporine and tacrolimus. Renal elimination accounts for 2% of a dose. The terminal half-life is ~57 to 63 hours and the time to steady state is 10 to 14 days in adults and shorter in children.

Everolimus is the newest FDA-approved mTOR inhibitor for use in both kidney and liver transplantation. Its mechanism of action is similar to that of sirolimus. Everolimus is hepatically metabolized through the CYP3A4 and CYP3A5 but has a shorter half-life,

average 30 hours, and a different dose and frequency schedule than does sirolimus. Similar to sirolimus, it requires monitoring of trough blood concentrations. Its role in transplantation is generally similar to that of sirolimus, but direct comparison to sirolimus is needed.[17]

BELATACEPT

This agent is the first FDA-approved intravenous (IV) maintenance agent. Belatacept is a CTL4-Ig that blocks the costimulatory pathway of CD28 or CTL-A4:CD80/CD86 binding interactions. CTLA4-Ig binds to CD80/CD86 to a greater degree than does CD28, resulting in inhibition of costimulation and T-cell activation. Belatacept is given once every few weeks in combination with other agents, such as mycophenolate and prednisone, and generally well tolerated. It has been used as initial therapy, or for CNI avoidance or withdrawal (conversion) to reduce development or progression of CNI-induced reduction in renal function. Benefits on renal function have been demonstrated as well as other CNI-associated adverse effects. However, it should be noted that there is an increased risk of acute rejection when belatacept is used in combination with mycophenolate, as compared to a cyclosporine- and mycophenolate-based regimen. There are no large-scale studies comparing it to tacrolimus-based regimens or in combination with cytolytic induction therapy. In clinical practice, some transplant centers utilize belatacept as a conversion agent in patients who cannot tolerate CNIs. There is an ongoing multicenter study to assess the efficacy of this. Other small studies that utilize belatacept with mTOR therapy have been published. It should be noted that belatacept is contraindicated in patients who are Epstein–Barr virus (EBV) antibody negative because of the risk of posttransplant lymphoproliferative disorder (PTLD). The phase III studies that demonstrated a higher risk of PTLD in those who received belatacept noted this was the case only in EBV-naive recipients, and CNS PTLD was of particular concern. Recent data presented in abstract form, which followed up patients from the phase III studies out for >7 years posttransplant, have now demonstrated improved

graft survival in the belatacept arm, as compared to the cyclosporine group. Thus, this agent may offer beneficial outcomes for certain low-risk kidney transplant recipients. Use in other organs, particularly in liver transplant recipients, is not recommended because of previous studies demonstrating inferior outcomes, as compared to CNI-based therapy.[18]

Induction

POLYCLONAL ANTIBODIES

Antithymocyte globulins

Polyclonal antibody products have been used for decades to prevent and treat acute rejection. Polyclonal products used today are administered IV and include equine (lymphoglobulin) and rATG, which is considered the polyclonal antibody of choice.

ATG preparations have also been made in goats and sheep for investigational study. However, the following discussion is limited to the products produced in horses and rabbits. Regardless of the species from which they are produced, all ATG products have similar pharmacologic effects. Their potency and antibody specificity vary, however, from batch to batch and between products. The production of polyclonal equine or rabbit antibody begins with the injection of homogenized human spleen or thymus preparations into the animals. This injection induces an immune response in the animals directed against human T lymphocytes; serum containing antibodies to T cells is collected from the animals and purified. However, other antibodies to human cells are produced as well. These antibodies bind to all normal blood mononuclear cells in addition to T lymphocytes and B lymphocytes, resulting in depletion of lymphocytes, platelets, and leukocytes from the peripheral circulation. The mechanism of action of these agents is thought to be linked to lysis of peripheral lymphocytes, uptake of lymphocytes by the reticuloendothelial system, masking of lymphocyte receptors, apoptosis, and immunomodulation. These agents contain antibodies to a number of cell-surface markers on lymphocytes, including CD2,

CD3, CD4, CD8, CD11a, CD25, CD44, CD45, HLA-DR, and HLA class I antigens. They also interfere with leukocyte adhesion and trafficking and have effects against $CD20^+$ B cells. ATG preparations can produce a rapid and profound depletion of circulating T cells, often within 24 hours of the initial dose. The duration of the effect can last several weeks after a course of therapy, particularly with rATG. Antibodies can be produced to these products as well. This, however, does not appear to influence clinical outcomes.[19]

MONOCLONAL ANTIBODIES

Basiliximab

Basiliximab is an IL-2R antagonist, monoclonal antibody approved for use in combination with other immunosuppressives to prevent acute cellular rejection in kidney transplantation. Basiliximab is a chimeric antibody that contains both murine and human antibody sequences. This agent prevents episodes of acute rejection in kidney transplant recipients. It has been used, although not as frequently, in liver transplants. Comparative studies between basiliximab and other antibodies, such as rATG, have been conducted. Advantages over these other agents include ease of administration, minimal side effects, low immunogenicity, no greater infections or malignancy rates, and fewer required doses. It is well tolerated, although there are rare reports of anaphylaxis. Basiliximab appears to be most effective in immunologically low-risk patients, whereas in high-risk patients, its use may be limited. It binds to the α-subunit of the IL-2R, also known as CD25 or the tacrolimus (TAC) subunit, which is expressed only on the surface of activated T cells; this subunit is critical to IL-2 activation of T cells in the acute rejection process. Basiliximab prevents the IL-2R from binding with IL-2, thereby blocking T-cell activation. It does not cause lymphocyte depletion. Basiliximab, with the two-dose IV regimen, on days 0 and 4 posttransplant, saturates the receptor for ~30 to 50 days in kidney transplants.[20]

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody against CD52 proteins on the surface of T cells and B cells, natural killer cells, macrophages, and granulocytes. Binding of CD52 elicits antibody-dependent lysis of these cells. It is approved for use in certain types of blood cancers, but not in organ transplant. Because it causes a profound reduction or depletion in lymphocytes, especially T_H lymphocytes, a number of studies have evaluated its effect as induction therapy to prevent acute rejection after kidney transplant. Several studies have investigated its use in low and high immunologic risk transplants and in steroid avoidance or withdrawal regimens and CNI avoidance or withdrawal regimens. Short-term studies have indicated a role for this agent in these situations. It is rarely used in liver transplantation. Most protocols with this agent give a single IV or subcutaneous (SC) dose in the operating room. With this dose, significant neutropenia and lymphopenia can occur, lasting for months to years in some patients. This single-dose regimen has been successful in reducing the incidence of fungal and viral infections as compared with multiple-dose regimens, although infection is still a concern with a single dose.[21,22]

OTHER AGENTS

These agents, although not indicated for kidney transplantation, are being used and studied primarily in kidney transplantation. IVIG and rituximab, an anti–B-cell CD20 monoclonal antibody, are being used pre- and posttransplant in order to transplant patients with ABO incompatibility or who are highly sensitized. Use of immunosuppression to reduce circulating antibodies is a process called *desensitization*. Desensitization is used to facilitate transplant across traditionally prohibitive immunologic barriers. Care is needed following transplant to ensure that appropriate immunologic monitoring is done to prevent rejection and graft loss. Eculizumab, a C5 complement inhibitor, and bortezomib, a proteasome inhibitor, are also being used and studied in these situations, as well as for the treatment of antibody-mediated acute cellular rejection.[23,24]

KIDNEY TRANSPLANTATION

Indications and Evaluation

All patients with end-stage renal disease (ESRD) are potential candidates for kidney transplantation unless contraindicated. The contraindications (absolute or relative) are determined by the individual transplant center. Absolute contraindications include current malignancy, active infection, active liver disease, hepatitis B surface antigen (HbsAg)-positive, severe or symptomatic cardiac or pulmonary disease, specific renal diseases with an accelerated recurrence rate, substance abuse, and abnormal psychosocial and noncompliant behavior. Relative contraindications for the recipient of a kidney transplant include chronic liver disease, active infection, current hepatitis C viremia, human immunodeficiency virus (HIV) positive if uncontrolled on antiviral therapy, morbid obesity, current positive cross-match, and older age, which may vary based on center. The relative contraindication for the elderly with ESRD is controversial because ~40% of the ESRD population is older than 65 years, and an increasing number of these patients are undergoing kidney transplantation. Patients with ESRD need not wait until they are receiving dialysis before being considered for a kidney transplant because early transplantation is associated with lower cost, better quality of life, and longer survival than patients on dialysis awaiting transplantation. The primary diseases leading to ESRD and transplant are diabetes, hypertension, glomerulonephritis, and polycystic kidney disease.

Diabetes and hypertension are the most likely causes of ESRD. A kidney transplant should return renal function to near normal (ie, a glomerular filtration rate between 50 and 80 mL/minute), improve quality of life, and correct the complications of ESRD such as anemia, hypocalcemia, and hyperphosphatemia, but not diabetes, hypertension, or hyperlipidemia.

The risk–benefit ratio must be considered when evaluating a patient for any organ transplantation. In general, kidney transplants

are performed to improve the quality of life and avoid the complications and outcomes associated with dialysis and renal failure. It is also more cost-effective than is dialysis. On the other hand, patients who are candidates for liver transplantation will die if the transplanted liver fails. Therefore, the criteria established for organ transplantation must be evaluated carefully before it is offered to any patient.

Donor and Recipient Matching

HLA matching of donor and recipient at the HLA-A, HLA-B, and HLA-DR loci is associated with better graft survival and longer half-lives for both living-related and deceased-donor kidney transplants. A six-antigen match is ideal, whereas a zero-antigen match is less favorable. The half-life refers to the time it takes for half of the grafts that survive the first year to fail. Organ half-lives are longer with living donors (average 15.9 years) compared with deceased donors (average 11.9 years).[25] For kidney recipients, the 1- and 3-year graft survival for a first deceased-donor transplant is >94% and 85%, respectively.[2] These positive factors may be offset, however, by ethnicity. Patient and graft survival after kidney transplantation is reduced in the African American population compared with others because of immunologic, medical, pharmacologic, pharmacokinetic, pharmacogenomic, and socioeconomic reasons. Along with African American race, other risk factors associated with decreased survival include advanced donor age, donation after cardiac death, recipient age younger than 15 years and older than 50 years, retransplantation, a high PRA, and delayed graft function. Recipients who fall into these categories are referred to as high-risk patients.

Because of a limited number of donors, the organ transplant community has devised methods to increase the donor pool by attempting to safely utilize marginal donors. In its most current form, this allocation system has incorporated the use of a predictive tool that determines the degree of marginality, termed the Kidney Donor Profile Index (KDPI). The KDPI uses donor information, including

age, height, weight, ethnicity, hypertension, diabetes, cause of death, serum creatinine (SCr), hepatitis C status, and circulatory death status to rate kidneys from 0% to 100%. Those in the higher percentile are more likely to fail, as compared to kidneys with lower KDPIs. In the current allocation system, donors with a high KDPI (≥85%) are reserved for older recipients who consent to receive these organs.[26]

CASE 34-1

Question 1: G.P. is a 52-year-old, 158.73-pound (72-kg) African American male with ESRD secondary to type 2 diabetes mellitus, hypertension, and hyperlipidemia. He has been undergoing hemodialysis three times a week for 4 years. Other medical problems include anemia, hypocalcemia, and hyperphosphatemia. G.P.'s medications include amlodipine 10 mg daily, ramipril 10 mg twice daily (bid), atorvastatin 20 mg daily, calcium carbonate two tablets with meals and at bedtime, sevelamer 800 mg with meals, glargine insulin 30 units daily, insulin aspart 8 units with meals, and erythropoietin 8000 IU IV three times weekly. He has been on the kidney transplant waiting list for 4 years. He is called by the transplant coordinator and admitted for a possible deceased-donor (formerly called cadaveric) kidney transplant. G.P. has the same blood type as the donor. His most recent calculated panel-reactive antibody (cPRA) is 99%. Cross-match is negative, and HLA typing reveals a three-antigen match (A1, A2, and B35) between donor and recipient. On admission to the hospital, his laboratory values are as follows:

Na^+, 141 mEq/L
Potassium (K^+), 4.7 mEq/L
Cl^-, 102 mEq/L
Bicarbonate (Hco_3), 23 mEq/L
Blood urea nitrogen (BUN), 44 mg/dL
SCr, 13.9 mg/dL
Calcium (Ca^{2+}), 7.8 mEq/L
Phosphorus, 6.2 mg/dL
Glucose, 225 mg/dL
Albumin, 3.5 g/dL
White blood cell (WBC) count, 8.4 cells/mL
Hemoglobin (Hgb), 10.8 g/dL
Hematocrit (Hct), 32%

His serology is negative for HIV, HbsAg, hepatitis C, and cytomegalovirus (CMV), and is positive for antibody to the surface antigen of hepatitis B (anti-Hbs) and positive for EBV antibody.

Before the transplant procedure, G.P. receives MMF 1 g orally (PO) and cefazolin 1 g IV. During surgery, just before reperfusion of his new kidney, he received methylprednisolone 500 mg IV and rATG 1.5 mg/kg IV. He is also given furosemide 100 mg IV after the kidney has been transplanted. Methylprednisolone 250 mg IV is to be given on the day after surgery. The methylprednisolone dose is to be decreased to 100 mg IV on the second postoperative day for one dose. Prednisone 60 mg (1 mg/kg/day) PO is to be given on the subsequent day for one dose and tapered by 0.3 mg/kg/day to 20 mg daily by day 7 after surgery and further tapered to 5 mg daily within a month. Tacrolimus nasogastric (NG) or PO 0.1 mg/kg/day or 3 mg every 12 hours will be started within 12 hours of surgery if renal function improves. The dosage will be adjusted according to tacrolimus whole-blood trough concentrations. MMF will be continued at 1 g PO bid. He will also continue with antibody induction with rATG 100 mg IV on days 1, 2, and 3 after surgery.

Why is G.P. being treated with this immunosuppressive regimen?

Immunosuppressive Therapy

The major goal of immunosuppressive therapy is to prevent rejection and balancing the risk of infection from overimmunosuppression with minimal adverse effects and to ensure long-term patient and graft survival as well as improve quality of life. Overall acute rejection rates are <10% during the first year after kidney transplantation. Most of these episodes respond to acute antirejection therapy.

No consensus exists on the best induction and maintenance immunosuppressive regimen, and selection primarily depends on the program and the specific organ to be transplanted. Although studies have evaluated the various regimens, comparisons are influenced by differences in donor selection and condition, organ preservation and procurement, organ ischemic (cold and warm) time, recipient's pretransplant conditions, comorbid and high-risk or low-risk immunologic factors, surgical procedures, postoperative management and monitoring, and length of follow-up. Another important consideration is that many of these agents show significant effects during the first year, but fail to show a significant impact on long-term effects such as chronic rejection and graft survival.[3] The choice of a particular regimen generally depends on the risk factors present at the time of transplantation. During this early time period,

because the risk of acute rejection is highest in the first few weeks to months, the number of agents, doses, and target drug concentrations are higher than later on after transplantation.

Most initial combination immunosuppressive drug regimens rely on two to three maintenance agents, although in some cases monotherapy has been used, depending on organ type and risk factors. Common combination regimens include a CNI (tacrolimus and cyclosporine) with MPA or sirolimus/everolimus, and prednisone. The most common regimen is tacrolimus, mycophenolate, and prednisone along with short-term administration of a monoclonal antibody (alemtuzumab, basiliximab) or a polyclonal antibody (rATG). Regimens that avoid steroids and CNIs, or use a short course, in the early transplantation period, or are withdrawn some time (usually several months) after transplantation in an attempt to avoid the long-term side effects of these agents, are another option. In HLA-identical, living-related kidney transplants, dual therapy (eg, tacrolimus or mycophenolate, and prednisone) gives excellent results; however, acute rejection may still occur, as with other regimens. Combination therapy is used to take advantage of different mechanisms of action and to reduce drug toxicity by using sequential therapy and smaller doses of multiple agents rather than larger doses of any agent used alone. These multidrug combinations can lead, however, to increased drug costs, compliance issues, a higher incidence of infection and malignancy, and difficulty in assessing and managing adverse effects.[11]

Because G.P. is receiving a deceased-donor transplant and is considered an immunologically high-risk recipient (he is African American with a high PRA), an antibody plus several maintenance agents would be appropriate. He is started on tacrolimus, mycophenolate, and prednisone. This combination, based on the literature, is the most effective.[16]

Depending on the transplant center, drug dosages are reduced over time. In G.P., tacrolimus doses are adjusted based on target trough concentration ranges, which are reduced over time as well. MMF may be discontinued later. Although the discontinuation of a drug may reduce adverse effects, it must be counterbalanced

against the risk of rejection and potential graft loss. Monotherapy, generally with tacrolimus or cyclosporine, may be achieved in low-risk kidney and liver transplant recipients at some time after transplantation. Most patients require lifetime immunosuppression, and nonadherence in the setting of reduced immunosuppression may predispose the recipient to acute and, subsequently, chronic rejection.

Case 34-1, Question 2: What is induction therapy, and which is the preferred agent for G.P.?

Induction therapy at the time of transplantation refers to the use of an antibody, typically at time of transplant and during the first few days after transplant. rATG, alemtuzumab, and basiliximab are induction agents. Acute rejection and delayed graft function (need for dialysis during the first 7 days after transplant) can occur in the early transplant period. Both of these have a negative impact on graft survival. Antibody induction reduces the incidence of early acute rejection, delayed graft function, and has typically been used in immunologically high-risk patients. They allow the use of lower doses, or slower introduction or sequential use of maintenance immunosuppression. They are a major component of early therapy in high-risk patients. Their use in patients at low-to-moderate risk has increased, often as a means of reducing or avoiding the use of CNI and steroids. Currently, ~80% of all kidney transplants receive induction therapy, with rATG making up about 60%.[2,27]

rATG was chosen as induction because G.P. is African American and is at higher risk for acute rejection. In general, rATG appears to be more effective than is equine antithymocyte globulin (horse ATG) and is the antibody of choice. rATG, when used for induction, results in reduced acute rejection, improved survival, and manageable side effect profile. In kidney transplants, this agent is effective in reducing acute rejection and improving short- and long-term graft survival compared to horse ATG and especially in high-risk patients.[27]

ANTITHYMOCYTE GLOBULINS

Dosing and administration

Case 34-1, Question 3: How would rATG be administered and monitored in G.P.?

Both rATG and horse ATG are effective as induction therapy, and rATG was recently FDA approved for induction. Both rATG and horse ATG are effective treatments for severe acute rejection. The dose of rATG ranges from 1 to 6 mg/kg but is typically 1.5 mg/kg/day for four to six doses, and the dose of horse ATG is 10 to 20 mg/kg/day but is typically 15 mg/kg/day. These drugs can be diluted in 0.9% NaCl for injection and administered for 4 to 6 hours. Both are usually infused into a high-flow central vein to reduce pain, erythema, and phlebitis at the injection site. Peripheral administration has been used successfully with rATG.[28] Skin testing is recommended before horse ATG use, but not before rATG. Patients previously sensitized to horse serum are at risk for an anaphylactoid reaction, but the prevalence of anaphylaxis has diminished with improved purification of this product. Patients with a positive pretherapy skin test could undergo desensitization, but alternatives, such as rATG, may be substituted.[19]

Dose regimen and duration of therapy

The first dose of rATG is usually given intraoperatively. Intraoperative administration of rATG reduces the incidence and severity of delayed graft function as compared with postoperative administration. Duration of therapy with rATG or horse ATG is variable (3–10 days), but, more recently, shorter courses have been employed for induction therapy. Protocols used to treat rejection commonly use a 7- to 10-day course of therapy. In patients such as G.P., a four-dose prophylactic regimen has been shown to be as effective as a longer regimen.[19]

Adverse effects

A number of adverse effects have been related to the use of rATG or horse ATG. Local phlebitis and pain usually can occur. Anaphylaxis is rare. Chills and fever, erythema, rash, hives, pruritus, headache, leukopenia, and thrombocytopenia are commonly encountered. Fever, chills, hypotension, nausea, and vomiting may be caused by the release of cytokines, such as TNF and IL-6, from lysed lymphocytes. These symptoms can be minimized by premedication with acetaminophen and diphenhydramine before each dose.

Methylprednisolone, up to 500 mg, is given 1 hour before rATG typically for the first one to two doses to minimize infusion reactions. Opportunistic viral (CMV and EBV) and fungal infections are the predominant delayed side effects. Susceptibility to malignancy, such as PTLD, is also a concern. Because of the increased risk of CMV infection, patients are often given oral valganciclovir or IV ganciclovir during therapy and then oral valganciclovir, which is continued up to several months after induction.[19]

Monitoring

Vital signs should be monitored hourly during infusion, and WBC and platelet counts should be monitored daily. If the patient's WBC count drops to <3000 cells/mL or if the platelet count drops to <75,000 cells/mL, the dose of drug is decreased by 50% or held entirely for WBC <2000 cells/mL or platelets <50,000 cells/mL until the counts return to desired levels. Patients who receive rATG for the treatment of acute rejection may have doses held or decreased based on the degree of leukopenia and thrombocytopenia; however, the need for and response to therapy would be carefully considered in this decision.

Dosages also can be adjusted based on absolute lymphocyte counts or lymphocyte subsets as a way of maximizing efficacy and minimizing infectious complications. For example, the dose can be adjusted using a target absolute T-lymphocyte count (CD2 or CD3) of <25 to 50 cells/mL, particularly if used for treatment of acute rejection. It is less common to adjust doses based on CD2 of CD3 counts when used for induction as in G.P.'s case. Using CD2 and

CD3 counts results in a lower dose, less frequent dosing (eg, every other day instead of daily), lower costs, and a lower rate of viral infection. rATG produces a more profound and longer duration of effect on lymphocytes than does horse ATG; however, it does not result in a greater risk of infection and malignancy, although still a concern.[19]

Case 34-1, Question 4: Could basiliximab or alemtuzumab be used as an alternative to rATG?

Basiliximab is approved for use as induction therapy in kidney transplantation; however, it is also used in other organ transplant recipients. It is administered in combination with cyclosporine or tacrolimus and steroids with or without MMF or sirolimus. It has a similar safety profile compared to placebo and better safety profile than does rATG. It has a limited role in high-risk populations such as G.P., or patients with high PRA or long ischemic times, delayed graft function, or patients who have received a previous transplant. In these patients, induction with polyclonal antibodies is used in most centers. The large initial trials with this IL-2R antibody included very few high-risk patients or excluded them altogether. More potent agents, such as rATG, are still preferred in high-risk patients. A prospective study comparing rATG with basiliximab in high-risk kidney transplants demonstrated that acute rejection rates were lower in patients receiving rATG.[21] Basiliximab is often used for low-risk to intermediate-risk patients and in patients where CNI minimization or steroid avoidance is implemented.

Alemtuzumab is another alternative and is used by some centers for low- and intermediate- to high-risk patients. It has been shown to be no less effective than is rATG in high-risk patients and more effective in reducing acute rejection than is basiliximab in low-risk patients.[29] Adverse effects include frequent and prolonged neutropenia, lymphopenia, thrombocytopenia, anemia, nausea, vomiting, and diarrhea. Infusion reactions can occur although it is given, as a single dose and under anesthesia, in the operating room

during the transplant. As with rATG, there is an increased risk of opportunistic infections and malignancy. Rituximab has also been studied as potential induction therapy in nonsensitized or ABO-compatible transplants and found not to be very effective in this population, unlike that in ABO-incompatible recipients.[23]

Postoperative Course and Delayed Graft Function

Case 34-1, Question 5: G.P. is admitted to the transplant ward for initial posttransplantation management. His urine output during the next 3 hours has decreased from 300 to 40 mL/hour. He is receiving IV fluids at a rate equivalent to his urine output. He received 3 L of fluids in the operating room. His blood pressure (BP) is 140/83 mm Hg, heart rate is 87 beats/minute, and temperature is 98.42 °F (36.9 °C); he has no signs of dehydration. His BUN is 56 mg/dL and his SCr is 12.8 mg/dL. Another dose of furosemide 100 mg IV increased his urine output to 140 mL/hour, but his urine output returned to <40 mL/hour in a few hours. Fluids and IV furosemide were given again with similar results. Renal ultrasound indicates no urine leaks, fluid collections, or ureteral obstruction. A diethylenetriamine penta-acetic acid renal scan result indicates good perfusion, but decreased accumulation and clearance. During the next 2 days, G.P.'s BP is 150/93 mm Hg, weight is 167.55 pounds (76 kg; 8.82 pounds [4 kg] higher than in pretransplantation), urine output has fallen to <200 mL/day, and relevant laboratory values are as follows:

BUN, 85 mg/dL
SCr, 13.2 mg/dL
K^+, 5.8 mEq/L

The decision is made to institute hemodialysis. What has happened to G.P.'s renal function? What is the most likely diagnosis?

The initial renal function after kidney transplantation can reflect excellent, moderate, or delayed graft function. In recipients with excellent function, a good diuresis begins immediately and continues; the SCr rapidly declines to <2.5 mg/dL within the first few days of transplantation. Most living-related transplants and between 30% and 50% of deceased-donor transplants generally experience this pattern. Kidney transplant recipients with moderate or slow graft

function usually experience a slower decline in SCr, which stabilizes within the first week. Recipients with delayed graft function usually have anuria or oliguria, require dialysis in the early period, and take days to weeks to recover. Delayed graft function is most common in recipients of organs from deceased transplant donors, occurring in between 10% and 50% of cases.[30] The diagnosis of delayed graft function is based on clinical, laboratory, and diagnostic criteria that may vary among centers. Traditionally, delayed graft function has been defined as the need for dialysis within the first 7 days posttransplant. *Slow graft function* is another term that has been used to describe a lag in improvement and does not involve dialysis. Delayed graft function is influenced by the donor (age, condition of organ, prolonged ischemic time), intraoperative conditions (hypotension, fluid imbalance, ischemia, or reperfusion injury), and recipient characteristics such as prior transplantation, postoperative hypovolemia or hypotension, and use of nephrotoxic drugs.[30]

In G.P., poor urine output in the first hours after transplantation and subsequent oliguria, the exclusion of other causes of acute tubular necrosis, the results of the renal scan, the lack of improvement in BUN and SCr, and the need for dialysis are indicative of delayed graft function. Delayed graft function reduces kidney long-term graft survival, increases the risk of acute rejection, and influences a patient's early management by requiring dialysis, increasing the length of hospital stay, and increasing the costs of therapy. It also may make the assessment of acute rejection more difficult because the patient already has impaired renal function. In delayed graft function, a renal biopsy may be obtained if no improvement in SCr is seen by day 7 unless there are risk factors present to indicate that delayed graft function was expected, such as donation after cardiac death or prolonged cold ischemia time.[30]

Case 34-1, Question 6: What adjustments should be made in G.P.'s immunosuppressive regimen at this time? Are there any therapies that can prevent or treat delayed graft function?

The adverse renal effects of CNIs may contribute to the onset of delayed graft function as well as prolong its duration. Therefore, tacrolimus may be discontinued temporarily if appropriate T-cell depleting induction was provided or its dose significantly reduced. Because of this effect, some protocols do not include CNIs, use them only in low doses for the first week, or delay their use until kidney function improves. These protocols often include induction therapy and provide more intense immunosuppression early after transplantation when the risk of delayed graft function and acute rejection is highest. rATG is commonly used in patients with delayed graft function because it may shorten the duration and the need for dialysis when compared with the CNI. Another potential option would be to use basiliximab, which has been shown to reduce acute rejection rates and extend the time to first rejection. One concern with the use of basiliximab is that a CNI may be required sooner than with rATG because this agent does not provide as long a duration of protection from rejection. One should also confirm that MPA doses be maintained and continue prednisone taper. In G.P., rATG would be administered for 5 to 10 days, depending on improvement in his SCr and urine output, along with his current regimen of prednisone and mycophenolate. A typical dose would be 1.5 mg/kg/day or every other day, depending on his $CD3^+$ level and WBC and platelet counts.

Recent studies have focused on developing therapies that prevent or reverse delayed graft function, with mixed results. There are several therapies being tested within this context, which include therapies to inhibit p53 (I5NP), complement (eculizumab), TLR2 (OPN-305), and hepatocyte growth factor (BB3). Other therapies that have been tested include alteplase, etanercept, ischemic preconditioning, erythropoietin, and dopamine, with the latter showing reduced dialysis requirements but none demonstrating improved graft survival. Because this is a common and important clinical dilemma, it continues to be a significant area of research and discovery.[30]

Rejection

Case 34-1, Question 7: G.P. was started on rATG 1.5 mg/kg as a 6-hour IV infusion on days 0, 1, 2, and 3 for induction, but because of his delayed graft function, he received an additional dose on day 5. He received this along with his prednisone taper and MMF. Tacrolimus PO 3 mg bid was initiated on day 2 after transplant. G.P.'s urine output has increased gradually to 1600 mL/day after stopping rATG. His weight has decreased to 160.94 pounds (73 kg), and the following is recorded:

BP, 142/84 mm Hg
Heart rate, 82 beats/minute
Temperature, 98.06 °F (36.7 °C)
BUN, 23 mg/dL
SCr, 3.2 mg/dL
K^+, 4.6 mEq/L

Sixty days after stopping rATG, he is on a regular diet and taking all oral medications. His current medications include MMF 750 mg bid, prednisone 5 mg daily, tacrolimus 5 mg bid, ranitidine 150 mg at bedtime, dioctyl sodium sulfosuccinate 100 mg bid, amlodipine 10 mg daily, metoprolol 50 mg PO bid, glargine insulin 40 IU daily, insulin aspart 10 IU with meals, valganciclovir 450 mg daily, and trimethoprim–sulfamethoxazole (TMP-SMX) double-strength, one tablet on Mondays, Wednesdays, and Fridays. His weight increased to 166.67 pounds (75.6 kg); and note the following:

BP, 160/94 mm Hg
Heart rate, 98 beats/minute
Temperature, 99.68 °F (37.6 °C)
BUN, 30 mg/dL
SCr, 3.4 mg/dL
K^+, 4.8 mEq/L
Trough whole-blood tacrolimus concentration, 5 ng/mL (target range 8–10 ng/mL)
Urine output decreased during the past 24 hours to 750 mL.

He feels tired and has a decreased appetite, but his fluid intake has been adequate during the past day. What evidence is consistent with rejection in G.P.?

Although significant improvements in reduction in acute rejection and improved graft survival have occurred over the past decade, certain types of acute rejection and chronic rejection continue to be a major reason for graft loss in kidney transplants. Rejection episodes

can be categorized as cellular and/or antibody mediated, hyperacute, accelerated, acute, or chronic. Kidney biopsy is considered the gold standard for making the diagnosis of rejection after kidney transplant. Approved criteria are used to classify and grade the type and severity of rejection.

HYPERACUTE REJECTION

Hyperacute rejection, which occurs within minutes to hours of transplantation of the allograft, is the result of preformed cytotoxic antibodies against donor-specific class I antigens. This type of rejection is rare because of ABO matching and improved HLA typing before transplant, but it remains associated with a poor prognosis. Clinically, the patient presents with anuria, hyperkalemia, hypertension, metabolic acidosis, pulmonary edema, and, in some cases, disseminated intravascular coagulopathy. A perfusion scan of the kidney would indicate no uptake. If other causes of anuria are excluded and this diagnosis is made, then the transplanted kidney must be removed.

ACCELERATED REJECTION

Accelerated rejection usually occurs within a few days of organ transplantation. This is a result of prior sensitization to antigens that are similar to those of the donor and newly developed donor-specific antibodies (DSAs) to the donor graft. Accelerated rejections of transplanted kidneys occur primarily in recipients who have had prior transplantation, multiple pregnancies, or blood transfusions. These patients usually maintain good renal function for a few days before developing acute renal failure. Accelerated organ rejections generally are more resistant to pharmacologic therapy.

ACUTE REJECTION

Acute rejection is the most common type of kidney rejection in transplant recipients and most episodes respond to therapy. Most episodes of acute rejection are T-cell mediated (cellular), although some can be B-cell (antibody or humoral) mediated, and others are a

combination of both types. Acute rejection of a transplanted kidney is associated with reduced half-life and survival of both living-donor and deceased-donor transplants. Acute rejection often occurs in the first week to months after kidney transplantation. The prophylactic use of antibody induction may, however, delay the onset for several weeks, as illustrated by G.P.'s case. If acute rejection occurs, its onset is generally within the first year, with most episodes occurring within the first 60 days of transplantation. Acute rejection can, however, also occur at any time after transplant and can be a result of patient nonadherence (also called noncompliance) to medications and monitoring. The clinical presentation of patients with acute rejection of a kidney ranges from an asymptomatic patient with mild renal dysfunction as indicated by an elevated SCr, which is common, to patients presenting with a flulike illness, hypertension, and acute oliguric renal failure. G.P. presents with subjective reports of malaise or tiredness and lack of appetite. Such nonspecific symptoms occur often in patients with rejection and can be accompanied by myalgias. Objectively, G.P.'s increased weight, hypertension, decreased urine output, and increase in SCr are consistent with acute kidney rejection. In addition, the tacrolimus trough concentration is low, suggesting inadequate immunosuppression. Acute rejection of a transplanted kidney must be distinguished from CNI nephrotoxicity, and infections (eg, pyelonephritis, CMV, polyomavirus BK) also must be ruled out. Although the clinical evidence in G.P. probably represents an acute cellular rejection, a kidney biopsy is the gold standard for establishing the diagnosis. Biopsy results usually are available within 6 to 8 hours. If there is acute rejection, the biopsy will show an interstitial infiltration of mononuclear cells with tubulitis or intimal arteritis in more severe cases. The severity of acute rejection will be classified and graded according to standardized pathologic criteria and is important in determining treatment. Less severe grades will receive high-dose steroids, whereas more severe grades will often receive rATG.[6]

ANTIBODY-MEDIATED REJECTION

Antibody-mediated rejection (AMR; previously called humoral) can be either acute or chronic rejection mediated by antibodies. Over the past several years, there has been an increased recognition of the importance and detrimental impact of this type of rejection on graft outcomes. AMR is ≤10% of acute rejection episodes but graft loss is near 30%. Histologically, criteria for AMR differ from that for acute cellular rejection (ACR). Presence of positive staining for the complement component C4d indicates AMR, although this type of rejection can also occur with negative C4d. Many patients either before transplant or after have DSAs that can occur hours to years after transplantation. AMR often is associated with hemodynamic compromise and is more resistant to drug therapy.[31]

CHRONIC REJECTION

Chronic rejection is a major cause of long-term kidney graft loss after the first year. It can be either a cellular- or an antibody-mediated graft loss. It occurs slowly in most cases over several years. The characteristic signs of chronic rejection are hypertension, proteinuria, and a progressive decline in renal function leading to renal failure. Because no specific treatment exists, therapy is supportive (eg, dialysis in the case of kidney transplantation). Ultimately, retransplantation is needed. Data suggest that some patients may benefit from some of the newer agents, such as mycophenolate and sirolimus, that are considered non-nephrotoxic, but this requires further study. The diagnosis of chronic rejection is determined by clinical signs and biopsy findings indicative of fibrosis of hollow structures and vessels within the graft. The chronic rejection of a kidney must be distinguished from chronic CNI nephrotoxicity, chronic infection, recurrence of the original kidney disease, and other causes of CAI, and further causes.

CHRONIC ALLOGRAFT INJURY

Chronic allograft injury (CAI) is a term that has been used, generally, as a diagnosis of exclusion that indicates a slow deterioration in renal function over months to years after kidney transplant, where

the exact cause is unknown and results in graft loss. Immunologic and nonimmunologic mechanisms play a role in CAI. Immunologic factors that increase the likelihood of CAI include a history of acute rejection, inadequate immunosuppression, nonadherence to immunosuppressive therapy, and previous infection, such as CMV. Nonimmunologic factors are donor related (age, hypertension, diabetes), increased ischemic times, recipient hypertension, hyperlipidemia, CNI nephrotoxicity, and elevated body mass index (BMI). Another term, *interstitial fibrosis/tubular atrophy (IF/TA)* is used to describe this deterioration. It is often considered irreversible and unaffected by increased immunosuppressive therapy.[32]

Acute Rejection Treatment

Case 34-1, Question 8: A biopsy of G.P.'s transplanted kidney shows grade 1A, moderate acute cellular rejection. G.P. is started on methylprednisolone 500 mg daily IV for three doses. His next level of baseline immunosuppression is increased by increasing his MPA and TAC doses as well as continuing his prednisone dose. His maintenance oral prednisone is discontinued and MPA and TAC doses will be increased. Why is methylprednisolone therapy of G.P.'s first acute episode of rejection appropriate?

High-dose or "pulse" IV methylprednisolone, IV rATG, and IV and oral prednisone are options to treat acute rejection in all types of solid organ transplants. A high-dose corticosteroid (usually IV methylprednisolone) is considered first-line therapy because it works very quickly in decreasing lymphocyte responsiveness, is easy to administer, and reverses at least 75% of acute rejection episodes. rATG is usually reserved for steroid-resistant rejection or more severe grades of rejection. IVIG has also been used as an alternative for resistant rejection. The ideal corticosteroid dosage, route, and regimen are unknown. Corticosteroid protocols vary among transplant programs. IV methylprednisolone and oral prednisone are equally effective in reversing rejection, but oral corticosteroids are given for a longer period and have been associated with a higher incidence of adverse effects. Even though

50 mg of IV methylprednisolone has a lymphocyte suppressive effect similar to that of a 1-g IV dose, most programs use methylprednisolone 250 to 1000 mg (most commonly 500 mg) IV every day for three doses and may adjust the prerejection oral prednisone regimen for a period of time. An example of an oral prednisone regimen is 100 to 200 mg/day tapered for 1 to 3 weeks to baseline maintenance dose. For G.P., IV methylprednisolone is appropriate because corticosteroids are considered first-line therapy for acute rejection of a transplanted kidney, and first rejection episodes (such as G.P.'s) are very responsive. In addition, G.P. has received a prophylactic course of rATG recently and additional doses should be avoided, if possible. rATG is associated with a higher risk of CMV infection and malignancy; it is more difficult to administer, requires more intensive monitoring, is more expensive, and usually is held in reserve for corticosteroid-resistant or more severe forms of rejection.

Nevertheless, high-dose corticosteroids are not without risk. They increase the risk of infection, and long-term therapy can induce ocular, bone, cardiovascular, and endocrine abnormalities. Although G.P. will be receiving high-dose IV methylprednisolone for only 3 days, because he is diabetic, he should be monitored for hyperglycemia, and a change in his insulin requirements should be anticipated because corticosteroids can alter glucose metabolism. Short-course methylprednisolone also can mask signs of infection (eg, fever, changes in WBC counts, pain associated with inflammation) and delay the diagnosis. Insomnia, nervousness, euphoria, mood shifts, acute psychosis, and mania also can occur with short-term corticosteroid use. If the methylprednisolone regimen is effective in reversing G.P.'s acute rejection, his SCr concentration should decline within 2 to 5 days and his urine output should increase.

In addition, it would be appropriate to increase G.P.'s tacrolimus dosage to 7 mg twice a day because the concentration is low (5 ng/mL) and low trough has been associated with a higher risk of acute rejection. Because small changes in tacrolimus dose can increase levels disproportionately, a trough whole-blood

concentration should be reevaluated in 2 to 3 days. The MMF dose could be increased to 1 g bid and up to 1.5 g bid, because this dose in combination with a CNI has reduced acute rejection in African American patients, particularly if the patient was on cyclosporine therapy. There are limited data supporting the increase of the MMF dose beyond 1 g bid with tacrolimus-based regimens.[33,34] If G.P. had been on cyclosporine, another option would be to change cyclosporine to tacrolimus, which has been shown to reduce future episodes of acute rejection. Another important aspect for prevention of future rejection would be to assess G.P.'s adherence to, and understanding of, his medication regimen. Nonadherence is a major cause of acute rejection and graft loss.[35]

Case 34-1, Question 9: Six months later, G.P. is noted to have another elevation in SCr. In addition, DSAs are also detected in the blood. Did kidney biopsy indicate it as AMR? How would this type of acute rejection be treated?

AMR is more difficult to treat, and approaches vary. It may not respond to steroids and rATG, which are used initially. The most common treatment is plasmapheresis or immunoadsorption. These modalities are used to remove circulating antibodies and low- or high-dose IVIG for residual antibody inhibition, given after these procedures. Because of increased recognition and diagnosis, and resistance to treatment, a number of approaches are being used and investigated. Along with plasmapheresis and IVIG, rituximab may be used to treat acute AMR. Other agents, not currently approved for transplantation, are being utilized and studied as treatment, including bortezomib, which causes plasma cell apoptosis/depletion, and eculizumab, which is an anti-C5 antibody. Given the sparsity of large-scale, randomized trials assessing which agents to utilize to treat AMR, there is no consensus regarding which should be considered first-line therapy to treat AMR, although most clinicians do utilize plasmapheresis with IVIG as a starting point, and add on the aforementioned therapies at various stages or severities of AMR.[36]

Calcineurin Inhibitor–Induced Nephrotoxicity

CASE 34-2

Question 1: C.C. is a 60-year-old male who received a deceased-donor kidney transplant 3 years ago. His SCr at 1 year after transplant was 1.5 mg/dL; at 2 years, it was 1.7 mg/dL; now it is 1.9 mg/dL. He says he feels fine. His BP is controlled, and urinalysis is negative for protein. A kidney biopsy conducted at this time indicates that he has no signs of acute or chronic rejection but has evidence of CNI nephrotoxicity. His current regimen is cyclosporine 275 mg bid, MMF 500 mg bid, and prednisone 5 mg daily. His current labs show the following:

Cyclosporine blood trough, 220 ng/mL (target 100–150 ng/mL)
K^+, 5.5 mEq/mL
Mg, 2.3 mg/dL
Uric acid, 8.0 mg/dL

Why does C.C. have CNI nephrotoxicity?

CNI nephrotoxicity is one of the most common adverse effects and occurs to some degree in all patients. The rise in the SCr concentration is more gradual than, and not as high as, that seen with rejection. CNI concentrations may be elevated, although some patients may experience CNI nephrotoxicity even with levels below or within the targeted therapeutic range. Two forms of CNI nephrotoxicity have been identified: functional or acute renal dysfunction and chronic nephrotoxicity.[37]

Acute CNI nephrotoxicity is more likely to occur in the first months after transplantation and associated with high CNI doses and levels. Functional renal dysfunction or acute nephrotoxicity, the most common form of renal dysfunction, is characterized by rapid reversal when the CNI dose is held or reduced. This syndrome typically is not associated with histopathologic abnormalities. Repeated episodes of transient acute renal dysfunction can result in protracted acute renal dysfunction. Recovery of renal function after repeated episodes may not be complete even if the CNI is withdrawn. Protracted acute renal dysfunction can lead to direct tubular toxicity and can be associated

with the development of thrombosis of glomerular arterioles or diffuse IF.

Chronic nephrotoxicity is associated with proteinuria and tubular dysfunction. Renal biopsies in patients who had allograft and have chronic CNI-related nephropathy show tubulointerstitial abnormalities, sometimes with focal glomerular sclerosis. These findings are considered nonspecific. Recently, the role of CNI chronic nephrotoxicity in the development of irreversible chronic renal dysfunction has been challenged and thought to be overdiagnosed in many patients. However, long-term use can result in chronic nephrotoxicity, is usually seen after 6 months of therapy, and may be irreversible. In this situation, renal function progressively declines to a point that dialysis or retransplant is required. The pathophysiology of cyclosporine- or tacrolimus-induced transient acute renal failure is not understood completely but seems to be related to its effects on renal vessels. For example, CNI can induce glomerular hypoperfusion secondary to vasoconstriction of the afferent glomerular arterioles, thereby reducing glomerular filtration. One possible explanation for these effects is that cyclosporine alters the balance of prostacyclin and thromboxane A_2 in renal cortical tissue. Increased thromboxane A_2 results in renal vasoconstriction. Endothelin release from renal vascular cells stimulated by CNI also may contribute to this acute effect through its potent vasoconstrictive properties. Activation of the renin–angiotensin–aldosterone system may also play a significant role. CNI also can cause a reversible decrease in tubular function. The alterations in tubular function reduce magnesium reabsorption and decrease potassium and uric acid secretion. This may be a result of direct tubular toxicity and possibly the result of thromboxane A_2 stimulation of platelet activation and aggregation.

C.C.'s rise in SCr in conjunction with an elevated cyclosporine level suggests acute cyclosporine toxicity as the most likely cause of his findings. In this case, the total cyclosporine dose should be lowered by ~25% to 225 mg twice a day, to keep the level in target range, and C.C. should be monitored closely for resolution of any

symptoms and decrease in SCr or worsening if rejection results from lowering the dose. His elevated potassium and uric acid and low magnesium should correct themselves with this dose reduction if it is acute CNI toxicity. If the nephrotoxicity is caused by cyclosporine, a decrease in the SCr may be evident when the cyclosporine dose is reduced. If no such reduction occurs or if the SCr continues to increase, then other nonimmunologic or immunologic causes should be considered and CNI will also need to be substituted with an agent such as sirolimus, everolimus, or belatacept.

Calcineurin Inhibitor Avoidance, Withdrawal/Conversion, or Minimization

Case 34-2, Question 2: Would it be appropriate to withdraw cyclosporine in C.C.? If attempted, how could this be accomplished?

Cyclosporine and tacrolimus are associated with a number of metabolic, cardiovascular, neurologic, and cosmetic side effects, but the most concerning is nephrotoxicity, which is a contributor to graft loss. The potential benefit of withdrawing cyclosporine would be to reduce toxicity, but this has to be weighed against the risk of rejection, graft loss, and toxicities of replacement agents.

Concern for chronic nephrotoxicity, as well as other long-term side effects, has led to the development of cyclosporine or tacrolimus minimization, withdrawal or substitution/conversion protocols, using agents such as mycophenolate or sirolimus, everolimus, and belatacept, or protocols using low doses of cyclosporine or tacrolimus.

Antibody induction, sirolimus, everolimus, mycophenolate, and belatacept, which are not associated with nephrotoxicity, have been evaluated in combination protocols that attempt to avoid, minimize, or withdraw CNI. Protocols completely avoiding CNIs usually contain combinations of these agents. Studies, which were usually done in low-risk populations, observed lower SCr levels and fewer CNI-

induced toxicities, but were associated with higher rates of acute rejection, especially when CNI is not used at all. Other trials that compared combinations of rATG, alemtuzumab, or basiliximab, sirolimus, everolimus, mycophenolate, and steroids with either cyclosporine or tacrolimus withdrawal, or minimization protocols have shown equal effectiveness compared to standard therapy.[38,39]

In the case of early cyclosporine withdrawal, there is a 10% to 20% increased risk of acute rejection, but no change in graft survival. Protocols that withdraw the CNI or at least reduce the dose to a minimal level are used. Many attempts are within the first 3 to 12 months of transplantation in the hope that the nephrotoxic effects can be reversed before significant chronic damage occurs. These approaches add mycophenolate, sirolimus, or both as the CNI is withdrawn or reduced in dose, but they have been primarily tested in low-risk patients. Data with sirolimus suggest that patients without proteinuria and an estimated glomerular filtration rate (eGFR) >40 mL/minute in the first year had better renal function. Whether this applies to other agents remains to be determined. Usually, when sirolimus is added to the CNI regimen, the CNI dose is reduced by 50% initially and in some cases slowly withdrawn altogether during several weeks to months. Improvement in SCr may be seen initially, which may be attributed to the diminution of the CNI vasoconstrictive effects.

CNI minimization or withdrawal may not reverse the nephrotoxicity observed in C.C.'s biopsy, but it may slow the rate of deterioration of his renal function. Because C.C. is currently receiving mycophenolate, one approach would be to continue to reduce his cyclosporine, increase his mycophenolate, and maintain steroids. Another approach would be to replace the mycophenolate with sirolimus/everolimus because he has no proteinuria and his eGFR is >40 mL/minute, maintain steroids, and reduce or withdraw slowly the cyclosporine. Belatacept could also be used as replacement for cyclosporine while continuing mycophenolate and steroids. Some studies indicate better eGFR, lower incidence of new-onset diabetes after transplant, lower BP, lower cholesterol, but no difference in survival compared to CNI.[38] The best regimen for someone such as

C.C. has not been established, because the long-term consequences of these changes are not known. If this approach is attempted, C.C. should be watched carefully for acute rejection, and side effects of these agents, which some patients do not tolerate, and infections should be closely monitored. In addition, BP control as well as control of hyperlipidemia and hyperglycemia could improve with reduction or withdrawal of cyclosporine, depending on the agent used, and could also be important in minimizing renal injury.

Steroid Avoidance or Withdrawal

CASE 34-3

Question 1: D.T., a 65-year-old Caucasian female, will receive a deceased-donor kidney transplant today. She has a negative cross-match to this donor, and her previous cPRA was <10%. She will be given alemtuzumab 30 mg IV × 1 and methylprednisolone 500 mg IV × 1, intraoperatively. After transplant, she will be started on tacrolimus 0.05 mg/kg bid, adjusted to trough levels of 8 to 10 ng/mL for the first 3 months, along with MMF 750 mg bid. Methylprednisolone IV will be given as 250 mg IV on postoperative day 1, 125 mg IV on postoperative days 2 and 3, and no maintenance steroids thereafter.

Is D.T. a good candidate for steroid avoidance or withdrawal?

Another important issue after kidney transplantation is the role of short-term and long-term steroid use. Most transplant protocols incorporate steroid therapy, although ~30% of transplant centers use steroids only in the early postoperative period.[2] The concept of either avoiding or discontinuing corticosteroids is appealing because they cause significant adverse effects such as diabetes, cataracts, infection, hypertension, hyperlipidemia, osteoporosis, avascular necrosis, and psychiatric, neurologic, and cosmetic effects. Steroid withdrawal or avoidance, however, may increase the risk of acute rejection, compromise long-term graft function, and necessitate higher doses of the other immunosuppressives. Steroid avoidance is defined as either no steroid use or steroid use only for the first few days after transplant. Short-term studies, generally in low-risk patients, suggest that no adverse impact on short-term graft survival

exists and no need is seen for higher doses of other immunosuppressives when corticosteroids are not included in maintenance regimens. These protocols have included regimens such as using induction agents, alemtuzumab, basiliximab, or rATG along with tacrolimus and cyclosporine, mycophenolate, sirolimus, or everolimus.[40]

Steroid withdrawal is the complete discontinuation of prednisone, typically a few months posttransplant. In the era of cyclosporine (Sandimmune) and azathioprine-based regimens, withdrawal was associated with a high rate of acute rejection and late graft loss. With the introduction of newer agents, steroid avoidance or withdrawal has been viewed with renewed interest. Steroid withdrawal has been successful in at least 50% of kidney transplant recipients, resulting in reductions in BP and lipid levels. Some protocols withdraw corticosteroids within the first few days to weeks of the initial transplantation period, whereas others withdraw them in 3 to 6 months or later after transplantation. The rate of success depends not only on the immunosuppressives used but also on the population (high risk vs low risk) and timing of the withdrawal. Most success takes place in low-risk patients receiving antibody induction, such as rATG, with tacrolimus and mycophenolate with short-term steroids (≤1 week). African Americans, pediatric patients, patients who have retransplants, highly sensitized patients, patients with a high SCr (>2.5 mg/dL), and those who have had a recent rejection episode are more difficult to withdraw from steroids. This is particularly true early (<3 months) after transplantation. Withdrawal in these cases is associated with a higher rate of rejection. Later withdrawal may be attempted, but the benefits in terms of side effect profile may not be as great. Not all studies have demonstrated significant differences in side effect profiles between steroid withdrawal and continuation. Long-term outcomes are also limited using this approach. Low-risk populations are candidates for steroid avoidance or early withdrawal. First-time transplantation, living-donor, well-matched transplantation, older age, and stable graft function without rejection are factors associated with a positive benefit to steroid withdrawal.[40]

D.T. would be considered a low-risk patient because of her low immunologic activity evidenced by first-time transplant, a living donor, low PRA, older age, and ethnicity. Therefore, a steroid avoidance protocol, such as the one indicated here, would be appropriate. As with other transplant recipients, she must be closely monitored for rejection and adverse effects.

CASE 34-4

QUESTION 1: B.B. is a 27-year-old African American male who received a kidney transplant for focal segmental glomerulosclerosis (FSGS). Shortly following transplant, he developed GI intolerance, nausea, vomiting, and diarrhea, to both mycophenolate products and cannot take either one anymore. A decision is made to use an mTOR inhibitor, sirolimus or everolimus, instead.

What would be important pharmacokinetic considerations, an appropriate regimen, and monitoring parameters for this agent?

Mammalian Target of Rapamycin Inhibitors

Sirolimus, and, more recently, everolimus, could be used as a substitute for other immunosuppressives. Experience and literature are more extensive with sirolimus.[17] Sirolimus can be used in the immediate posttransplant period, although impaired wound healing and lymphocele development in kidney transplantation have limited its use in the early period. In the case of liver transplantation, its use is contraindicated in the early posttransplantation period because of hepatic artery thrombosis. Sirolimus can be added later, as is the practice in many centers, as replacement for or minimization of cyclosporine, tacrolimus, steroids, or mycophenolate. In addition, sirolimus may be used as a substitute for these agents in patients predisposed to or with evidence of malignancy.[41] Early experience advocated an initial loading dose followed by a once-daily maintenance dose; however, because of its adverse effect profile, not all centers use loading doses. The starting maintenance dose is 2 to 5 mg. The typical loading dose is 6 mg followed by 2 mg every day. In high-risk patients, such as African Americans, a 15-mg

loading dose and 5-mg daily dose are recommended along with cyclosporine. Other centers have used loading doses of 10 to 15 mg, followed by 5 to 10 mg/day for the first week with target troughs of 10 to 15 ng/mL for the first month and 5 to 10 ng/mL thereafter when used with tacrolimus. Sirolimus is often given 4 hours after the morning dose of cyclosporine. If administered at the same time as cyclosporine, sirolimus concentrations are on average 40% higher.[42]

As with other immunosuppressives, sirolimus is associated with a number of side effects, including impaired wound healing, lymphedema, oral ulcerations, hypercholesterolemia, hypertriglyceridemia, diarrhea, arthralgias, epistaxis, rash, acne, leukopenia, thrombocytopenia, nausea and vomiting, lymphocele, hypokalemia, anemia, hypertension, pneumonitis, reproductive endocrine disorders, and infection. Dose-related hypertriglyceridemia, as well as hypercholesterolemia, occurs within the first few weeks of therapy and is sufficiently significant to require intervention with lipid-lowering agents, although it may respond to dosage reduction to some degree. Leukopenia and thrombocytopenia are also dose related. Sirolimus is associated with the development of proteinuria in kidney transplant recipients. The exact mechanism is unknown, but many transplant centers are now routinely monitoring for proteinuria in patients on sirolimus therapy and generally avoid its use in patients with preexisting proteinuria. Unfortunately, adverse effects are often the reason for discontinuing this agent in many patients.[43]

Trough blood concentration monitoring plays an important role in the dosing of sirolimus. Trough concentrations correlate well with sirolimus AUC. Because it has a longer half-life than does the CNI, concentrations are obtained less frequently and only 5 to 7 days after a dose change. The target trough is usually 5 and 15 ng/mL; however, this continues to be refined with more experience. Early studies achieved concentrations >15 ng/mL, especially when used without a CNI, which were associated with a greater immunosuppression and adverse events. Because sirolimus is synergistic with CNIs, the target concentrations of the CNIs are also reduced when these agents are used together. Target tacrolimus

trough targets are 5 to 10 ng/mL, and the cyclosporine trough targets are 75 to 100 ng/mL, and in some patients, lower when used with sirolimus.[43]

B.B. could be started on sirolimus at 2 to 5 mg daily. Sirolimus blood trough concentration should be obtained 5 to 7 days after initiation. B.B.'s cyclosporine may need to be reduced if concentrations exceed 100 ng/mL. Monitoring parameters should include a fasting lipid panel, complete blood count, chemistries, and electrolytes. If everolimus was used, the starting regimen would be 0.75 mg twice daily. Everolimus blood concentrations should be obtained in 3 to 4 days after initiation. Target trough goal would be 3 to 8 mg/mL. Monitoring parameters and side effect profile are similar to those of sirolimus.

LIVER TRANSPLANTATION

CASE 34-5

QUESTION 1: B.T. is a 52-year-old, 200.62-pound (91-kg) male with a history of chronic liver disease secondary to nonalcoholic fatty liver disease (NAFLD). His chronic liver disease course was complicated by hepatorenal syndrome, hepatic encephalopathy, and ascites. He received an offer call for a potential liver transplant. Later that evening, he received an orthotopic liver transplantation (OLT). He received basiliximab and IV methylprednisolone for induction in the operating room. His Model for End-stage Liver Disease (MELD) at the time of transplant was 38. CMV serology for B.T. was positive, and the donor liver was CMV positive (CMV D+/R+). His SCr at the time of transplant was 2.5 mg/dL.

After the transplantation, B.T. was started on continuous renal replacement therapy. His immunosuppression included IV methylprednisolone taper to an oral steroid taper that is expected to end at 1-month posttransplant, MMF 500 mg NG bid with the plan to give the second dose of basiliximab and start tacrolimus on postoperative day 4. An antimicrobial regimen consisted of perioperative piperacillin/tazobactam to continue postoperatively for 48 hours with valganciclovir, fluconazole, and trimethoprim/sulfamethoxazole.

How should B.T. be monitored in the initial postoperative period?

Indications and Evaluation for Liver Transplant

B.T. was diagnosed with end-stage liver failure (cirrhosis) caused by NAFLD. Each center varies with respect to the most common causes of cirrhosis leading to liver transplant, but nationwide, alcohol-induced liver disease is one of the highest reported causes of liver transplantation. In recent years, hepatitis C virus (HCV) etiology has declined, whereas it used to be higher than alcohol-induced liver disease (OPTN/SRTR 2018 Annual Data Report: Liver). Nonalcoholic steatohepatitis (NASH), which is a type of NAFLD, has been increasing in incidence and is expected to become the most common indication within the next 10 years. Indications for liver transplantation in adults include cholestatic liver disease (eg, primary biliary cirrhosis and primary sclerosing cholangitis), hepatocellular liver disease (eg, chronic viral hepatitis B or C, autoimmune, drug induced, NASH, cryptogenic cirrhosis), vascular disease (eg, Budd–Chiari), hepatic malignancy, inherited metabolic disorders, and fulminant hepatic failure (eg, viral hepatitis, Wilson disease, drug induced, or toxin induced). Controversial indications include alcohol-induced disease and some types of hepatic malignancies. The concern with these indications is either recurrence of disease, as in the case of hepatic malignancies, or recidivism in the case of patients with alcoholism.[44,45]

Contraindications to transplantation have decreased over the past few years. Current contraindications to liver transplantation include malignancy outside the liver, cholangiocarcinoma (unless the center has a United Network for Organ Sharing [UNOS]-approved protocol), active uncontrolled infection outside the biliary system, patients with alcoholic liver disease who continue to abuse alcohol, psychosocial instability and noncompliance, severe neurologic disease, and advanced cardiopulmonary disease. Patients with active infections are considered candidates after the infection has been eradicated.[45] HIV infection is not considered an absolute contraindication to transplantation.[46]

B.T. was within the age limitations for transplantation (in general, up to age 75 years is considered, although exceptions are common).

The graft survival continues to improve with graft survival of 91.2% at 1 year and 84% at 3 years for deceased-donor liver transplants.

The liver allocation system is based on the MELD, in which higher MELD scores move patients higher on the waitlist. Some patients qualify for MELD exception scores, which will raise their native MELD score and allow them to be more competitive to receive organ offers. Patients who have an acute liver failure and their life expectancy is only a few days or less without a transplant are considered for Status 1a and are prioritized first. Blood type compatibility, body size, wait time in current urgency status, and how close their transplant hospital is to the donor hospital are other factors involved in the matching process.[47]

Patient Monitoring

Ideally, B.T. should be awake and alert within 12 to 24 hours of the operation, transferred from the intensive care unit to a regular bed in 1 to 2 days, and discharged home within 5 to 10 days. Because function of the transplanted liver is essential for the survival of the patient, extensive clinical, laboratory, and radiologic monitoring are necessary. B.T. has three Jackson–Pratt (JP) abdominal drains that must be monitored for output production. The serum concentrations of BUN, creatinine, liver function tests (LFTs), potassium, sodium, magnesium, calcium, phosphate, and glucose should be monitored every 6 hours on the first postoperative day.[48] The surgical transplantation of a liver has been associated with coagulopathies and bleeding. Therefore, platelets, prothrombin time, fibrinogen, and factor V levels also should be monitored and deficiencies rapidly corrected when clinically indicated.[48] Initial LFT results are highly variable; they can either increase for the first day or two after transplantation because of ischemic and reperfusion injury to the allograft or they can decrease because of initial dilution by high-volume blood replacement. If the liver is functioning well, the LFTs, bilirubin, and prothrombin time all should begin to trend toward normal within a few days of the transplant.

Magnesium, phosphate, and calcium levels may fall in the early postoperative period and should be monitored closely. Ionized calcium serum concentrations are often monitored rather than total calcium because most patients have low serum albumin concentrations. Hypocalcemia can occur because these patients may receive large amounts of citrate through blood transfusions, which can lower serum calcium concentrations. Magnesium deficiency is common in patients with end-stage liver disease and may be exacerbated in the early posttransplantation period by tacrolimus or diuretics. Why patients experience hypophosphatemia is not fully known, but increased demand for phosphate for incorporation into adenosine triphosphate is a possible explanation. Hypokalemia or hyperkalemia can occur, depending on renal function and fluid status.

Hyperglycemia, which is a good indication of a properly functioning liver because of its role in glucose homeostasis (gluconeogenesis and glycolysis), may need to be controlled with a continuous IV infusion of insulin initially, and then SC insulin dosed on the basis of periodic glucose measurements. In contrast, persistent refractory hypoglycemia indicates a poorly functioning liver. Hypertension, which is multifactorial, also is sometimes seen during this time and usually is treated with calcium channel blockers (CCBs) or β-blockers. Renal dysfunction and neurologic complications can also occur.[48] Neurologic complications, including those that are drug induced, include oversedation, acute psychosis, depression, tremor, headaches, peripheral neuropathy, cortical blindness, paresthesias, paresis, and seizures.[49]

Additional complications that are common within the first 3 days to 3 months of liver transplantation include respiratory distress, intra-abdominal hemorrhage, biliary tract leaks and strictures, hepatic artery thrombosis, and primary graft nonfunction. Because infection is another early postoperative concern, B.T. should be monitored for bacterial, fungal, and viral infections.[48]

Case 34-5, Question 2: Ten days after his liver transplantation, B.T.'s renal function had improved and he is off renal replacement therapy. Unfortunately,

he was noted to be altered with some hallucinations mainly in the evening and an increase in tremors in his hands throughout the day. His tremors became worse a couple days later with shaking in his legs as well. Antipsychotic medications were started, with minimal improvement in his altered mental status.

Current immunosuppression medications include tacrolimus 9 mg bid, MMF 500 mg bid, and prednisone 20 mg PO daily. B.T.'s current laboratory values include the following:

BUN, 24 mg/dL
SCr, 1.2 mg/dL
Aspartate aminotransferase (AST), 32 IU/L
Alanine aminotransferase (ALT), 92 IU/L
γ-Glutamyl transferase (GGT), 106 IU/L
Total bilirubin, 1.5 mg/dL
Tacrolimus, 8.2 ng/dL

The transplant team decided to convert B.T. to cyclosporine from tacrolimus because of the continued neurotoxicity. What pharmacokinetic and monitoring parameters and adverse effects should be considered when using cyclosporine?

Cyclosporine

Cyclosporine pharmacokinetic parameters exhibit significant intrapatient and interpatient variability. A number of factors are known to influence its pharmacokinetic behavior and outcomes. These include age, ethnicity, transplant type, underlying disease, time after transplantation, GI metabolism and motility; biliary and liver function; metabolism, body weight, cholesterol, albumin, and red blood cell mass; and drug interactions and formulation.[50] For example, children, African Americans, and patients with cystic fibrosis tend to have reduced absorption, increased clearance of cyclosporine, or both. Patients who are obese or who have decreased liver function will have reduced clearance. Oral absorption of cyclosporine, which has been characterized as slow, incomplete, and highly variable, is the parameter that is most significantly affected. Absorption can depend on the type of transplant, time after transplantation, presence of food and its composition, intestinal function (eg, diarrhea, ileus), small bowel

length, and the presence or absence of external bile drainage. Bioavailability ranges from <5% to 90%.[51] In most transplant recipients, cyclosporine absorption increases over time. The original cyclosporine (Sandimmune) is rarely used today because of its poor and erratic absorption compared to newer formulations. Cyclosporine can be given IV as a continuous infusion (2–3 mg/kg/day) or intermittently (2.5 mg/kg/day) over 2 to 6 hours divided into two equal doses.

Cyclosporine is extensively distributed into red blood cells, whereas, in plasma, it is highly bound to lipoproteins. It is extensively metabolized by both the gut and liver CYP3A4 enzymes and transported by P-glycoprotein. The average half-life is about 15 to 20 hours. Cyclosporine is an inhibitor of CYP3A4 and PGP, so it can interact with other drugs.[51]

Cyclosporine can cause a number of adverse effects, of which nephrotoxicity is the most frequent and worrisome. Other major effects include hypertension, hyperlipidemia, tremors, headaches, seizures, paresthesias, hypomagnesemia, hypokalemia or hyperkalemia, hyperuricemia, hyperglycemia, gout, gingival hyperplasia, hirsutism, hemolytic–uremic syndrome, and hepatotoxicity. Hyperlipidemia and hypertension are more common with cyclosporine than with tacrolimus, whereas neurotoxicity (tremors, headaches, seizures) and hyperglycemia are more common with tacrolimus. If adverse effects occur, usually a dose reduction/reduction of goal trough concentration or discontinuation of the agent is needed.[52]

Cyclosporine concentrations are monitored to prevent toxicity, optimize efficacy, and assess patient compliance to the prescribed regimen. Most institutions monitor trough cyclosporine levels. During the early postoperative period, cyclosporine levels are often measured daily, keeping in mind these may not reflect steady-state concentrations. The target trough therapeutic concentration of cyclosporine during the first 6 months posttransplant will vary based on institution and patient-specific factors and range from 150 to 300 ng/mL, with a usual reduction in goal around 2 to 3 months. After 6 months, the targeted cyclosporine trough concentration is lowered

even further to 50 to 150 ng/mL. The range is reduced over time, given less immunosuppression is required after transplantation and the pharmacokinetics change over time. A few programs may monitor cyclosporine level at 2 hours post-dose, obtained 2 hours after a dose, or determine AUC; however, these are more cumbersome.[53]

B.T. was started on Neoral 300 mg bid. Because he was on a higher dose of tacrolimus, he may require further dose increases to reach his goal trough concentration of 200 to 250 ng/mL. His trough concentration will be monitored closely along with signs of improved neurotoxicity. Other adverse effects due to cyclosporine and signs of rejection should be monitored.

Rejection

Case 34-5, Question 3: B.T. was discharged from the hospital on cyclosporine with improved neurotoxicity. He went to stay with his brother and was followed up with laboratory tests obtained three times a week. He reported feeling great and no longer had any altered mental status/hallucinations or tremors. The following laboratory values were obtained 2 weeks later:

AST, 31 IU/L; ALT, 52 IU/L; GGT, 65 IU/L; total/direct (T/D) bilirubin, 1.0/0.3 mg/dL
Cyclosporine tough concentration, 123 ng/mL
And another week later:
AST, 450 IU/L; ALT, 364 IU/L; GGT, 321 IU/L; T/D bilirubin, 2.5/2 mg/dL
Cyclosporine trough concentration, 116 ng/mL

B.T. was readmitted because of rise in LFTs and bilirubin, which are suggestive of acute liver dysfunction. A liver ultrasound and a percutaneous needle liver biopsy were obtained. On admission, he reported lethargy and some mild abdominal pain. He endorsed poor nutritional intake for the past 2 to 3 days. The pathologist interpreted the liver biopsy as moderate rejection, and B.T. was given a 500-mg IV bolus of methylprednisolone daily for three doses followed by tapered doses of IV methylprednisolone: 50 mg every 6 hours for four doses; 40 mg every 6 hours for four doses; 30 mg every 6 hours for four doses; 20 mg every 6 hours for four doses; 20 mg every 12 hours for two doses; and then back to the pretaper oral prednisone dose. What subjective and objective evidence for acute cellular rejection is present in B.T.?

HYPERACUTE REJECTION

Hyperacute rejection rarely occurs with liver transplantation; when this occurs, treatment is supportive and retransplantation is required.[54] Unlike other organs, however, the liver may function adequately, but survival is lower when the organ is transplanted across blood types (ABO incompatible) or in patients who are presensitized to the HLA antigens.[55]

ACUTE CELLULAR REJECTION

Although acute cellular liver rejection can occur at any time after the transplantation, it is most commonly experienced within the first 3 to 6 months of transplant and in ~20% to 50% of patients treated with either cyclosporine or tacrolimus and prednisone.[56] Data in patients treated with tacrolimus, mycophenolate, and prednisone indicate lower rejection rates.[57] Late acute rejections often are a result of either nonadherence, a reduction in dose, or a discontinuation of immunosuppressive agents. These rejection episodes, although somewhat common, rarely lead to graft loss.

B.T. presented with some of the subjective symptoms of rejection. Commonly, patients feel unwell and report anorexia, abdominal discomfort, and headache. Other symptoms, such as a low-grade fever, back pain, or respiratory distress, may rarely occur. With the use of more potent immunosuppression, symptoms are no longer commonly present with acute rejection and cannot be relied upon for early indication of rejection. Objective evidence of rejection in B.T. included an abrupt rise in transaminases and bilirubin and a liver biopsy that was interpreted as “moderate rejection.” These observations led to a diagnosis of rejection. Acute rejection is associated with mononuclear cell infiltration of the graft, edema, and parenchymal necrosis. Rejection should be diagnosed by biopsy using histologic criteria. Areas commonly damaged by rejection are the bile ducts, veins, and arteries, known as *portal triaditis*.[58]

TREATMENT OF REJECTION

Case 34-5, Question 4: Was the treatment of B.T.'s rejection of his transplanted liver appropriate?

The treatment decision was reasonable because high-dose corticosteroids reverse the majority of acute rejection episodes.[54] Acute cellular rejection in liver transplant patients is usually treated with 200 to 1000 mg/day of IV methylprednisolone (usually 500 mg IV for 3 days) and tapered rapidly, similar to B.T.'s. A high-dose corticosteroid (usually IV methylprednisolone) is considered first-line therapy because it works very quickly in decreasing lymphocyte responsiveness and is easy to administer. The ideal corticosteroid dosage, route, and regimen are unknown, and corticosteroid protocols vary among transplant programs. IV methylprednisolone and oral prednisone are equally effective in reversing rejection, but oral corticosteroids are given for a longer period and have been associated with a higher incidence of adverse effects.

Nevertheless, high doses of corticosteroids are not without risk. They increase the risk of infection, and long-term therapy can induce ocular, bone, cardiovascular, and endocrine abnormalities. Although B.T. will be receiving high-dose IV methylprednisolone for a short period of time, it can result in euphoria, mood shifts, acute psychosis, and even mania. Short-course methylprednisolone also can mask signs of infection (eg, fever, changes in WBC counts, pain associated with inflammation) and delay the diagnosis. If the methylprednisolone regimen is effective in reversing B.T.'s acute rejection, his LFTs and bilirubin should start to decline within 2 to 5 days.

Case 34-5, Question 5: After 3 days into the high-dose IV methylprednisolone course, B.T.'s liver enzyme values had not improved.

AST, 431 IU/L; ALT, 344 units/L; GGT, 351 units/L; T/D bilirubin, 3/2.5 mg/dL
The 12-hour cyclosporine trough level at the end of the treatment course was 168 ng/mL.

What other treatment options are available for B.T.?

High-dose or “pulse” IV methylprednisolone, IV rATG, and oral prednisone are options to treat acute rejection in all types of solid organ transplants. The decision to determine B.T.’s response to the initial bolus steroid dosage and the severity of rejection by biopsy also was appropriate before proceeding with further treatment. Subsequent therapy would include rATG. Most centers use rATG as a second-line agent if there is no response to high-dose corticosteroids or as a first-line agent for severe rejection. The typical dose is 1.5 mg/kg/day given as an infusion for 4 to 6 hours and is continued for 7 to 14 days. The duration will depend on clinical response, such as improvement in LFTs and bilirubin as well as the lowering of his absolute lymphocyte count. Treatment of corticosteroid-resistant rejection with rATG is effective in about 70% to 80% of liver transplant patients. rATG is associated with a higher risk of CMV infection and malignancy; it is more difficult to administer, requires more intensive monitoring, is more expensive, and usually is held in reserve for corticosteroid-resistant or more severe forms of rejection. Another alternative agent that could be used in both kidney and liver transplant patients with severe or resistant acute cellular rejection is alemtuzumab, although this is considered more of a last-line option.

In addition to starting rATG in B.T., changes to the maintenance immunosuppression regimen can be made to assist in further suppressing the immune system. B.T.’s cyclosporine level has been consistently lower than his initial goal of 200 to 250 ng/mL, and low trough concentrations have been associated with a higher risk of acute rejection. Continued dose adjustments are needed for B.T. to reach a therapeutic concentration, and in some rejection cases, a higher goal trough concentration than the patient was on prior is targeted. For example, B.T.’s goal trough concentration could increase to 250 to 300 ng/mL, but first he would need to at least reach his prior goal concentration. The prednisone dose may also be increased or added to the maintenance regimen. The MMF dose could be increased to 1 g bid, and, in some abdominal transplant patients, up to 1.5 g bid because this dose in combination with a CNI has reduced acute rejection in African American patients, particularly

if the patient was on cyclosporine therapy. There is limited data supporting the increase of the MMF dose beyond 1 g bid with tacrolimus-based regimens.[33,34] Another important aspect for prevention of future rejection would be to assess B.T.'s adherence with, and understanding of, his medication regimen. Nonadherence is a major cause of acute rejection and graft loss.[35]

CHRONIC LIVER REJECTION

Chronic liver rejection, also called ductopenic rejection, usually develops months to years after the transplant in <5% of recipients. Characteristics of chronic liver rejection include occlusive arterial lesions, destruction of small intrahepatic bile ducts (often referred to as *vanishing bile duct syndrome*), intense cholestasis, accumulation of foamy macrophages within the portal sinusoids, and fibrosis, which can lead to the development of cirrhosis.[58] Chronic rejection is almost always irreversible and unaffected by increased immunosuppressive therapy. Retransplantation has been considered the only viable alternative. Some patients with early ductopenic rejection unresponsive to cyclosporine-based therapy have responded to tacrolimus.[59]

CASE 34-6

QUESTION 1: D.C. received a liver transplant roughly 4 months ago for autoimmune hepatitis. At the time of transplant, he was started on tacrolimus 0.05 mg/kg bid and MMF 500 mg bid along with a steroid taper to his prior prednisone dose of 5 mg daily.

What are MMF's pharmacokinetic characteristics and adverse effects?

How will these characteristics affect the dosing and monitoring of MMF in this patient?

Mycophenolic Acid Derivatives

In the vast majority of transplant centers, MPA derivatives (MMF, EC-MPS) have replaced azathioprine as the antiproliferative agent used in maintenance immunosuppression. Liver transplant patients,

similar to D.C., with an autoimmune etiology for their liver disease are at higher risk of acute cellular rejection and are at risk for graft failure due to recurrent disease.[60] It is important to ensure these individuals are adequately immunosuppressed, and in many cases, they require more immunosuppression than do other liver transplant patients.

PHARMACOKINETICS

MMF is a prodrug for the active form, MPA. MMF is well absorbed (bioavailability 94%) and is rapidly hydrolyzed to MPA. The C_{max} for MPA occurs between 1 and 3 hours, and it is hepatically and renally glucuronidated to inactive MPAG, which is eliminated by the kidney, but mainly excreted into the bile. Once MPAG is excreted into the bile, it then may undergo enterohepatic recycling in the GI tract, where it is deconjugated to MPA (which is reabsorbed back into the systemic circulation). This recycling produces a second peak around 6 to 12 hours after dosing; however, this is blocked when coadministered with cyclosporine. As a result, the MPA AUC is significantly lower. MPA has an elimination half-life of 17 hours on average; the volume of distribution is 4 L/kg, and it is highly protein bound to albumin (98%). Protein binding correlates well with albumin, and free MPA concentrations somewhat correlate with the immunosuppressive effect. Renal impairment, liver dysfunction, and elevated MPAG concentrations in transplant recipients can reduce protein binding. This may be a function of low albumin concentrations seen in these patients.[13]

ADVERSE EFFECTS

The most commonly reported side effects for MMF are GI (anorexia, nausea, vomiting and diarrhea, gastritis), hematologic (leukopenia, thrombocytopenia, anemia), and infections. GI side effects are common, and all side effects are more common with higher dosages. Patients with GI problems may respond to administering the dose without other medications, smaller more frequent doses, or lowering of the dose and titrating upward as tolerated.[61] If the WBC count is

<3000 or the absolute neutrophil count is <1300 cells/mL, the MMF dose should be reduced or discontinued.

DOSING

The MMF starting dose in adults will vary based on type of transplant and institution-specific protocols. Doses usually range from 500 to 1000 mg bid. There is a drug–drug interaction between MMF and cyclosporine owing to cyclosporine inhibiting the enterohepatic recycling of MPAG. Several studies and some practices may dose MMF higher when administered with cyclosporine compared to tacrolimus.[13,33]

THERAPEUTIC DRUG MONITORING

Monitoring MPA plasma concentrations is controversial and not generally recommended at this time because of the lack of data demonstrating improved outcomes with therapeutic drug monitoring (TDM). In kidney transplant recipients, low MPA AUCs and troughs have been shown to correlate with acute rejection. In centers routinely performing MPA monitoring, typical $AUC_{0–12}$ targets are 30 to 60 µg/hour/mL and troughs are 1 to 3.5 µg/mL. MPA monitoring appears to be more beneficial in protocols where CNI sparing, withdrawal, or minimization is used. Once started on MMF, D.C. should be monitored for GI and hematologic side effects as well as for any signs and symptoms of infection and rejection.[34]

Case 34-6, Question 2: D.C. was admitted to the hospital with fevers, chest pain, cough, shortness of breath, and consistent leukopenia. His immunosuppression therapy was recently increased to prednisone 20 mg daily, MMF 750 mg bid, and tacrolimus 8 mg bid with a goal trough concentration close to 8 ng/mL (the most recent tacrolimus trough concentration was 8.9 ng/mL) because of concern for a mild rise in LFTs. Cultures were obtained and a chest x-ray was performed. On chest x-ray, there was concern for a fungal mass, possible aspergilloma. The infectious disease team was consulted and voriconazole was initiated. Owing to D.C.'s leukopenia and infection, his MMF was held. What drugs interact with immunosuppressive agents? Will the initiation of voriconazole require any adjustments in current medication doses?

Drug Interactions With Immunosuppressives

Some immunosuppressants, such as tacrolimus, have a highly variable pharmacokinetic profile, with a narrow therapeutic index highlighting the importance of managing their drug–drug interactions. Drug interactions can be separated into two main categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic interactions occur when one medication alters the absorption, distribution, metabolism, or elimination of the immunosuppressant agent.[62,63] **Table 34-2** displays the most clinically relevant pharmacokinetic drug interactions that are likely to be encountered in transplant patients and how to manage these interactions. These include drugs that alter either the absorption or metabolism of the immunosuppressants. Note that this table is not comprehensive.

Table 34-2

Immunosuppressant Drug Interactions

Immunosuppressant	Interacting Drugs	Mechanism	Consequence	Clinical Management
CNIs (cyclosporine and tacrolimus), mTOR inhibitors (sirolimus and everolimus)	Clarithromycin,[a] erythromycin,[a] telithromycin,[a] ketoconazole,[a] itraconazole,[a] fluconazole, posaconazole,[a] voriconazole,[a] fluoxetine, fluvoxamine, citalopram, nefazodone,[a] diltiazem,[a] verapamil,[a] delavirdine,[a] ritonavir,[a] cimetidine,[a] grapefruit juice,[a] amiodarone, saquinavir, nelfinavir, indinavir, amprenavir, chloramphenicol[a]	Inhibit CYP3A isoenzyme in the liver and intestines	Increase the blood concentration of the IS	Either prospectively decrease the IS dose or monitor trough concentrations and AUC more closely and adjust doses accordingly.
CNIs (cyclosporine and tacrolimus), mTOR inhibitors (sirolimus and everolimus)	Carbamazepine,[a] dexamethasone, phenobarbital,[a] phenytoin,[a] St. John wort,[a] rifampin,[a] rifabutin,[a] efavirenz,[a] nevirapine,[a] nafcillin, clindamycin	Induce CYP3A4 isoenzyme in the liver and intestines	Decrease the blood concentration of the IS	Either prospectively increase the IS dose or monitor trough concentrations and AUC more closely and adjust doses accordingly.
CNIs (cyclosporine and tacrolimus), mTOR inhibitors (sirolimus and everolimus), mycophenolic acid derivatives	Cholestyramine, colestipol, probucol, sevelamer, antacids (magnesium and aluminum containing)	Bind to IS and prevent absorption	Decrease the blood concentration of the IS	Avoid concomitant administration with IS and monitor trough concentrations.
Azathioprine	Allopurinol, febuxostat	Inhibit metabolism by inhibiting xanthine oxidase	Increase the blood concentration of azathioprine	Avoid use together or prospectively reduce azathioprine dose to one-third or one-fourth normal dose and monitor for increased toxicity.

AUC, area under the curve; CNI, calcineurin inhibitor; CYP, cytochrome P450; IS, immunosuppressant; mTOR, mammalian target of rapamycin.

[a]These are considered either potent inhibitors or inducers.

Pharmacodynamic interactions occur when one medication either potentiates an adverse effect or alters the pharmacologic effects of the immunosuppressant agent.[63] An example is the use of CNI in combination with angiotensin converting enzyme (ACE) inhibitors. Because both classes of agents can cause hyperkalemia and potentially decrease renal function, toxicity may be more pronounced when given in combination.[64] Pharmacodynamic drug interactions are usually more difficult to identify and require a thorough knowledge of the pharmacologic effects of the agents. Often, little or no information in the literature on these types of interactions exists to guide the clinician in determining whether this drug interaction will occur. As a general rule, if an agent is known to cause a particular toxicity similar to a toxicity associated with the immunosuppressant agent, then there is a high likelihood a pharmacodynamic interaction will occur. Another example is an interaction between metoclopramide and MMF. Both agents are known to cause diarrhea, and a higher incidence or severity of diarrhea likely occurs when these agents are used together.[63]

It is important to be alert for drugs with pharmacologic effects that may alter the efficacy of an immunosuppressant.[63] For example, a drug with immunosuppressant properties, such as cyclophosphamide, could lead to overimmunosuppression of the transplant patient and a higher incidence or severity of opportunistic infections. Conversely, a drug with immunostimulant properties, such as the herbal medication echinacea, may reduce the efficacy of the immunosuppressant agent and increase the risk of rejection in the transplant patient.[62,63] Although agents that have pharmacodynamic drug interactions with the immunosuppressants are not absolutely contraindicated, transplant patients should be closely monitored for either increased risk of drug toxicity or decreased drug efficacy when these agents are used in combination. When a transplant patient adds any new medication—whether prescription, over the counter, or herbal—it should be thoroughly researched to determine whether there is a potential interaction with the immunosuppressant regimen.

In D.C., the addition of voriconazole will lead to a pharmacokinetic drug interaction by inhibiting the CYP3A4 and CYP3A5 system and will increase tacrolimus trough concentrations.[65] Therefore, D.C.'s tacrolimus dose should be empirically reduced when voriconazole is started. The package insert for voriconazole mentions reducing the tacrolimus dose by 66%.[66] A more recent study found, owing to the patients' polymorphisms in CYP3A4, that the dose reduction of 66% may not be enough, whereas a reduction of 75% may be more appropriate if there is more concern for the patient having supratherapeutic levels rather than subtherapeutic levels.[67] Tacrolimus and voriconazole trough concentrations should be monitored, as should signs and symptoms of toxicity of these agents. In general, drug interactions can be managed and, in some cases, may only require separate administration times. In other cases, an alternative agent that does not interact with the immunosuppressant regimen can be used.

Posttransplant Complications

CASE 34-7

Question 1: J.V. is a 52-year-old African American female who received a deceased kidney transplant 4 months ago for hypertension. Her medical history is also significant for gout and depression. She currently weighs 202.83 pounds (92 kg) and is 66 inches (167.64 cm) tall, with a BMI of 32.7 kg/m^2. Before the transplant, she was taking lisinopril 20 mg PO daily, hydralazine 100 mg PO tid, amlodipine 10 mg daily, and carvedilol 25 mg PO bid to control her BP. After the transplant, amlodipine 10 mg PO daily, carvedilol 25 mg PO bid, and hydralazine 50 mg PO tid were continued. J.V. is on tacrolimus 8 mg PO bid, MMF 750 mg PO bid, and prednisone 5 mg PO daily. Her tacrolimus trough concentrations have been between 8 and 11 ng/L, with a recent goal of 6 to 8 ng/L.

After transplant, she was discharged on an insulin regimen including correctional insulin lispro at mealtimes and insulin glargine at bedtime. Currently, she is on two oral antiglycemic agents to maintain adequate blood glucose. Her BP readings during the past 2 weeks have ranged between 150/85 and 164/90 mm Hg. Fasting lipid panel is a total cholesterol, 265 mg/dL; low-density lipoprotein (LDL), 173 mg/dL; high-density lipoprotein (HDL), 45 mg/dL; and triglycerides, 220 mg/dL.

Why would J.V. have issues with controlling her blood glucose levels, BP, and lipid levels?

POSTTRANSPLANT DIABETES MELLITUS

Posttransplant diabetes mellitus (PTDM) has also been referred to as new-onset diabetes after transplant (NODAT). Diabetes significantly affects morbidity and mortality in transplant patients. It is often a preexisting condition in kidney transplant patients and a cause of ESRD. In recipients of other organs, such as livers, diabetes is common as well, both as a preexisting condition and as a posttransplantation complication. The definition of PTDM varies among studies. It has been based on symptoms, plasma glucose and HbA_{1c} levels, oral glucose challenge results, or the need for insulin or oral antidiabetic drugs after transplantation. It is recommended that diagnosis occurs once transplant patients have been discharged from the hospital and is on their maintenance immunosuppression. Within the first year posttransplant, diagnosis should not be made based on HbA_{1c} alone. Reported rates are 3% to >40%, with most cases of PTDM occurring within the first year of transplantation. Risk factors, besides pretransplantation diabetes, include advanced age, family history, CMV infection, certain HLA phenotypes, race (African American or Hispanic), increased BMI, and hepatitis C infection in the liver transplant population. One of the most critical factors in the development of PTDM is the immunosuppressive regimen. Cyclosporine, tacrolimus, and prednisone are all associated with PTDM. The CNIs appear to have a direct toxic effect on the pancreatic β cells, leading to decreased insulin synthesis and secretion; this effect seems to be dose related and generally reversible. Although still debated, the literature suggests that tacrolimus is more likely to cause PTDM than cyclosporine. In addition, conversion from tacrolimus to cyclosporine or belatacept has been beneficial. Prednisone is a major contributor to PTDM via multiple effects on β-cell sensitivity to glucose and ability to release insulin, and insulin resistance in multiple tissues. Sirolimus has also been implicated in the development of PTDM,

although its role and mechanism are unclear. Other risk factors, such as CNI drug concentrations, steroid doses, transplant type, and time lapsed after transplantation, must also be considered.[68] As with diabetes in the general population, a similar intensive approach in controlling blood glucose should be undertaken. Also, other conditions (eg, hypertension and hyperlipidemia) should be managed aggressively to reduce cardiovascular and kidney damage. Reducing or withdrawing diabetes-inducing immunosuppression as much as possible without jeopardizing graft function or using agents that are nondiabetogenic (such as mycophenolate) may be beneficial. One important aspect of posttransplant diabetes management is to realize the differences in pharmacologic management in this population, as compared with patients who are not transplant recipients. Often, in the immediate posttransplant period, because of the rapidly changing organ function and the dramatic tapering of corticosteroids, a patient's antidiabetic medicines may need frequent adjustment. During the first several weeks posttransplant, insulin is the agent of choice owing to the ability of the clinician to use sliding scales, the availability of several insulin products, and the ease in changing doses. Once patients are stabilized on their immunosuppressant regimen, and their organ function also, the use of oral antidiabetic agents can be introduced or restarted. Metformin, glitazones, gliptins, and sulfonylureas have been used in kidney transplants, but the use of oral agents is often dictated by renal function. Other considerations would be liver function and weight gain.[69] Newer antiglycemic agents, dipeptidyl peptidase-4 inhibitor (DPP-4) inhibitors and sodium–glucose cotransporter-2 (SGLT2) inhibitors have been studied in the transplant population, whereas, to date, there are no studies examining the use of glucagon-like peptide-1 (GLP-1) agonists in this population.[70] Limitations to the use of SGLT2 inhibitors are increased risk of urinary tract infections; however, both DDP-4 inhibitors and SGLT2 inhibitors have been found to lower HbA_{1c} with either no change in kidney markers or kidney graft survival, respectively.[70] Both SGLT2 inhibitors and GLP-1 agonists have been

shown in other populations to provide cardioprotective and nephroprotective effects.[71]

J.V. was not diabetic pretransplant but required insulin at her initial discharge; she is currently on two oral antiglycemic agents to manage her glucose levels and would classify for PTDM. Some would classify her as having PTDM. Risk factors J.V. has for PTDM are being African American, having a higher BMI, advanced age, and the use of tacrolimus and prednisone. The risks and benefits of changing immunosuppressant regimens to reduce PTDM must always be weighed. For instance, changing her tacrolimus to cyclosporine, or reducing or removing prednisone, may reduce her blood glucose level and may prevent PTDM, but it also will put J.V. at higher risk for developing acute rejection.

POSTTRANSPLANT HYPERTENSION

Case 34-7, Question 2: What pharmacologic options would be used for J.V.'s hypertension?

Cardiovascular disease is very common in patients with ESRD and after kidney transplantation. These patients with prior ESRD can have coronary artery disease (CAD), left ventricular hypertrophy (LVH) and congestive heart failure (CHF), and arrhythmias and valvular heart disease. Cardiovascular disease after transplant is associated with graft loss and lower patient survival. In those patients who die with a functioning graft, 40% die secondary to a cardiovascular event. Some immunosuppressives, including cyclosporine, tacrolimus, and steroids, contribute to the development of hypertension. Studies have indicated BP is higher, with high nighttime systolic BP, and more difficult to manage in patients on cyclosporine compared with tacrolimus.[72] The appropriate BP goals are similar to those in the general population, that is, <140/90 mm Hg in patients without proteinuria, as seen in this case. Nonpharmacologic therapies should be implemented; however, in

transplant patients, pharmacologic management is a key, often requiring multiple antihypertensives similar to J.V.

Pharmacologic agents used in transplant patients are the same as those used in the general population. In the transplant patient, one must consider the drug interaction profile and comorbidities. For example, non-dihydropyridine CCBs, such as amlodipine, are less likely to interact with CNIs than does diltiazem or verapamil. CCBs may also ameliorate some of the vasoconstrictive effects produced by the CNIs. In many programs, CCBs are considered first-line therapy. β-Blockers such as metoprolol are also frequently used in transplant patients. Many patients have or are at risk for CAD, and these agents can be effective in these situations. ACE inhibitors and angiotensin receptor blockers (ARBs) can be used in transplant patients, those with LVH. Historically, these agents were avoided because of concern for their association with impaired kidney function. However, these have significant cardiovascular and renal benefits in patients with comorbidities such as diabetes, proteinuria, and CHF. Their use in transplant patients has increased and is introduced usually months after transplant when renal function is more stable. If an ACE inhibitor or ARB is used, SCr and potassium levels must be monitored closely. Diuretics are useful in patients with evidence of fluid overload. In refractory patients, agents such as clonidine, hydralazine, and minoxidil may be required. In J.V.'s case, she could increase her hydralazine dose and, if needed, restart lisinopril with close monitoring and follow-up.

POSTTRANSPLANT HYPERLIPIDEMIA

Case 34-7, Question 3: What would be an appropriate lipid-lowering therapy for J.V.'s hyperlipidemia?

Hyperlipidemia is another cardiovascular issue to be addressed in transplant patients. As with hypertension, it is fairly common pre- and posttransplant. It is associated with negative cardiac outcomes and reduced graft and patient survival. Immunosuppressives including

cyclosporine, tacrolimus, steroids, sirolimus, and everolimus can cause elevations in total cholesterol, LDL, and triglycerides and reduce HDL. Goals of treatment and the level of intensity of statin therapy needed are based on individual risk factors, such as diabetes and age, along with the calculation of American College of Cardiology/American Heart Association (ACC/AHA) atherosclerotic cardiovascular disease risk to assess risk for heart disease and stroke in individuals. Application of the cholesterol clinical practice guidelines is also followed in this population.[73]

Treatment involves diet, which alone appears to have a minimal effect; therefore, pharmacologic treatment is usually required. Agents utilized in the nontransplant population are effective in reducing lipids in transplant patients. Considerations in selecting treatments for hyperlipidemia include drug interactions with the immunosuppressives and the side effect profile. Statins are considered first-line treatment and have substantial evidence to support their use. With the drug interaction of cyclosporine and statins, there is an increase in the concentration of statins, such as simvastatin and rosuvastatin. Therefore, there are recommended maximum statin doses when used in combination to limit adverse events. Atorvastatin and pravastatin are often used and appear to be safe and effective in this population. PCSK9 inhibitors are also effective in lowering cholesterol levels with minimal side effects; however, its affordability may be a challenge for some individuals. Fibrates, ezetimibe, bile acid binders, and niacin are considered second-line agents.[72] In J.F., atorvastatin would be an appropriate choice.

POSTTRANSPLANT OSTEOPOROSIS

Rapid bone loss with the subsequent development of osteopenia or osteoporosis is another common posttransplantation disorder. Osteoporosis increases bone fragility and eventually leads to fracture. Studies estimate that osteoporosis occurs in 11% to 56% and fractures in 5% to 44%, and increases in time in the transplant population. Osteoporosis risk factors for transplant patients are

similar to those in the general population. Additional risk factors in kidney transplant include time on hemodialysis before transplant, vitamin D deficiency, pretransplant parathyroid hormone (PTH) and fibroblast growth factor (FGF)-23 levels, diabetes, and steroid dose. Patients with ESRD commonly have at least some evidence of renal osteodystrophy, which includes hyperparathyroidism, osteomalacia, osteosclerosis, and adynamic or aplastic bone disease. Therapy options to prevent organ rejection predispose patients to osteoporosis, especially corticosteroids. The most dramatic reduction in bone loss after transplantation occurs within the first 3 to 6 months, when high doses of steroids are tapered off or to a lower maintenance prednisone dose. Most studies suggest a minor effect of CNI on bone. Other currently used agents appear to have little or no effect. Most recommendations are based on the American College of Rheumatology's guidelines for the prevention and treatment of corticosteroid-induced osteoporosis. These recommendations focus on providing calcium and vitamin D (variable dosing depending on kidney and liver functions) to patients who will be receiving continuous corticosteroid therapy. Patients with osteopenia or osteoporosis with bone mineral density scans using dual-energy x-ray absorptiometry (DEXA) scans, calcium, and vitamin D analogs are recommended in conjunction with a bisphosphonate, calcitonin, or teriparatide.[74–77] Bisphosphonate use is limited by patients' renal dysfunction, resulting in the need for alternative therapies. The use of denosumab has also been found to improve bone density in solid organ transplant recipients.[76]

MALIGNANCY

As a percentage of all malignancies, PTLD occurs more commonly in thoracic than in other types of solid organ transplants and is even more common in children. Lymphomas develop in about 1% of kidney transplantations and 2% of liver transplantations. These tumors often appear early and progress rapidly. The overall prevalence of malignancies in the transplantation population averages about 6%, and the risk of cancer increases with time after

a transplantation. Major organ transplant recipients are 100 times more likely to have cancer than the general population. Furthermore, the most common types of cancer observed in transplant recipients (eg, lymphomas, and cancer of the skin and lips) are uncommon in the general population. The development of skin and lip cancers in the transplant population has been attributed partially to exposure to sunlight and sensitization of skin to sunlight by an azathioprine metabolite, methylnitrothioimidazole.[78]

CASE 34-8

QUESTION 1: A.L., a 16-year-old, 92.59-pound (42-kg) female, underwent liver transplant 1 year ago secondary to biliary atresia with a failed Kasai procedure. She now presents with low-grade fever, malaise, pain, and a 1-week history of decreased appetite. She has experienced two episodes of rejection that were treated with 1 to 2 g of methylprednisolone each time, with the last rejection episode requiring rATG therapy. She received tacrolimus and prednisone after transplantation and had MMF added to her immunosuppressant regimen after the second rejection episode. She has just finished a course of IV ganciclovir (4 weeks) for CMV infection. The donor was CMV-positive, and she is CMV-positive. Her EBV DNA polymerase chain reaction (PCR) is now 18,000 copies/mL (normal, <500 copies/mL); this value was negative at the time of transplant. On physical examination, she was noted to have mediastinal adenopathy. She denies chills, sweats, nausea, vomiting, or diarrhea. A chest computed tomography scan revealed a mediastinal mass. Vital signs and all laboratory tests are within normal limits. Her tacrolimus trough is 9.8 ng/mL (goal is 8–10 ng/mL). Seven days after admission, a biopsy of this mass shows a thoracic lymphoproliferative lesion identified as a thoracic immunoblastic lymphoma adherent to the right side of the heart. Ten days later, she developed tachy/brady syndrome, and a pacemaker was implanted. Given the location of her lymphoma and symptoms, surgery and radiation therapy are not viable options, and chemotherapy is started the next day.

What clinical signs and risk factors in A.L. are associated with lymphoma?

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

Risk factors

A.L. has developed a PTLD, one of many types of malignancies reported after solid organ transplantation. The exact etiology of this condition is unclear and probably multifactorial. The presentation of

PTLD varies significantly. Patients can present asymptomatically, with mild mononucleosis-like symptoms or with multiorgan failure. A.L. presents with fever, lymphadenopathy, malaise, and lack of appetite. Although these symptoms are consistent with PTLD, they also are consistent with infection. Because PTLD can involve various organ systems, patients can present with organ-specific symptoms (eg, acute abdominal pain, perforation, obstruction). Depending on its location, a tumor can impinge on the function of other organs, as seen in A.L.[78] Besides immunosuppression, two factors associated with PTLD are the presence of EBV and the age of the patient. Children have a higher incidence of PTLD.[79] A.L. developed EBV DNA viremia, indicating she had been exposed to this virus at the time of transplantation or afterward. EBV also can be transmitted from the donor liver and/or blood products. Also, EBV-positive recipients at the time of transplantation can experience reactivation of this virus as a result of immunosuppression.

A.L. received a significant amount of immunosuppression. This could lead to an inability to suppress an active viral infection by cytotoxic T cells and result in uncontrolled B-cell proliferation and polyclonal and monoclonal expansion. In addition to this T-cell defect, an imbalance or alteration in cytokine production in response to EBV, which infects B lymphocytes, may contribute to the exaggerated B-cell expansion and transformation; most are classified as non-Hodgkin lymphomas primarily of B-cell origin. Small percentages are of T-cell origin, however, and are harder to treat.[78]

Newer, more potent immunosuppressive agents used in different combinations, increased numbers of transplantation procedures, and closer monitoring contribute to the increase in incidence and detection of PTLD. When cyclosporine-based regimens were compared with azathioprine- or cyclophosphamide-based regimens, lymphomas made up 26% and 11% of all cancers, respectively. The lymphomas occurred, on average, within 15 months of transplant in the cyclosporine group versus 48 months in the azathioprine group. One-third of these malignancies occurred in the first 4 months in the cyclosporine group compared with only 11% in the latter group.[78] The incidence of PTLD increases with rATG therapy and appears to be

related to a cumulative dose and multiple courses. PTLD is not caused by any single agent but probably reflects the intensity of immunosuppression as a whole and the combination usually of multiple agents. Chronic antigenic stimulation by foreign antigens, repeated infections, genetic predisposition, and indirect or direct damage to DNA are other variables that might affect the development of PTLD.[80] A.L. had a recent CMV infection, which also could have contributed to this process.

Treatment and outcomes

Case 34-8, Question 2: What are the therapeutic maneuvers and outcomes that would be expected in A.L.?

Treatment of a PTLD depends on timing, presentation, symptoms, extent of involvement, histologic type, and transplant type. Early experiences with PTLD indicated that a reduction in or discontinuation of immunosuppression led to the regression of the cancer. Therefore, the first step in treating PTLD is to consider the reduction in or discontinuation of immunosuppressive agents, with the potential exception of discontinuing the corticosteroids. This course of action is not feasible for all transplant patients based on prior course of the transplanted organ (eg, rejection history) or the life-saving need to ensure functioning of the transplanted organ. Therefore, A.L.'s MMF probably should be discontinued to minimize the potential for severe bone marrow toxicity. In addition, A.L. will likely have a small reduction in her tacrolimus doses, with the goal of achieving trough concentrations on the lower end of her therapeutic range (4–6 ng/mL); her prednisone should also be reduced to the lowest dose possible. If her immunosuppressive drug therapy is diminished, she should be monitored closely for rejection. A.L. will also need to pursue chemotherapy for treatment.

Antiviral therapy with IV acyclovir or ganciclovir has been used to inhibit EBV replication in an effort to treat PTLD. Response is variable and may depend on the type and extent of PTLD. A.L.

already has received ganciclovir for 4 weeks during which time she presented with PTLD. Surgery, radiation therapy, and chemotherapy are used to treat PTLD depending on the situation. IFN and Ig have been effective in a few cases that appeared unresponsive to other therapies. Monoclonal or immunoblastic, disseminated, rapidly progressive PTLD responds poorly to traditional therapy and has a mortality rate as high as 70%. Rituximab (an anti-B-cell, anti-CD20 antibody) is considered first-line therapy for CD20-positive B-cell PTLD along with a reduction in or withdrawal of immunosuppression if possible. Patients usually get 375 mg/m^2 weekly for 4 weeks; some groups have used prolonged therapy. Patients may have relapse or disease progression that may respond to chemotherapy regimens such as cyclophosphamide, adriamycin, vincristine, prednisone, or dexamethasone (CHOP); CHOP plus rituximab (CHOP-R); and cyclophosphamide, doxorubicin, etoposide, prednisone, cytarabine, bleomycin, vincristine, and methotrexate (PROMACE-cytaBOM). Transplant recipients have a higher risk of myelotoxic side effects, depending on their maintenance immunosuppression. A.L.'s prognosis is poor given the type and extent of her PTLD, which would have been more responsive to therapy if it had been diagnosed early. Polyclonal PTLD responds well to reduction in or discontinuation of immunosuppression and high-dose acyclovir or ganciclovir therapy for several weeks to months. The roles of prophylactic antivirals, Igs, and EBV PCR monitoring in the prevention of PTLD are currently controversial, with mixed results in current literature.[81]

Infection Prophylaxis

CASE 34-9

Question 1: M.C. is a 61-year-old male who underwent liver transplantation for end-stage liver disease secondary to alcoholic cirrhosis. His MELD at the time of transplant was 22, CMV serology was D+/R−, and he received an HCV Ab+ nucleic acid amplification testing (NAT)+ organ. Besides his immunosuppressives, he received ampicillin-sulbactam 1.5 g every 8 hours for

24 hours perioperatively. After transplantation, he also was started on TMP-SMX single-strength (SS, 400/80 mg) one tablet Mondays, Wednesdays, and Fridays; micafungin 100 mg daily; and valganciclovir 900 mg daily.

What is the rationale for the aforementioned agents? Should other measures be considered to prevent infection?

Infection continues to be a major source of morbidity and mortality in transplant patients. Transplant patients have the same risk of infection from transplant surgery as any other patient having a surgical procedure. The incidence of infections has decreased since the advent of cyclosporine. Infection rates, however, remain high—upward of 50% in transplant patients.[82] Infections can occur at any time after transplantation, but there are predictable time patterns for certain kinds of infections.[82] The time of highest risk for infection in transplant patients is during the first 6 months, because they are receiving the highest doses of immunosuppressive agents during this period. Another time of high risk is during and after treatment of acute rejection with high-dose immunosuppression. Patients can acquire new infections, reactivate old infections, or experience recurrence of underlying disease.

PERIOPERATIVE AND POSTOPERATIVE ANTIBACTERIAL THERAPY

Prophylactic antimicrobial therapy decreases the risk of surgical infections; however, prophylactic regimens and antibiotic therapies are highly institution dependent.[83] Kidney transplant recipients typically receive a first-generation cephalosporin, such as cefazolin, to cover uropathogens and staphylococci. Usually, antibiotic prophylaxis is given preoperatively, before skin incision and continued for one to three doses posttransplant. Owing to how severely ill a patient with cirrhosis is going into transplant and with the surgery requiring multiple anastomoses in a nonsterile environment (the bowel), liver transplantations are associated with the highest rate of life-threatening bacterial infection. Piperacillin–tazobactam is commonly used to cover staphylococci, enterococci, and *Enterobacteriaceae.* Duration of therapy in these patients is

individualized based on the patient's postoperative recovery, but usually lasts from 24 to 96 hours posttransplant.[83]

DONOR-DERIVED INFECTIONS

Donor-derived infections are any infection present in the donor that is transmitted to one or more recipients. There are numerous pathogens that could be transmitted, whether expected or unexpected. Some expected transmissions are CMV, syphilis, and hepatitis B virus (HBV; core antibody-positive donors) because there is knowledge before the transplant of the infection in the donor. These infections potentially require monitoring, prophylaxis, and/or treatment.[84] With a continued shortage of available organs and the need to expand the donor pool along with advances in antiviral therapy for these disease states, there is a more recent use of HIV-positive organs to HIV-positive recipients and organs from HCV Ab+ NAT+/– donors to HCV-negative recipients.[85–87] Some unexpected infections are bacteremic donors or those with positive donor urine cultures.

M.C. received an HCV Ab+ NAT+ donor. He will require monitoring of his HCV RNA PCR and obtain an HCV genotype. Usually, a test to predict the presence of fibrosis in the liver, if any, is also completed. These labs will assist in obtaining antiviral therapy for the patients to achieve a sustained virologic response (HCV is not detected in blood ≥12 weeks after completing treatment) posttransplant.

PNEUMOCYSTIS JIROVECI PNEUMONIA

Pneumocystits jiroveci is an opportunistic fungus that infiltrates the lungs causing pneumonia. *P. jiroveci* pneumonia (PJP) is associated with a high mortality rate in transplant patients, and routine prophylaxis is required for usually the first six months posttransplant. First-line prophylaxis therapy is TMP/SMX, which can be dosed as SS daily or double strength with a frequency of three times weekly. For patients with sulfa allergies, alternatives such as dapsone 50 to

100 mg PO daily, inhaled monthly doses of pentamidine 300 mg, and atovaquone 1500 mg daily are used.[88,89]

OTHER OPPORTUNISTIC INFECTIONS

Because the opportunistic infections shown in **Table 34-3** occur at such a high rate, it is routine to provide specific prophylaxis for many of them. Similar to PJP, CMV and herpes virus infections should be covered by universal or preemptive prophylaxis postoperatively.

Table 34-3
Common Opportunistic Infections After Transplantation

Organisms	Usual Time of Onset After Transplantation
Cytomegalovirus	1–6 months
Herpes simplex virus	2 weeks–2 months
Epstein–Barr virus	2–6 months
Varicella-zoster virus	2–6 months
Fungal	1–6 months
Mycobacterium	1–6 months
Pneumocystis jiroveci pneumonia	1–6 months
Listeria	1 month–indefinitely
Aspergillus	1–4 months
Nocardia	1–4 months
Toxoplasma	1–4 months
Cryptococcus	4 months–indefinitely

ANTIFUNGAL

Thrush prevention with the use of nystatin suspension 500,000 to 1,000,000 IU by “swish and swallow” three to four times a day is commonly used in abdominal transplant patients during their inpatient stay or for a duration of 1 to 3 months posttransplant. Other antifungal prophylaxis such as fluconazole can be used to reduce fungal colonization of the GI tract in liver and pancreas transplant patients. For high-risk liver transplant patients, there are several

studies assessing the use of fluconazole, echinocandins, and even amphotericin B posttransplant to reduce the incidence of invasive fungal infections, in particular, aspergillosis.[90–92]

HEPATITIS B

HBV can be acute or chronic, and some patients may have a recovered HBV infection. As mentioned earlier, transplant patients who have not been exposed to HBV may be candidates to receive a donor who is HBV core positive. To treat and prevent HBV recurrence, antiviral therapy is used, such as lamivudine, entecavir, tenofovir, and others. In liver transplant patients with acute or chronic HCV, the use of hepatitis B immune globulin (HBIG) with oral antiviral therapy is used postoperatively. Dual therapy is used because monotherapy with HBIG is associated with a higher recurrence rate (in 10%–50% of patients). HBIG 10,000 IU IV is commonly given intraoperatively and daily for the first week. After the first week, there are a variety of redosing methods based on the risk of hepatitis B recurrence and on hepatitis B surface Ab titers. Because HBIG is expensive (up to $50,000 per patient per year) and with the newer, more potent oral antivirals available, more transplant centers now target lower titers (>100 IU/L rather than >500 IU/L) and HBIG doses of 1500 IU intramuscularly every 3 to 4 weeks.[93]

HEPATITIS C

Another virus of concern is hepatitis C and the recurrence of hepatitis C viral replication after transplantation.[94] Overimmunosuppression can have a significant detrimental effect on this disease after transplantation. Survival rates are significantly lower at 5 years after transplant compared with patients who received liver transplants for non-hepatitis C causes.[94] Recently, there have been dramatic advances in the treatment of hepatitis C, with the advent of non-IFN–based DAA therapies. In addition, the newer DAA therapies have a much-improved tolerability profile and are able to be used in patients with renal dysfunction. They have less cytopenias and limited constitutional symptoms, thus

substantially reducing the need to hold or discontinue therapy, as compared to IFN and ribavirin.[95,96]

CASE 34-10

QUESTION 1: R.S., a 42-year-old, 149.91-pound (68-kg) female with end-stage liver disease caused by alcoholic cirrhosis, received an orthotopic liver transplant 6 months ago. She presents to the clinic with general fatigue, diarrhea, and nausea. At the time of transplantation, both the donor and the recipient were positive for CMV antibodies (D+/R+). Her maintenance immunosuppression regimen postoperatively included a taper to prednisone 5 mg daily and tacrolimus 8 mg PO bid for a goal trough concentration of 8 to 10 ng/mL. She was also on valganciclovir prophylaxis for 3 months posttransplant. Last month, her postoperative course was complicated by acute cellular rejection likely due to her nonadherence to taking her medications, resulting in a consistent subtherapeutic tacrolimus concentration. For her rejection, she received high-dose methylprednisolone with a prednisone taper. MMF was also initiated at this time at a dose of 1 g bid. Since this episode, her liver has functioned well. It was decided to admit the patient from clinic because of her symptoms and lab values. A physical examination was remarkable for an oral temperature of 102.02 °F (38.9 °C), a BP of 121/82 mm Hg, a heart rate of 98 beats/minute, and a respiratory rate of 23 breaths/minute. All other findings on her examination were benign. Pertinent laboratory findings during admission include the following:

WBC count, 1800 cells/μL
Platelet count, 52,000 cells/μL
BUN, 20 mg/dL
SCr, 0.96 mg/dL
Total bilirubin, 1 mg/dL
AST, 23 IU/L
ALT, 25 IU/L
CMV PCR, 342,000 copies/mL (normal <500 copies/mL)
12-hour tacrolimus concentration, 12.1 ng/mL

What is the most likely diagnosis for R.S.?

CYTOMEGALOVIRUS

A major concern for R.S. is her CMV infection, which is commonly encountered within 1 to 6 months of solid organ transplant. It is a ubiquitous virus belonging to the herpes virus group. In healthy immunocompetent adults, infection with the virus is usually

asymptomatic, whereas in immunocompromised patients, CMV can cause significant morbidity and mortality. CMV can potentiate the risk of developing bacterial and fungal infections and induce chronic injury to the transplanted organ (arteriosclerosis in the heart, obliterative bronchiolitis in the lungs, vanishing bile duct syndrome in the liver, and chronic arteriopathy in the kidneys).[97] Also, CMV infection and disease can result in dysregulation of the immune system, increasing the risk of rejection.

Etiology

CMV infection in transplant recipients usually occurs when latent viruses from a seropositive donor organ are reactivated owing to immunosuppression. Without prophylaxis, transmission of CMV from a positive donor to a negative recipient leads to an 80% to 100% infection rate and a 40% to 50% disease rate; a positive donor to a positive recipient leads to a 40% to 60% reactivation rate and a 20% to 30% disease rate; and a negative donor to a negative recipient leads to a 0% to 5% infection rate. Transplant recipients at highest risk for developing the disease are (a) those who are or have a serologically positive donor and negative recipient (D+/R−) at the time of transplant, (b) elderly, (c) those who received antilymphocyte antibodies, (d) those who received a retransplantation because of acute rejection, and (e) those who received larger amounts of immunosuppressive agents.[97] R.S. is at risk for CMV infection and disease because she was treated for rejection and is currently on a more intense immunosuppression regimen, which is likely oversuppressing her immune system.

Diagnosis

Diagnosis of CMV is based on both clinical and laboratory findings. CMV may be detected by culturing body fluids, such as bronchoalveolar lavage, urine, blood, ophthalmologic examination, and tissue biopsies. CMV is contained within the host's leukocytes, which appear to have large intranuclear inclusion bodies. CMV PCR is primarily used for measuring viral loads in the patient's blood and

is called *CMV DNAemia*. The lower and upper limit of quantification of the assay will vary among tests, and a CMV PCR (of the whole blood or plasma) result of >1000 IU/mL is probably concerning for CMV DNAemia. Depending on the sensitivity of the assay, R.S. has laboratory findings consistent with CMV infection: evidence of CMV replication in any body fluid or tissue specimen regardless of symptoms. R.S. is also presenting with CMV disease: evidence of CMV infection with attributed symptoms. CMV disease can be either a viral syndrome where symptoms are present or a tissue-invasive disease (confirmed by tissue biopsy). She has leukopenia, thrombocytopenia, and clinical symptoms consistent with CMV infection and disease, including fatigue, nausea, and diarrhea.[98]

Clinical manifestations

In healthy immunocompetent adults, the CMV-infected individual is usually asymptomatic but may present with mild malaise, fever, and myalgias as well as abnormal liver enzymes and lymphocytosis. More severe reactions are rare.[96,97] CMV may, however, be life-threatening in the immunocompromised. The actual CMV course may be limited to fever and mononucleosis, or it may extend to organs presenting as pneumonitis, hepatitis, gastroenteritis, colitis, disseminated infection, encephalopathy, or leukopenia.

At this time, it is unclear whether R.S. has any end-organ involvement/disease. She presents with GI symptoms, such as diarrhea and nausea, which may be indicative of CMV gastroenteritis or CMV colitis. These symptoms could also be caused by side effects of her MMF or other medications. To fully differentiate between CMV tissue-invasive disease and medication side effects, a tissue biopsy should be obtained and/or an altering of immunosuppression/medications that are likely a cause of her symptoms.

Case 34-10, Question 2: What is the duration of therapy and treatment options?

Duration of therapy

CMV viral load should be monitored weekly to determine duration of therapy. CMV viral load should be below a threshold (usually <200 IU/mL for sensitive assays) on one or two consecutive tests drawn several days apart (minimum of 2-week duration) and resolution of clinical signs of CMV disease before discontinuing treatment.[98]

Ganciclovir

Before ganciclovir was available, CMV infection was "treated" by reducing the level of immunosuppression. This may be one of the explanations for an increased prevalence of rejection associated with CMV infections. Treatment has been largely unsuccessful with acyclovir, adenine arabinoside, and immune globulin. Ganciclovir is the first-line agent for the treatment of CMV disease in solid organ transplant recipients. Ganciclovir, a virostatic agent, is a nucleoside analog phosphorylated in infected cells to its active form and is then incorporated into replicating viral DNA. R.S. should receive ganciclovir IV or oral valganciclovir for mild CMV disease. Ganciclovir IV is recommended for life-threatening and severe cases of CMV disease.[98]

The usual dose of ganciclovir is a 5 mg/kg/dose every 12 hours, and the dose of valganciclovir is 900 mg PO bid. Both require renal dosage adjustments, which is the only recommended reason for altering the dose.[98] The most common adverse effect associated with ganciclovir therapy is neutropenia, occurring in up to 27% of patients.[99] Neutropenia is defined as an absolute neutrophil count of <500 to 1000 cells/mL. The use of a granulocyte colony-stimulating factor, such as filgrastim, to improve neutropenia and/or the discontinuation of other potential medications causing neutropenia is recommended before changing treatment therapy.[98,100] Because CMV has a propensity to cause neutropenia as well, it is often difficult to distinguish the cause. If laboratory findings and clinical signs and symptoms of CMV disease are resolving and the patient remains neutropenic, the most likely cause is ganciclovir. Thrombocytopenia occurs in ~20% of ganciclovir recipients. Patients

with initial platelet counts <100,000/mL appear to be at greatest risk. Other adverse effects include CNS effects, fever, rash, and abnormal LFT findings.[97,99] R.S.'s WBC with differential and platelet counts should be assessed every 3 to 4 days during therapy.

Immunoglobulins

The use of Igs to treat CMV disease in solid organ transplantation is controversial. They are expensive and sometimes in short supply. Igs provide passive immunization by potentiating an antibody-dependent, cell-mediated cytotoxic reaction. Basically, the Igs modify the immunologic response that damages host tissue. Some evidence suggests that Igs may have synergistic or additive effects with current antiviral drugs in the treatment of CMV disease.[100] Both unselective Igs and CMV hyperimmune globulin have been studied in combination with ganciclovir, although not usually recommended. CMV hyperimmune globulin is prepared from high-titer pooled sera that have a fourfold to an eightfold enrichment of CMV titers compared with unscreened Ig.

CMV Ig may be given as a 100 mg/kg/dose every other day for 14 days. This is the dose recommended for the treatment of CMV when used in combination with ganciclovir. The most common adverse effects associated with the administration of Igs are infusion related and include fever, chills, headache, myalgia, light-headedness, and nausea and vomiting.

Foscarnet

Foscarnet is a virostatic pyrophosphate analog that inhibits DNA synthesis; however, unlike ganciclovir, no phosphorylation is required for activation. Because this drug has a high nephrotoxicity propensity and because most transplant recipients are already receiving drugs that are nephrotoxic, experience with the use of foscarnet in solid organ transplantation is limited. At most centers, foscarnet is a second- or third-line agent to be used only if intolerance or resistance develops with ganciclovir therapy.

The usual dosage of foscarnet is 60 mg/kg/dose every 8 hours and should be dose adjusted for renal dysfunction. The most serious adverse effect with foscarnet is nephrotoxicity, which occurs in up to 50% of patients and is probably induced by acute tubular necrosis. Therefore, prehydration is suggested to help minimize or avoid nephrotoxicity. GI effects, a decrease in hemoglobin and hematocrit, an increase in LFTs, and an alteration of serum electrolyte concentrations are other side effects of foscarnet. All of these appear to be reversible on discontinuation of the drug. SCr should be monitored daily during therapy.[99]

Cidofovir

Similar to foscarnet, cidofovir inhibits DNA synthesis and does not require phosphorylation for its activity. It is approved for CMV retinitis in patients with acquired immunodeficiency syndrome. Cidofovir may be used for CMV treatment as salvage therapy in the setting of ganciclovir and foscarnet resistance. Its use is limited because of its nephrotoxic side effect, and the addition of probenecid is used to competitively inhibit the uptake of cidofovir in the proximal tubular epithelial cells to lessen its nephrotoxicity.

Letermovir

A CMV UL56 terminase inhibitor with specific activity for CMV and not for other herpesviruses, letermovir may be useful for salvage therapy in combination with reduced immunosuppression; however, its overall efficacy for treatment is still to be determined and limited by its mechanism of action. It has undergone a phase IIa randomized, controlled study for a potential treatment option for preemptive CMV strategy in kidney transplant recipients at lower doses than that approved for prophylaxis in hematopoietic stem cell transplant (HSCT). It is available in both IV and PO formulations. Adverse effects tend to be more favorable and uncommon, with mainly GI (gastritis, nausea), dyspnea, and hepatitis.[101,102]

Cytomegalovirus resistance to antiviral therapies

Although uncommon, CMV resistance to antiviral therapies, as defined by continued viral replication despite prolonged treatment, may be present in 5% to 12% of patients who have a high-risk serostatus (D+/R−). There have been two primary gene mutations associated with this resistance, one to the UL97 kinase and the other to the UL54 DNA polymerase gene. The vast majority (90%) of resistant strains to ganciclovir contain mutations to the *UL97* gene, which usually does not confer cross-resistance to other antiviral therapies, including cidofovir or foscarnet.[103] As illustrated by R.S.'s case, a patient who has received prophylactic therapy does not preclude the development of CMV infection or disease after the prophylaxis is withdrawn or, in rare instances, during prophylactic therapy.[104–106]

Prophylaxis

Case 34-10, Question 3: What are the methods and therapy options to prevent CMV in transplant patients?

Because of its significant consequences, efforts should be made to prevent CMV infection and disease. Many studies have tried to ascertain the easiest, most cost-effective regimen to prevent CMV. CMV-specific immune monitoring assays are currently being used and studied to monitor CMV-specific T-cell responses to assist with determining a patient's risk for CMV disease. These assays may be valuable to assist with clinical decisions regarding the need for and duration of secondary prophylaxis along with treatment duration. Duration of universal prophylaxis is for 3 months posttransplant for intermediate risk (D− or +/R+) and recommended for 3 to 6 or 6 months in CMV high-risk (CMV D+/R−) liver and kidney patients, respectively.[98]

Universal Prophylaxis

Ganciclovir

The use of both the IV and oral formulations of ganciclovir to prevent CMV disease has been studied in liver and kidney recipients.[107] Very few large trials have been conducted, and most of the data in the solid organ transplantation population are from small uncontrolled trials. Another difficulty lies in the large discrepancies that exist between the trials with regard to the terminology used to define prophylaxis and high-risk patients. Until the introduction of valganciclovir, ganciclovir was the most widely used prophylactic agent. In the United States, oral ganciclovir therapy has not been commercially available for a number of years. Thus, most transplant centers are now solely using valganciclovir therapy as their first-line agent. IV ganciclovir is still available and can be used for short periods if the patient is not able to tolerate oral therapy.

Valganciclovir

Valganciclovir was developed because oral ganciclovir has a very low bioavailability (<10%). Valganciclovir is the L-valyl ester of ganciclovir, which is a prodrug that is rapidly and completely converted into ganciclovir by hepatic and intestinal esterases once absorbed across the GI tract. The absolute bioavailability of valganciclovir is ~60%, so that a 900-mg single PO dose given with food is an AUC equivalent to a 5 mg/kg IV dose of ganciclovir. This is roughly twice the AUC achieved by 1000 mg of ganciclovir given PO tid. Valganciclovir is currently FDA approved for the treatment of HIV-associated CMV retinitis and to prevent CMV disease in heart, kidney, and pancreas transplantation.[104,105] Valganciclovir is not FDA approved for the prevention of CMV disease in liver transplantation, although it is often used in such cases. Several small studies have demonstrated that valganciclovir is effective in treating CMV infection preemptively and potentially preventing CMV disease.[104]

Because valganciclovir is very expensive and has a high potential for causing hematologic toxicities, several studies have been conducted using reduced dosing strategies. Some centers use half the recommended dose of 900 mg PO daily in patients with good renal function and have shown equivalent clinical outcomes with the

potential of reducing cost and toxicities. These studies were conducted in kidney transplant patients, and the dosing of this agent is transplant center specific based on institutional protocols.[106]

Valacyclovir

One published meta-analysis of 12 trials that included 1574 patients evaluated valacyclovir as a prophylactic agent in transplant recipients.[108] Valacyclovir was found to be more effective than acyclovir in preventing herpes viruses, including CMV. Most transplantation centers, however, do not use valacyclovir for routine prophylaxis of CMV, and still consider valganciclovir as first line. The use of valacyclovir or acyclovir is commonly used for prophylaxis for low-risk patients with CMV (CMV D–/R–).

Letermovir

This drug is currently approved for CMV prophylaxis in patients with CMV-seropositive allogeneic HSCT, with a dosing of 480 mg daily. When administered with cyclosporine, a dose of 240 mg daily is recommended because of drug–drug interaction. Because letermovir has a narrow antiviral effect, is active against CMV, and has no activity against other herpesviruses, other antiviral drugs should be used for the prevention of herpes simplex virus, such as acyclovir. Studies are under way evaluating its use in solid organ transplant patients.[109]

Preemptive Therapy

Owing to recent advances in the laboratory tests used to identify and quantify CMV, possible ineffectiveness of prophylactic therapy, and the toxicity and cost of valganciclovir, preemptive therapy may be used to prevent CMV. The technique involves withholding prophylactic therapy and using weekly laboratory tests to identify presymptomatic CMV DNAemia, mainly using serum CMV DNA PCR. Once a patient develops CMV DNAemia, he/she receives treatment. This strategy has been prospectively studied and is as

effective as universal prophylaxis, with some potential drug cost advantages. However, a few recent studies have demonstrated a higher incidence of the indirect effects of CMV in the preemptive group—graft loss being the most concerning in one study. Thus, the preemptive therapy role is controversial, with many centers still using universal CMV prophylaxis in all solid organ transplant recipients.[100]

Role of mammalian target of rapamycin inhibitors

mTOR inhibitors have been found to inhibit viral cell growth and enhance memory T-cell function, such as CMV-specific memory cells, CD4+ helper T cells, and CD8+ killer T cells. Its use has been studied to reduce the incidence of CMV events, and its benefit has been found to be more evident in reducing CMV events in CMV moderate-risk patients (CMV R+) than in high-risk patients (CMV D+/R−).[110–113] R.S. is CMV moderate risk (R+) and may be a candidate for use of an mTOR inhibitor, especially if she had CMV recurrence or is unable to tolerate CMV prophylaxis if requiring prophylaxis again posttransplant.

BK POLYOMAVIRUS INFECTION

CASE 34-11

Question 1: G.H. is a 41-year-old Caucasian male 20 months' post deceased kidney transplant. His posttransplant course has been more recently complicated by an episode of mixed antibody-mediated and cellular rejection, which was treated with IVIG, Plasma exchange (PLEX), high-dose steroids, and ATG therapy. His current immunosuppressant regimen consists of tacrolimus 8 mg PO bid (tacrolimus goal 8–10 ng/mL), MMF 1 g PO bid, and prednisone 5 mg PO daily. Today, he is in the transplant clinic for a routine follow-up visit. He presents with some mild pain when urinating and a slight brownish red color to his urine. Pertinent results are as follows: BUN, 36 mg/dL, SCr, 2.4 mg/dL (baseline 1.5 mg/dL), and tacrolimus trough concentration of 9.6 ng/mL. A urinalysis finding showed negative for bacteria, moderate for blood, and a urine test result showed "decoy" cells. In addition, his BK virus PCR was >10.

What is BK virus? How is it diagnosed and what are its clinical manifestations?

BK virus is a human polyomavirus, first isolated in 1971. Polyomaviruses are small, nonenveloped viruses with a closed, circular, double-stranded DNA sequence. Little is known about the transmission or about the primary infection of BK virus. It is believed that viremia during the initial exposure results in systemic seeding and subsequently becomes a latent infection. The kidney is the main site of BK virus latency in healthy people. More than 50% of the general population express BK virus antibodies by age 3 years. Immunosuppression after transplantation probably leads to the reactivation of the virus, but other factors, such as organ ischemia and coinfection with other pathogens, may contribute to reactivation. Reactivation inevitably leads to viruria or viral shedding into the urine. Asymptomatic viruria occurs in ~10% to 45% of kidney transplant patients.[114]

Decoy cells in the urine and BK virus PCR in blood are used as screening tools. Blood or plasma BK virus PCR is a more sensitive and stable test, and correlates better with renal dysfunction than do decoy cells. The American Society of Transplantation recommends screening for BK virus in all kidney transplants, by measuring serial BK PCRs monthly for the first 3 to 6 months posttransplant, then every 3 months until the end of the first year posttransplant, whenever there is an unexplained risk in SCr, and after treatment of acute rejection. If the BK PCR is consistently >10,000 copies/mL, it is recommended to reduce immunosuppression.[115] Most cases of BK virus occur within the first 3 months of transplantation, although a number of cases have been reported as long as 2 years after transplantation. The major risk factor is the degree of immunosuppression. G.H., like many patients with BK virus, is mildly symptomatic with an elevated SCr along with a change in urine color and painful urination. Other more common symptoms are difficulty urinating, increased frequency of urination, fever, muscle pain, or weakness. Because G.H. has recently received higher doses of immunosuppression, he is at higher risk of having BK virus, whether BK viruria, viremia, or even BK virus–associated nephropathy.

Treatment

Case 34-11, Question 2: G.H. is told to discontinue his MMF and to reduce his tacrolimus dose to 4 mg PO bid with a lower target trough goal of 5 to 7 ng/mL. Why was G.H.'s immunosuppressive regimen significantly reduced?

Because BK virus reactivation and BK virus–associated nephropathy (BKVAN) are strongly associated with the degree of immunosuppression, the reduction in or discontinuation of immunosuppressant agents is considered first-line therapy, and the most effective approach. Beneficial clinical responses have been demonstrated in some patients when the dose of the CNI is reduced and/or other agents are removed. Not all patients, however, respond to this maneuver. In addition, reduction in immunosuppression places patients at higher risk for rejection. Close clinical follow-up after reduction of immunosuppression is important, and monitoring viral loads from both the urine and the serum has been shown to correlate with clinical disease.[116]

Case 34-11, Question 3: With his initial lab results and rejection history, a kidney biopsy was completed and displayed no rejection. However, intranuclear inclusion bodies and IF was observed and its immunohistochemistry was consistent with BKVAN. During the month with reduced immunosuppression, G.H.'s SCr remains unchanged, and his serum and urine viral loads also remain approximately the same. What is BKVAN? Are there any additional treatment options for G.H.'s BKVAN at this time?

BK virus–associated nephropathy and antiviral therapy

Diagnosis of BKVAN is made by careful review of clinical, laboratory, and histologic findings. Patients are often asymptomatic, although hematuria has been noted in some patients. Clinically, BK virus nephritis mimics acute rejection, with an increase in SCr often leading to a tissue biopsy. Tissue histology is similar to cases of acute rejection and BK virus nephritis, with mononuclear infiltration as the predominant finding. The abundance of plasma cells, prominent tubular cell apoptosis, collecting duct destruction, and

absence of endarteritis are features that may distinguish BKVAN from acute cellular rejection. Although BK virus has been implicated in up to 5% of all cases of interstitial nephritis (of which 30% go on to graft failure), it is still unclear whether asymptomatic biopsy findings in the kidney transplant patients are a prognostic indicator. In addition, accelerated graft loss has been demonstrated in patients who received antilymphocyte antibodies in the presence of BKVAN nephropathy misdiagnosed as an acute rejection episode.

For antiviral therapy, there is cidofovir, which inhibits polyomavirus replication in vitro; however, to date, no well-conducted clinical trials have proved this agent to be effective in treating or preventing BKVAN in the transplant population. In a small number of case reports and case series, this agent was beneficial, but the appropriate dose and frequency are still undetermined. Most reports have used very small doses (0.25–1.0 mg/kg/dose) to minimize nephrotoxicity. It is given IV either weekly or every other week and usually continued until renal dysfunction is resolved and a decrease in the viral load occurs. Cidofovir is associated with a high incidence of nephrotoxicity, especially at much higher doses; therefore, patients usually receive pre- and postdose hydration with 0.9% NaCl boluses. Per the package insert, probenecid should be administered with high doses of cidofovir; however, this should be avoided with the low doses used to treat BKVAN to promote excretion of the drug into the kidney. Close clinical monitoring of the patient is advised if this treatment option is used. Other therapies that have been tried with mixed success are IVIG and leflunomide in place of the discontinued antimetabolite, such as mycophenolate.[117] Retransplantation has also been conducted with some success.[116]

35

Basics of Nutrition and Patient Assessment

Margaret K. Murphy, Leigh Furman, and Kathleen M. Gura

CORE PRINCIPLES		CHAPTER CASES
1	A complete nutritional assessment of the patient is imperative before specialized nutrition is initiated. Parameters to be considered are nutrition and weight history, physical examination, anthropometric and biochemical measurements, and malnutrition risk.	**Case 35-1 (Question 1)**
2	The nutritional status of a patient can be assessed using the subjective global assessment (SGA) technique, which has been found to be highly predictive of outcome, because the SGA correlates strongly with other subjective and objective measures of nutrition.	**Case 35-1 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	Patients who cannot meet their nutritional needs by consuming food orally should be considered for specialized nutritional support, which is the provision of parenteral or enteral nutrients.	**Case 35-1 (Question 2)**
4	Protein and calorie goals are assessed on the basis of the disease status and body weight of the patient.	**Case 35-1 (Question 3)**
5	Nutritional support regimens should be tailored on the basis of the requirements, response, and tolerance of the patient. Patients with inflammatory bowel disease are particularly at risk for developing vitamin and other micronutrient deficiencies, and, therefore, supplementation is warranted.	**Case 35-1 (Question 4)**
6	The fluid needs of a patient are determined by the following steps: (a) need to correct fluid imbalances, (b) maintenance of fluid requirements, and (c) replacement of ongoing fluid losses.	**Case 35-1 (Question 5)**

CORE PRINCIPLES		CHAPTER CASES
7	Continued success of a nutritional support regimen can be accomplished by appropriate nutritional assessment after the initiation of therapy. The parameters such as patient weight trends, nitrogen balance, and prealbumin are considered when determining the need to adjust therapy.	**Case 35-1 (Question 6)**
8	Overfeeding should be avoided in patients, and a gradual and conservative approach to instituting nutritional support should be used to prevent potential metabolic abnormalities.	**Case 35-1 (Question 7)**

INTRODUCTION

Diet and nutritional status are fundamental for good health. Adequate and appropriate nutrition is essential for growth and development, consisting of a complex system of macronutrients, vitamins, minerals, and fluids. When an imbalance exists between the supply and the demand for the sources of energy and nutrients by the body, a nutritional disorder may result. Many chronic diseases such as cancer and coronary artery disease have dietary associations. Clinicians must be aware of the importance of proper nutrition in disease prevention and the interrelationships of the biochemical roles of nutrients and their impact on deficiency states and disease processes. Years of research and clinical experience have led to the creation of various screening tools, assessment techniques, and guidelines to aid practitioners in their quest to delay

or prevent patients from developing dangerous sequelae associated with deviations from optimal nutrition.[1] This chapter reviews the basic concepts of nutrition and how diet can influence the management of disease.

NUTRITION BASICS

Adequate levels of energy sources and essential nutrients are critical for retaining the structural and biochemical integrity of the human body. Energy is provided in the diet by macronutrients such as carbohydrates, proteins, and lipids. Essential nutrients, none of which offer any caloric value, are supplied to the body in the form of water, electrolytes, vitamins, and minerals.

Macronutrients

Humans need to consume food to sustain life. The unique structure and function of our cellular architecture allow human beings to convert the chemical free energy contained within the diet into high-energy, biologically active compounds. This transformation of food energy into forms of viable free energy through cellular respiration is an extremely inefficient process. Close examination of the distribution of food energy within the human body reveals that ~50% is lost as heat, 45% is available to the body in the form of adenosine triphosphate, and the remaining 5% is thermodynamically required for the conversion to heat because the entropy of the final products is greater than that of the initial substrates. Ultimately, all of the energy derived from food is expended in the form of external work or heat.

In nutritional contexts, the energy available from food is expressed in terms of calorie. A calorie is technically defined by the amount of heat required to raise the temperature of 1 g of water by 33.08 °F (1 °C). This unit, however, is too small from a dietary perspective. A food calorie (sometimes written as *Calorie* with a large *C*, although

this convention is not strictly followed) is equivalent to 1000 calories or 1 kilocalorie (kcal). One food calorie is also equal to 4.184 kilojoules.[2] It is not uncommon for a single kilocalorie to be referred to as a calorie when communicating the energy content of food. This ambiguity must be understood by practicing clinicians to communicate properly not only with colleagues but also with patients and the general public who may not have an appreciation for this subtlety and thus remain confused when reading calories on nutrition labels while seeing kilocalories in textbooks, scientific publications, patient records, and the Internet.

CARBOHYDRATES

Carbohydrates, also known as saccharides, are organic compounds that consist of carbon, hydrogen, and oxygen. There are four main types of carbohydrates: monosaccharides, disaccharides, oligosaccharides, and polysaccharides. Carbohydrates may be classified as either simple (monosaccharides and disaccharides) or complex (oligosaccharides and polysaccharides), yet the exact delineation of these categories is often not clear. Although carbohydrates serve as a common source of energy for living organisms, these compounds also function as structural components and building blocks for complex genetic molecules.

Monosaccharides (eg, glucose) are the simplest carbohydrates and cannot be hydrolyzed into smaller saccharide molecules. They are the major sources of fuel for metabolism, with glucose serving as a nearly universal and accessible reservoir of calories. Disaccharides (eg, sucrose) consist of two monosaccharides joined by a glycosidic bond. In the context of food science, monosaccharides and disaccharides are commonly referred to as *sugars*. Natural sources of monosaccharides and disaccharides include fruits and vegetables, but these compounds are also found in commercially manufactured products such as high-fructose corn syrup.

Oligosaccharides are short chains of monosaccharides typically composed of 3 to 10 molecules linked through glycosidic bonds.

These molecules are typically found connected to proteins or lipids functioning as chemical markers for cellular recognition. Their important role in the classification of blood groups is an example. Polymeric carbohydrate structures are referred to as *polysaccharides*, and function either as storage forms of energy, such as glycogen in animals or starch in plants, or as a structural component, such as cellulose in plants. Dietary polysaccharides must be broken down into their constituent monosaccharides in the digestive tract before absorption can occur.

Dietary carbohydrates are composed of ~60% polysaccharides, mainly starch, and disaccharides such as sucrose and lactose, which represent 30% and 10%, respectively. All carbohydrates provide 4 kcal of energy/gram. Although the exact amount of dietary carbohydrates sufficient for good health is not known, a mixed-fuel diet in which carbohydrates constitute 45% to 65% of the total energy intake is considered as an acceptable distribution range.[3]

PROTEIN

Polypeptides are linear chains of amino acids. These polypeptides can twist and fold alone or in groups into three-dimensional structures, generating a biochemical compound known as protein. Proteins are crucial to all living organisms, playing important and diverse roles in the structure, function, and regulation of the body's systems. Many proteins function as enzymes, which serve as catalysts to biochemical reactions and are important for metabolism. Proteins such as actin and myosin play a role in muscle contraction and movement. Some proteins stabilize blood by giving it the appropriate viscosity and osmolarity, whereas others participate in cell signaling and immune responses.

Protein is the second largest store of energy in the body after adipose tissue.[4] Although protein differs from the other two primary dietary energy sources because of its inclusion of nitrogen, the amino acid residues from proteins can be converted to glucose via gluconeogenesis to supply a continuous source of glucose for the body after the depletion of glycogen. Similar to carbohydrates, each

gram of protein supplies 4 kcal of energy. The loss of >30% of body protein, however, can compromise muscle strength, affect respiratory function, and negatively influence the immune system, all of which ultimately lead to organ dysfunction and death. It should be noted that protein and energy requirements of the body are intimately connected. During the times of infection or injury, metabolic rates rise, and body protein is suddenly oxidized into amino acids and mobilized for fuel utilization. In most instances, the injuries that patients experience are minimal and self-limiting; however, patients with chronic illnesses or those with complicating factors that result in a long-term hypermetabolic state can subsequently experience a dangerous loss of body nitrogen.

LIPIDS

Lipids comprise a broad spectrum of molecular species ranging from hydrophobic triglycerides and sterol esters to hydrophilic phospholipids and cardiolipins, as well as dietary cholesterol and phytosterols. Depending on their structure and composition at room temperature, they may be either solid or liquid. *Lipids* is used to refer to both liquid and solid fats, as well as other related substances. The term *oil* is used for any substance that does not mix with water and has a greasy feel, regardless of its chemical structure. Biologic lipids function as a form of energy storage, serve as the structural components of cell membranes, and participate as messengers in the vital process of cellular signaling.

In a nutritional context, fats that exist as liquids at room temperature are typically called *oils*, whereas fats that remain solid at room temperature are labeled as *fats*. Although the term lipid is often used synonymously for fat, fats are actually a subgroup of lipids also known as triglycerides. Triglycerides are synthesized by chemically combining glycerol with three fatty acid molecules. These fatty acids are generally nonbranched hydrocarbons containing an even number of carbon atoms ranging from 4 to 26 carbons. Adipose tissue is composed of fatty acids in varying lengths.

An unsaturated fat is a fatty acid that includes at least one double bond within the fatty acid chain, whereas a saturated fat is one that contains no double bonds. Unsaturated fatty acids result in less energy after the oxidation process of cellular metabolism compared with an equivalent amount of saturated fatty acids. Commercial manufacturers of processed food favor saturated fats because they are less vulnerable to rancidity (lipid peroxidation) and remain solid at room temperature. Foods containing unsaturated fats include avocado, nuts, and vegetable oils such as canola and olive oils. Meat products contain both saturated and unsaturated fats.

Importantly, each gram of fat yields 9 kcal of energy, twice that of either carbohydrate or protein. Approximately 35% to 40% of the total daily calories consumed by the average person are lipids. Higher fat diets can lead to more rapid weight gain, a positive attribute if the individual is malnourished or underweight, but a negative attribute if the individual is trying to achieve weight loss.[5] Triglycerides make up by far the largest proportion of dietary lipids consumed by humans. Fats play an essential role in maintaining the integrity of the hair and skin, insulating body organs against shock, and maintaining body temperature.

Although humans possess the biologic pathways to synthesize lipids, two polyunsaturated fatty acids must be obtained from the diet to prevent essential fatty acid (EFA) deficiency. Currently, there are only two identified EFAs for humans, α-linolenic acid (an ω-3 fatty acid) and linoleic acid (an ω-6 fatty acid). Fatty acids derived from these EFAs, such as arachidonic acid (ARA, derived from linoleic acid) and docosahexaenoic acid (DHA, derived from α-linoleic acid), are important constituents of membrane lipids. Recent evidence suggests that along with eicosapentaenoic acid (EPA, derived from α-linolenic acid) that DHA and ARA should also be considered EFAs. These particular fatty acids are important in growth and neurodevelopment and are precursors of critically important metabolic products. These include inflammatory mediators (eicosanoids such as prostaglandins, leukotrienes, and thromboxanes), gene regulators, substances that assist in the resolution of an inflammatory response (eicosanoids such as

protectins, resolvins, and lipoxins), and substances that regulate overall lipid metabolism.[6] In addition to these properties, specific fatty acids are also important for membrane fluidity, membrane and intracellular cell signals, and modulation of apoptotic pathways.

Essential Nutrients—Water

Water plays a critical role in nearly every biologic function necessary for life. The total body water in an adult male without fluid and electrolyte disorders is ~50% to 60% of the lean body weight.[7] Infants and children possess a much higher fractional water content, which then decreases progressively with age. Individuals with a greater percentage of body fat, such as females or obese patients, also tend to have less water for a given weight.

The total aqueous volume in the body can be divided into the intracellular and extracellular compartments. Because the intracellular fluid is the site of major metabolic activity, homeostatic mechanisms are therefore in constant execution to provide an environment of optimal ionic strength. The primary function of the extracellular fluid is to serve as a conduit between cells and between organs. Substantial ionic alterations within extracellular fluid can occur without a clinically significant impact on body function. This extracellular compartment can be further divided into three fractions: the interstitial volume, plasma volume, and transcellular water volume. Interstitial fluid flows around cells, allowing the total surface area of a cell to serve as an area of exchange. Plasma is the route for rapid transit within the body. Transcellular water is the smallest component of extracellular fluid and is the portion of total body water that is found within epithelial-lined spaces. Transcellular water includes the luminal fluid of the gastrointestinal (GI) tract, the fluids of the central nervous system, and the fluid in the eye, as well as the lubricating fluids at serous surfaces.

The basal requirement of water for a given individual is dependent on the sensible (urinary) and insensible losses of water. Urine osmolality and the total amount of solute excreted from the body

dictate the volume of water comprising urine. Fever can promote dehydration by increasing one's basal metabolic rate (BMR) in addition to raising the vapor pressure of expired air and sweat, resulting in higher respiratory and skin water losses, respectively. In the absence of fever and sweating, water loss through the skin is relatively fixed; however, urinary water excretion can vary greatly.

Essential Nutrients—Micronutrients

ELECTROLYTES

An electrolyte is a substance that, when dissolved in the body's fluids, dissociates into electrically charged ions. Electrolytes include sodium, potassium, chloride, magnesium, phosphorus, calcium, and bicarbonate. A subtle and complex balance of electrolytes exists between the intracellular and extracellular space. The precise maintenance of these electrolyte gradients is critical because such gradients regulate hydration and acid–base balance and ultimately have an impact on nerve and muscle function. Sodium, chloride, and bicarbonate are the main solutes in the extracellular fluid, whereas potassium, magnesium, phosphate, and proteins are the dominant solutes inside the cell.

Water can freely travel across the membrane of a cell, whereas the cell membrane itself is only selectively permeable to solutes. Osmotically active solutes are those that cannot cross the cell membrane and thereby exert an osmotic pressure that determines the distribution of water between fluid compartments. Electrolyte balance is traditionally maintained by the oral intake of substances containing electrolytes. Fruits and vegetables, milk, and sports drinks are replete with electrolytes. In oral rehydration therapy, electrolyte drinks containing sodium and potassium salts replenish the water and electrolyte levels in the body after dehydration caused by exercise, diarrhea, vomiting, intoxication, or starvation. The kidneys, in concert with hormones, such as antidiuretic hormone, aldosterone, and parathyroid hormone help to maintain electrolyte homeostasis within the body.

VITAMINS

Vitamins are organic compounds that cannot be biologically synthesized in sufficient quantities by humans and yet remain a vital requirement to sustain life. The biochemical functions of vitamins are diverse. Some vitamins assist in the regulation of electrolyte metabolism, whereas others participate in the control of cell and tissue growth and differentiation. Most vitamins function as cofactors, which are molecules that bind to enzymes to promote their catalytic activities.

Vitamins are classified by their biologic and chemical activity. Vitamins are designated as either water soluble or fat soluble. There are four fat-soluble vitamins (A, D, E, and K) and nine water-soluble vitamins (eight B vitamins and vitamin C) in humans. Water-soluble vitamins are used by the body quite rapidly, and amounts in excess are readily excreted from the body in urine. The fat-soluble vitamins are absorbed by the body using processes that closely parallel the absorption of lipids. Fat-soluble vitamins are more likely to lead to toxicity, or hypervitaminosis. Fat-soluble vitamin regulation is also of particular significance in cystic fibrosis.

Vitamins are procured through the diet or supplements. The body can manufacture only three vitamins from nondietary sources: vitamins D and K, and the B vitamin, biotin. Critically ill patients experiencing metabolic stress possess vitamin needs that may increase dramatically. Many disease states such as inflammatory bowel disease, liver and renal disease, intestinal failure, cancer, and acquired immunodeficiency syndrome–associated wasting can also result in a higher demand for vitamins. A parenteral formulation of multivitamins combining both fat- and water-soluble vitamins into an aqueous solution designed for incorporation into intravenous infusions is available for these classes of patients.

TRACE ELEMENTS

Appropriate intake levels of certain dietary minerals are required in small amounts to maintain optimal health. These dietary minerals are known as *trace elements* or *ultratrace elements*. Iron, zinc, copper,

manganese, and fluoride are classified as trace elements. These minerals are required in amounts between 1 and 100 mg/day by adults. Ultratrace elements, or those dietary minerals, that are required in quantities <1 mg/day, include arsenic, boron, chromium, iodine, selenium, silicon, nickel, and vanadium.

Most trace elements act as catalysts in enzyme systems and some, such as copper, are important in energy metabolism. Iron, as a component of hemoglobin, plays a vital role in oxygen transport within the body. Consuming a well-balanced diet is the recommended method for satisfying these micronutrient requirements. Many trace elements are naturally present in foods; however, some are added to foods to prevent nutrient deficiencies, such as fortifying salt with iodine to prevent development of hypothyroidism and goiter. When dietary intake is insufficient to meet the daily nutrient requirements of an individual or when chronic or acute deficiencies develop from pathology and injury, dietary supplements remain a viable option.

MALNUTRITION

Malnutrition may occur when there is any disruption of nutritional status, including disorders resulting from overfeeding, underfeeding, or through impaired nutrient metabolism. Clinically, malnutrition results in subcellular, cellular, or organ function changes that may increase risk of morbidity and mortality.[8,9]

Overnutrition results from excess intake of calories. Obesity has become a significant national health issue. From 1999 to 2000 through 2017 to 2018, the prevalence of obesity in U.S. adults increased from 30.5% to 42.4%.[10] More commonly, malnutrition refers to undernutrition. Undernutrition is the lack of calories, protein, or other nutrients necessary for tissue maintenance and repair. Undernutrition results from inadequate intake, increased requirements, impaired absorption, altered transport, or altered utilization of nutrients.[11] Inflammation, which promotes breakdown of

skeletal muscle, has become recognized as an important underlying factor for the development of malnutrition.[12,13]

An International Guideline Committee has proposed three categories for adult malnutrition diagnoses in the clinical setting[12]:

- Starvation-related malnutrition, which involves chronic starvation without inflammation, an example of which is seen in anorexia nervosa
- Chronic disease-related malnutrition, in which mild-to-moderate inflammation is present, examples of which are seen in patients with cancer or organ failure
- Acute disease- or injury-related malnutrition, in which acute and severe inflammation is present, examples of which are seen in patients suffering major infections, traumas, or burns

Risk of severe malnutrition increases if one of these categories concurrently exists with another, for example, a chronically malnourished patient who suffers an acute trauma.[13]

Patients in starvation or semistarvation states slowly adapt to inadequate nutrient intake. In this scenario, endogenous fat stores are used for energy and a slow loss of muscle proteins ensues. Nevertheless, energy and protein stores are not unlimited, and death occurs in previously normal-weight individuals after about 60 to 70 days of starvation.[14,15]

An incidence of malnutrition as high as 30% to 50% has been reported among hospitalized patients.[13] In hospitalized patients, the risk of acute malnutrition development is greater because nutrient intake is often inadequate, nutrient stores can be depleted, or the patients may experience concurrent injury or stress (infection, major surgery). The presence of acute stress or injury increases energy requirements to repair tissues. Breakdown of skeletal muscle to release amino acids for energy production by conversion to glucose occurs if exogenous energy is not provided to stressed patients. Even patients who were well nourished before the stressful event may quickly become at risk for this type of iatrogenic malnutrition. Usually, such acute malnutrition resolves once the illness or injury

improves and normal nutrient intake is resumed. The most common type of nutritional deficiency in hospitalized patients is protein-calorie malnutrition, which includes depletion of both tissue energy stores and body proteins. Complications develop more frequently for hospitalized patients who are malnourished as a result of organ wasting and functional impairments. These complications may include weakness, decreased wound healing, altered hepatic metabolism of drugs, increased respiratory failure, decreased cardiac contractility, and infections such as pneumonia and abscesses. Complications often increase the length of hospital stay and costs of care.[8,16–18]

No single parameter is definitive for the diagnosis of adult malnutrition; however, the presence of two or more of the following criteria is recommended for diagnosis[10]:

- Insufficient energy intake
- Weight loss
- Loss of muscle mass
- Loss of subcutaneous fat
- Fluid accumulation that may mask weight loss
- Diminished functional status (eg, hand grip strength)

On the other extreme of undernutrition lies obesity, an unhealthy accumulation of fat mass, defined as a body mass index (BMI) >30 kg/m^2. Obesity is a global pandemic that is also associated with increased morbidity and mortality with diminished quality and length of life while dramatically increasing individual, national, and global health costs.[19] It is important to emphasize that many obese individuals may often present with deficits of their nutrition status.[20] Sarcopenia (ie, sarcopenic obesity) is associated with adverse effects, putting obese persons at higher risk of complications when ill.[21] Owing to the lack of routine nutrition screening and assessment, the significance of undernutrition in sick obese individuals is often underdiagnosed.[22]

Defining Malnutrition

There is a wide variety of tools to identify nutrition risk factors. Ideally, these tests should be both reliable and valid while still providing rapid results in a cost-effective manner. In contrast, nutrition assessment permits the clinician to obtain more information and perform a nutrition-focused examination to ascertain if a nutrition derangement exists and to what severity.

Although a patient's weight is often used to determine nutritional status, there are limitations depending on how that value is obtained. It is best assessed in context with a patient's height. Because adults tend to overestimate their height and underestimate their weight, it is preferred that actual measurements are obtained. When estimating body fat, the usual body weight is more helpful than using normal reported values such as those contained in insurance tables.[23] Similarly, in children, body weight is more useful than is height in determining nutrient intake as well as body fat. Trends in weight changes are used in assessing nutritional status, although changes in fluid status may falsely influence these values. Likewise, in an obese patient, a loss in lean body mass may be undetected in the presence of excess body fat. Typically, a significant weight loss is defined as a 5% loss in 1 month, 7.5% loss in 3 months, or 10% in 6 months.[24] Whenever weight loss exceeds these amounts, it is termed as severe weight loss.

NUTRITION SCREENING AND ASSESSMENT

The nutrition status of an individual is a determinant of body composition and functional status. Aberrant states negatively affect patients' outcomes, increasing morbidity/mortality, time spent in the hospital, and readmission rates as well as costs, while decreasing quality of life.[9] Screening and assessment are different processes that encompass related variables to identify nutrition problems.[25] There is a wide variety of tests to identify nutrition risk factors.

Ideally, these tools should be both reliable and valid, yet be cost-effective while providing rapid results. In contrast, nutrition assessment allows the clinician to obtain more information and perform a nutrition-focused examination to determine whether a nutrition malfunction exists and to categorize its severity.

Nutrition Screening

Within 24 hours of hospital admission, the Joint Commission (http://www.jointcommission.org) requires patients to be screened to determine whether they are malnourished or at risk for developing malnutrition. The nutrition screening process identifies needs for further nutritional intervention or monitoring based on nutritional risk. The information obtained in the screening process depends on the patient population, the health care setting, and institutional specific policies. A number of screening tools have been described in the literature with varying reliability, specificity, and sensitivity. In some instances, the parameters included in nutrition screening may be more applicable in the outpatient setting rather than in the inpatient areas.[1,26]

The nutrition status of an individual is a determinant of body composition and functional status. Deficient states negatively affect patient outcomes, increasing morbidity/mortality, time spent in the hospital, and readmission rates as well as costs, while decreasing quality of life.[9] Therefore, screening for risk factors associated with deficiencies and, when indicated, assessing an individual's nutritional status should be part of the evaluation of a patient. Deficiencies in the nutrition status (ie, undernutrition) are still the most prevalent conditions in both the hospital and outpatient settings in the world, with rates ranging from 20% to 80%, based on the group of patients evaluated or the method used to provide the diagnosis.[27]

Patient Assessment

Nutritional assessment of a patient incorporates a collection of past medical data, analysis of body composition, evaluation of physiologic function, and complete physical examination. Proper patient assessment should include the examination of multiple factors and should not rely on any one parameter. This assessment serves to identify the presence and severity of malnutrition or the risk of developing malnutrition. A complete patient assessment performed by a trained practitioner can help determine the goals of therapy and specify the need for specialized nutritional support. Goals of therapy may be maintenance of existing nutritional status, repletion of fat and lean body mass, and prevention of complications associated with malnutrition.

NUTRITION HISTORY

A nutrition history is crucial to an effective nutritional assessment. Practitioners may gain valuable information by interviewing the patient or the patient's family and by reviewing the medical record to identify factors that can contribute to malnutrition or increase the risk of developing malnutrition.

Multiple factors can contribute to the development of malnutrition, including the patient's underlying disease states, past medical history, and socioeconomic circumstances. Medications can adversely affect nutritional status by decreasing the synthesis of nutrients, minimizing food intake through alteration of appetite and taste, changing the absorption or metabolism of nutrients, or increasing nutrient requirements. A complete evaluation of present and past body weight fluctuations contributes significantly to an appropriate nutrition history.

The components of a nutrition history are summarized in **Table 35-1**, some of which are expanded subsequently.

Table 35-1

Components of a Nutrition History

Medical history
Chronic illnesses

Surgical history
Psychosocial history
Socioeconomic status
History of gastrointestinal problems (nausea, vomiting, or diarrhea)
Diet history, including diets for weight gain or loss
Food preferences and intolerances
Medications
Weight history
Increase or decrease
Intentional or unintentional
Time period for weight change
Functional capacity

WEIGHT HISTORY

Weight history and influences are important in evaluating nutritional status. Weight loss is a sign of negative energy and negative protein balance, and is often associated with poor outcome in hospitalized patients.[26,28] A patient's current weight often is compared with a standard for ideal body weight (IBW). Percentage of IBW[26] is determined as shown in Eq. 35-1:

$$\% \text{ IBW} = \text{Current weight } (100)/\text{IBW} \qquad \textbf{(Eq. 35-1)}$$

The primary limitation of this method of assessing weight is that the patient's weight is compared with a population standard rather than using the individual as the reference point. For example, a patient who is significantly overweight but has lost large amounts of weight may still be more than 100% of IBW and therefore not considered at risk for developing malnutrition. A more patient-specific method of evaluating weight is to compare current weight with the patient's usual weight. This can be determined using Eq. 35-2:

$$\% \text{ Usual body weight} = \text{Current weight } (100) / \text{Usual body weight} \quad \text{(Eq. 35-2)}$$

Using this method, the obese patient who has lost weight may be determined to be <90% of usual weight and therefore nutritionally at risk. It is also important to assess over what period the change has occurred. Involuntary weight loss is considered severe if loss exceeds 5% of usual weight within 1 month, or 10% of usual weight within 6 months. A nonvolitional weight loss of >10% is considered significant for malnutrition.[29] Patterns of weight loss must be evaluated to determine whether the loss is stabilizing or continual, the latter being a more serious concern. Weight gain after a significant weight loss may be considered a positive sign.

BODY WEIGHT AND BODY MASS INDEX

BMI is used to estimate adiposity in adults. Both height and weight are needed to calculate this value. The formula is weight (kg) ÷ height (m^2). **Table 35-2** shows how BMI can be used to define underweight, normal, or obese individuals. However, it is not a perfect tool. In trained athletes, BMI tends to overestimate body fat, whereas it underestimates body fat in elderly patients because of a loss of lean body mass.

Table 35-2

Interpretation of Nutritional Status Using the Body Mass Index (BMI)

Nutritional Status	BMI Measure (kg/m^2)
Underweight	<18.5
Normal	18.5–24.9
Overweight	25–29.9
Obese	30–39.9
Severe obesity	>39.9

PHYSICAL EXAMINATION

Nutritional deficiencies may be identified on physical examination and may require further evaluation. Physical examination may include measurement of subcutaneous fat and skeletal muscle mass. Assessment of fat stores provides information about fat loss or gain and assumes fat is gained or lost proportionally throughout the entire body. The subcutaneous compartment contains ~50% of body fat. Muscle and fat wasting (often noticed in the temporal area), loss of subcutaneous fat and muscle in the shoulders, and loss of subcutaneous fat in the interosseous and palmar areas of the hands are readily identifiable. Other physical parameters that may be less obvious are assessment of hair for color changes and sparseness; skin for turgor, pigmentation, and dermatitis; mouth for glossitis, gingivitis, cheilosis, and color of the tongue; nails for friability and lines; and abdomen for signs of ascites or enlarged liver. In addition, the patient's fluid status must also be evaluated as a part of the physical examination.

Assessment of body composition

Body composition is used to describe the percentages of bone, fat, muscle, and water in human bodies.[30] Two people of the same sex and body weight may look completely different because they have a different body composition. This is because muscle mass takes up less space within the body than does fat mass; thus, body composition, as well as weight, determines leanness. The methods used to measure body composition differ in their ease of determination, cost, accuracy, use of radiation, and utility for estimating body fat or other body compartments relevant to nutritional status (eg, bone density). The most commonly used techniques are discussed here.

ANTHROPOMETRICS

Anthropometric measurements accurately reflect total body fat and skeletal muscle mass when used for the long-term comparisons of large, nutritionally stable populations. The most widely used anthropometric measurements to assess body composition are the triceps skinfold (TSF) and the mid-upper arm circumference. Reference standards are used to compare against values obtained in the examination.[31,32] Skeletal muscle mass or somatic protein mass can be estimated by measuring mid-arm circumference (MAC) and then calculating arm muscle circumference as given subsequently.

Skinfold thickness

Measurements of multiple skinfold thicknesses are frequently used because it is noninvasive, inexpensive, and easy to perform. In comparison to other methods, however, skinfold thickness measurements often are less accurate in comparison to measurements of weight or height, especially in obese individuals.[33] The TSF measurement reflects body fat. TSF and subscapular skinfold thickness measurements are used to assess subcutaneous fat, allowing associated estimations of total body fat. However, this measurement may over- or underestimate individual fat mass by ~10%.[34] Skinfold thickness measurements may be more useful in the long-term monitoring of nutritional therapy in individuals who are malnourished, have diseases that are associated with changes in body composition, or are obese. When performed on acutely ill or hospitalized patients, however, these measurements are of little value.

Mid-arm muscle circumference

The mid-upper arm cross-sectional area reflects lean body mass. The mid-arm muscle circumference (MAMC) can be calculated from the TSF and the MAC as follows:

$$\mathrm{MAMC} = \mathrm{MAC} - (3.1416 \times \mathrm{TSF}) \qquad \textbf{(Eq. 35-3)}$$

The measured values for TSF and MAC and the calculated MAMC are compared with reference values. Values <5th percentile for age are consistent with acute malnutrition, and values >90th percentile are consistent with obesity.[35]

Limitations

Changes experienced during acute illness and stress may result in errors of interpretation of subcutaneous fat and weight assessments, and peripheral edema can result in inflated values for MAC and skinfold thickness.[26,28]

Other methods of determining body composition

Owing to the aforementioned limitations, most research studies seeking a measure of body composition will use one of the more precise measures such as air-displacement plethysmography, hydrostatic weighing, or isotope dilution.

Hydrodensitometry

Underwater weighing is one of the oldest methods for determining body density; it has been largely replaced by dual-energy x-ray absorptiometry (DEXA). Body density is estimated from the weight of the individual in air and water, using appropriate correction factors for temperature, air in the respiratory tract, and constants for the densities of fat-free tissue and fat mass.[36]

Isotope Dilution

Body composition may be determined using stable isotope dilutions. The volume of a body compartment is determined by calculating the ratio of the dose of a tracer to its concentration in the body compartment after a defined equilibration period has elapsed. For example, total body water can be estimated using stable isotopes of deuterium ($2H_2O$) or oxygen ($H_2(18)O$).[37] The fat-free mass of the body can then be calculated based on the premise that the hydration of lean tissue is constant. Errors may occur when hydrogen isotopes

are used as they exchange with nonaqueous hydrogen, resulting in overestimation of total body water by 5% to 10%. Owing to its expense and the need for special analytic equipment, isotope dilution is not often used in clinical practice.

Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) uses an electrical current to measure the fat and fat-free mass.[38] The lean tissues of the body contain dissolved electrolytes and conduct electrical current, whereas body fat and bone are relatively poor conductors. BIA measures total body water from which an estimate of fat-free mass is calculated. BIA is used because it is noninvasive, portable, and inexpensive. Errors in measurement can occur if the electrodes are placed in the wrong location.[39] BIA is also influenced by gender, age, disease state, and amount of body fat.[40]

Air-Displacement Plethysmography

Air-displacement plethysmography is a method for determining body volume and, indirectly, fat mass. Using the same whole-body measurement principle as underwater weighing, air-displacement plethysmography uses a device that measures a subject's mass and volume, from which the whole-body density is calculated. The individual sits inside the device, and computerized pressure sensors determine the amount of air displaced by the subject's body, and body fat and lean muscle mass are then calculated.[41] In comparison to hydrostatic weighing or isotope dilutions, the accuracy of air-displacement plethysmography is very good.

Dual-Energy X-ray Absorptiometry

DEXA estimates fat-free mass, body fat, and bone mineral density using the differential absorption of x-ray or photon beams of two levels of intensity. It relies on the concept that the intensity of an x-ray or a photon beam is altered by the thickness, density, and chemical composition of an object in its path.[42] The technique is

limited because estimates of fat mass become less accurate as the individual's trunk thickness increases, and it appears more accurate at a group level, compared with the individual level.[43]

Other Methods

Other parameters such as hand grip and forearm dynamometry may be used to assess skeletal muscle function, which relates changes in body composition to body function.[1,26,28] Another nutritional assessment method, subjective global assessment (SGA), combines objective parameters and physiologic function.[44] This easy-to-use tool for diagnosing malnutrition is based on a history of weight change, dietary intake, presence of significant GI symptoms, functional capacity, and physical examination to assess edema and the loss of subcutaneous fat and muscle. Using the SGA system, patients are rated as well nourished, moderately malnourished, or severely malnourished.

Biochemical Assessment

No single test or group of tests can be recommended as a routine or reliable indicator of protein status. It is a combination of measures (ie, anthropometric, biochemical, dietary, and clinical findings) that results in a more complete picture of protein status. Within the human body, protein is viewed as a two-compartment model, visceral and somatic proteins. Skeletal muscles are composed of somatic proteins, accounting for ~75% of total body protein. Visceral proteins account for the remaining 25% of total body protein, which are found in the internal organs and serum.

Visceral protein stores are often evaluated as part of a nutritional assessment. The most commonly used serum protein markers are albumin, prealbumin, transferrin, and retinol-binding protein.[45] These proteins are produced within the liver, and often reflect hepatic synthetic capability. The serum concentration of visceral proteins decreases when hepatic insufficiency develops or when intake of substrates is inadequate for synthesis of proteins. Serum protein

concentrations are altered during acute stress or inflammatory states and chronic starvation. During injury or stress, inflammatory cytokines are released and substrates are shunted away from the synthesis of visceral proteins to synthesize other acute-phase proteins such as C-reactive protein (CRP), haptoglobin, fibrinogen, and others.[46]

ALBUMIN

Albumin is the classic visceral protein and is the most widely used prognostic indicator of nutritional status. This complex, high-molecular-weight protein is produced by the liver. Because it is a negative acute-phase protein, albumin is not a sensitive marker, and levels decrease in the presence of sepsis or inflammation. Because of its long serum half-life (18–20 days) and a fractional replacement rate of 10% per day, in the absence of stress, an improvement in serum albumin level due to nutritional repletion is generally observed within 2 weeks. There are other limitations to using serum albumin as an indicator of nutritional status. Serum concentrations of <3 g/dL correlate with poor outcomes and an increased length of stay in hospitalized patients.[47] Albumin serves as a carrier protein for fatty acids, hormones, minerals, and drugs, and is necessary for maintaining oncotic pressure. Albumin has a large body pool of 3 to 5 g/kg, and 30% to 40% is localized to the intravascular space. The normal hepatic rate of albumin synthesis is 150 to 250 mg/kg/day. Because of its long half-life, a decrease in serum albumin concentrations is generally not observed until after several weeks of inadequate nitrogen intake. Serum albumin concentrations decrease rapidly in response to stress (which causes albumin to shift from the intravascular to the extravascular space), burns, nephrotic syndrome, protein-losing enteropathy, overhydration, and decreased synthesis with liver disease.[28,46] If exogenous albumin is administered, then the serum albumin level loses its predictive value. Similarly, certain states of impaired synthesis (eg, hepatic dysfunction) or major albumin loss (eg, protein-losing enteropathy, nephrotic syndrome) may make it difficult to interpret.

PREALBUMIN

A more useful measure of nutritional status is prealbumin (transthyretin). In comparison to albumin, prealbumin is more sensitive to changes in energy and protein intake. This visceral protein has a small body pool (10 mg/kg) and serves as a carrier for retinol-binding protein and functions in thyroxine transport. Its shorter serum half-life of 2 to 3 days allows for measurable changes within 1 week of a dietary modification. Normal serum prealbumin concentrations are 15 to 40 mg/dL. False elevations in prealbumin levels can occur in renal failure and corticosteroid use. Similar to albumin, prealbumin is a negative acute-phase protein and will decrease in periods of inflammation. A CRP level can be obtained to assess the extent of inflammation and assist in the interpretation of visceral protein status.

TRANSFERRIN

Transferrin is a less commonly used visceral protein marker. This is a β-globulin involved in the transport of iron. Normal serum concentrations of transferrin are 250 to 300 mg/dL, and it has a half-life of 8 to 10 days. Similar to albumin, serum levels of transferrin are affected by nutritional factors and iron metabolism. Serum transferrin levels, as with albumin and prealbumin, are inversely correlated with the risk of morbidity and mortality in hospitalized patients. Serum transferrin levels also respond to iron status. High serum transferrin levels are found in patients with iron deficiency. Low levels are found in those with iron overload. Thus, a patient with coexisting protein malnutrition and iron deficiency may have a higher serum transferrin level than one with a similar degree of protein malnutrition but with normal iron status.[48]

RETINOL-BINDING PROTEIN AND OTHER MARKERS OF NUTRITIONAL STATUS

In comparison to other visceral proteins, retinol-binding protein has the shortest half-life, 12 hours; normal serum concentrations are 2.5 to 7.5 mg/dL. However, because serum concentrations of retinol-

binding protein change rapidly in response to alterations in nutrient intake, monitoring it has limited use in clinical practice. The visceral proteins commonly used for nutritional assessment are summarized in **Table 35-3**.

Table 35-3
Visceral Proteins for Nutritional Assessment

Visceral Protein	Half-Life (days)	Normal Serum Concentration
Albumin	18–21	3.5–5 g/dL
Transferrin	8–10	250–300 mg/dL
Transthyretin (prealbumin)	2–3	15–40 mg/dL
Retinol-binding protein	0.5	2.5–7.5 mg/dL

Other proteins, such as fibronectin and somatomedin-C (insulin-like growth factor-1), are also used as markers of nutritional status. Fibronectin is a glycoprotein found in blood, lymph, and many cell surfaces. Somatomedin-C is important in regulating growth. Both fibronectin and somatomedin-C have half-lives of <1 day and respond to fasting and refeeding. Urinary measurement of 3-methylhistidine, a by-product of muscle metabolism that is excreted unchanged, has been used to estimate skeletal muscle mass. Although these markers have potential use in nutritional assessment, they are used primarily as research tools and are not readily available for routine clinical use.[28]

The interpretation of serum protein concentrations in hospitalized patients may be difficult because other factors more important than hepatic synthesis rate can alter serum concentrations. These factors may include renal, hepatic, or cardiac dysfunction, hydration status, and metabolic stress. Visceral proteins, as with any nutritional assessment parameter, must be used in conjunction with other parameters and comprehensive consideration of the patient's clinical status. Practitioners should evaluate markers of inflammation and stress, such as CRP, in conjunction with visceral protein markers periodically to ensure that an accurate assessment is made.

Classification of Malnutrition

Malnutrition is categorized through a variety of descriptive terms, each with varying characteristics. Three classic categories include marasmus, kwashiorkor, and mixed protein-calorie malnutrition. A chronic deprivation of energy (calories), or partial starvation, leads to marasmus, which means a “dying away state.” For patients with marasmus, physical examination reveals severe cachexia with loss of both fat and muscle mass; however, visceral protein production is preserved, and serum levels may remain at or near the normal range. Patients with chronic wasting diseases such as cancer or anorexia are likely to present with marasmus malnutrition.

Classic kwashiorkor malnutrition results from diets devoid of adequate protein, but with adequate caloric intake. Kwashiorkor-like malnutrition in hospitalized patients often refers to patients who are extremely catabolic from their medical complication (eg, sepsis) or injury (eg, trauma, thermal injury). Carbohydrate metabolism involves endogenous production of insulin, which in turn prevents lipolysis and promotes the movement of amino acids into muscle. To meet increased protein demands, protein can be mobilized from internal organs and circulating visceral proteins. Consequently, an individual with kwashiorkor-like malnutrition may have adequate fat and muscle mass but may demonstrate depleted serum proteins.

Hospitalized patients commonly exhibit components of both marasmus and kwashiorkor-like malnutrition, and are classified as having mixed protein-calorie malnutrition. This mixed condition occurs when an acute injury or stress compounds chronic starvation or semistarvation, resulting in wasting of fat and muscle mass, as well as depletion of serum proteins.

Estimation of Energy Expenditure

Estimating energy expenditure constitutes an important aspect of patient evaluation. The most common approach used to determine energy requirements is based on body weight in kilograms. Energy

requirements are standardized and are determined by the metabolic condition of the patient.

Many predictive equations for estimating expenditure have been described in the literature.[49,50] The traditional method of assessing energy expenditure is the basal energy expenditure (BEE): the amount of energy (kilocalories) needed to support basic metabolic functions in a state of complete rest, shortly after awakening, and after a 12-hour fast. BEE is most commonly calculated using the Harris–Benedict equations (see **Table 35-4**). Alternatively, BEE can be estimated at 20 to 25 kcal/kg/day. Utilizing either method is supported by the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN).

Table 35-4

Estimation of Energy Expenditure

Basal Energy Expenditure	
Harris–Benedict equations BEE_{male} (kcal/day) = 66.47 + 13.75 W + 5.0 H − 6.76 A BEE_{female} (kcal/day) = 655.10 + 9.56 W + 1.85 H − 4.68 A Or 20–25 kcal/kg/day	
Energy Requirements	
Hospitalized patient, mild stress	20–25 kcal/kg/day
Moderate stress, malnourished	25–30 kcal/kg/day
Severe stress, critically ill	30–35 kcal/kg/day

A, age in years; BEE, basal energy expenditure; H, height in centimeters; kcal, kilocalories; W, weight in kilograms.

BMR is the energy expended in the postabsorptive state, ~2 hours after a meal. BMR is ~10% greater than is BEE. Calculations of BEE or BMR do not include additional energy required as a result of stress or activity. The Harris–Benedict equations can be modified to include stress and physical activity factors, or these variables are estimated at 20 to 35 kcal/kg/day for moderate-to-severe stress (Table 35-4).

Indirect calorimetry determines energy expenditure using a machine known as a *metabolic cart* that measures the patient's breathing or respiratory gas exchange. The cart measures oxygen consumption and carbon dioxide production when standard testing conditions are maintained. The amount of oxygen consumed and carbon dioxide produced for carbohydrate, fat, and protein is constant and known. Energy expenditure, including that caused by stress, is measured for a defined time, and the information is then subjected to a series of equations to extrapolate the estimated 24-hour energy expenditure.[28,51] This is the measured energy expenditure (MEE). Because the measurement is usually conducted while the patient is at rest, activity is not included in MEE.

Indirect calorimetry is available to many clinicians and is considered the gold standard for energy expenditure determination. Its usefulness is particularly valuable in the energy assessment of critically ill or obese patients. In 2016, the SCCM and the ASPEN published guidelines for the provision and assessment of nutritional support therapy for the adult critically ill patient.[52] Based on expert consensus, the guidelines suggest that determination of nutritional risk be performed on all patients in the intensive care unit (ICU) for whom volitional intake is anticipated to be insufficient. High-risk patients would likely benefit from early enteral nutritional therapy. In addition, the guidelines suggest that the nutritional assessment should include evaluation of comorbid conditions, function of the GI tract, and risk of aspiration. Traditional nutrition indicators or surrogate markers should likely not be used to assess nutritional status in critically ill patients because they have not been validated in the critically ill patient population.

Estimation of Protein Goals

Estimation of protein needs is necessary in nutritional assessment. Protein needs are calculated based on body weight, degree of stress, and disease state. The initial estimation is often made with a degree of subjectivity and clinical judgment, with adjustments made

based on patient response. The United States–recommended dietary allowance is 0.8 g of protein/kg/day. Well-nourished, hospitalized patients with minimal stress need 1 to 1.2 g of protein/kg/day to maintain lean body mass. The requirement for protein intake may be as high as 2 g/kg/day for a patient in a hypermetabolic, hypercatabolic state secondary to trauma or burns. In addition, protein provision may need to be adjusted and reduced in patients with renal or hepatic dysfunction as a result of altered metabolism. Guidelines for protein needs are summarized in **Table 35-5**.

Table 35-5
Estimation of Protein Requirements

U.S.-recommended dietary allowance	0.8 g/kg/day
Hospitalized patient, minor stress	1–1.2 g/kg/day
Moderate stress	1.2–1.5 g/kg/day
Severe stress	1.5–2 g/kg/day

NITROGEN BALANCE

Nutritional status as reflected by protein stores is traditionally assessed by calculating nitrogen balance, a measure of nitrogen losses in relationship to nitrogen intake. The amount of protein in the diet is measured in comparison to the nitrogen losses in the urine and feces using the following formula:

$$\text{Nitrogen balance} = \text{nitrogen intake} - \text{nitrogen losses}$$
$$\text{Nitrogen intake} = \text{Protein intake (gram/day)}/6.25$$
$$\text{Nitrogen losses} = \text{Urine urea nitrogen (UUN; gram/day)} + 4^{\star}$$

UUN is determined from a 24-hour urine collection.

*4 g is a "correction factor" to account for miscellaneous nitrogen losses.

(Eq. 35-4)

A negative value occurs with burns, fevers, serious injuries, wasting diseases, and during periods of fasting. This means

that the amount of nitrogen excreted from the body exceeds the amount of nitrogen (in the form of protein) ingested. Conversely, a positive value is often found during periods of growth, tissue repair, or in pregnancy. This means that the intake of nitrogen into the body is greater than the loss of nitrogen from the body, so there is an increase in the total body pool of protein. In periods of growth, a nitrogen balance of +2 to +4 is considered average. As with other measurements of nutritional status, it also has limitations. It is difficult to accurately assess actual protein intake in an orally fed patient. It is easier to determine in patients receiving specialized nutrition support, such as enteral or parenteral nutrition, where intake is more tightly controlled.

SPECIAL CONDITIONS THAT IMPACT NUTRITIONAL REQUIREMENTS

In most instances, individuals who have conditions that increase their metabolic rate will also have increased nutritional requirements (**Table 35-6**). Similarly, there are situations that can negatively impact nutrient intake such as the ability to obtain food, secondary impaired mobility/declining health, or poverty. Other conditions affecting digestion (ie, acid blockade, cystic fibrosis, pancreatitis) or nutrient absorption (ie, celiac disease, Crohn disease, intestinal failure), metabolism (ie, corticosteroid use), and excretion (ie, diarrhea) may also influence overall nutritional needs. Table 35-6 provides examples of situations that can negatively affect nutrient utilization.

Table 35-6

Examples of Conditions That Impact Nutrient Requirements

Increase Nutrient Requirements			
Burns	Cystic fibrosis	Infection	Surgery
Cancer	Healing wounds	Lactation	Trauma
Chronic lung disease	Hyperthyroidism	Pregnancy	
Decrease Nutrient Utilization			
Alcohol abuse	Cholestasis	Glycosuria	Pancreatic insufficiency
Bacterial overgrowth	Cystic fibrosis	Intestinal failure	Protein-losing enteropathy
Celiac disease	Diarrhea	Irritable bowel disease	Radiation enteritis

Assessing Growth

The growth of children is typically trended on age- and gender-appropriate growth curves. Growth charts consist of a series of percentile curves that illustrate the distribution of selected body measurements in U.S. children. Pediatric growth charts have been used by pediatricians, nurses, and parents to track the growth of infants, children, and adolescents in the United States and internationally since 1977.[53] Currently, the Centers for Disease Control and Prevention (CDC) recommends that World Health Organization (WHO) growth standards be used to monitor growth for infants and children ages 0 to 2 years in the United States; for children age 2 years and older, the CDC growth charts should be used. The CDC clinical growth charts have the grids scaled to metric units with English units as a secondary scale. The charts are available for boys and girls. Table 35-6 summarizes the available charts. Infants (birth to 24 months) are measured for length, and the sex-appropriate length-for-age or weight-for-length charts for infants, birth to 36 months, are used to plot the measurements. At age 24 months and older, if children can stand unassisted and follow directions, stature should be measured and plotted on the stature-for-age chart for children (2–20 years). If unable to stand unassisted, length can continue to be used in place of stature for children between 24 and 36 months. In 2000, the CDC issued a revised version of the 1977 growth charts.[54]

Adults are compared against standard height–weight tables. In 1943, the Metropolitan Life Insurance Company introduced their standard tables for males and females. The tables were later revised in 1983. They were called “desirable” weights, which would indicate those persons with the lowest mortality rates. However, the phrase “ideal weight” has become associated with these tables, even though the word “ideal” was not specifically published with the tables. To compensate for the differences between body shapes and skeletal muscle mass, “frame size” was used. In theory, elbow width or wrist width correlates fairly well with muscle and bone mass. There are several limitations to using these tables.[55] The tables were designed

for adults ages 25 to 59 years, and height must be determined while the individual wears 1-inch (2.54 cm) heel shoes. Furthermore, these tables are not suitable for children or older individuals.

Micronutrients

Micronutrients are the electrolytes, vitamins, and trace minerals needed for metabolism. A complete assessment will include identification of risks for deficiencies or toxicities with micronutrients based on the patient's specific nutritional status and concurrent disease processes. These nutrients are available enterally and parenterally from various manufacturers as either single entities or in combinations. It is important to be aware of the specific products available in each institution to avoid providing inadequate or excessive amounts of various micronutrients.

SIGNIFICANCE

Patients who cannot meet their nutritional needs by consuming enough food orally should be considered for an alternative nutrition mechanism. Specialized nutritional support is the provision of parenteral or enteral nutrients, which are specifically formulated or delivered to maintain or restore nutritional status.[56] For those who cannot eat by mouth but have a functional GI tract, the first line of nutritional intervention to be considered should be the enteral route using an appropriate access device (see Chapter 37, Adult Enteral Nutrition, and Chapter 38, Adult Parenteral Nutrition). To mimic the normal physiologic state when possible, the GI tract should be used for providing nutrients. Enteral nutrients may be more beneficial and are generally less costly than those provided by the parenteral route.[57] Enteral nutrients stimulate the intestine, thus maintaining the mucosal barrier structure and function. This has been associated with decreased infectious morbidity in critically ill patients compared with those receiving nutrients parenterally.[57–61] Parenteral nutrition is therefore reserved for patients whose GI tracts are not functional or

cannot be accessed, or who do not absorb enough nutrients to maintain adequate nutritional status.[46]

CASE 35-1

Question 1: C.W. is a 46-year-old male admitted to the hospital with GI distress. C.W. states that he has been struggling with abdominal pain, diarrhea, and nausea for some time now. Upon further evaluation, C.W. admits that he has attempted to see a specialist; however, challenges with his work schedule and busy family life have delayed this. C.W. shares that his initial symptoms presented 12 months ago, and the reason he is here today is because of blood in his stool. Upon further examination, C.W. appears to have wasting of subcutaneous fat in his face and muscle in his arms. He reports weighing 331 pounds (150.14 kg) before symptom initiation, he was excited because he noticed he was losing weight, and this was a contributing factor to ignoring the GI upset he experienced. However, his weight loss was not initiated by lifestyle changes or pharmacotherapy. Over the past 2 months, C.W. has lost an additional 22 pounds (9.98 kg), today weighing 209 pounds (94.80 kg) with a height of 69 inches (175.26 cm). His past medical history is significant for gastroesophageal reflux disease, hypertension, and obesity. C.W. states that his eating habits have not changed, but he does have to skip meals often because of nausea.

Admission laboratory values are as follows:

Sodium, 135 mEq/L
Potassium, 4.0 mEq/L
Chloride, 100 mEq/L
Bicarbonate, 25 mEq/L
Blood urea nitrogen, 4 mg/dL
Creatinine, 0.6 mg/dL
Glucose, 87 mg/dL
Calcium, 8.2 mg/dL
Magnesium, 1.7 mg/dL
Phosphorus, 2.8 mg/dL
Total protein, 6.0 g/dL
Albumin, 3.5 g/dL
Prealbumin, 14 mg/dL
CRP, 3 mg/L

His white blood cell count is 14,300/μL. Based on history and physical findings, the medical team performs a complete workup for inflammatory bowel disease and identifies ulcerative colitis with an active bleeding ulcer.

What is his current nutritional status?

PATIENT ASSESSMENT: MALE WITH ULCERATIVE COLITIS

To develop an accurate nutritional assessment of any patient, it is important to elicit a thorough history and conduct an appropriate physical examination. Although history and physical examination are of utmost importance, laboratory studies are also integral components to the assessment of C.W.'s nutritional status. C.W.'s nutrition history indicates that he is at times unable to eat because of nausea, and the ulcerative colitis diagnosis raises the question of nutrient malabsorption. Most striking about C.W.'s history is his weight loss of 22 pounds (9.98 kg) in 2 months. He is now 63% of his usual weight (see Eq. 35-2). Another way of analyzing this is that he has lost 33% of his original weight, which is characterized as severe weight loss. The physical findings of cachectic appearance, subcutaneous fat wasting in his face and arms, are significant. No anthropometric measurements are available. C.W.'s visceral proteins are also in low to normal ranges, indicating both short-term (prealbumin) and long-term (albumin) malnutrition. Consideration of these factors leads one to conclude that C.W. is severely malnourished. This assessment can be further validated using other tools such as the SGA.[44] It is often challenging to identify malnutrition and significant weight loss in patients who are presently obese. Although C.W. is obese on presentation, it is vital to consider the patient's history when assessing nutritional status because changes from baseline are influential in interpretation.

Because nutritional assessment can often be difficult, a clinician may choose to use the SGA to appropriately categorize their patients. Application of the SGA technique classifies patients into three areas: class A (the well-nourished patient), with <5% weight loss or >5% total weight loss but recent gains and improvements in appetite; class B (moderately malnourished), identified by those patients with 5% to 10% weight loss without recent stabilization or gain, poor dietary intake, and mild loss of subcutaneous tissue; and

class C (severely malnourished), with an ongoing weight loss of >10% with severe subcutaneous tissue loss and muscle wasting, often with edema. The utility of the SGA is its simplicity for implementation and strong correlation with other subjective and objective measures of nutrition.

Clinicians place patients into one of the three categories on the basis of their subjective rating of two broad factors: history and physical examination. There are four elements to the history: (a) weight loss in the 6 months before the examination, expressed as a proportionate loss from previous weight, (b) dietary intake in relation to the patient's usual pattern, (c) presence of significant GI symptoms, and (d) functional capacity or energy of the patient, ranging from full capacity to bedridden. Applying these four elements to C.W., one first finds that C.W. is reporting a 33% weight loss during the past 12 months. It is also important to recognize the pattern of weight loss. Inquiring about a patient regarding recent weight loss (in conjunction with the weight change in 6 months), often in the past 2 weeks, can help establish a pattern of chronic weight loss. In C.W.'s case, he reports increasing weight loss in the past 2 months, which confirms a progression. It is also recommended that clinicians explore weight history by asking for the patient's maximal weight at specific times, such as 1 year ago, 6 months ago, 1 month ago, and at the present time. Confirmation of weight history can be conducted by having the patient discuss their change in clothing size or how their clothes fit.

With respect to the second element regarding dietary intake, C.W. says he has to skip meals due to nausea. Using the SGA, patients are classified as having either normal or abnormal intake in the weeks to months before the examination. In this case, C.W. is experiencing abnormal intake; however, one can also ask C.W. certain questions such as "How has the amount of food you have consumed over the past several weeks to months changed?" or "Are there certain kinds of foods that you no longer can eat?" and "Give me an example of a typical meal" to establish eating patterns. It is also important to determine why a patient is eating less—intentional reduction or unintentional reduction. C.W. has communicated that

while initially the weight loss was positive because of his past medical history of obesity, he has not had any intention of wanting to lose weight or initiating lifestyle changes to do so. His change in consumption is related to his chronic pathology of underlying inflammatory bowel disease.

In terms of the third element of the history, significant GI symptoms are those that have persisted on virtually a daily basis for a period >2 weeks. Given the presentation of C.W. to the hospital with his history of 12 months of abdominal pain, diarrhea, nausea, and, ultimately, blood in stool, it is highly likely that he satisfies the definition for possessing significant GI symptoms.

The final element of C.W.'s history, functional capacity, is one that should be explored further, yet it is not likely to have an impact on the final nutritional assessment given the prior objective findings of the patient. Patients who cannot eat may feel weak and tired—many times to the point of which they are bedridden. Observation of the activity levels of patients, their overall mood, skeletal muscle function, and their respiratory movements can all provide clues to the clinician regarding functional impairment. C.W. did not mention systemic symptoms; however, he is at risk for functional impairment and has experienced physical changes in the loss of fat and muscle tissue.

Having completed the history component of the SGA, the clinician moves to the second component of the SGA or the physical. This section of the SGA essentially asks the clinician to look for physical signs of malnutrition such as loss of subcutaneous fat in the triceps and chest region, muscle wasting in areas such as the quadriceps and deltoids, presence of ankle or sacral edema, and, finally, any presence of ascites. For each of the traits, the clinician should consider the severity, if anything is present. In the case of C.W., there is definite muscle wasting. Given the history and physical components of the SGA, C.W. would be classified as severely malnourished (class C) because there are obvious signs of malnutrition such as subcutaneous tissue loss and muscle wasting in the presence of a clear and convincing pattern of ongoing weight loss >10%.

Case 35-1, Question 2: Is C.W. a candidate for specialized nutritional support therapy?

The fundamental goal of specialized nutritional support therapy is to meet the energy requirements of metabolic processes, to support the hypermetabolism associated with critical illness, and to minimize protein catabolism. Ulcerative colitis is classified as an inflammatory bowel disease that is associated with nutritional insult. Nutritional abnormalities can arise in patients with ulcerative colitis from malabsorption, decreased food intake, medications, and intestinal losses. Disease location along the GI tract, symptomatology, and dietary restrictions all contribute to the development of protein-energy malnutrition with specific nutritional deficiencies. C.W. is admitted to the hospital for tests to evaluate his GI concerns and is found to have ulcerative colitis due to weight loss and associated symptoms. The subjective and objective evidence points to a nonfunctioning GI tract. C.W. may require parenteral nutritional therapy until enteral therapy can be established because of the current state of the active bleeding ulcer and the new diagnosis of ulcerative colitis (see Chapter 38, Adult Parenteral Nutrition). With his malnourished state, continued inadequate nutrition in the hospital will result in further deterioration of his nutritional status.

Goals of Therapy

Case 35-1, Question 3: What are C.W.'s calorie and protein goals?

Nutritional support begins with an estimation of the patient's caloric requirements.[49,50] Accurate determination of caloric needs is essential to obtain the full benefits of nutritional therapy and aids in preventing the problems associated with underfeeding as well as overfeeding. The Harris–Benedict equation is one of the most commonly used methods for estimating caloric needs or BEE; however, there is still controversy regarding the best method to

accurately estimate the caloric needs of a patient. In critically ill obese patients, it is recommended to utilize the Penn State University predictive equation. This equation requires data from a patient's hospitalizations including temperature and ventilation rate. In the event this data is unavailable, in hospitalized obese patients, the equation that may be utilized is the Mifflin–St Jeor equation utilizing actual body weight. Equations are included in Table 35-4. The most common approach is based on body weight in kilograms. The energy requirements are standardized and are determined by the metabolic condition of the patient. C.W.'s initial calorie goals are to meet his current energy expenditure needed for basal metabolism and activity of ambulating. C.W. would fall into the category of "moderate stress, malnourished," requiring 25 to 30 kcal/kg/day. For this calculation, C.W.'s actual weight of 209.43 pounds (95 kg) should be used because his metabolism and current energy expenditure reflect this decrease in body mass. Using usual weight or IBW in patients who have severe weight loss may result in overfeeding. For C.W., the caloric goal should be from 2375 to 2850 kcal/day.

Protein is the building block of life. Once hepatic glycogen stores are depleted, muscle protein is degraded to provide three-carbon backbones for hepatic gluconeogenesis. Initially, protein catabolism is resistant to the administration of exogenous amino acids, and it can sometimes take weeks until a patient is found to be in a state of positive nitrogen balance. In addition to protein catabolism, exogenous protein is required for wound healing and to replace protein lost in wounds and fistulae. Protein goals are estimated based on weight, degree of stress, and disease state. The goal is to minimize the loss of lean body mass, and, as a general rule, this requires anywhere from 1.0 to 1.5 g/kg/day of protein depending on the degree of illness and injury. Because C.W. has not had surgery and his stress is minimal, his protein goal should be based on the desire to maintain his current protein status. Using the guidelines provided in Table 35-5, C.W.'s protein dose is 1.2 to 1.5 g/kg/day, or 114 to 143 g/day. As with energy expenditure, calculations of protein needs are only estimates; the patient's clinical course should be

monitored, and the protein dose should be adjusted accordingly. It is important to note that in obese patients, utilizing actual body weight is supported by ASPEN. If IBW is preferred, the conversions and dosing should be adjusted. For example, the ASPEN guidelines for nutritional management of obese patients suggest the use of 2 to 2.5 g/kg protein requirements with IBW. If C.W. requires surgery, his energy or calorie goals should be reassessed to include an additional stress factor.[62]

Micronutrients

Case 35-1, Question 4: What vitamin and mineral deficiencies would you expect to find in C.W.? What options are available to the clinician to address them?

The therapeutic effects of specialized nutritional support accrue through the combined provision of macronutrients and micronutrients. These elements support vital cellular and organ functions, immunity, tissue repair, protein synthesis, and capacity of skeletal, cardiac, and respiratory muscles. As with any medical therapy, a nutritional support regimen should be adjusted based on the requirements, response, and tolerance of the patient. Patients who have inflammatory bowel disease are particularly at risk for developing altered levels of vitamins and other micronutrients. The etiology of these micronutrient losses is multifactorial and encompasses decreased oral intake, increased losses secondary to diarrhea, and malabsorption. In particular, deficiencies in vitamin D, folate, vitamin B_{12}, calcium, magnesium, and zinc are common to this patient population.

Given the prevalence of these deficiencies, C.W. should be prescribed a daily multivitamin and mineral supplement. If it is determined that C.W. has significant fat malabsorption, a water-miscible fat-soluble vitamin formulation can be considered. There is an increased incidence of osteoporosis in patients with ulcerative colitis (with or without corticosteroid use), and, therefore, C.W.

should be assessed to ensure that his calcium and vitamin D intake is normal. Recommended daily oral calcium requirements are from 800 to 1500 mg/day, but increase from 1500 to 2000 mg/day when replacement is needed for a deficiency. C.W. should be consuming a daily amount of 400 international units (IU) of vitamin D orally; however, if serum 25-hydroxyvitamin D levels are subtherapeutic, greater amounts will be required and also doses based on the specific disease progression and functionality of C.W.'s GI tract.

Medications such as methotrexate (a folate antagonist) and sulfasalazine (which blocks folate absorption) can be used to treat inflammatory bowel disease and, therefore, increase folate requirements for patients. Daily folate supplementation at a dose of 1 mg orally can be beneficial to C.W. if he is prescribed either of these medications.

Magnesium deficiency can be a concern in patients with increased intestinal losses, as is the case with many individuals who have inflammatory bowel disease. When considering enteral magnesium supplementation, the change in pH along the GI tract, GI transit time, and fat content of a meal can all affect magnesium absorption. Large doses of enteral magnesium can result in diarrhea; therefore, administering smaller doses throughout the day can lead to improved tolerance and therapeutic efficacy. Choosing a magnesium supplement that can deliver 150 mg of elemental magnesium and dosing it four times a day is the recommended oral replacement regimen for patients.

Patients with inflammatory bowel disease can experience excessive stool losses resulting in a zinc deficiency. C.W. should receive an oral zinc supplement that delivers 50 mg of elemental zinc daily.

Maintenance Fluids

Case 35-1, Question 5: What is C.W.'s daily fluid requirements while he receives specialized nutritional support?

When determining the fluid needs of a patient, the clinician should consider the following steps: (a) correction of fluid imbalances, (b) maintenance fluid requirements, and (c) replacement of ongoing fluid losses.

The extended periods of diarrhea, vomiting, or both that occur with inflammatory bowel disease may lead to dehydration. Dehydration results in a loss of body weight, decreased urine output, dry mouth, and progressive thirst. Hypotension, tachycardia, and poor skin turgor are all clinical signs of dehydration. Apathy, stupor, coma, and death will follow if fluid replacement is not undertaken. Fluid deficits should be estimated from the clinical appearance of the patient, recent weight loss, and serum sodium and blood urea nitrogen concentrations, and replaced by giving half the estimated deficit intravenously over the course of 8 hours. After 8 hours, a new assessment of fluid status should be made, and half of the new estimated deficit should be replaced during the next 8 hours. This process should be repeated until normal hydration is achieved (see Chapter 27, Fluid and Electrolyte Disorders).

Maintenance fluid is that volume of daily fluid intake that replaces the insensible losses and at the same time allows excretion of the daily production of excess solute load in a volume of urine that is of an osmolarity similar to that of plasma. Maintenance fluid needs can be estimated using several methods. The simplest method uses 30 to 35 mL/kg/day as the basis. Another method is to provide 1500 mL for the first 20 kg of body weight plus an additional 20 mL/kg for actual weight beyond the initial 20 kg. Both methods provide estimates of fluid needs for basic maintenance. C.W.'s fluid needs are estimated as follows:

$$\begin{aligned} \text{mL/day} &= 1500\ \text{mL}\ ([20\ \text{mL/kg}]\,[95\ \text{kg} - 20\ \text{kg}]) \\ &= 1500\ \text{mL}\ (20\ \text{mL/kg})\ (75\ \text{kg}) \\ &= 1500\ \text{mL} + 1500\ \text{mL} \\ &= 3000\ \text{mL} \end{aligned} \quad \text{(Eq. 35-5)}$$

If C.W. experiences vomiting, nasogastric tube output, diarrhea, or other significant fluid losses, additional fluid must be provided. Some losses are measurable and can be directly replaced milliliter for milliliter on a regular basis. Others, however, are not measurable and can only be estimated. The electrolyte composition of the lost fluid is an important consideration for the clinician and dictates the ultimate choice of the replacement fluid.

Evaluating Specialized Nutritional Support Effectiveness

Case 35-1, Question 6: What parameters should be examined to determine the effectiveness of C.W.'s nutritional support regimen?

Implementing a successful nutritional support regimen begins with proper nutritional assessment of the patient. Nutritional goals that identify macronutrient, micronutrient, and fluid requirements are then established. Follow-up support and monitoring of the patient once nutritional support has been instituted is important to maintain the integrity and efficacy of the therapy.

To minimize the risk of refeeding syndrome in C.W. (a metabolic and electrolyte disturbance that occurs as a result of supplying nutrition to patients who are severely malnourished), all electrolyte abnormalities must be corrected before any nutrition is initiated. Because C.W.'s electrolytes are within normal ranges, no adjustments are necessary. Nutrition should then be implemented slowly, and vitamins administered routinely. Electrolytes, including phosphorus, potassium, magnesium, and glucose, should be monitored at least daily during the first week. Although electrolyte and mineral abnormalities may not be avoided, careful recognition of and close monitoring for refeeding syndrome will prevent serious complications.[63,64]

Although it can sometimes be difficult to obtain a reliable weight for a patient, weight can be an important parameter to help assess

not only fluid balance but also the long-term appropriateness of caloric intake. Most patients should gain or lose no >1 kg/week when receiving nutritional support (assuming normal fluid status). However, clinicians must be aware of the impact that fluids have on the weight of a patient. Large intake or loss of fluids can influence weight measurements and mask the trends of body mass. Having C.W.'s record of daily weights, in addition to fluid intake and output, and monitoring trends can serve as one, but not the only, key in determining the effectiveness of his regimen.

Nitrogen balance is another parameter that can help determine the degree of catabolism and protein requirements in a patient. Nitrogen balance is the difference between nitrogen intake and nitrogen excretion. It is estimated by the nitrogen intake along with collecting a 24-hour UUN sample from the patient. Positive nitrogen balance is a reasonable goal during nutritional support therapy for recovery of a patient, but may also require increasing caloric loads on a periodic basis. If a nitrogen balance study is ordered for C.W., increasing protein intake should be considered if results indicate a negative nitrogen balance; however, a negative nitrogen balance may be unavoidable during high-stress states, regardless of the amount of nutrients provided.

Although evaluating calcium is important in determining electrolyte needs, it is critical to remember that calcium is influenced by a number of factors, one of which is serum albumin. The mechanism driving this relationship is calcium binding to albumin, which is therefore reflected in serum levels when albumin is low. Low calcium in the setting of low albumin, however, is not indicative of ionized calcium levels because of this relationship. It is for this reason that calculating a corrected calcium should be performed for all patients in this scenario. The equation is as given:

$$\text{Corrected calcium} = \text{serum calcium} + 0.8\,(4.0 - \text{serum albumin}) \quad \textbf{(Eq. 35-6)}$$

Utilizing this equation, 4.0 refers to a normal average serum albumin and allows for the normalization of this value. The corrected

calcium for C.W. is 8.6 mg/dL, which meets the criteria for borderline hypocalcemia postcorrection calculation.

Finally, prealbumin levels for C.W. should also be monitored once a week as a marker for short-term gross adequacy of calorie and protein intake. A lack of prealbumin increase is an indicator of poor patient outcomes. With adequate feeding, prealbumin can increase >4 mg/dL/week. It should be noted that in the case of C.W., who is suffering from ulcerative colitis and may likely be receiving either oral or parenteral corticosteroids as treatment, administration of corticosteroids can falsely elevate prealbumin levels, making C.W. appear to be at a lower nutritional risk.

Case 35-1, Question 7: Members of the medical team are anxious to have C.W. gain weight and are concerned by his malnourished appearance. Therefore, there is a desire to increase the calories provided to C.W. What potential complications could result from overfeeding C.W.?

Overfeeding should be avoided in all patients including obese persons because of a number of potential complications, especially those with respiratory concerns.[65] Although restoration and maintenance of body cell mass is the goal of nutritional support therapy, a gradual and conservative approach yields fewer metabolic abnormalities. Supplying an abundance of calories to a patient in need of nutritional support increases the metabolic rate, which in turn places greater demands for cardiopulmonary effort and oxygenation. Overfeeding with carbohydrates is particularly detrimental because of the amount of carbon dioxide produced relative to the amount of oxygen consumed. This results in carbon dioxide retention that may lead to acid–base disturbances. Hyperglycemia is also a common metabolic abnormality secondary to excessive carbohydrate administration that can lead to osmotic diuresis and immune dysfunction.

Obesity

Kaelen C. Dunican and Aimee Dawson

CORE PRINCIPLES		CHAPTER CASES
1	Body mass index (BMI) should be measured at each patient encounter, and patients should be assessed for overweight, obesity, and the presence of obesity-related conditions.	**Case 36-1 (Questions 1, 3)**
2	The medication profile of patients with increased body weight should be evaluated for drugs associated with weight gain, and alternative agents that are weight neutral or associated with weight loss should be considered.	**Case 36-1 (Question 1)**
3	Obesity is a chronic disease, and therapeutic interventions must be long term. It is common for patients to regain weight after discontinuation of lifestyle or pharmacologic therapy.	**Case 36-1 (Questions 2, 7, 9)**

	CORE PRINCIPLES	CHAPTER CASES
4	An appropriate weight loss goal for most patients is 5% to 10% of baseline body weight; goals may be more aggressive depending on the presence of obesity-related conditions.	**Case 36-1 (Question 4)**
5	Management and treatment of overweight and obesity should include lifestyle therapy (a combination of diet and increased physical activity along with behavioral modifications).	**Case 36-1 (Questions 4, 5)**
6	In addition to lifestyle therapy, medication to treat obesity should be considered for patients with a BMI >30 kg/m^2 without risk factors or >27 kg/m^2 with an obesity-related condition.	**Case 36-1 (Questions 4, 6, 7)**
7	Short-term weight loss drugs are unlikely to be clinically useful and should not be recommended.	**Case 36-1 (Question 6)**
8	Medication for chronic weight management includes orlistat, phentermine/topiramate, naltrexone/bupropion, liraglutide, or semaglutide.	**Case 36-1 (Question 7)**
9	The use of dietary supplements for weight loss is not supported by clinical literature, and generally should be avoided because of safety concerns and lack of regulation.	**Case 36-1 (Question 8)**

CORE PRINCIPLES		CHAPTER CASES
10	Medical devices are available for the treatment of overweight and obesity, and may be considered for some patients.	**Case 36-1 (Question 10)**
11	Bariatric surgery may be considered for patients with BMI ≥40 kg/m^2, or BMI ≥35 kg/m^2 with one or more obesity-related conditions, or BMI ≥30 kg/m^2 and type 2 diabetes with inadequate glycemic control.	**Case 36-1 (Question 11)**
12	Alteration of gastrointestinal tract and stomach size after bariatric surgery can alter drug pharmacokinetics, cause nutrition deficiencies, and place patients at risk for adverse events associated with some medications.	**Case 36-1 (Question 11)**

INTRODUCTION

Obesity is a chronic disease characterized by excess body fat accumulation that may impair health.[1,2] The prevalence of obesity has become an epidemic. It is recognized by the World Health Organization (WHO) and the U.S. Federal Government as a growing problem that burdens health care organizations and the economy.[1,2] More than one-third of the worldwide population is overweight.[3] More than two-thirds of the U.S. adult population is overweight, with more than one-third considered obese.[4] Analyses estimate the medical expenses associated with obesity in the United States as $149.4 billion.[5]

DEFINITIONS

Overweight and obesity are defined by body mass index (BMI), a measure of weight in relation to height. BMI is calculated as weight (in kilograms) divided by height (in meters) squared. Normal weight is defined as BMI of 18.5 to 24.9 kg/m^2, overweight is defined as BMI of 25 to 29.9 kg/m^2, and obesity is defined as BMI ≥30 kg/m^2 (**Table 36-1**).[6] Obesity is further divided into class I (BMI 30–34.9 kg/m^2), class II (BMI 35–39.9 kg/m^2), and class III (BMI ≥40 kg/m^2).[6] Class III obesity is also referred to as *very severe obesity*, and was formerly known as extreme or morbid obesity.[6] Lower BMI cutoffs, including overweight beginning with a BMI ≥23 kg/m^2 are recommended for some ethnicities including South Asian, Southeast Asian, and East Asian adults.[6] Obesity is a chronic metabolic disorder that is determined by multiple biologic and environmental factors, an obesogenic lifestyle, and a genetic predisposition. The increase in the prevalence of obesity and negative health outcomes are major public health problems throughout the world.[1]

Table 36-1
Body Mass Index and Guidelines for Weight Classes

Weight Status	BMI[a]	Obesity Class
Underweight	<18.5	
Normal	18.5-24.9	
Overweight	25-29.9	
Obesity	30-34.9	(I)
Severe obesity	35-39.9	(II)
Very severe obesity	≥40	

BMI, body mass index.

[a]Metric conversion formula using kilograms and meters: body mass index (BMI), weight in kg/height in m^2. Nonmetric conversion formula using pounds and inches: BMI, weight in pounds/height in inches^2 × 703.

BMI is widely accepted as the standard to classify weight. However, a major limitation of BMI is that it does not consider body composition. According to BMI, a person may be classified as "overweight" if their muscle mass is great enough to significantly contribute to total weight. On the other hand, a patient may be considered "normal weight" while having excess fat accumulation and decreased muscle mass. The use of BMI to assess body fat and risk of morbidity and mortality is particularly problematic in certain ethnic groups because BMI does not account for differences in distribution of body fat.[6] For example, research suggests that in the Asian population, BMI underestimates body fat.[6] BMI should always be used in conjunction with clinical evaluation and judgment, particularly with those with increased muscle mass (athletes) or decreased muscle mass (sarcopenia).[6] Another limitation of BMI is that it does not consider the location of fat in the body.

Fat distribution in the abdominal region has been linked to many of the metabolic consequences of obesity.[7] Measurement of waist circumference (WC) is used to assess for increased abdominal fat accumulation and to determine health risk. WC measurements >40 inches (102 cm) in males and 35 inches (88 cm) in females are associated with increased risk of metabolic diseases.[7] Increased WC has been shown to predict obesity-related diseases such as diabetes, hypertension, dyslipidemia, and cardiovascular disease.[7–9] The waist-to-hip ratio (WHR) also provides an assessment of regional fat distribution. A WHR >1 in males and >0.8 in females indicates high intra-abdominal fat. Some research suggests that WHR is superior to both WC and BMI in determining obesity-related cardiometabolic risk.[6] Independent of BMI classification, higher WC is correlated with increased mortality.[10] Therefore, measurement of WC and the WHR are useful in identifying individuals who are normal weight or overweight with health risks owing to increased abdominal fat accumulation.

EPIDEMIOLOGY

Obesity is a major public health concern worldwide, and is a leading cause of numerous medical conditions (eg, cardiovascular disease, hypertension, dyslipidemia, diabetes, sleep apnea) and premature death[6] (**Table 36-2**). According to the WHO, there were ~1.9 billion overweight and 650 million obese adults globally in 2016.[1] In the United States, the prevalence of obesity has been examined as part of the National Health and Nutrition Examination Survey (NHANES). The NHANES data from 2017 to 2018 indicates that the prevalence of obesity and severe obesity among U.S. adults was 39.8% and 9.2%, respectively.[4] Data from 2017 to 2018 shows 73.6% of U.S. adults are overweight or obese.[11] Adult obesity usually results from steady weight gain starting in the mid-20s to between ages 40 and 59 years, when the prevalence of obesity peaks.[4] Severe obesity is more common in females, and the prevalence of obesity is highest among non-Hispanic Black females.[4] The prevalence of obesity and severe obesity among adults has continued to increase from 1999 through 2018.[4]

Table 36-2
Obesity-Related Health Conditions

Cardiovascular	**Dermatologic**
Cardiovascular disease[a]	Striae distensae (stretch marks)

Sources: Garvey WT, Mechanick JI, Brett EM, et al. American Association of Clinical Endocrinologists and American College of Endocrinology comprehensive clinical practice guidelines for medical care of patients with obesity. *Endocr Pract.* 2016;22 Suppl 3:1–203. doi:10.4158/EP161365.GL; Malnick SD, Knobler H. The medical complications of obesity. *QJM.* 2006;99:565–579. doi:10.1093/qjmed/hcl085.

Obesity is also a significant problem among children and adolescents, with alarmingly high prevalence rates. Overweight and obesity in children and adolescents (ages 2–19 years) are based on the Centers for Disease Control and Prevention (CDC) growth charts; overweight is defined as BMI in the 85th to 95th percentile, and obese is defined as BMI >95th percentile.[6] The WHO estimates

that 38 million children age younger than 5 years and >340 million children and adolescents ages 5 to 19 years have overweight or obesity worldwide.[1] The U.S. NHANES data from 2015 to 2016 reported that 35.1% of children and adolescents (ages 2–19 years) had either overweight or obesity including 18.5% with obesity and 5.6% with severe obesity.[12] Asian youth show the lowest prevalence followed by non-Hispanic White youth, non-Hispanic Black, and Hispanic youth. Mexican American youths show the highest prevalence, with 29.2% in boys and 24.3% in girls.[12] This prevalence rate has remained alarmingly high; childhood obesity must be addressed because of the health consequences the child takes on into adulthood. Childhood and adolescent obesity shows an increased risk for adult overweight and obesity.[13] Also, studies have shown that overweight and obesity in childhood and adolescence are correlated with an increased risk of adult diabetes, hypertension, ischemic heart disease and stroke physical morbidity, and premature mortality.[14]

ETIOLOGY AND PATHOPHYSIOLOGY

Simply stated, obesity results from an imbalance of energy intake and energy expenditure. Body fat accumulation will occur when an individual consumes more calories than are burned. However, this simple principle becomes increasingly complex when considering the effects of hormonal and neural signals that control the body's energy homeostasis.[15] This explains why simple calorie counting in relation to physical activity or calorie expenditure is not always an easy or successful method for reducing weight; the body has in place counterregulatory systems that limit the degree of a calculated weight loss.[15,16]

The exact cause of obesity is difficult to identify and is likely a mixture of genetic, neurohormonal, environmental, and behavioral factors. Investigators have tried to understand the origin of this disease by studying the influences of society, culture, socioeconomic

status, medical conditions, medications that stimulate appetite, parental weight, and hereditary traits on dietary habits and physical activity.[17] Each potential cause of obesity continues to be investigated as a possible target for treatment and prevention. It has been concluded that there are physiologic and metabolic differences in persons with a history of obesity compared to those who were never obese. These physiologic differences and the body's adaptations to weight loss are suggested to cause the weight loss plateaus and relapses commonly seen in persons with obesity after a period of weight loss. This speaks to the importance of treating obesity as a chronic disease that requires lifelong monitoring and long-term treatment strategies.

Genetic Features

There is a clear link between genetics and obesity, both in childhood and adulthood, shown mostly through twin and adoption studies.[18–23] One study by Wardle et al demonstrated a heritability estimate of 77% for BMI and 76% for WC.[20] Genetic studies have identified genes that may be associated with weight.[18,30] There is also evidence that body fat distribution is controlled by genetic factors with WHR showing heritability of up to 60%.[24]

HYPOTHALAMUS DYSREGULATION

The hypothalamus plays a key role in body weight regulation by controlling appetite and energy expenditure.[25] This occurs particularly in the arcuate nucleus within the hypothalamus. The hypothalamus is sensitive to a variety of facilitatory and inhibitory neurotransmitters and polypeptide neurohormones from the brain and gastrointestinal (GI) tract.[15,25] The hypothalamus receives input from peripheral satiety sites (eg, gastric and pancreatic peptides released secondary to food passing through the GI tract), from leptin that is produced by fat cells, and from the catecholamine neurotransmitter system in the brain.[26,27]

NEUROPEPTIDE AND LEPTIN DYSREGULATION

Leptin

Leptin is a protein synthesized by adipocytes, gastric chief cells, skeletal muscle, and other organs. It acts on receptors of the hypothalamus as an afferent satiety signal in the brain to regulate body fat mass.[26,28] Leptin reduces food intake, decreases serum glucose and insulin levels, increases metabolic rate, and reduces body fat mass and weight.[29,30] Serum leptin levels are highly correlated with BMI and body fat; leptin secretion has a circadian rhythm and an oscillatory pattern similar to that of other hormones.[26,29]

Although rare, it is estimated that 1% to 5% of children with severe obesity may have a genetic mutation that causes a leptin deficiency.[31] Without the inhibitory signaling of leptin, patients can experience imbalances in their energy homeostasis, neuroendocrine pathways, and autonomic nervous systems leading to obesity. Leptin deficiency–related obesity as well as certain types of lipodystrophy can be successfully treated with exogenous leptin.[29,30] In contrast to leptin deficiency, leptin resistance is much more common. Many patients with obesity have been shown to have high levels of leptin, but experience leptin resistance.[28,29] A potential mechanism for leptin resistance may be reduced leptin receptor protein expression found in the skeletal muscle of patients with obesity.[32] The body's failure to respond to leptin signaling results in a net positive energy imbalance similar to that seen in leptin deficiencies. Utilizing exogenous leptin, or leptin-like products, has been unsuccessful in clinical settings for most patients with obesity, likely owing to leptin resistance.[28–30] In addition, it has been demonstrated that elevated baseline serum leptin levels are associated with inability to maintain weight loss.[33]

Neuropeptides and neurohormones

Appetite is regulated in part via a feedback loop of orexigenic neuropeptides—neuropeptide Y (NPY) and agouti-related peptide (AgRP) that signal hunger and anorexigenic neuropeptides (pro-opiomelanocortin [POMC])—which, in turn, signal satiety within the

hypothalamus.[30,34] Neurons expressing the *POMC* gene release melanocyte-stimulating hormones (MSHs).[30,34] These hormones can stimulate melanocortin-3 receptors (MC3R) and melanocortin-4 receptors (MC4R) to suppress food intake.[27,30,35]

Several other neurohormonal signals and peptides play a role in appetite regulation. Ghrelin is a hormone that is released from the stomach before meals and acts to increase appetite via stimulation of NPY and AgRP.[34,35] There is a negative correlation between ghrelin levels and BMI, in which patients with obesity have increased ghrelin, and levels remain elevated even after weight loss.[35] Peptide tyrosine tyrosine (peptide YY or PYY) and pancreatic polypeptide (PP) are chemically related to NPY, but work as appetite suppressants.[35,36] Both NPY receptor antagonists and PYY have been investigated as potential anti-obesity drugs, and research is ongoing.[37] Amylin is a pancreatic hormone that is released in response to eating and has an anorectic effect.[35] Administration of amylin has been shown to result in reduced food intake and weight loss.[38] Glucagon-like peptide (GLP)-1 is secreted from the gut in response to food intake and works to reduce food intake, suppress GLP secretion, and delay gastric emptying.[35] Cholecystokinin (CCK) is a hormone that is released from the small intestines in response to food intake and works to suppress further food intake.[35]

NEUROTRANSMITTER DYSREGULATION (SEROTONIN, DOPAMINE, NOREPINEPHRINE)

POMC and AgRP neurons are responsive to central neurotransmitters (including serotonin, NPY, γ-aminobutyric acid [GABA], and melanocortin) to control appetite.[25] Serotonin has an inhibitory effect on appetite, and is responsible for satiety or the feeling of fullness after food intake.[39] Agents that block postsynaptic serotonin activity (eg, clozapine, mirtazapine, and atypical antipsychotics) can stimulate appetite and may cause weight gain.[40] Research has correlated similarities between drug addiction and food addiction, through the body's neuroadaptations in the dopamine reward system.[41] Studies have shown that people with obesity may

have impairments in dopaminergic pathways that may lead to overeating.[42] Dopamine-augmenting agents such as amphetamines were once used for the treatment of obesity, but produced tolerance, dependence, and withdrawal reactions. Conversely, dopamine receptor antagonists such as chlorpromazine and clozapine may cause dysphoria, and are often associated with weight gain. Obesity has been linked to the activation of the sympathetic nervous system (SNS).[43] This increase in the SNS response is thought to be mediated by both norepinephrine and leptin.[44] The increase in SNS activity is thought to be the primary mechanism of obesity-related hypertension.[43,45]

Medical Conditions and Medications

Although less common, certain medical conditions may cause overweight and obesity.[46] Genetic syndromes may be the primary cause of obesity such as Prader–Willi, Bardet–Biedl, Cohen, Alström, and Froehlich syndromes. Other primary causes of obesity include monogenic disorders such as MC4R mutation, leptin deficiency, and POMC deficiency.[28,29,47] Setmelanotide (Imcivree™), a novel MC4R agonist, was approved in 2020 for patients with obesity caused by proprotein subtilisin/kexin type 1 (PCSKI) deficiency, POMC deficiency, and leptin receptor deficiency.[47,48] Setmelanotide is administered as a subcutaneous injection once daily.[47] Secondary causes of obesity include neurologic issues such as brain injury, brain tumors, and hypothalamic injury.[46] Endocrine disorders may also be a secondary cause of overweight and obesity such as polycystic ovarian syndrome, Cushing syndrome, and growth hormone deficiency.[46] Hypothyroidism is often cited as a secondary cause of obesity because elevated thyroid-stimulating hormone (TSH) is correlated with obesity.[49] But the relationship between hypothyroidism and obesity is complex; because leptin and melanocortin influence the release of TSH, causality has yet to be established.[49,50] Psychological causes of obesity include eating disorders and depression when associated with overeating or

binging. Several medications are also associated with weight gain. These include antipsychotics, steroids, insulin, sulfonylureas, thiazolidinediones, some antidepressants, and some anticonvulsants.[46,51–53] When treating overweight and obesity, if medications associated with weight gain are identified, substitution with possible alternatives should be considered. **Table 36-3** provides a list of medications that may cause weight gain, along with potential alternatives.

Table 36-3

Common Drugs and Their Effect on Weight

	Associated With Weight Gain	Associated With Less Weight Gain or Weight Neutral	Associated With Weight Loss
Antidepressants	TCAs (particularly amitriptyline), citalopram, escitalopram, sertraline, paroxetine, mirtazapine	Fluoxetine, duloxetine, venlafaxine	Bupropion
Antipsychotics	Clozapine, olanzapine, paliperidone, quetiapine, risperidone, haloperidol	Aripiprazole, amisulpride, asenapine, brexpiprazole, lurasidone, ziprasidone	
Neurologic	Valproic acid, gabapentin, pregabalin, carbamazepine, vigabatrin, lithium	Lamotrigine	Topiramate, zonisamide, felbamate
Glucose lowering	Insulin, sulfonylureas (especially glyburide), meglitinides, thiazolidinediones	DPP-4 inhibitors	GLP-1 agonists, metformin, pramlintide, SGLT-2 inhibitors, α-glucosidase inhibitors
Antihypertensives	β-Adrenergic blockers (especially propranolol), α-adrenergic blockers (prazosin, terazosin)	ACEIs, ARBs, CCBs, doxazosin	
Contraceptives	Depot medroxyprogesterone	Barrier methods, oral contraceptives	
Antihistamines	First generation	Second generation	
Anti-inflammatory	Corticosteroids	NSAIDs, DMARDs	

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; DMARD, disease-modifying antirheumatic drug; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; MAOI, monoamine oxidase inhibitor; NSAID, nonsteroidal anti-inflammatory drug; SGLT-2, sodium glucose–linked transporter-2; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Environmental Influences, Behavioral Factors, and Other Considerations

Despite the known genetic influences predisposing certain individuals to obesity, environmental influences play a role by providing exposure to a lifestyle promoting energy imbalance that may influence epigenetic factors. Modern society provides an overabundance of inexpensive, readily accessible calorie-dense food. Decreased energy expenditure owing to a sedentary lifestyle has become common, further exacerbating an obesogenic lifestyle.[30] A review of twin and adoption studies by Silventoinen et al clearly demonstrated that environmental factors affect BMI variation in childhood, but the effect of common environment disappears in adolescence.[19] These results portray a stronger influence of genetics in the incidence of obesity in adulthood.

Several association studies link short-term sleep duration and metabolic changes such as obesity, insulin resistance, and diabetes.[54,55] Alteration of the hypothalamic regulation of appetite and energy expenditure owing to sleep loss is one possible explanation. Sleep loss has also been shown to be associated with low leptin levels and high ghrelin levels; both factors contribute to signaling of energy deficit and hunger, which may contribute to overeating and obesity.[56]

Research has begun to investigate the role of gut microbiota in body composition. Data suggest that interventions that negatively impact the biodiversity of the gut microbiota such as cesarean delivery, elevated maternal prepregnancy BMI, and early antibiotic use may increase the risk of obesity.[57] A large cohort trial found that

the repeated use of broad-spectrum antibiotics during the first 2 years of life has been associated with early childhood obesity.[58]

CASE 36-1

QUESTION 1: S.B. is a 48-year-old female with a past medical history (PMH) of hypertension, sleep apnea, osteoarthritis, and depression. Her height is 66 inches (168 cm), current weight is 200 pounds (91 kg), and WC is 38 inches (96 cm). She presents to her primary physician for a routine physical examination. She notes dissatisfaction with her weight and states that she has been overweight since she was a child. She reports having tried multiple diets during the past 30 years, but has had little success with weight loss and always regains any weight she manages to lose. S.B. expresses a desire to attempt more intensive therapy for weight loss. Her current medications include hydrochlorothiazide 12.5 mg, acetaminophen 1000 mg prn, and paroxetine 20 mg. Her blood pressure is controlled at 128/78 mm Hg and her sleep apnea is managed with a continuous positive airway pressure (CPAP).

How is obesity defined and assessed in a patient such as S.B.? What factors (including medications) may be contributing to her obesity?

CLINICAL FEATURES

Initial Assessment

Current guidelines recommend that weight status should be assessed in all patients.[6] Initial assessment involves a physical exam and patient interview to classify the presence of overweight or obesity and any obesity-related comorbidities. The preferred method to classify overweight or obesity is to measure the BMI. Measurement of WC will also aid in determining risk of obesity comorbidities. However, measurement of WC in patients with BMI >35 kg/m^2 is not necessary because it will likely be elevated and will provide no additional risk information.[6,9] BMI, WC, and obesity-related comorbidities are used to determine the need to initiate treatment. S.B.'s BMI is 32.2 (91 kg/[1.68 m^2]), which is in obesity class I. Her WC >35 inches (>88 cm) indicating abdominal obesity

that puts her at additional risk for increased morbidity and mortality. S.B. also has hypertension, sleep apnea, and osteoarthritis, which are likely related to obesity and will need to be considered in her overall care plan.

During the patient interview, information should be obtained regarding the patient's eating habits and physical activity. It is important to establish baseline data so that response to changes in diet and exercise is noted throughout treatment. Successful weight loss involves a change in energy balance through reduced caloric intake or increased energy expenditure. In S.B.'s case, it will be beneficial to evaluate her current diet and physical activities to determine the most appropriate lifestyle recommendations. It is also important to evaluate a patient's "weight loss readiness" or self-motivation before initiation of therapy. A patient's motivation to lose weight is a significant predictor of success or failure in the weight management program. S.B.'s desire and willingness to make significant lifestyle changes to achieve this should be evaluated.

Patients should also be screened for medical conditions or medications that can increase the risk of obesity, and these underlying factors should be corrected before recommending treatment. S.B.'s PMH does not indicate any overt medical causes of obesity, but it would be appropriate to rule out whether she is overeating because of her depression and to check thyroid function to rule out hypothyroidism. Even though causality between obesity and thyroid dysfunction has yet to be firmly established, hypothyroidism is a common condition in females and may be associated with weight gain or inability to lose weight. S.B. is currently taking paroxetine for depression, which has been associated with weight gain.[53] S.B.'s prescriber may want to consider switching to fluoxetine, which is the selective serotonin reuptake inhibitor (SSRI) that is associated with the least amount of weight gain, or bupropion, which is associated with weight loss (**Table 36-3**).[51,53]

Course and Prognosis

Case 36-1, Question 2: S.B. states that she has struggled with her weight her whole life. She has progressively gained ~(4.4 pounds [2 kg])/year since her 20s. What is the typical course and prognosis of obesity?

Obesity is a chronic disease that often begins in childhood or adolescence, and is often characterized by a slow and steady increase in body weight during adult life. Most patients with obesity battle with weight loss and regain throughout their entire lives. The biologic response to weight loss favors regain with increased ghrelin and reductions in GLP-1, CCK, leptin, and PYY resulting in increased hunger.[46,59] Maintaining weight loss is key to long-term management of obesity. S.B. should be assured that her struggle is common and that she will need to commit to long-term lifestyle changes to manage her obesity.

Medical Complications

Case 36-1, Question 3: S.B. understands that she already has hypertension, sleep apnea, and osteoarthritis, which are comorbidities that are related to her obesity and increase her risk of morbidity and mortality. She is also at risk for experiencing additional obesity-associated medical comorbidities if she does not lose or continues to gain weight. What are the other common medical conditions associated with obesity?

Obesity is associated with an increased risk of morbidity and mortality. Obesity is linked to many significant health conditions such as type 2 diabetes mellitus; respiratory conditions; gallbladder disease; cancers; osteoarthritis; cardiac disease (hypertension, stroke, congestive heart failure, and coronary heart disease); dyslipidemia; and GI, hepatic, and gynecologic and obstetric complications (**Table 36-2**).[6,60] Weight loss helps control diseases associated with obesity, and may even help prevent development of these diseases. In S.B.'s case, weight loss could help her decrease or eliminate medications needed to control her hypertension, alleviate pain associated with osteoarthritis, decrease symptoms of

sleep apnea, and reduce her BMI and WC, thereby improving her morbidity and mortality risk.

ASSESSMENT AND TREATMENT

Case 36-1, Question 4: S.B. reports that she is highly motivated to lose weight. What are appropriate goals for S.B.'s weight loss? What should the initial treatment plan include?

The ultimate goal in the management of overweight or obesity is to prevent or improve obesity-related complications.[6] Weight loss goals should be individualized based on the patient and presence of obesity-related complications. Health benefits have been shown with >5% sustained weight loss.[6] Most health conditions including diabetes, hypertension, and dyslipidemia will improve with weight loss goals of 5% to 15%.[6] Higher goals of 10% to 40% may be necessary to demonstrate improvement for steatohepatitis.[6] Setting appropriate achievable weight loss goals is important to success; unrealistic expectations for more dramatic weight loss may lead to disappointment and ultimately cause patients to stop any efforts.

Obesity is a chronic disease that requires lifelong effort for successful treatment.[6,46] Treatment may involve a multidisciplinary approach including the expertise of a general practitioner, dietician or nutrition specialist, pharmacist, psychiatrist, or surgeon depending on the specific needs of the individual. The general goals of weight loss and management are to prevent or improve obesity-related complications, prevent further weight gain, reduce body weight, and maintain weight loss over a long period.

The American Association of Clinical Endocrinologists (AACE) and American College of Endocrinology (ACE) guidelines recommend implementing a strategy of primary, secondary, and tertiary prevention for overweight and obesity.[6] To determine the appropriate phase, BMI must be evaluated and then patients with a BMI ≥25 (overweight or obese) must be screened for the following obesity-

related complications: metabolic syndrome, prediabetes, type 2 diabetes, dyslipidemia, hypertension, cardiovascular disease, nonalcoholic fatty liver disease, polycystic ovary syndrome, female infertility, male hypogonadism, obstructive sleep apnea, asthma or reactive airway disease, osteoarthritis, urinary stress incontinence, gastroesophageal reflux disease, and depression.[6]

- Primary prevention: For patients with a BMI <25 (normal weight), the recommended therapy is to prevent patients from developing overweight and obesity through a healthy lifestyle.[6]
- Secondary prevention: For patients with BMI 25 to 29.9 (overweight) with no obesity-related complications; the recommended therapy is to implement lifestyle therapy. For patients with a BMI ≥30 (obesity) with no complications; the recommended therapy begins with lifestyle therapy, and if lifestyle therapy fails, pharmacotherapy should be considered.[6]
- Tertiary prevention: For patients with a BMI ≥25 and one or more obesity-related complications, the recommended therapy begins with lifestyle therapy. For patients with BMI ≥27, if lifestyle therapy fails, pharmacotherapy should be considered. For patients with a BMI ≥27 and at least one severe complication, the recommended therapy includes both lifestyle therapy and pharmacotherapy. Bariatric surgery may be considered for patients with BMI ≥35.[6]

S.B. is a candidate for tertiary prevention based on her BMI and presence of obesity-related complications. An appropriate weight loss goal for S.B. is 5% to 15% (10–30 pounds [4.55–13.65 kg]) because of her hypertension. Based on her BMI and obesity-related complications, S.B. is a candidate to initiate lifestyle therapy. The initial treatment plan should include a reduced-calorie diet, increased physical activity, and behavioral modifications.[6]

Lifestyle Therapy

Case 36-1, Question 5: S.B. reports that she has never received dietary counseling from a medical professional, and has always dieted on her own by

restricting fat intake. Although she has not attempted to lose weight recently, S.B. expresses the desire to try a program for weight loss and start an exercise regimen. What types of nonpharmacologic therapies are available for weight reduction and relapse prevention?

Comprehensive lifestyle interventions including a calorie-restricted diet, increased physical activity, and behavioral modifications are the foundation of weight-loss therapy.

DIET

Diets for weight loss promote caloric restriction. Caloric recommendations for females seeking to lose weight are 1200 to 1500 kcal/day and 1500 to 1800 kcal/day for males; alternatively, a deficit of 500 to 750 kcal/day is associated with weight loss.[61] Because of the high demand by consumers, there are numerous types of weight loss programs, diets, and products that may or may not be effective for each individual patient. A variety of dietary interventions have been proved successful in weight loss including low-fat diets, higher protein diets, low-carbohydrate diets, restricted carbohydrate diets, meal replacement and liquid diets, and dietary patterns such as the Mediterranean diet.[6] Research suggests that clinically meaningful weight loss is achieved through adherence to a nutritious reduced- calorie diet regardless of the composition of dietary macronutrients.[62–65] The most effective diet is one that the patient can be in compliance with long term.[62–65]

EXERCISE

Increased physical activity will contribute to the negative energy balance that is required for weight loss. Increased physical activity is essential in preventing weight gain. Overweight children and adults should have at least 30 minutes of moderate-intensity physical exercise daily (with a gradual increment of increasing exercise by several minutes each day up to 30 minutes/day). It has been shown that moderate exercise (eg, 4 kcal/g/week) can improve physiologic variables.[63,66]

BEHAVIOR THERAPY

Behavioral interventions are an essential component of lifestyle therapy that should enhance dietary and physical recommendations. Several behavioral therapies have been proved helpful in weight loss therapy ranging from simple goal setting to more intense cognitive restructuring. Guidelines recommend that patients include one or more of the following behavioral interventions: self-monitoring food intake, physical activity, and weight monitoring; goal setting, educational sessions centering on obesity, nutrition, and exercise; support meetings or group sessions; stimulus control; stress reduction; psychological evaluation; cognitive restructuring; motivational interviewing; and behavioral contracting.[6] Early weight loss is correlated with long-term success; if, after 1 month of lifestyle interventions, patients are unable to achieve 2.5% of their baseline weight, behavioral interventions should be intensified.[6]

Overall, a combination of a reduced-calorie diet and increased physical activity with support of behavioral interventions are most effective for reducing and maintaining weight loss. Given that obesity is a chronic condition, S.B. must select a comprehensive lifestyle intervention that is most appealing and feasible to her so that she will be able to be in compliance with it in the long term.

Case 36-1, Question 6: S.B. returns to her physician for follow-up 6 months later. She has managed to lose 15 pounds (7 kg) and is at a weight of 185 pounds (84 kg). Based on her BMI of 29.8 kg/m^2, her weight is classified as overweight. This weight loss has improved her mood and symptoms of osteoarthritis. Unfortunately, her hypertension has worsened, and is uncontrolled at 148/86 mm Hg despite additional therapy. Her current medication profile includes bupropion XL 150 mg, hydrochlorothiazide 25 mg, lisinopril 10 mg, and acetaminophen as needed. Although she has achieved her personal goal with 7.7% weight loss and is now considered overweight and not obese, S.B. is disappointed that her weight loss has plateaued. She still wants to lose additional weight. She asks the physician about short-term anti-obesity medications that can help accelerate her weight loss. Would a short-term agent be appropriate for S.B.? What are the mechanisms of action, efficacy, and potential adverse effects of the short-term anti-obesity medications?

Pharmacologic Therapy

As previously stated, a comprehensive lifestyle intervention is the foundation of weight loss management. Although weight loss is achievable for most patients, it is difficult to sustain, and weight regain is common.[6] Medication should be considered for patients with a BMI ≥30 kg/m^2 without risk factors or BMI ≥27 kg/m^2 with an obesity-related comorbid medical condition (**Table 36-2**).[6] Medications should not be considered a replacement for diet, behavioral modification, and exercise, but rather as adjunctive therapy. Currently, marketed anti-obesity drugs include short- and long-term therapies.[6,67–75]

S.B. is a candidate for pharmacotherapy even though her BMI is currently considered overweight at 29.8 kg/m^2, her obesity-related comorbidities of hypertension and sleep apnea qualify her for medication therapy. The most appropriate medication for S.B. must be based on her current medication profile and her comorbid health conditions.

SHORT-TERM THERAPY

Obesity is a chronic disease state; therefore, the clinical usefulness of short-term therapy is unlikely to have a meaningful impact. The Food and Drug Administration (FDA) has approved several weight-loss drugs for short-term use defined as <12 weeks including phentermine, diethylpropion, phendimetrazine, and benzphetamine. All are sympathomimetic agents that function as appetite suppressants.[6,76] Of these drugs, phentermine is the most commonly prescribed and is frequently used off-label for long-term therapy.[77,78]

Phentermine is approved for adjunctive therapy in patients older than age 16 years, at a dosage of 18.75 to 37.5 mg taken 2 hours after breakfast. Dosing may also be divided into 18.75 mg taken twice per day or 8 mg taken three times per day.[67,79] The most common adverse effects associated with phentermine therapy are insomnia, dry mouth, dizziness, and palpitations.[67,76] Phentermine has also been associated with cardiovascular effects, including case reports of pulmonary hypertension. It is contraindicated in patients

with cardiovascular disease, uncontrolled hypertension, and hyperthyroidism.[67,80] Phentermine is classified as a controlled substance (schedule IV drug) owing to concerns of abuse; however, this concern has been questioned in the literature.[67,78]

Diethylpropion, phendimetrazine, and benzphetamine exhibit appetite-suppressive actions similar to that of phentermine, but are less widely prescribed.[76] They also share adverse effects and contraindications similar to that of phentermine.[68–70] These agents are also reported to have an abuse potential. Diethylpropion is classified as a schedule IV drug, and benzphetamine and phendimetrazine are classified as schedule III drugs.[68–70] Based on their approval for short-term use, adverse effects, and abuse potential, none of these agents should be recommended for weight loss therapy.

S.B.'s physician should not prescribe short-term weight loss medications to S.B. Short-term agents for obesity may increase S.B.'s blood pressure and interfere with her sleep. Also, short-term agents will not provide the necessary long-term treatment for S.B.'s chronic condition.

Case 36-1, Question 7: S.B. now understands that her obesity is a chronic condition and inquires about long-term medications for weight loss. What agents are available for the long-term treatment of obesity? (See **Table 36-4**.)

Table 36-4
Medications for the Treatment of Obesity

Generic Name	Trade Name	Dosing
Orlistat	Xenical®	Age >12: 120 mg PO tid
	Alli®	Age >18: 60 mg PO tid
Phentermine/topiramate	Qsymia®	Age >12: 3.75/23 mg PO QAM × 14 days; then 7.5/46 mg QAM for 12 weeks, then evaluate weight loss, <3%, dose may be titrated to 11.25/69 mg QAM × 14 days, then 15/92 mg QAM

Generic Name	Trade Name	Dosing
Naltrexone/bupropion	Contrave®	Age >18: 8/90 mg PO QAM × 1 week, then 8/90 mg bid ×1 week, then 16/180 mg QAM and 8/90 mg QPM, then 16/180 mg bid
Liraglutide	Saxenda®	Age >18: 0.6 mg SC daily × 1 week, increase dose by 0.6 mg weekly until therapeutic dose of 3 mg daily
Semaglutide	Wegovy®	Age >18: 0.25 mg SC weekly × 4 weeks then 0.5 mg weekly × 3 weeks, then 1 mg × 3 weeks, 1.7 mg × 3 weeks, then 2.4 mg weekly
Phentermine hydrochloride[a]	Adipex-P®, Lomaira™	Age >16: 8 mg tid; 30–37.5 mg QAM

bid, two times a day; OTC, over the counter; PO, by mouth; QAM, every morning; QPM, every evening; SC, subcutaneously; tid, three times a day.

[a]Not recommended for routine or long-term use.

LONG-TERM THERAPY

Orlistat (Xenical®, Alli®)

Orlistat is FDA approved for long-term obesity management as an adjunct to lifestyle modification.[71] Orlistat 120 mg was originally marketed under the trade name Xenical®. Then, in February 2007, the FDA approved the over-the-counter (OTC) marketing of orlistat, under the trade name Alli®, at a 60-mg dose.[81] Orlistat works to reduce dietary fat absorption by inhibiting GI (stomach and pancreatic) lipase activity.[71,76,82] Gastric and pancreatic lipase are enzymes that play a pivotal role in the digestion of dietary fat (triglycerides). By inhibiting these lipase enzymes, orlistat prevents the hydrolysis and absorption of triglycerides.[71,81] This results in the excretion of ~30% of ingested fat in the feces.[71,76] Orlistat does not exert appetite suppressant effects, has no central nervous system (CNS) effects, and has no systemic absorption.[82] The therapeutic activity of orlistat takes place in the stomach and small intestine, and effects are seen as soon as 24 to 48 hours after dosing.[82]

Orlistat is administered three times per day during or up to 1 hour after meals containing fat.[71] If a meal does not contain fat, the dose may be skipped. In a meta-analysis, orlistat was shown to produce average weight loss of 5.73 pounds (2.6 kg) greater than placebo.[83] In addition, a 4-year prospective, double-blind, randomized study, XENDOS, found that orlistat plus lifestyle changes was associated with a 37.3% risk reduction of type 2 diabetes in >3300 high-risk obese patients.[84] Use of orlistat has also been associated with improvements in blood pressure, as well as improvement in metabolic parameters such as fasting serum lipid profiles and C-reactive protein.[84–86]

The most common adverse effects associated with orlistat include GI problems (loose stools, oily spotting, flatus with discharge, fecal urgency, fatty or oily stools, increased defecation, fecal incontinence, bloating, and cramping).[71] Side effects usually develop early in treatment and persist for 1 to 4 weeks, but occasionally last longer than 6 months.[71] Because GI adverse effects are worse with a high-fat diet, orlistat may enhance dietary compliance with a low-fat diet, further potentiating weight loss. In addition, bothersome side effects have been associated with nonadherence, causing variability in patient outcomes. Rare cases of oxalate-induced acute kidney injury and liver injury have been reported with use of orlistat.[87,88] Pancreatitis and cholelithiasis have also been reported; therefore, patients should be monitored for both.[71] Orlistat is contraindicated in patients with chronic malabsorption syndrome, cholestasis, and pregnancy.[71]

Orlistat may reduce the absorption of fat-soluble vitamins (A, D, E, and K), and patients should take a multivitamin supplement that contains these vitamins.[71] The supplement should be separated by at least 2 hours before or after the administration of orlistat, such as at bedtime. Patients using warfarin should be closely monitored, because the reduced absorption of vitamin K may potentiate the bleeding effects of warfarin. Orlistat may also reduce the absorption of levothyroxine and lipophilic drugs including amiodarone, cyclosporine, lamotrigine, and valproic acid.[71,89]

Phentermine/topiramate extended release (Qsymia®)

Phentermine/topiramate extended release (ER) is a combination drug approved by the FDA for long-term obesity management as an adjunct to lifestyle modification.[72] Phentermine is a sympathomimetic agent that functions as an appetite suppressant by increasing the concentration of norepinephrine in the central nervous system.[72] Topiramate is an antiepileptic agent also approved for the treatment of migraines, which acts as an agonist at $GABA_A$ receptors and as an antagonist at non-*N*-methyl-d-aspartic acid (NMDA) glutamate receptors.[76] The mechanism by which weight loss occurs with topiramate is unclear, but may be related to a direct action on adipose tissue.[90]

Therapy is initiated at a dose of phentermine 3.75 mg/topiramate 23 mg daily for 14 days, after which the dose is increased to phentermine 7.5 mg/topiramate 46 mg daily.[72] If the patient has not experienced ≥3% weight loss after 12 weeks of therapy at the maintenance dose, the drug should either be discontinued or the dose escalated to phentermine 15 mg/topiramate 92 mg daily. After an additional 12 weeks of therapy, if the patient has not experienced ≥5% weight loss, the drug should be discontinued via taper to avoid precipitating a seizure.[72]

The efficacy of phentermine/topiramate ER has been demonstrated in two phase 3 clinical trials and one expansion trial: CONQUER, EQUIP, and SEQUEL (an extension of the CONQUER trial).[90–92] Phentermine/topiramate ER 7.5/46 mg was shown to produce average weight loss of 7.8% of initial body weight after 1 year and 9.3% after 2 years.[90,91] Phentermine/topiramate ER 15/92 mg was shown to produce average weight loss of 9.8% of initial body weight after 1 year and 10.5% after 2 years.[90,91] Use of phentermine/topiramate ER has also been associated with improvements in cardiometabolic parameters including decreased blood pressure, reductions in triglycerides and low-density lipoprotein (LDL) cholesterol, and improvements in high-density lipoprotein (HDL) cholesterol.[91,92] Patients taking

phentermine/topiramate ER at doses ≥7.5/46 mg also showed reduced progression to type 2 diabetes.[92]

The most common adverse effects associated with phentermine/topiramate ER include paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth.[72] Cognitive effects and mood and sleep disturbances have also been observed.[72] Topiramate inhibits carbonic anhydrase activity that may lead to calcium phosphate kidney stones and interaction with other carbonic anhydrase inhibitors such as zonisamide, acetazolamide, or methazaolamide.[72] Increases in heart rate have been observed; thus, heart rate should be monitored, particularly in patients with preexisting cardiac or cerebrovascular disease.[72] Topiramate has been associated with birth defects, specifically oral clefts when taken during the first trimester, which led the FDA to approve phentermine/topiramate ER with a risk evaluation and mitigation strategy (REMS).[93] This REMS is designed to inform practitioners and patients about the risk of birth defects, the importance of contraceptive use, and the need to immediately discontinue the drug if the patient becomes pregnant.[93] Phentermine/topiramate ER is contraindicated in pregnancy and in patients with glaucoma, hyperthyroidism, monoamine oxidase inhibitor (MAOI) use within the past 14 days, and hypersensitivity to sympathomimetic amines.[72]

Naltrexone/bupropion (Contrave®)

Naltrexone/bupropion is a combination drug that is approved by the FDA for long-term obesity management as an adjunct to lifestyle modification.[73] Bupropion, an antidepressant that inhibits dopamine and norepinephrine reuptake, has a known side effect of weight loss when used for the treatment of depression and smoking cessation.[73,76] This weight loss effect is thought to be the result of appetite suppression induced by the stimulation of POMC neurons in the hypothalamus.[94] Naltrexone, an opioid receptor antagonist, is believed to enhance this appetite suppression by blocking opioid receptors on these same POMC neurons.[94] Naltrexone/bupropion is available as combination 8/90 mg tablets. Patients initiate treatment

at a dose of one tablet every morning. This dose is titrated up over the course of 4 weeks to a dose of two tablets twice daily, for a total daily dose of 32/360 mg.[73] If the patient has not experienced ≥5% weight loss after 12 weeks of therapy at the maintenance dose, the drug should be discontinued.[73]

The efficacy of naltrexone/bupropion has been demonstrated in four 1-year, placebo-controlled, phase 3 clinical trials: Contrave Obesity Research (COR)-I, COR-II, COR-Behavior Modification (BMOD), and COR-Diabetes.[95–98] Naltrexone/bupropion 32/360 mg was shown to produce average weight loss of 6.1% to 6.4% of initial body weight.[95,96] When coupled with intensive behavior modification, patients taking naltrexone/bupropion 32/360 mg experienced an average weight loss of 9.3% of initial body weight.[97] Use of naltrexone/bupropion has also been associated with improvements in cardiometabolic parameters, including hemoglobin A_{1c} (HbA_{1c}) reduction.[95–98]

The most common adverse effects associated with naltrexone/bupropion include nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth, and diarrhea.[73] Angle-closure glaucoma and hepatitis are potentially serious adverse effects.[73] Contrave® has a black box warning for suicidal thoughts and behavior, although increased rates have not been seen in phase 3 clinical trials.[73,95,96] Bupropion is an inhibitor of cytochrome P-450 (CYP) 2D6; caution should be used when coadministering naltrexone/bupropion with drugs metabolized by this enzyme.[73] Bupropion may reduce the seizure threshold; therefore, it should be avoided in patients with seizure disorders.[73] To minimize the risk of seizure, patients should be instructed to adhere to the dosing schedule, particularly during the titration period; also, patients should not take naltrexone/bupropion with high-fat meals because this will increase the absorption.[73] Naltrexone/bupropion is contraindicated in patients with seizures or who are at increased risk such as patients with anorexia or bulimia or who are undergoing abrupt discontinuation of alcohol, benzodiazepines, barbiturates, or anticonvulsant medication.[73] Blood pressure and heart rate may

increase with naltrexone/bupropion; thus, both parameters should be monitored, particularly in patients with underlying cardiac or cerebrovascular disease.[73] Naltrexone/bupropion is contraindicated in patients with uncontrolled hypertension.[73] Naltrexone/bupropion is also contraindicated in pregnancy, chronic use of opioids, use of MAOIs within the past 14 days, and in patients currently taking other bupropion-containing products.[73] Angle-closure glaucoma and hepatitis are also potentially serious adverse effects.

Liraglutide (Saxenda®) and semaglutide (Wegovy®)

Liraglutide and semaglutide are GLP-1 receptor agonists that are FDA approved for long-term obesity management as an adjunct to lifestyle modification.[74,75] Activation of the GLP receptor in the central nervous system promotes feelings of satiety, thereby reducing food intake and resulting in weight loss.[74,75] Both liraglutide and semaglutide are administered via subcutaneous injection. When used for obesity, the dose of liraglutide is titrated to 3 mg daily, and the dose of semaglutide is titrated to 2.4 mg weekly.[74,75] Both agents are also approved for the treatment of type 2 diabetes at lower doses. Liraglutide labeling specifies that if the patient has not experienced ≥4% weight loss by 16 weeks after initiating therapy, the drug should be discontinued.[74] Semaglutide labeling does not specify when to determine treatment failure; however, based on general treatment guidelines for other agents, it may be appropriate to discontinue semaglutide if the patient has not experienced 5% weight loss after 12 weeks at the 2.4 mg dose.

The efficacy of liraglutide for weight loss has been demonstrated in three phase 3 pivotal clinical trials: satiety and clinical adiposity—liraglutide evidence (SCALE) Maintenance, SCALE Obesity and Pre-Diabetes, and SCALE Diabetes.[99–101] The results of the SCALE Maintenance and SCALE Diabetes trials indicate that by the end of 56 weeks of treatment, liraglutide produces an average weight loss of 4% to 6.1% greater than placebo.[99,101] Use of liraglutide has also been associated with significant improvements in HbA_{1c}, fasting plasma glucose, and fasting insulin.[99–101]

Semaglutide is associated with placebo-subtracted weight loss ranging from 9.6% to 12.4% based on the findings from the four 68-week semaglutide treatment effect in people with obesity (STEP) trials.[102–105] The STEP trials also demonstrated improvement in total and LDL cholesterol, HbA_{1c}, fasting plasma glucose, and systolic blood pressure.[102–105] The most common adverse effects associated with both liraglutide and semaglutide include nausea, hypoglycemia, diarrhea, constipation, vomiting, headache, dyspepsia, fatigue, dizziness, abdominal pain, and injection-site reactions. Liraglutide also reports decreased appetite and increased lipase; semaglutide reports gastroesophageal reflux disease, abdominal distension, and eructation. To reduce the incidence of GI side effects, the dose of both agents is titrated. Liraglutide is initiated at a dose of 0.6 mg daily and titrated up to the effective dose of 3 mg daily over a 5-week period.[74] Semaglutide is initiated at a dose of 0.25 mg weekly and titrated to 2.4 mg over a 17-week period.[75] Suicidal ideation was also reported in trials; patients taking these agents should be monitored for depression, changes in mood, or suicidal thoughts.[74,75] Increases in heart rate were also observed during clinical trials; therefore, it is recommended to monitor heart rate while taking liraglutide or semaglutide.[74,75] Both agents have also been associated with an increased risk of acute pancreatitis and cholelithiasis.[74,75] Semaglutide has also been associated with exacerbations of diabetic retinopathy; therefore, patients with a history of diabetic retinopathy should be monitored.[75] Acute kidney injury has also been associated with semaglutide; therefore, renal function should be monitored when initiating or increasing the dose.[75] Both semaglutide and liraglutide have black box warnings pertaining to thyroid C-cell tumors including medullary thyroid carcinoma (MTC) and multiple endocrine neoplasia syndrome type 2 (MEN 2).[74,75] Therefore, both are contraindicated in patients with a personal or family history of MTC, or MEN 2.[74,75] Both are also contraindicated in pregnancy.

Lorcaserin

Lorcaserin, a selective serotonin 2C (5-hydroxytryptamine [5-HT_{2C}]) receptor agonist, was approved for long-term obesity management in 2012, but was withdrawn from the market in February 2020 owing to safety concerns. Data from a large-scale trial found increased risk of several types of cancer including pancreatic, colorectal, and lung. The risk was increased with longer duration of use.[106]

Investigational Agents

Several agents approved for the treatment of type 2 diabetes have been shown to cause weight loss and are currently being investigated for the treatment of obesity.[48] These include GLP-1 agonists, sodium-glucose-linked transporter-2 (SGLT2) inhibitors, amylin mimetics, and metformin.[48] Trials with the newer, oral formulation of semaglutide for diabetes have also demonstrated weight loss.[48] A clinical trial investigating the weight loss potential of the combination dapagliflozin (an SGLT2 inhibitor) and metformin for patients with diabetes and obesity is currently under way.[48]

Numerous other agents have shown promise as weight loss pharmacotherapy with a few progressing into phase III trials. A combination therapy of bupropion and zonisamide ER has been shown to produce weight loss.[37] Much like naltrexone/bupropion, this combination drug works through a dual mechanism: bupropion stimulates POMC neurons in the hypothalamus, and zonisamide acts synergistically by suppressing an appetite-stimulating neural pathway.[37] Cetilistat is a lipase enzyme inhibitor, which acts similarly to orlistat, with a more tolerable side effect profile.[107] Tauroursodeoxycholic acid has also been proposed as a weight loss agent; it is thought to induce weight loss by increasing sensitivity to leptin, which then suppresses appetite.[37] Other potential targets for investigation as weight loss therapy include a cannabinoid type-1 receptor antagonist, leptin analogs, and anti-obesity vaccines that target ghrelin, somatostatin, and adenovirus 36.[37]

The most appropriate pharmacotherapeutic option for weight loss depends on patient-specific parameters including other disease

states, concomitant medication use, adverse effects, patient preference, and cost. Given S.B.'s PMH of uncontrolled hypertension, S.B. should avoid naltrexone/bupropion; this agent would also duplicate her current antidepressant (bupropion). Guidelines recommend topiramate/phentermine, orlistat, and liraglutide as preferred agents for patients with hypertension[6]; all three options would be safe for S.B. to use. S.B. and her health care team should choose the most appropriate agent based on her personal preference including her lifestyle. Considerations for orlistat include the many GI side effects, restricted fat intake, and multiple daily doses; considerations for semaglutide and liraglutide include the subcutaneous route of administration as well as GI side effects. In addition, weight loss expectations should be considered; semaglutide is associated with the greatest amount of weight loss followed by phentermine/topiramate ER and then liraglutide.

Case 36-1, Question 8: S.B. began therapy with phentermine/topiramate because of greater weight loss expectations with this agent, but was unable to tolerate the mental "fogginess" associated with the topiramate. After 2 weeks of therapy, her regimen was changed to orlistat 120 mg, and she lost an additional 17.6 pounds (8 kg) in 6 months. After 6 months, S.B.'s weight loss began to taper, and she regained 4.4 pounds (2 kg). It has been 1 year since her first weight loss visit, and her total net loss is 28.2 pounds (13 kg). S.B.'s current weight is 172 pounds (78 kg), and her BMI is down to 27.6 kg/m^2, but she is disappointed that she has regained weight and inquires about dietary supplements for weight loss. How would you advise S.B. with regard to dietary supplements?

Numerous dietary supplements are marketed for weight loss (**Table 36-5**). Reliable evidence of efficacy for these agents is limited, and safety data are lacking. Clinical data do not support the use of these agents, and S.B. should be advised not to use dietary supplement for weight loss.

Table 36-5
Dietary Supplements for Weight Loss

Supplement	Proposed Mechanism	Clinical Data	Adverse Effects and Safety Concerns
Chitosan	A cellulose-type polysaccharide. reported to bind dietary fat and prevent absorption	Meta analysis (1A trials) demonstrated average placebo-subtracted weight loss of 3.74 pounds (1.7 kg); average weight loss 1 76 pounds (0.8 kg) in trials lasting >4 weeks	GI effects common (constipation. diarrhea. flatulence. bloating, nausea. heartburn) Avold in patlents with a shellfish allergy.
Caffeine	Increased thermogenesis by Inhiblting the breakdown of cAMP	Several cllnical trials demonstrate short-term weight loss when used in combination with ephedra (no longer availabie)	Common adverse effects: insomnia. irritabllity. tachycardia. anxiety
Green tea	Polyphenols and caffeine act synergisticaily to decrease fat absorption. reduce llpogenesis. and cause thermogenesis.	Several clinical trials demonstrate potential weight loss of up to 4.40 pounds (2 kg)	See caffeine Reports of hepatotoxicity
Guarana (Brazillan cocoa. *Paullima cupana*)	See caffeine (seed contains 2.5%–7% caffeine.)	See caffeine	See caffeine
Verba mate. *Ilex paraguaricnsis*)	See caffeine	See caffeine	See caffeine Hot drinks may increase risk of esophageal cancer.
Citrus aurantium (bitter orange. Seville orange. sour orange)	Contains synephnne (structurally similar to epinephrine)	No evidence of efficacy when used alone; limited data suggest minimal weight loss when used in combination with caffeine and St. Johrfs wort (<2.20 pounds [1 kg] weight loss).	Cardiovascular effects (increased heart rate. blood pressure) Reports of angina, increased QT interval, seizures. and ischemic colitis Potential drug Interactions because of inhibition of intestinal CYP3A4
Hydroxycitric acid (garcinia. *Oarama cambogia*)	Theorized to inhibit production of lipids	No evidence of weight loss	Reports of hepatotoxicity. rhabdomyolysis (avoid with statins) May inhibit platelet aggregatlon
Glucomannan (Konjac)	Fibrous polysaccharide may work slmilar to fiber (promote/prolong satiety).	Limited data suggest minimal weight loss (2.20–4 40 pounds 1–2 kg).	GI adverse effects (nausea. bloating. flatulence)
Hoodia	Unknown. reported to be an appetite suppressanr	No clinical trials to support use	Unknown

cAMP, cyclic adenosine monophosphate; CYP, cytochrome P-450; GI, gastrointestinal.

CASE 36-1, QUESTION 9: S.B.'s health insurance was changed, and she no longer is able to continue orlistat. Two years after discontinuing orlistat, SB has regained 15.4 pounds (7 kg). Her current weight is 187.2 pounds (85 kg), and her BMI is 30.1 kg/m^2. She is frustrated that she has regained weight despite compliance with comprehensive lifestyle interventions. She is questioning whether her results are usual.

S.B.'s weight regain after discontinuing orlistat is typical. Trials with a crossover design have shown that the weight loss achieved with anti-obesity agents is unlikely to be sustained after

discontinuation.[6,46] Weight regain is to be expected after discontinuing anti-obesity agents because the underlying pathology of obesity has not changed.

Medical Devices for Obesity Treatment

Case 36-1, Question 10: S.B. understands that weight regain is common after discontinuing anti-obesity medication. Although she is not ready for surgical interventions, she is interested in newly advertised medical devices. What medical devices are available for weight loss and what are the weight loss expectations of each?

Oral space-occupying devices are designed to be worn during meals to limit bite size. These devices are approved by the FDA for weight management (as opposed to weight loss); although patients can expect to avoid gaining weight, weight loss expectations are minimal. The only oral space-occupying device still being marketed is the Sensor Monitored Alimentary Restriction Therapy (SMARTbyte™).[108] This device is indicated for patients with a BMI of 27 to 35 kg/m^2.[109] Similar to a dental retainer, the device is custom fitted to the roof of the mouth and has a sensor that links to a smartphone app.[109] While wearing this device, the patient needs to take smaller bites and eat slower, leading to increased satiety with reduced portions.[109] The phone app keeps track of the patient's weight loss goals, and includes personal weekly coaching.[109] Adverse events are rare, but could include soreness in the mouth or gagging on the device or food.[109]

Plenity® is a transient, ingestible, space-occupying device that helps make a patient feel full.[110] It is FDA approved as a class II medical device and consists of capsules of cellulose and citric acid.[110] The dose is three capsules twice a day, with 16 ounces of water taken 20 to 30 minutes before meals.[110] The cellulose and citric acid swell and retain the water in the stomach, making the patient feel full.[110] This increased satiety causes the patient to ingest smaller portions of food, thus inducing weight loss.[110] The contents of

the capsules are not absorbed. Once the capsule contents are in the large intestine, the water is absorbed by the body, and the device is passed naturally.[110] In clinical trials, adverse events included diarrhea, distended abdomen, infrequent bowel movements, and flatulence, but these were similar to placebo.[110] Similar non–FDA-approved products are available, regulated as food or dietary supplements; however, they do not have the same level of effectiveness as this device. In the gelesis loss of weight (GLOW) pivotal trial, patients lost an average of 6% of initial body weight versus 4% with placebo within 6 months.[111] If a patient does not lose 3% of initial body weight within the first 8 weeks, they are likely to be a nonresponder and should consider discontinuation.[110,111]

A gastric emptying system (AspireAssist®) has been approved by the FDA for weight loss. The system involves a thin gastrostomy tube placed within the stomach that connects to a port on the patient's abdomen.[112] About 20 to 30 minutes after each main meal, patients can remove up to 30% of their stomach contents through the port using a small handheld device.[112] The reduction in caloric absorption is the main mechanism of weight loss. This device is approved for use in patients age 22 years and older with a BMI of 35 to 55.0 kg/m^2 who have failed nonsurgical weight loss therapy.[112] The pivotal aspiration therapy with adjusted lifestyle (PATHWAY) study demonstrated an 8.6% weight loss after 1 year with the AspireAssist® compared to placebo.[113] Sustained results were seen in a trial lasting 4 years.[114] Adverse events tend to be related to the initial placement procedure (pain, nausea/vomiting) or local irritation from the device. Infections at the site of the port can also occur.

Several intragastric balloon systems are approved by the FDA for patients with a BMI of 30 to 40 kg/m^2.[115] Two are liquid filled (Orbera® and ReShape™), and one is gas filled (Obalon™).[115] These balloons are swallowed (Obalon™) or inserted (Orbera/ReShape™) orally through the esophagus.[115] Once in the stomach, the balloons are filled and can be used for up to 6 months.[115] These space-occupying devices lead to weight loss by increasing satiety and limiting the portion size of food a patient can consume.[115] The FDA has updated their labeling to clarify the risks of overinflation (spontaneous

hyperinflation), acute pancreatitis, and deaths associated with the liquid-filled intragastric balloons.[115] The manufacturers of ReShape™ stopped distributing this product as of January 2019.[115]

An electrical stimulation system called the vBloc system was approved by the FDA as a treatment option for patients with class III obesity.[112] However, this device is no longer marketed as of September 2018.[108]

S.B.'s current BMI is 30.1 kg/m^2, which is below the threshold for use of AspireAssist®. However, she is a candidate for the other devices. After discussion, S.B. decided that Plenity® would be the easiest option. After an 8-week trial of Plenity®, she lost 1 kg. Based on this minimal weight loss, S.B. is considered a nonresponder and should discontinue use.

Case 36-1, Question 11: S.B. returns to her physician 3 years later. She has gained an additional 35.3 pounds (16 kg), and her BMI is now 35.8 kg/m^2. Laboratory tests provide the following results:

Blood pressure, 154/92 mm Hg
Fasting blood glucose, 162 mg/dL
A1C, 8.3%
Triglycerides (TG), 288 mg/dL
Total cholesterol, 272 mg/dL
HDL, 35 mg/dL
LDL, 179 mg/dL

S.B. requests a referral to a bariatric clinic for evaluation for surgical intervention for weight loss. Is S.B. a candidate for bariatric surgery? How could a bariatric surgical procedure affect medication administration in S.B. postoperatively?

Surgery

Surgery should be considered for individuals with BMI ≥40 kg/m^2, or BMI ≥35 kg/m^2 with one or more obesity-related conditions, or BMI ≥30 kg/m^2 and type 2 diabetes with inadequate glycemic control.[116] Bariatric surgery is not without risk; therefore, patients should be evaluated for potential complications, potential success of surgery, and their ability to adhere to surgical requirements.[116] For example,

patients must avoid tobacco use for at least 6 weeks before the procedure (optimally 1 year before), and must continue tobacco abstinence following the procedure.[116]

Bariatric surgical procedures either reduce the absorptive surface of the GI tract resulting in malabsorption or reduce the stomach volume so that the patient feels full after a smaller meal. Procedures include laparoscopic adjustable gastric banding (LAGB), sleeve gastrectomy (SG), Roux-en-Y gastric bypass (RYBG), and biliopancreatic diversion (BPD) or its related procedures; all have demonstrated efficacy, although the degree of weight loss and complications may differ.[116] Caution should be used when recommending BPD or its related procedures because of the nutritional risks.[116] Laparoscopic (vs open surgical) approaches are preferred for reducing postoperative complications and hospital stay.[116] LABG is considered to be the least invasive and safest procedure, and can also be reversed if necessary.[116] Each surgery has differing rates of efficacy, with estimated mean weight reduction at 1 year as 15% to 20% for LAGB and 30% for RYBG.[116,117] As with all weight-loss strategies, weight regain can commonly occur, with estimates of regain being 5% to 10% after 10 years.[116,117]

The mortality rate from bariatric surgery is estimated to be 0.3% to 1.9%, and literature has shown that centers that perform surgeries at higher volumes have better outcomes.[116,118] Some of the complications of bariatric surgery include nausea, stomach ulceration, stenosis, anemia, nutrient deficiencies, and cholelithiasis.[116] Postsurgical precautions include careful evaluation of meal sizes and timing along with meal content, especially immediately after surgery.[116]

Patients should be aware that they will not be able to resume their normal eating habits, and they should be properly educated on lifestyle modifications for maintenance of weight loss.[116] In addition, medications and adequate intake of necessary nutrients are important considerations after surgery because absorption can be impaired. An all-liquid diet will be required starting 24 hours postsurgery, with meal progression overseen by the surgeon and/or a registered dietician.[116]

Medications may need to be crushed, administered using liquid formulation, or delivered via other dosage routes to ensure absorption for the first couple of months after surgery.[119] Medications that are delayed or ER may not be absorbed, and will likely need to be changed to immediate release formulations for adequate effects.[119] Conversely, other medications may see increases in concentration because of the reduced volume of distribution as weight loss occurs.[120] Transdermal formulations, weight-based dosing, or drugs dosed using body surface area (BSA) may need to be adjusted to account for reductions in BSA.[119,120] Medications used for obesity and its associated comorbidities (including hypertension and diabetes) will require close monitoring, dose adjustments, and potentially discontinued as weight loss occurs.[116] In addition, TSH should be monitored in patients with thyroid disorders, and dose adjustments of thyroid hormone may be required.[116] Medications such as nonsteroidal anti-inflammatory drugs, salicylates, steroids, and bisphosphonates may cause ulcerations and should likely be avoided.[116,119,120] Importantly, vitamin supplementation is necessary to prevent nutritional deficiencies postoperatively.[116] The following supplements are recommended: vitamin A, vitamin B_1, vitamin B_{12}, folic acid, vitamin D, vitamin E, vitamin K, calcium, iron, zinc, and copper.[116] Dosing may vary depending on the procedure and whether an overt deficiency is present.[116] To assist with adherence to supplementation requirements, combination products such as high-dose multivitamins with minerals should be considered.[116] Liquid, orally disintegrating, sublingual, nasal, or intramuscular (IM) formulations may be needed because of the reduced potential for absorption following surgery.[116] Patients should be assisted in selecting high-quality dietary supplements, because some unregulated commercial products have been shown to be adulterated and/or mislabeled.[116]

Although S.B. is a candidate for bariatric surgery based on her BMI of 35.4 kg/m^2 and her obesity-related conditions, she is unable to commit to the dietary restrictions. She would like to consider alternative pharmacotherapeutic options. S.B.'s fasting blood

glucose and A1c indicate that she has type 2 diabetes. Semaglutide is a once-weekly option that will lower her blood glucose and result in clinically significant weight reduction.

Adult Enteral Nutrition

Carol J. Rollins

CORE PRINCIPLES		CHAPTER CASES
1	Patients should be assessed for the appropriate timing and route for nutrition support.	**Case 37-1 (Questions 1, 2)**
2	The type of tube placement and site of formula delivery are determined by several factors.	**Case 37-2 (Question 1)**
3	Formula selection is based on nutrient requirements, fluid restrictions, and the extent of impaired digestion and absorption.	**Case 37-2 (Questions 2–5)**
4	The administration regimen for feeding is influenced by the feeding route, formula selected, and duration of feeding.	**Case 37-2 (Questions 6–8)**

CORE PRINCIPLES		CHAPTER CASES
5	Although the preferred route for nutrition intervention in critical illness is enteral, the ideal formula composition remains unresolved.	**Case 37-3 (Questions 1–4)**
6	Macronutrient content should be considered when selecting an enteral formula for patients with diabetes.	**Case 37-4 (Question 1)**
7	Appropriate monitoring is essential to recognize and prevent complications associated with enteral nutrition.	**Case 37-4 (Question 2)**
8	Medication administration through a feeding tube requires selection of appropriate dosage forms and proper preparation.	**Case 37-4 (Question 3)**
9	Feeding tube occlusion is a common problem influenced by medication-related and non–medication-related factors.	**Case 37-4 (Question 4)**
10	Patients must meet strict criteria for Medicare coverage of home enteral nutrition.	**Case 37-5 (Questions 1, 2)**
11	Diarrhea in patients receiving enteral nutrition is multifactorial, including both tube-feeding-related and non–tube-feeding-related causes.	**Case 37-6 (Question 1)**

INTRODUCTION

Enteral nutrition (EN) refers to nutrition provided via the gastrointestinal (GI) tract. However, as commonly used, the term *enteral nutrition* (EN) is synonymous with delivery of nutrients into the GI tract by tube (eg, nasogastric [NG] or jejunostomy feeding). Tube feeding allows continued use of the GI tract when one or more steps in the normal process of obtaining nutrients from oral intake are disrupted. **Table 37-1** lists functional anatomic units of the GI tract along with major steps occurring in preparing nutrients for absorption and examples of conditions potentially impairing each region. Chewing or swallowing may be completely disrupted, but some digestive and absorptive function must remain for tube feeding to be a viable option.

Table 37-1

Functional Units of the Gastrointestinal Tract

Functional Unit	Major Steps	Conditions/Diseases Disrupting Function
Mouth and oropharynx	Chew and lubricate food; swallow; taste	Amyotrophic lateral sclerosis, muscular dystrophy, severe RA, CVA, end-stage Parkinson disease, paralysis, coma. Anorexia caused by other disease: cardiac or cancer cachexia, renal failure and uremia, liver failure, neurologic disease
Esophagus	Transport food to the stomach	Esophageal ulcer, cancer, obstruction, or fistula; esophagectomy; CVA
Stomach	Hold food for mixing and grinding; add acid and enzymes; release chyme to small bowel; osmoregulation	Severe gastritis or ulceration, gastroparesis, gastric outlet obstruction, gastric cancer, severe gastroesophageal reflux
Duodenum	Osmoregulation; neutralize stomach acid	Severe duodenal ulcer or fistula; cancer: gastric or pancreatic; surgical resection or bypass of the duodenum: Whipple-type procedures

Functional Unit	Major Steps	Conditions/Diseases Disrupting Function
Small bowel: jejunum and ileum	Digestion; absorption	Enterocutaneous fistula, severe enteric infection, malnutrition, malabsorption, Crohn disease, celiac disease, ileus, and dysmotility syndrome
Pancreas	Secretion of digestive enzymes	Pancreatitis, pancreatic cancer, pancreatic injury, pancreatic fistula
Colon	Absorb fluid; ferment soluble fiber and unabsorbed carbohydrate; absorb water	Ulcerative colitis, Crohn disease, colon cancer, colocutaneous fistula, colovaginal fistula, diverticulitis, colitis of any etiology, colon surgery

CVA, cerebrovascular accident; RA, rheumatoid arthritis.

PATIENT SELECTION AND ROUTE OF FEEDING

CASE 37-1

Question 1: T.R., a 55-year-old female, 64 inches (162.56 cm) tall, 205.03 pounds (93 kg), was admitted to the hospital last evening with acute pancreatitis and has "nothing by mouth" (NPO) orders in her chart. A nutrition support consult was ordered. The gastroenterology service has seen her and scheduled an endoscopic retrograde cholangiopancreatography (ERCP) for tomorrow. T.R. is currently receiving intravenous (IV) 5% dextrose/0.9% sodium chloride with KCl 20 mEq/L at 150 mL/hour. She is also receiving hydromorphone via a patient-controlled analgesia (PCA) pump.

T.R. has been experiencing crampy upper right quadrant pain on and off for nearly a month and saw her primary care physician a week ago. She is allergic (rash) to erythromycin. She was told that her symptoms are consistent with gallbladder inflammation; surgery will be necessary if her symptoms continue, or the pain worsens. In addition, her doctor said blood pressure and glucose control "could use improvement," and mentioned it might be because her weight was up several pounds. She states she has been snacking more frequently

because of stress from her work. She is not a smoker; she frequently drinks one glass of wine with dinner.

Laboratory values this morning are as follows:
Sodium, 137 mEq/L
Potassium, 3.8 mEq/L
Blood urea nitrogen (BUN), 11 mg/dL
Serum creatinine (SCr), 0.8 mg/dL
Glucose, 181 mg/dL
Albumin, 3.4 g/dL
Amylase, 700 units/L (down from 1250 units/L in the emergency department [ED])
Lipase, 685 units/L (down from 1208 in the ED)
Triglycerides, 179 mg/dL
White blood cells (WBCs), 12.6×10^3/mL
Hemoglobin (Hgb), 12.4 g/dL
Hematocrit (Hct), 37.4%
C-reactive protein (CRP), 2.3 mg/dL

Does T.R. require nutritional intervention at this time? When should nutrition intervention be considered for T.R.?

Patients generally are considered at risk for nutrient depletion and associated increased morbidity and mortality when intake is <50% to 75% of requirements for 5 to 7 days acutely or when weight loss exceeds 5% or more in 1 month, 7.5% or more in 3 months, or 10% or more of preillness weight within a 6-month period.[1,2] For adequately nourished patients, specialized nutrition support is generally not warranted when support will be needed for fewer than 7 to 10 days.[3] Undernourished patients require nutritional intervention sooner. See Chapter 35, Basics of Nutrition and Patient Assessment, for further information on malnutrition. T.R. was adequately nourished before admission based on her weight for height and overall health status. She has weight gain per the clinic visit, although edema should be ruled out as a cause, and has been NPO for <24 hours. Nutrition support is not warranted at this time. However, once the ERCP has been completed, the need for nutrition intervention should be reassessed. If T.R. must remain NPO for a week or more, nutritional intervention would be warranted. Obesity does not preclude the need for nutritional intervention.

Case 37-1, Question 2: What route of nutrition intervention would be most appropriate for T.R. if she cannot restart her diet in a timely manner?

Routes of nutrition intervention may include modified oral diet, including oral supplements or altered consistency diets (eg, thickened liquids, pureed foods), EN by tube, or parenteral nutrition (PN). Tube feeding is considered the route of choice in patients with a functional GI tract in whom oral nutrient intake is contraindicated or is insufficient to meet estimated requirements.[3] Other than potential "gallstone" pancreatitis, T.R. is expected to have a functional GI tract. The ERCP and pain symptoms will help determine whether T.R. will remain NPO or have a diet started. It appears her pancreatitis is improving based on decreasing amylase and lipase values. For patients with severe acute pancreatitis, the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) Critical Care guidelines recommend initiation of EN as soon as volume resuscitation is completed.[4] For well-nourished patients such as T.R. with mild-to-moderate acute pancreatitis, which is indicated by non–intensive care unit (ICU) status, nutrition support should be considered only after 4 days if advancement of an oral diet fails.[5] Because EN may reduce the inflammatory response and decrease complications, EN is preferred over PN.[4,5]

EN may be appropriate for patients with the disorders listed in Table 37-1, depending on the extent to which normal intake, transport, digestion, and absorption of nutrients are impaired. Clinical circumstances, not specific diagnoses, should be the determining factor for initiating tube feeding. EN should be used with caution in patients with severe necrotizing or hemorrhagic pancreatitis, distal high-output (>500 mL/day) enterocutaneous fistulae, hypotension with significant inotropic support, GI ischemia, and partial bowel obstruction.[3,4] Contraindications to EN generally include diffuse peritonitis, complete bowel obstruction, severe paralytic ileus, intractable vomiting or diarrhea, severe malabsorption, severe GI bleed, inability to access the GI tract, and when aggressive

intervention is not warranted or desired. Frequent reassessment is recommended because patients may become candidates for EN as the condition improves or resolves.

FEEDING TUBE PLACEMENT AND SITE OF FORMULA DELIVERY

CASE 37-2

QUESTION 1: J.B., an 83-year-old male, was hospitalized 6 days ago after collapsing while playing with his grandchildren. He was diagnosed with ischemic stroke, and his condition has changed little since admission. J.B. is estimated to be 69 inches (175.26 cm) tall; his weight is 136.69 pounds (62 kg); clinic notes from 3 months ago show his weight at 147.71 pounds (67 kg). He appears thin, with mild wasting of arm and leg muscles. His maintenance IV drip is 5% dextrose/0.45% sodium chloride with potassium chloride (KCl) 10 mEq/L at 85 mL/hour. Laboratory evaluation today shows the following:

Sodium, 140 mEq/L
Potassium, 3.8 mEq/L
Chloride, 106 mEq/L
Glucose, 85 mg/dL
SCr, 0.9 mg/dL
Serum albumin, 3.1 g/dL

J.B. failed his swallow study today and will remain NPO for 5 weeks before a repeat swallow study, which he must pass before an oral diet is initiated. Nutrition support via tube feeding is ordered.

What is the most appropriate type of enteral access device (EAD) for J.B.?

The type of EAD (ie, feeding tube) is determined by the anticipated duration of tube feeding, disrupted region or process in the GI tract, and the risk of aspiration. **Figure 37-1** illustrates the two basic types of EAD placement—nasal versus ostomy—and the sites available for formula delivery (ie, gastric, duodenal, or jejunal). The name of the EAD usually includes both the type of tube placement and the site of formula delivery. For example, NG indicates nasal placement with

gastric delivery of formula, whereas gastrostomy indicates ostomy placement with gastric delivery of formula.

Figure 37-1 Nasoenteric and enterostomy feeding sites.

Nasal tube placement is preferred for short-term use in patients expected to resume oral feeding and without obstruction of nasal, pharyngeal, or esophageal passages. The tube is secured to the nose or cheek after placement to prevent the tube from being displaced. Radiographic confirmation of tube placement is mandatory to rule out pleural perforation and pulmonary intubation in unconscious patients, and remains the standard to ensure correct tube placement in all patients.[6]

Feeding ostomies (tube enterostomies) generally are reserved for long-term EN, interpreted as anywhere from 4 weeks to 6 months, depending on clinical circumstances and the type of tube enterostomy placed. Access for enterostomies can be achieved through open surgery, laparoscopy, or via percutaneous access. Percutaneous access is usually performed under local anesthesia or conscious sedation by endoscope (percutaneous endoscopic gastrostomy [PEG] or percutaneous endoscopic jejunostomy [PEJ])

or by radiography (percutaneous radiologic gastrostomy [PRG] or jejunostomy), including fluoroscopy, ultrasound, or computed tomography.[6] Most patients requiring long-term EN receive either a PEG or a PRG. From the clinical standpoint (ie, maintenance, feeding protocols), PEGs and PRGs are the same, and PRGs are commonly referred to as PEGs. Combined gastric and jejunal EADs (PEGJ or G-J) experience malfunctions and migration or clogging of the jejunal extension in up to 70% of patients; therefore, use is limited to selected patient situations.[6]

Major advantages of percutaneous access are shorter procedure time and lower cost; morbidity and mortality appear to be similar to surgical EADs.[6] Major complications, such as aspiration, peritonitis, hemorrhage, gastrocutaneous fistula formation, necrotizing fasciitis, gastric perforation, and migration of the tube through the gastric wall, are generally low but have been reported in up to 2.5% of patients.[6]

Formula delivery into the stomach is preferred because it is the most physiologically normal feeding site. Stimulation of normal digestive processes and hormonal responses associated with eating occur. The stomach serves as a reservoir, typically allowing tolerance of bolus, and intermittent or continuous feeding. Gastric feeding requires adequate gastric motility to prevent accumulation of formula in the stomach. Patients with gastric outlet obstruction, gastroparesis, gastric distension, or gastroesophageal reflux are poor candidates for gastric feeding.

Postpyloric feeding into the duodenum or jejunum may be appropriate when gastric dysfunction or disease is present, for early postoperative feeding when gastric emptying may be impaired or when risk of aspiration is high. Critically ill patients are at risk for aspiration and ventilator-associated pneumonia, yet evidence of reduced aspiration and improved outcomes with postpyloric feeding in any patient population remains controversial.[4,6] Moderate-quality evidence does indicate that aspiration may be reduced by 30% with postpyloric feeding versus gastric feeding; however, this has not been shown to result in reduced length of stay (LOS) or mortality.[3] Calorie and protein provision appear to be improved, and the EN goal rate achieved more quickly with postpyloric feeding compared

to gastric feeding.[7] SCCM-ASPEN Critical Care guidelines suggest postpyloric feeding for patients at high risk for aspiration, but acknowledge that gastric feeding is better than delaying EN for postpyloric tube placement.[3,4]

J.B. will require EN for at least 5 weeks, and may require longer term EN depending on repeat swallow study results. A feeding ostomy is appropriate for him based on expected minimum duration of therapy. In addition, a feeding ostomy will make discharge on EN more feasible to either home or a nursing facility. Because there does not appear to be a contraindication to feeding into the stomach, a gastrostomy is appropriate. He will likely have a PEG or PRG placed to avoid the need for surgery. However, given that J.B. has indications of malnutrition (ie, 8% weight loss, muscle wasting), he should have had a temporary EAD placed earlier in his hospitalization to provide EN. He should continue to receive EN via a temporary EAD until his feeding ostomy is placed.

FORMULA SELECTION

Case 37-2, Question 2: What factors should be considered in selecting an enteral formula for J.B.?

Enteral formula selection is based on nutrient requirements, fluid restrictions, and the extent of impaired digestion and absorption. Many enteral formulas are available, but because of similarities between products, institutional formularies are generally limited but still provide an adequate selection to meet a variety of patient needs. Categorizing formulas as listed in **Table 37-2** simplifies the formula selection process. There are three major categories of enteral formulas: (a) polymeric formulas, (b) oligomeric formulas, and (c) specialized formulas. Within each category there are other considerations such as the specific sources of carbohydrate, protein, and fat, as well as their caloric distribution in the product.

Table 37-2

Generic Groups and Subgroups of Enteral Formulas

Type of Formula	Examples from Abbott Laboratories (Abbott Park, IL)	Examples from Nestle Health Science (Vevey, Switzerland)
Polymeric Formulas[a]		
Standard Caloric Density, Standard (or High Nitrogen[b]) Content With Varied Fiber Content		
Fiber free for oral supplement or tube feeding	Ensure®	Boost®; Nutren® 1.0
Low fiber (from 1 to 9 g/1000 kcal)	Ensure®; Enlive®b	
Moderate fiber (>9–<14 g/1000 kcal)	Glucerna® 1.2 Cal[b]; Jevity® 1.0 Cal	Fibersource® HN[b]
High fiber (≥14 g/1,000 kcal)	Jevity® 1.2 Cal[b]	Nutren® 1.0 with fiber
Standard-Nitrogen Content, Fiber Free (or Low Fiber) With Varied Caloric Density		
Standard caloric density (1–1.2 kcal/mL)	Ensure®	Nutren® 1.0
Moderate density (1.5 kcal/mL) Ensure® Plus	Ensure® Plus	Boost Plus®; Isosource® 1.5 Cal[c]; Nutren® 1.5
Calorically dense (1.8–2 kcal/mL)		Nutren® 2.0
Standard Caloric Density, Fiber Free With Varied Nitrogen (Protein) Content		
Low nitrogen (6%–10% of kcal as protein)		Resource® Breeze
Standard nitrogen (11%–16% of kcal as protein)	Ensure®	Nutren® 1.0
High nitrogen (17%–20% of kcal as protein)	Osmolite® 1.2 Cal	Isosource® HN
Very high nitrogen (>20% of kcal as protein)	Promote®	Boost® High Protein; Replete®
Oligomeric Formulas		

Type of Formula	Examples from Abbott Laboratories (Abbott Park, IL)	Examples from Nestle Health Science (Vevey, Switzerland)
Polymeric Formulas[a]		
Elemental (free amino acids)		Vivonex® (RTF, T.E.N., Plus)
Peptide Based		
Standard protein		Peptamen®; Peptamen® with Prebio™
High protein	Vital® Peptide 1.5	Peptamen® 1.5
Very high protein (NPC:N <100:1; >20% calories as protein)	Pivot® 1.5	Peptamen AF®
Specialized Formulas		
Renal Failure		
Essential amino acid enriched		Renalcal®
Polymeric, low electrolyte (less than standard potassium, phosphorus, and magnesium)		
▪ Low nitrogen	Suplena®	
▪ Standard nitrogen		Novasource® Renal
▪ High nitrogen (for dialysis)	Nepro®	
Hepatic Failure (high BCAA, low AAA)		NutriHep®
Stress or Critically Ill (altered protein or fat content)		
Branched-chain enriched		Vivonex® RTF
High to very high nitrogen plus conditionally essential nutrients	Perative®, Pivot® 1.5 Cal	Impact®, Impact® Peptide 1.5
Pulmonary Disease		
Immune modulating	Oxepa®	
Standard Pulmonary (not IMP)	Pulmocare®	Nutren® Pulmonary

Type of Formula	Examples from Abbott Laboratories (Abbott Park, IL)	Examples from Nestle Health Science (Vevey, Switzerland)
Polymeric Formulas[a]		
Glucose control	Glucerna® 1.0 Cal; Glucerna® 1.2 Cal; Glucerna® 1.5 Cal	Diabetisource® AC; Glytrol®

AAAs, aromatic amino acids; BCAAs, branched-chain amino acids; IMP, immune-modulating pulmonary; NPC:N, nonprotein calorie to nitrogen ratio.

[a]All products listed in the table are lactose free.

[b]High nitrogen; 17% to 20% of calories from protein.

[c]Low fiber.

Polymeric Formulas

Polymeric formulas are designed for patients with full digestive capability and are used most often. Osmolality is decreased and palatability increased in these formulas by the use of relatively intact nutrients, including whole (ie, intact) proteins. Administration of ~1.5 to 2 L of most polymeric formulas provides 100% of dietary reference intakes (DRIs) for vitamins and minerals; thus, these formulas are considered “complete” formulas.[8] The relative cost of polymeric formulas tends to be less than that of oligomeric or specialized formulas, although prices can vary considerably based on specific nutrient content (eg, ω-3 fatty acids [ω-3FAs], antioxidants).

Oligomeric Formulas

Oligomeric formulas, also called hydrolyzed, predigested, monomeric, or chemically defined formulas, are designed for patients with reduced digestive function. Pancreatic enzyme activity is required for digestion of oligosaccharides (carbohydrates) and fats. Brush-border disaccharidase activity also is required. Minimal digestion is required, however, for the hydrolyzed protein and medium-chain triglyceride (MCT) components. These formulas can

be used for patients with pancreatic insufficiency, reduced mucosal absorption, or reduced hydrolytic capability. Although the Canadian Clinical Practice (CCP) guidelines noted that patients with GI complications, such as short-bowel syndrome and pancreatitis, may benefit from oligomeric formulas, insufficient data were available to make recommendations regarding use of such formulas.[9] Pancreatic enzyme supplementation combined with polymeric formulas may be tried before oligomeric formulas for some patients with pancreatic insufficiency (eg, cystic fibrosis, chronic pancreatitis).

Two subgroups of oligomeric formulas can be differentiated based on the protein source. Available oligomeric formulas are predominately peptide based; thus, oligomeric formulas are sometimes referred to as *peptide formulas*. However, true "elemental" formulas contain free amino acids, whereas "peptide-based" formulas contain oligopeptides plus dipeptides, tripeptides, and free amino acids from hydrolysis of protein. Amino acids require no digestion, but the sodium-dependent active transport mechanism is somewhat slow and inefficient, with only about one-third of dietary protein absorbed as free amino acids; the remaining two-thirds are absorbed as dipeptides and tripeptides.[10,11] Specific carriers for dipeptide and tripeptide absorption, located in small-bowel mucosa, do not compete with the free amino acid transport system. Peptides longer than three amino acids require further hydrolysis within the lumen of the small bowel before they are absorbed. Most peptide-based formulas contain a significant portion of peptides requiring hydrolysis before absorption. No well-designed, randomized, controlled trials have clearly delineated clinical differences in elemental (free amino acid) versus peptide-based formulas. Elemental formulas generally have the lowest fat content (≤10% of calories from fat). Peptide formulas typically contain one-fourth to one-third of calories from fat, but provide 20% to 70% of the fat as MCT to minimize the risk of malabsorption.

Oligomeric formulas are typically hypertonic owing to their partially digested nature; peptide-containing formulas are typically less hypertonic than are free amino acid products. Osmotic diarrhea can occur with hyperosmolality; however, peptide formulas may be used

for patients with diarrhea. SCCM-ASPEN Critical Care guidelines recommend consideration of a peptide formula when critically ill patients have persistent diarrhea, possible malabsorption, or diarrhea fails to respond to fiber.[4] The CCP guidelines, however, recommend considering an intact protein formula in critically ill patients with diarrhea.[9] In 2018, a systematic review comparing intact protein (polymeric formula) to peptides found no differences in mortality or infections, and for patients in ICU, no differences in LOS, diarrhea, or nutrition provided.[12] Taste and cost are disadvantages of oligomeric formulas. Bitter taste can limit intake by the oral route. The cost of oligomeric formulas tends to be considerably higher than that of polymeric formulas, although prices vary greatly depending on formula composition and institutional contract arrangements.

Specialized Formulas

Specialized formulas are designed for specific disease states or conditions; however, clinical benefits are often controversial. Formulas generally have a good theoretic basis for use, yet many lack conclusive clinical evidence of improved efficacy compared with standard formulas. Well-designed studies showing a difference in outcome between specialized and standard enteral formulas providing equal nitrogen and equal calories are limited for most types of specialized formulas. As shown in Table 37-2, there are several different types of specialized formulas; costs and evidence for use vary greatly among them.

J.B. requires EN because he cannot adequately protect his airway when swallowing. There is no evidence presented to suggest he has problems with digestion or absorption. One of the polymeric formulas on the hospital EN formulary should be selected for J.B. The choice of polymeric formula can be narrowed by several factors, including requirements for calories, protein, fluid, and fiber, as well as potential nutrient intolerances.

Case 37-2, Question 3: What are J.B.'s requirements for calories, protein, and fluid? Does he have any special nutrient requirements?

J.B.'s nutrient requirements must be assessed before proceeding in the selection of enteral formula. Based on his body mass index (BMI), 8% weight loss over 3 months, slightly elevated CRP, and mild muscle wasting, J.B. has moderate-to-severe malnutrition in the context of chronic illness. Low serum albumin is a risk factor for morbidity and mortality, but is not a reliable indicator of nutritional status.[2] J.B.'s BMI of 20 kg/m^2 is within an acceptable range based on typical U.S. standards; however, the Global Initiative on Malnutrition (GLIM) criteria include BMI <22 kg/m^2 as an indicator of malnutrition in those older than 70 years of age.[13] Weight loss most likely is caused by chronic deficiency in total energy intake, but may also be associated with sarcopenia-associated loss of muscle mass.[2,14]

Because J.B. has an actual weight less than the ideal for his height, his actual weight should be used to estimate energy and protein requirements. Use of ideal body weight (IBW) to estimate requirements for undernourished patients may result in fluid and electrolyte imbalance. Once the patient is stabilized on nutrition support, calories can be increased, if necessary, to achieve weight gain.

J.B.'s level of metabolic stress is relatively low. He has no surgical wounds, fractures or skeletal trauma, burns, or major infections, although CRP indicates mild inflammation. Caloric requirements are only slightly higher than is the resting metabolic rate (RMR), the calories needed to maintain bodily functions without activity. Although the term *calorie* is used interchangeably with kilocalorie (kcal) in nutrition literature, the large "Calorie" or kilocalorie technically is correct, and energy requirements generally are listed as kcal/day or kcal/kg body weight when specific numbers are given for a patient. See Chapter 35, Basics of Nutrition and Patient Assessment, for methods of determining nutrient requirements. An estimation of 20 to 25 kcal/kg actual weight can be used to initiate

feeding based on J.B.'s low level of metabolic stress, but higher caloric intake (25–30 kcal/kg/day) will likely be needed as mobility increases and for weight gain after he is stable. The Mifflin–St Jeor equation is a predictive equation commonly used to estimate RMR. Using this method, the RMR for J.B. is 1335 kcal/day [(10 × 62 kg) + (6.25 × 175.3 cm) − (5 × 77 years) + 5], but he needs up to 1.4 times RMR (1869 calories) to meet his total daily caloric requirement, especially if weight gain is desired.

Protein requirements for healthy elderly people are controversial, but estimated to be 1 to 1.2 g/kg/day, which is higher than the DRI of 0.8 g/kg/day.[14] J.B.'s protein needs are estimated at 1 to 1.2 g/kg actual weight per day, minimum, but slightly higher protein intake may be beneficial based on inflammation and chronic malnutrition. Renal function appears adequate for J.B. to tolerate 1.2 g/kg/day, up to 1.5 g/kg/day; however, SCr may provide a poor estimate of renal function in underweight patients owing to less-than-normal muscle mass.

Daily fluid requirements for geriatric patients can be estimated at 30 mL/kg or 1 mL/kcal ingested, with a minimum of 1500 mL daily, plus replacement of excess losses from hyperthermia, vomiting, or diarrhea.[14] Baseline requirements of 1500 mL for the first 20 kg plus 20 mL per each additional kilogram of body weight also can be used to estimate fluid requirements. J.B. does not appear to have any excess fluid losses at this time; therefore, calculation of baseline fluid requirements should provide adequate fluids.

J.B.'s estimated daily requirements are ~1240 to 1550 total calories using 20 to 25 kcal/kg but up to 1869 calories using 1.4 times RMR, a minimum of 62 to 74 g protein, and about 1860 to 2340 mL of fluid. These are estimated requirements that should be adjusted based on frequent reassessment of J.B.'s response to therapy and changes in his clinical situation. Additional calories and protein may be needed for repletion of weight and protein status.

J.B.'s apparently suboptimal nutrition before hospitalization, age, and acute illness increase his risk for vitamin deficiencies, and he may have at least some subclinical deficiencies (see Chapter 35, Basics of Nutrition and Patient Assessment). Medical, medication,

and dietary histories should be evaluated to determine nutritional risks associated with specific conditions. J.B. should receive 100% of the DRI, minimum, for vitamins and minerals daily.[8] If actual deficiencies are identified, J.B. will require higher, therapeutic doses for the specific vitamins that are deficient. For patients at risk for refeeding syndrome, consensus recommendations include supplementation of 100 mg thiamine before feeding is initiated, and, if at high risk, for 5 to 7 days during feeding.[15] A complete multivitamin product is recommended daily for 10 days in patients at risk for refeeding syndrome receiving oral nutrition or EN.

Clinical judgment suggests J.B. is at risk for refeeding syndrome. He has an 8% weight loss, his weight is below IBW, his BMI is considered at risk for malnutrition given his age, and older patients at risk for malnutrition may be at high risk for refeeding syndrome.[3,13,15] Chronic malnutrition can lead to intracellular depletion of potassium, phosphorus, and magnesium, whereas serum concentrations are maintained. When aggressive feeding by any route (oral, EN, PN) begins, refeeding syndrome may develop because these electrolytes move from the extracellular space into the cells, causing a decrease in serum concentrations, especially phosphorus, during the first few days of feeding.[15] Failure to monitor the patient and replace electrolytes as necessary can result in serious electrolyte abnormalities.

Case 37-2, Question 4: Which category of polymeric formulas would be most appropriate for J.B. based on his estimated nutritional requirements?

Polymeric formulas can be divided into several categories based on nutrient sources, caloric density, and protein content. Each category should be evaluated because formula characteristics overlap between the categories.

NUTRIENT SOURCE

Polymeric formulas can be subdivided based on lactose content. Hospitalized patients are presumed to be lactose intolerant because

of reduced disaccharidase production during fasting, malnutrition, and various GI tract diseases. In addition, most ethnic groups, except northern Europeans, have reduced lactase production in adulthood, leading to lactose intolerance. Lactose ingestion can cause bloating, flatulence, abdominal cramps, and watery diarrhea in patients with permanent or transient lactose intolerance. Lactose-free formulas are the standard for tube-fed adults. Proteins, even those derived from milk, do not contribute to lactose content because lactose is a carbohydrate. The majority of enteral formulas are also gluten-free ones to avoid GI symptoms associated with gluten intolerance or celiac disease.

CALORIC DENSITY

Caloric density influences the volume of formula needed to meet nutrient requirements. Standard caloric density is 1 to 1.2 kcal/mL. **Table 37-3** lists the general descriptions for caloric density and macronutrient quantities in enteral formulas. Increased caloric density increases formula osmolality. Gastric emptying can be reduced when osmolality exceeds 600 mOsm/kg, and this may result in feeding intolerance.[16] GI intolerance (eg, nausea, flatulence, abdominal discomfort) also can occur if the capacity of intestinal enzymes is overwhelmed by infusion of a calorically dense formula.

Table 37-3

General Descriptions of Macronutrient Quantity in Enteral Formulas

Description	Caloric Density (kcal/mL); corresponding Free Water (%)	Protein Content: % kcal as protein; typical NPC:N ratio	Fiber Content (g/1,000 kcal)
Low	<1; >85%	6%–10%; >200:1	1–9
Standard	1–1.2; 80%–85%	11%–16%; 200:1–130:1	None
Moderate	1.5; 75%–80%		>9 but <14
High	1.8–2; 65%–75%	17%–20%; 120:1–100:1	≥14
Very high	>2; ≤ 65%–75%	>20%; <100:1	

NPC:N, nonprotein calorie to nitrogen ratio.

Caloric density reflects the free-water content of EN formulas. Risk of dehydration increases with increasing caloric density; however,

standard caloric density formulas can result in fluid overload in patients with congestive heart failure, renal failure, or other fluid-sensitive conditions. Calculation of water provided by EN helps determine the volume of additional fluid needed to meet daily fluid requirements. Free-water content is generally 80% to 85% (800–850 mL/L of formula) for formulas with 1 to 1.2 kcal/mL. Table 37-3 lists free-water content associated with other caloric densities. The available history for J.B. does not suggest a need for fluid restriction; therefore, it would be reasonable to initiate feedings with a standard caloric density product (1–1.2 kcal/mL).

PROTEIN CONTENT

Protein needs increase disproportionately to caloric needs during injury and critical illness, whereas protein tolerance may limit protein provision in other conditions. To meet the need for varying ratios between calories and protein, polymeric formulas are available with a range from low- to very high-protein content. Either percentage of calories from protein or nonprotein calories to nitrogen (NPC:N) ratio can be used to define protein content. Table 37-3 lists general descriptions for protein content. High-nitrogen enteral formulas are designed for patients with an increased protein requirement without a proportional increase in caloric needs. Very high-nitrogen formulas are generally intended for critically ill patients or those with large wounds to heal, although they may be appropriate when calorie provision is to be low but protein is to be higher (ie, refeeding syndrome risk, intended weight loss). Low-nitrogen formulas are available for patients requiring protein restriction. Some low-nitrogen formulas are designed for patients with reduced renal function and can be classified as specialized formulas.

A formula with standard protein content is marginal for meeting J.B.'s protein needs. A high-nitrogen formula that meets J.B.'s calorie needs will provide protein at 1.1 to 1.2 g/kg/day, whereas a standard-nitrogen formula will provide between 0.8 and 1 g/kg/day. With J.B. at risk for refeeding syndrome, a high-nitrogen formula is the better choice initially.

Case 37-2, Question 5: Should the EN product selected for J.B. contain fiber, and, if so, what type and amount?

Fiber has potential physiologic benefits, including increased fecal bulk, decreased bowel transit time in patients susceptible to constipation, increased transit time in patients with diarrhea, reduction of serum cholesterol, and improved glycemic control in patients with diabetes. Recommended daily fiber intake for healthy Americans is 21 to 25 g for females and 30 to 38 g for males, with the lower end of these amounts for people 51 years of age or older.[17–19] Adequate intake is determined by calorie intake and fiber intake observed to protect against coronary artery disease (14 g/1000 calories). Optimal fiber intake for ill persons has not been determined. Fiber-supplemented formulas vary considerably in fiber content. There is no standardized terminology for low-fiber, moderate-fiber, and high-fiber content; however, the amounts listed in Table 37-3 can serve as a general guideline.

Enteral formulas may contain either insoluble or soluble fiber, or both types (eg, mixed fiber). Insoluble fiber is associated with changes in fecal bulk and transit time, whereas soluble fiber tends to be responsible for effects on cholesterol and glycemic control. Fructooligosaccharides (FOS) are naturally occurring sugars that are added to some enteral formulas for soluble fiber benefits. Soluble fibers and FOS are prebiotics that can be fermented to short-chain fatty acids by *Bifidobacterium* in the colon.[18,19] Short-chain fatty acids stimulate colonic blood flow, enhance fluid and electrolyte absorption, and provide a trophic effect in the colon. SCCM-ASPEN Critical Care guidelines suggest consideration for routine, prophylactic use of 10 to 20 g fermentable soluble fiber (eg, FOS, inulin) in divided doses over 24 hours to promote bowel health in “all hemodynamically stable” patients in the ICU receiving standard EN formulas.[4]

The most common fiber source for enteral formulas is soy polysaccharide, or soy fiber, which has mixed fiber effects. Although soy polysaccharide demonstrates beneficial effects in healthy

subjects and non–critically ill patients, studies do not provide clear evidence of improved bowel function in critically ill patients.[4,9,20] SCCM-ASPEN Critical Care guidelines do not recommend routine use of a mixed fiber formula to prevent diarrhea or promote bowel regularity in critically ill patients.[4] When persistent diarrhea is evident, however, the guidelines suggest that a mixed fiber formula be considered. Given available data, stable patients on long-term EN appear most likely to benefit from mixed fiber formula, and some patients on short-term EN without significant GI pathology may benefit.

The addition of fiber to enteral formulas creates some potential problems. Fiber increases viscosity and fiber-containing formulas often require a pump for administration through feeding tubes. GI symptoms from fiber can include increased gas production and abdominal discomfort.[17,19] Flatulence and bloating can limit tolerance to fiber for some patients; gradual introduction may help reduce these symptoms. Surgical and trauma patients receiving mixed fiber EN formulas have developed bowel obstruction; therefore, avoidance of fiber is recommended by the SCCM-ASPEN Critical Care guidelines when severe dysmotility or a high risk of bowel ischemia exist in critically ill patients.[4] Caution is advised for the use of fiber-containing formulas in any patient with poor GI motility and underlying GI dysfunction, and patients receiving medications that inhibit bowel motility. Inadequate fluid intake may also contribute to the risk of intestinal blockage with fiber.

J.B. does not appear to have bowel pathology precluding use of a fiber-containing formula. He will require EN for a moderate duration of time and potentially long term. It would be reasonable to provide a formula with at least moderate-fiber content. However, J.B. could experience GI symptoms from the fiber, especially if his diet has previously been of low-fiber content. If necessary, a low-fiber formula could be used initially and then transitioned to higher fiber once symptoms of bloating and gas improve.

Case 37-2, Question 6: What is an appropriate administration regimen for J.B.'s tube feeding?

The feeding route, formula selected, and anticipated duration of feeding influence the administration regimen. Patient location (eg, hospital, nursing facility, home) and cost also are considered when developing the regimen, including the rate for initiating and advancing feedings, and the administration method (ie, syringe, gravity drip, pump).

Limited scientific data exist regarding EN administration regimens; thus, expert opinion plays an important role, and different regimens can be used in various settings, all of which appear to meet the needs of the patients and personnel. The administration regimen should be adjusted as necessary for feeding intolerance. Four basic schedules for formula delivery are available: (a) continuous infusion, (b) cyclic infusion, (c) intermittent infusion, and (d) bolus delivery of formula.

Continuous Infusion

Continuous infusion provides formula at a continuous rate for 24 hours/day and can be used with any route of feeding. Intragastric continuous infusion is most commonly used for hospitalized patients, although small-bowel feeding may be more appropriate in some patients.[9] Risks of gastric distension and aspiration may decrease with continuous infusion compared with intermittent gastric infusion.[4,21,22] In addition, the slower infusion rate associated with continuous infusion may be better tolerated as judged by stool frequency and time to attain full nutrition support. However, data were considered insufficient to include a recommendation for continuous infusion versus other administration methods for critically ill patients in the CCP guidelines.[9] Feeding into the duodenum or jejunum is best initiated with continuous infusion because rapid infusion of large formula volumes into the small bowel can result in symptoms of dumping syndrome, including sweating, lightheadedness, abdominal distension, cramping, hyperperistalsis, and watery diarrhea. With time, the jejunum may adapt to larger

volumes over a shorter time, allowing cyclic or longer intermittent infusions.

Cyclic Feeding

Cyclic feeding provides formula at a continuous rate for <24 hours daily. This method is most commonly used for patients who need supplemental nutrition because of an inability to consume adequate oral nutrients, during transition to an oral diet, and for long-term home EN patients. Infusions are typically given at night for 8 to 12 hours to minimize interference with oral intake and normal activities during the day, although cycles can be as long as 20 hours. Most patients do not start on a cyclic regimen; rather, they transition from continuous feeding. Formula volume and osmolality can limit tolerance to cyclic feedings, especially jejunal feedings; transition often occurs within a couple of days for gastric feeding, but may require weeks for jejunal feeding, depending on patient tolerance and cycle time.

Intermittent and Bolus Feedings

Formula is provided in three to eight gastric feedings daily for intermittent and bolus administration. Intermittent infusion occurs for 30 to 60 minutes using a feeding container or bag, with or without an enteral pump, and bolus feedings are for about 15 minutes using gravity administration via a syringe.[3] The stomach's reservoir capacity allows administration of relatively large volumes on an intermittent or bolus schedule. This is more physiologic than continuous feeding and more convenient for patients in nursing facilities and ambulatory patients at home on EN.

INITIATION OF FEEDINGS

The regimen for initiating EN primarily depends on the site of feeding and condition of the patient's GI tract. Use of full-strength (ie, undiluted) formula is recommended for initiation of feedings.[3,21] Dilution delays delivery of adequate nutrients without significantly affecting the incidence of GI intolerance. Hypertonic formulas are diluted rapidly in the GI tract, reaching isotonicity before or shortly beyond the ligament of Treitz (distal end of the duodenum). Continuous feedings are commonly initiated at goal rate, or at 50 mL/hour with advancement by 15 mL/hour every 4 hours to reach the goal within 24 to 48 hours in non–critically ill patients.[3] For critically ill patients, those with abnormal GI function, patients without use of the GI tract for a prolonged time, those at risk for refeeding syndrome, and when calorically dense or high-osmolality formulas are used, starting at 10 to 40 mL/hour and advancing by 10 to 20 mL/hour every 8 to 12 hours may be preferable, although this is based on consensus rather than on evidence from well-designed studies.[3,15,22] Using more rapid advancement protocols does allow adequate nutrient delivery more quickly, unless intolerance requires return to lower rates of delivery. Consistently adequate nutrient delivery is also more likely with volume-based feeding protocols in which daily formula volume is ordered (rather than rate) and nurses adjust volume based on patient tolerance to achieve the daily goal volume.[3,21,23]

Hospitalized patients are typically started on continuous infusion feedings, then transition to intermittent infusions, and eventually to bolus feedings, if desired. Bolus feedings are started with 240 mL over 4 to 10 minutes (maximum rate 60 mL/minute) with a minimum of 3 hours between feedings, then advanced by 60 to 120 mL every 8 to 12 hours until the goal volume and number of feedings is achieved.[3] For intermittent feeding, volumes of 240 to 720 mL over 20 to 60 minutes four to six times per day are typical. Initiation of feedings at goal rate may be tolerated by some patients, although starting slower is appropriate for many patients. The schedule for nonhospitalized patients should allow all feedings during waking hours.

J.B. receives gastric feeds; therefore, continuous infusion, intermittent infusion, or bolus feedings could all be used. Continuous infusion most commonly is used for hospitalized patients despite no clearly established difference in tolerance compared with intermittent infusion. Full-strength formula should be used to initiate feedings. The goal volume of EN for J.B. is 1440 mL/day of a standard caloric density formula (1.06 kcal/mL, 0.44 g protein/mL, 83.5% free water), or 60 mL/hour continuous infusion. The infusion could be started at 60 mL/hour (goal rate); however, given J.B. is at risk for refeeding syndrome, it is preferable to start slower. Starting at 15 mL/hour for 12 hours and then increasing by 15 mL/hour every 12 hours would achieve the goal rate of 60 mL/hour within 48 hours. If J.B. experiences diarrhea or abdominal distension, the feeding may be held at 15 mL/hour for 24 hours, then increased by only 10 mL/hour every 12 to 24 hours as tolerated. Extra care is required to ensure he receives an adequate fluid intake until the formula is at goal rate, and that electrolytes are replaced as necessary should refeeding syndrome develop.

To prevent potentially fatal inadvertent IV infusion of non-IV products, the International Organization for Standardization (ISO) standard 80369 was developed for non–Luer-compatible connectors for small-bore liquid and gas medical device tubing, including enteral feeding connectors known as ENFit® devices.[24] Oral syringes will not fit ENFit® connectors; therefore, ENFit®-compatible syringes are required for medication administration, tube flushes, and bolus feeding via syringe when the EAD has an ENFit® connector. The type of connector should be verified because long-term EADs, such as PEGs, may have been placed before ENFit® connectors.

TRANSITION FROM CONTINUOUS TO INTERMITTENT/BOLUS FEEDING

Case 37-2, Question 7: J.B. has received EN for 5 days. He has tolerated his continuous tube feeding without problems and has not required electrolyte replacements for the past 2 days. The plan is to transfer J.B. to a skilled nursing facility (SNF) within the next 2 days. The SNF requests that J.B. be on an intermittent/bolus feeding regimen before he transfers. How should J.B. be changed from continuous infusion to intermittent or bolus feeding?

Many nursing facilities do not routinely use enteral pumps because of increased cost. Without a pump, delivery of the prescribed volume of formula at a consistent rate may not be reliable, and increased nursing time may be required to prevent tube occlusion and ensure adequate volume of formula is delivered. J.B. is currently receiving continuous infusion feedings. The transition to intermittent delivery of formula can be accomplished by various methods. An overlapping regimen of gradually decreasing the continuous infusion rate and increasing the intermittent volume can be used, but can be disruptive when a closed enteral feeding system is used in a hospital setting. For J.B., decrease the continuous rate from 60 mL/hour down to 30 mL/hour and add four intermittent feedings of 180 mL over 60 minutes every 6 hours initially. If tolerated, stop the continuous and increase intermittent feeding to 240 mL every 4 hours (six feedings daily). If tolerated, the feeding volume can be increased to 360 mL four times daily plus one 120-mL feeding, or to 380 mL four times daily. To reduce risk of contamination and waste when individual containers of formula are being used, versus large bags (1–3 L) in a closed feeding system, increments of 240 mL (full 8-ounce container), or, if necessary, 120 mL, are preferred. To keep the feeding volume in preferred increments, J.B. could receive two feedings of 360 mL and three feedings of 240 mL, no closer than every 3 hours. Based on tolerance, the feeding regimen could be changed to 480 mL four times daily during waking hours.

Another transition method is to stop continuous feedings and restart feedings with a regimen for initiating intermittent feedings. Starting volume is typically 240 mL for the first two or three feedings, and feeding intervals are often every 4 hours. Volume is increased by 60 to 120 mL every 8 to 12 hours, as tolerated, until the goal is

reached.[3] Feeding intervals can be increased once goal volume is reached. J.B. could start with 240 mL over 60 minutes every 4 hours for two feedings, then advance to 360 mL per feeding. If tolerated, the volume per feeding could increase to 480 mL to allow feedings every 6 hours. Then reduce the time between feeding to not <3 hours to fit all feedings into waking hours. Once at the regimen, the infusion time could be decreased based on tolerance. If feeding for 30 minutes is well tolerated, J.B. could be changed to bolus administration for 15 to 20 minutes.

The discharge EN prescription should include patient identifiers as required for any prescription.[21] The formula should be given in generic descriptive terms (ie, standard vs special features related to caloric density, protein content, and fiber content per 1000 kcal). The brand name may be included, but the SNF may not carry the same brand of formula. Delivery site (gastric or small bowel), the specific EAD, administration method (continuous, cyclic, intermittent, bolus), formula volume, and rate or administration time (ie, 15, 30, or 60 minutes) should be included. Total daily formula volume, and the daily calories, protein, fiber, and fluid goals should be specified. Flush orders should include the solution (ie, purified water), volume per flush and total flushes per day, frequency, and timing. Any special considerations for the feeding schedule also should be communicated (eg, J.B. does not tolerate feeding after 9 pm; raise the head of the bed to 45° for 3 hours after the last daily feeding to avoid regurgitation).

FLUID PROVISION

Case 37-2, Question 8: How much additional fluid must be included in the feeding regimen to meet J.B.'s estimated daily fluid requirements?

The free-water content of EN must be calculated to determine the volume of additional fluid that must be provided. As noted previously,

standard caloric density formulas generally contain 80% to 85% free water. The formula selected for J.B. contains 83.5% free water; therefore, at his goal volume of 1440 mL/day (six, 240 mL containers), the formula provides ~1200 mL of free water daily. Using 1860 mL daily (30 mL/kg/day × 62 kg) as J.B.'s fluid requirement (see Case 37-2, Question 5), he will need 660 mL/day in addition to the enteral formula. If J.B. had additional losses from vomiting, diarrhea, or other sources, this volume would be added to the 660 mL to determine total volume in addition to enteral formula. The additional fluid is typically provided with medications and tube irrigation (flushes). EADs should be irrigated with 30 mL of fluid every 4 hours during continuous feeding, or before and after each intermittent or bolus feeding.[3,21] The tube should be flushed with a minimum of 15 mL, although some suggest 30 mL, of water before and after medication administration through the tube, as well as with 15 mL between each medication.[3,16,21,22] Fluid also is required for diluting medications before administration through the EAD. The flush volume and/or number of flushes will need to be increased to provide J.B. with adequate fluid because 30 mL every 4 hours plus fluid for medication administration will not provide the 660 mL of fluid needed in addition to his EN. Because J.B. is receiving gastric feedings, hypotonic fluid is of less concern than in the jejunum, where the normal sodium concentration is 90 to 140 mEq/L.[25] Increasing flush volumes to between 100 and 150 mL should meet J.B.'s daily fluid requirement, depending on the amount needed for medication administration. Diluting the formula itself to increase fluid provision is not recommended because this increases the risk of error and contamination.

NUTRITION IN CRITICAL ILLNESS

Nutrition support is an important component of care in critical illness, where patients are typically in a catabolic stress state and metabolism may be altered. Multiorgan dysfunction, as well as fluid

and electrolyte imbalances, adds to the complexity of this population and confounds attempts to provide proper nutrition. The preferred route for nutrition support is generally EN, although the ideal formula composition remains unresolved. The most recently published guidelines should be consulted to determine current recommendations for formula composition, including specialized components. In addition, it is essential to review the most current summation of data from major nutrition support and/or critical care organizations to determine which populations may benefit or be harmed by specific components because guidelines may lag behind the newest data.

CASE 37-3

QUESTION 1: N.R., a 68-year-old male with a past medical history of hypertension, presents to the ED with shortness of breath, productive cough, wheezing, and fever. N.R. subsequently requires intubation and is transferred to the ICU with a diagnosis of pneumonia. His SARS-CoV-2 antibody test result for COVID-19 is negative. During the next 24 hours, his respiratory status further declines, and he is diagnosed with adult respiratory distress syndrome (ARDS). In anticipation of a prolonged course of mechanical ventilation, a feeding tube is placed into the small bowel. The chart indicates a height of 70 inches (177.80 cm) and an admission weight of 165.35 pounds (75 kg).

Laboratory evaluation today includes the following:

Sodium, 140 mEq/L
Potassium, 3.9 mEq/L
Chloride, 109 mEq/L
Carbon dioxide content, 22 mM
BUN, 18 mg/dL
SCr, 0.8 mg/dL
Glucose, 118 mg/dL
Albumin, 3.6 g/dL
Aspartate aminotransferase, 32 international units (IU)/L
Alanine aminotransferase, 37 IU/L

Should a specialized critical care formula be used for initiation of EN in N.R.?

N.R. is critically ill, and several types of EN formulas have been developed for critically ill patients. However, the role of specialized EN formulas, and certain components in particular, remains controversial in critical illness. **Table 37-4** shows a few formulas marketed for critical illness and lists the components that are altered compared to standard polymeric formulas. Owing to the catabolic nature of critical illness, formulas are generally high protein, many with an NPC:N ratio <100:1 (ie, high or very high-protein content). Supplementation of specific amino acids, including branched-chain amino acids (BCAAs), glutamine, and arginine, in EN for critical illness remains an unsettled issue. Other formulas containing slightly lower protein content (ie, NPC:N ratio between 100:1 and 125:1) target the inflammatory element of critical illness with components designed to mitigate the inflammatory response, including altered fatty acid composition and antioxidant components. Formulas designed for critical illness are typically fiber-free ones, although a few formulas include small amounts of soluble fiber. As a whole, specialized formulas are not recommended for routine use in the ICU.

Table 37-4

Selected Enteral Formulas With Altered Protein or Fat Sources

Formula[a,b,c]	kcal/mL (mOsm/kg)	Free Water (%)	Protein g/L (% kcal)	NPC:N	Protein Source	ARG g/La	GLN g/La	Fat g/L (% kcal)	Fat Sources	%Fat kcal as MCT	Ratio of ω-6FA to ω-3FA[d]	Fiber g/La

[c]Nestle product, Nestle Health Science, Vevey, Switzerland.

[d]None or unknown indicated by "–."

Enhanced Branched-Chain Amino Acid Content

Standard EN formulas contain 15% to 20% of protein as BCAAs; enhanced BCAA formulas for critical care contain over 35%, and hepatic failure formulas contain 45% to 50%. High-BCAA stress/critical care formulas are not therapeutically interchangeable with hepatic formulas because of the lower than normal concentrations of aromatic amino acids (AAAs), especially phenylalanine, in hepatic formulas.

High to very high protein is currently emphasized over BCAA content for critically ill patients. A standard enteral formula is

recommended by SCCM-ASPEN Critical Care guidelines for patients in the ICU with acute or chronic liver disease.[4]

Glutamine

The proposed role of glutamine in critical illness is enhanced neutrophil function and maintenance of intestinal barrier function, thereby preventing translocation of bacteria and endotoxins from the GI tract into systemic circulation and reducing bacteremia.[26] Glutamine is considered a nonessential amino acid, because it is synthesized in sufficient quantities for its roles in transamination, as an intermediate in numerous metabolic pathways, such as gluconeogenesis and renal ammoniagenesis, as a fuel source for rapidly dividing lymphocytes and enterocytes, and in the synthesis of glutathione. However, during periods of metabolic stress, endogenous synthesis may become inadequate.

Study results are conflicting regarding effects of enteral glutamine supplementation in the critically ill population. The 2015 CCP guidelines recommend against the use of enteral glutamine in critically ill patients.[9] The exception may be patients with burns who appear to have a reduced hospital LOS and reduced mortality with enteral glutamine supplementation, although the number of patients in studies was small.[27,28] Monitoring for potential complications is essential when glutamine supplementation is used.

Protein-bound glutamine is present in all enteral formulas, but free glutamine is unstable in ready-to-use formulas. Glutamine is available as a modular supplement, which can be administered separately from the EN formula. Glutamate functions in many roles attributed to glutamine and is stable in water; therefore, it could be added to ready-to-use formulas. Additional research is needed to determine whether physiologic effects are equivalent for glutamate, protein-bound glutamine, and free glutamine.

Arginine

Arginine is a nonessential amino acid synthesized by the urea cycle during detoxification of ammonia and is normally available in sufficient quantities for growth and tissue repair. In times of metabolic stress, however, endogenous synthesis may become inadequate, making arginine conditionally essential. The postulated benefit of arginine in critical illness is related to enhanced protein synthesis, cellular growth, and immune system support. In contrast, several mechanisms that suggest potential adverse effects with arginine supplementation have been proposed, including one in which arginine is used as a substrate in the synthesis of nitric oxide (NO), a potent vasodilating agent, which may also have implications in mitochondria damage, organ dysfunction, and increased gut barrier permeability.[29] Although synthesis of NO increases during sepsis (thereby creating a negative arginine balance), the exact role of this effector molecule remains controversial. Many believe that excess NO is part of an adaptive response directed toward limiting infection, ischemia, coagulation, inflammation, and tissue injury.

Conflicting study results leave considerable uncertainty regarding use of arginine-supplemented EN in critically ill patients.[4,9,29–32] Interpretation of studies is often confounded by inclusion of other potentially immune-modulating components in the formula. As a result, clinical guidelines most often refer to “immune-modulating” formulas (IMFs) with specific references to the arginine component.

IMMUNE-MODULATING FORMULAS

Formulas included in Table 37-4 have an NPC:N ratio of 125:1 or less and contain supplemental arginine, glutamine, or nucleic acids, or a modified fat component. Such formulas are known as IMFs based on their proposed beneficial modulation of biologic responses to stress. Study formulas frequently contain varying portions of two or more potentially immune-modifying components, making it difficult to determine the effect of any given component. The subset of IMFs intended for patients with ARDS and acute lung injury (ALI) is distinct

from other IMFs, and is discussed in more detail in the section Pulmonary Disease.

The population that appears to have better outcomes with IMFs is patients undergoing major elective surgery, particularly surgery for GI malignancy. Reduced postoperative infection risk and shorter LOS, but not reduced all-cause mortality, was reported in a systematic review and meta-analysis of surgical oncology patients.[30] More than 90% of patients included in the analysis had undergone surgery for GI-related malignancy, and the majority of those in the IMF study arms (vs control arms) received a combination of arginine, nucleotides, and ω3FAs perioperatively with caloric goals of 25 to 30 kcal/kg/day. Patients who are malnourished may show greater benefit from an IMF.

SCCM-ASPEN Critical Care guidelines recommend routine use of an IMF containing arginine in postsurgical patients in the ICU requiring EN, as an option in patients with traumatic brain injury, and for consideration in patients with severe trauma.[4] The arginine dose should not exceed 15 to 30 g/day with the IMF.[4,31] Routine use is not recommended in the medical ICU. Conversely, CCP guidelines advise against use of formulas with “arginine and other nutrients” in all critically ill patients because higher quality studies indicated no effect on mortality with these formulas, and increased mortality was reported for patients with sepsis in some studies.[9] A more recent systematic review indicates no effect on overall mortality, rate of infectious complications, or hospital or ICU LOS with arginine-containing IMFs in critically ill patients.[32] Effects on reduced duration of mechanical ventilation were uncertain. Neither the CCP guidelines nor the SCCM-ASPEN Critical Care guidelines recommend use of an arginine-supplemented IMF for patients with severe sepsis.[4,9] The effects of combinations of immune-modulating components (arginine, glutamine, nucleic acids, ω-3FAs), optimal component and dose combinations, and the most beneficial timing for administration of immune-modulating components in well-defined patient populations continues to be explored.

Altered Fat Components

Stress or critical care formulas and IMFs contain different sources of fat to alter the type of fatty acids provided. Fat sources commonly include MCTs, along with predominantly canola oil, high-oleic oils, or fish oils. Absorption of MCTs is relatively independent of pancreatic enzymes and bile salts, and is carnitine independent; thus, they can be absorbed in patients experiencing malabsorption of the long-chain triglycerides. Formulas containing a relatively large percentage of fat calories as MCTs are frequently marketed for critically ill patients with malabsorption.

Canola oil and high-oleic oils have high monounsaturated fatty acid (MUFA) content. MUFAs have been popularized by reports of low cardiovascular disease in populations using olive oil; research to define the role and doses of these fatty acids in ill patients continues. Usual polyunsaturated vegetable oils (ie, corn, soy, and safflower oils) are avoided or provided in relatively small quantities in critical care formulas to limit ω-6 fatty acids (ω-6FAs), which are precursors to inflammatory, vasoconstrictive, and platelet-aggregating agents.[33,34] Small amounts of ω-6FAs are required in the diet to prevent deficiency of linoleic acid, an essential fatty acid not provided by MCT and fish oils.

Fish oils, including menhaden oil, provide fatty acids primarily from the ω-3 family, with the very long-chain fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) predominating. The proposed role of ω-3FAs in critical illness is to reduce excessive inflammatory responses, with subsequent reduction of thrombotic risks, cardiac arrhythmias, infectious complications, and, ultimately, reduce death in selected patient populations.[29] The ω-3FAs are precursors to less inflammatory and more vasodilatory eicosanoids than those from ω-6FA.[29,33,34]

Limited data are available evaluating effects of only fat modification in EN for critical illness. Although the ability of ω-3, -6, and -9FAs to modulate differences in prostaglandin, leukotriene, and thromboxane production are well known, effects in critically ill patients remain less certain.[29,35] Improved clinical outcomes for

postsurgical and critically ill patients have been associated with EN-containing ω-3FAs, usually in conjunction with other immune-modulating components, in some studies; other studies suggest data are inadequate to support routine use of fish oil.[4,9,29,32,35]

Studies suggest a minimum of 5 to 7 days of supplementation with immune-modulating components, including ω-3FAs, is necessary to see beneficial effects on postoperative outcomes.[29,33] Incorporation of ω-3FAs into cell membranes may be required to see benefits. Fat modification to provide high-ω-3FA content also has been studied in ARDS and ALI (as discussed in the section Pulmonary Disease).

The question of whether to initiate EN in N.R. with an IMF appears straightforward. The data provided for N.R. do not indicate sepsis, and he is in the medical ICU rather than in the surgical ICU. Neither SCCM-ASPEN Critical Care nor CPP guidelines recommend routine use of IMFs in patients in the medical ICU.[4,9] Because N.R. was admitted with pneumonia and now has ARDS, the more appropriate question at this time would be whether a specialized pulmonary formula would be more appropriate for his EN.

PULMONARY DISEASE

Case 37-3, Question 2: How do pulmonary formulas differ from standard polymeric formulas? If N.R. receives a specialized pulmonary formula, what nutrient modifications should the formula contain?

There are two types of EN formulas intended for patients with pulmonary conditions. Both have a moderate caloric density (1.5 kcal/mL) and the percentage of calories from fat is relatively high (40%–55%), although the types of fats differ. The premise for higher fat content is that fat metabolism produces less carbon dioxide (CO_2) than does carbohydrate metabolism, thereby reducing the work load of the lungs. Caloric intake in the older studies showing a benefit of high-fat, low-carbohydrate diets was excessive by current standards.

Excess caloric intake contributes to higher CO_2 production; thus, the early studies are of questionable relevance. In practice, preventing overfeeding is as important for control of CO_2 as high-fat, low-carbohydrate diets.[36] In addition, improved respiratory parameters with a high-fat EN product are unlikely in patients without excess CO_2 production or retention. Data from 60 malnourished, underweight patients with chronic obstructive pulmonary disease (COPD) do suggest that respiratory status in this population is more likely to benefit from a high-fat, low-carbohydrate (28% of calories) formula compared with a high-carbohydrate (60%–70% of calories) formula.[37] The percentage of calories from fat (55%) in the high-fat formula was similar to pulmonary formulas in the older studies; however, fat distribution was considerably different, reflecting that currently marketed pulmonary formulas contain 20% to 40% of fat calories as MCTs and fat sources providing higher MUFAs. During a period of high caloric intake for weight gain, pulmonary formulas may be reasonable; however, they are not warranted for routine use in most patients.

The second type of pulmonary EN formula is an immune-modulating pulmonary (IMP) formula with an anti-inflammatory lipid profile (fish oils rich in ω-3FAs, borage oil rich in γ-linolenic acids [GLAs]; reduced ω-6FA content) and antioxidants (vitamins C and E, beta carotene), which has been studied in patients with ARDS and ALI.[4,9,29,32] There is no supplemental glutamine or arginine in IMP formulas. Most studies of IMP formulas have used the specific brand Oxepa® (Abbott Laboratories, Abbott Park, IL), which contains fish oils, borage oil, antioxidants, vitamin E and C, β-carotene, taurine, and l-carnitine.[38] Interpretation of studies has often been confounded by use of a high-fat pulmonary formula as the control rather than a typical ICU EN formula. Overall, the IMP formulas appear to reduce ventilator-dependent days, and reduce mortality for patients with sepsis, ALI, or ARDS.[4,9,29,38] These formulas may reduce LOS in the ICU, but do not appear to affect infectious complications.

The SCCM-ASPEN Critical Care guidelines recommend that patients with ARDS or ALI be placed on an IMP formula, whereas

CCP guidelines have a slightly lower recommendation that such an IMP formula be considered.[4,9] However, the CCP guidelines do not reflect the more recent systematic review, indicating reduced ventilator-dependent days and lower mortality in patients with ARDS/ALI or sepsis with continuous administration of an IMP formula.[38]

N.R. was diagnosed with ARDS; therefore, an IMP formula should be considered based on the CCP and SCCM-ASPEN Critical Care guidelines.[4,9] The formula should contain fish oils to provide a high ω-3FA content, borage oil to provide GLA, and increased antioxidant vitamin content. Delayed gastric emptying is associated with high-fat diets and must be considered when evaluating possible benefits and adverse effects of high-fat EN. This applies to both IMP and routine pulmonary formulas. Abdominal distension, increased gastric residuals, nausea, and vomiting can result from delayed gastric emptying. N.R. has his feeding tube placed in the small bowel, so delayed gastric emptying is not a concern. However, the potential to overwhelm pancreatic lipase activity resulting in fat malabsorption should be considered when a high-fat load, especially long-chain triglycerides, is delivered into the small bowel. Continuous infusion is more likely to be tolerated than other, more rapid delivery methods in most patients. With continuous feeding, EN can continue at full support even if N.R. undergoes rotation to a prone position for his ARDS, although a reverse Trendelenburg position is suggested with the prone position.[39] In the reverse Trendelenburg position, the head is higher than the feet, which is equivalent to raising the head of the bed, as suggested to reduce aspiration in patients in a supine position. The cost of routine pulmonary formulas is typically slightly higher than for standard polymeric formulas, whereas IMP formulas tend to cost significantly more.

RENAL FAILURE

Case 37-3, Question 3: N.R. has been in the ICU for 10 days. His ARDS has improved; however, he now has acute kidney injury and hemodialysis will start today. Morning laboratory results include the following:

Sodium, 131 mEq/L
Potassium, 5.9 mEq/L
BUN, 85 mg/dL
SCr, 4.0 mg/dL
Glucose, 110 mg/dL on an insulin drip
Magnesium, 2.9 mg/dL
Phosphorus, 5.8 mg/dL
WBC, 9.7 × 10^3/mL
Hgb, 11.4 g/dL
Hct, 34.3%

An EN formula for renal failure is ordered. How do the nutrient components in renal formulas differ from standard polymeric EN formulas? Is a renal formula appropriate for N.R.?

Two types of EN formulas for renal disease/injury are available, balanced amino acid and essential amino acid-enriched ones. Both are calorically dense (1.8–2 kcal/mL) to limit fluid provision and contain reduced potassium, phosphorus, and magnesium content.

Balanced amino acid polymeric enteral formulas designed for renal failure or renal insufficiency are the standard for hospitalized patients with impaired renal function. These formulas are not enriched with essential amino acids. The protein content varies from high (for patients with increased nitrogen losses from dialysis) to low (typically used for patients who are nondialyzed). Many critically ill patients receiving dialysis for acute kidney injury tolerate a nonrenal formula; however, those with elevated serum potassium, phosphorus, or magnesium concentrations generally require a renal formula to control electrolyte levels. Based on his electrolytes, N.R. will require a renal formula, at least initially. A polymeric formula with high-protein content (eg, NPC:N 120:1–100:1, 17%–20% calories from protein) would be appropriate given the plan for dialysis, although a slightly lower protein formula would be acceptable as well. The choice would depend on protein provided by the formula with low potassium, phosphorus, and magnesium content on

formulary. Polymeric renal formulas meet 100% of the DRI with <2000 mL/day.

Highly specialized formulas with enriched essential amino acid content, the second type of renal formula, are based on the theory that recycling of urea nitrogen for nonessential amino acid synthesis reduces the accumulation of BUN.[36] However, clinically significant recycling of nitrogen and incorporation into nonessential amino acids does not appear to occur. Currently available essential amino acid–enriched formulas such as Renalcal® (Renalcal Nestle Health Sciences, Vevey, Switzerland, contains two-thirds essential amino acids combined with one-third nonessential amino acids) are not intended as the only source of nutrition, but may be appropriate to supplement the diet of patients with chronic renal failure for whom dialysis is not an option. Use should be limited to no more than 2 to 3 weeks, because hyperammonemia and metabolic encephalopathy have been associated with longer use. These formulas are not appropriate for patients with acute kidney injury, such as N.R., or for those receiving dialysis.

Modular Components

Case 37-3, Question 4: After several days on the renal formula (NPC:N ratio, 113:1), there are indications that N.R.'s protein intake should be higher. Serum electrolytes today include the following:

Sodium, 137 mEq/L
Potassium, 4.9 mEq/L
Phosphorus, 5.2 mg/dL
Magnesium, 2.7 mg/dL

What are the options for increasing protein provision?

N.R. is receiving a renal formula with high-protein content based on 18% of calories from protein (NPC:N ratio of 113:1). There are no very high-protein formulas with low potassium, phosphorus, and magnesium content on the market; therefore, a very high-protein formula will provide significantly more of these electrolytes than N.R.

currently receives. His current serum levels of the renally eliminated electrolytes are near the upper end of acceptable and would likely rise if the EN is changed to a nonrenal formula. Using a lower potassium concentration in the dialysis bath might keep serum potassium within an acceptable range. Addition of a phosphate binder to the medication regimen could be considered; however, the risk of tube occlusion may be increased with a phosphate binder. A better option is to provide additional protein from a modular protein component, although this can also increase the risk of tube occlusion if not administered properly.

Modular components are individual nutrient substrates, or combinations of two substrates, designed for addition to oral diets or enteral formula regimens. They provide only the macronutrient(s) without electrolytes or vitamins, and should only be used to supplement a diet or an EN, not as a sole source of nutrition. Protein modules are powders containing 3 to 5 g protein/tablespoon. Most protein modules are intact protein. Arginine and glutamine are available as individual packets to allow supplementation as a single amino acid. Glucose polymers are used to supplement calories as carbohydrate. They do not increase osmolality or alter food or formula flavor. Powdered carbohydrate modules contain 20 to 30 kcal/tablespoon, whereas liquids contain 2 kcal/mL. Protein and carbohydrate modular components typically are mixed with water and administered through the feeding tube rather than being mixed directly into the formula. Additional fat can be provided as 50% safflower oil emulsion (Microlipid®, Nestle Health Science, Vevey, Switzerland) or as MCT oil. A combination carbohydrate and fat modular product is available if both sources of calories are appropriate. A modular fiber product containing soluble fiber in the form of partially hydrolyzed guar gum is also available.

Glucose Control Formulas

CASE 37-4

QUESTION 1: T.L., a 49-year-old female, is admitted to the hospital secondary to dehydration and for a GI workup related to a 15-pounds (6.80-kg) unintentional weight loss during the past month. She states she has been unable to eat for 8 days owing to continual nausea, although she reports no vomiting. T.L. received IV fluids in the ED and currently has 0.9% sodium chloride infusing at 125 mL/hour. Past medical history includes hypertension, hyperlipidemia, gastric reflux, and diabetes mellitus type 2. T.L. is 69 inches (175.26 cm) tall and her admit weight is 275.58 pounds (125 kg). Laboratory values from this morning show the following results:

Glucose, 245 mg/dL
BUN, 18 mg/dL, down from 35 mg/dL in the ED
SCr, 1.1 mg/dL, down from 2.3 mg/dL in the ED
Sodium, 140 mEq/L
Potassium, 4.2 mEq/L
Chloride, 105 mEq/L

Her small-bowel follow-through study indicates severely delayed gastric emptying. A feeding tube is to be placed into the small bowel for a trial of enteral feeding.

Should a "glucose control" or "diabetic" formula be used for initiating tube feedings in T.L.? How do formulas for glucose control differ from standard polymeric EN formulas?

No ideal macronutrient distribution has been identified for meals intended for patients with diabetes mellitus, and general dietary guidelines for healthy eating are considered appropriate.[40] However, specialty formulas for patients with diabetes mellitus, known as diabetic formulas, do not necessarily follow this recommendation. Diabetic formulas have caloric distributions of 33% to 40% carbohydrate, 42% to 49% fat, and 16% to 22% protein. The carbohydrate content is lower, and the fat content is higher than in most standard polymeric formulas. High MUFA sources (eg, high oleic oils, canola oil) predominate to provide >60% of fat as MUFAs. The source and type of carbohydrates in diabetic formulas vary, with a predominance of more complex and slowly digestible carbohydrates (ie, oligosaccharides, isomaltulose, fiber) with a low glycemic index. Fiber sources associated with improved glycemic control, mainly soluble fibers (ie, vegetable, gums, inulin, FOS) but also soy polysaccharide, are included in these formulas to help

minimize postprandial hyperglycemia. Fiber content ranges from 10.7 to 15.2 g/1000 calories, and the recommended fiber intake of 25 to 38 g daily generally can be achieved with <2000 kcal/day.[17]

Multiple studies comparing diabetic formulas to standard EN formulas providing equal calories and protein have been conducted. Diabetic formulas have been shown to improve fasting blood glucose, lower insulin requirements, and lower glycosylated hemoglobin concentration.[41,42] Effects on total cholesterol and triglyceride concentrations do not appear to be significant, despite their high-fat content. However, many studies have been of low methodologic quality, and most have been in ambulatory or nonacute care settings and of short duration. For hospitalized patients with hyperglycemia, no well-designed clinical trials of adequate size were found to make a recommendation regarding use of diabetic formulas in the ASPEN guidelines regarding adults with hyperglycemia.[43]

T.L. could receive either a diabetic formula or a standard formula. Glucose control may be better with a diabetic formula; however, the ASPEN guidelines found inadequate data to make a recommendation regarding use of diabetic formulas in hospitalized patients with hyperglycemia.[43] Either a diabetic or standard formula would be acceptable for T.L. based on available data. Problems with delayed gastric emptying or fat malabsorption must be weighed against possible benefits of improved glucose control with diabetic formulas. These problems are of minimal concern for T.L. because she is being fed into the small bowel and her history does not suggest fat malabsorption. Treatment goals for EN in patients with diabetes mellitus should include individualization of macronutrient composition, avoidance of excess calories, and maintenance of euglycemia.[41–43] T.L. may benefit from a treatment plan that includes gradual weight loss, and this may influence the decision of whether to use a diabetic formula or a very high-protein formula that would permit lower total calories while still providing adequate protein.

MONITORING ENTERAL NUTRITION SUPPORT

Case 37-4, Question 2: What types of complications can occur with tube feeding? What steps can be taken to prevent complications in T.L., and how should she be monitored for complications?

Appropriate monitoring of patients receiving EN is essential to recognize and prevent complications. Complications can be divided into three groups: mechanical, metabolic, and GI (**Table 37-5**).

Table 37-5
Complications of Tube Feeding

Complication	Cause/Contributing Factor	Treatment/Prevention
Mechanical Complications		
Aspiration	Deflated tracheostomy cuff	Inflate tracheostomy cuff before feeding; keep inflated 1 hour after feeding; consider small-bore feeding tube placed past the ligament of Treitz.
	Displaced feeding tube	Reinsert tube, check placement; consider hand restraints or feeding tube bridle.
	Reduced gastric emptying	Check residuals every 4–6 hours for gastric tube; raise head of bed 30–45 degrees; use lower fat formula; use prokinetic medication; use small-bowel feeding tube.
	Lack of gag reflex; coma	Place feeding tube into jejunum; keep head of bed elevated to 45 degrees; provide continuous feeding.
Nasal or pharyngeal irritation or necrosis; esophageal erosion; otitis media	Large-bore, polyvinyl chloride tube for long periods of time	Reposition tube daily, change tape; use smaller bore tube; position tube to avoid pressure on tissues; moisten mouth and nose several times daily.

Complication	Cause/Contributing Factor	Treatment/Prevention
Tube obstruction	Poorly crushed medications	Crush medications thoroughly, dissolve in water; consider using liquid medications; check compatibility of medication with tube and formula.
	Inadequate flushing after medications or thick formula	Flush tube with 50–150 mL of water after medications or thick formula and every 4–6 hours with 30 mL minimum.
	Poorly dissolved or mixed formula	Use blender to mix powdered formula (check manufacturer's mixing guidelines); use ready-to-use formula.
	Formula mixed with low-pH substance	Avoid checking gastric residuals when safe to do so; use larger diameter tubes when checking residuals; avoid administering acidic medications through small-diameter tubes; consider a nonacidic therapeutic alternative; flush with a minimum of 30 mL water before and immediately after medication administration.
Gastrointestinal Complications		
Nausea, vomiting, distension, cramping	Too rapid administration	Slow administration rate; change bolus to intermittent infusion.
	Osmolarity too high; intolerance to volume of formula	Use isotonic formula; increase the number of bolus or intermittent feedings so the volume per feeding is reduced, or change to continuous infusion; change to a more calorically dense formula if volume is the major problem (osmolarity will likely increase with higher caloric density).
	Gastric retention; poor GI motility	Place feeding tube distal to the pylorus; consider a promotility agent, such as metoclopramide; evaluate medications and change those possibly contributing to gastric dysmotility, if possible.

Complication	Cause/Contributing Factor	Treatment/Prevention
Dumping syndrome (weakness, diaphoresis, palpitations)	Hyperosmolar load bolused or infused rapidly into the small bowel	Do not bolus into the small bowel; temporarily decrease continuous infusion rate and gradually increase rate after symptoms subside; use an isotonic formula.
	Rate or volume of feeding increased too fast	Temporarily decrease continuous infusion rate or volume of intermittent or bolus feeding, and gradually increase rate after symptoms subside.
Diarrhea	Atrophy of microvilli; malabsorption related to a disease process (eg, pancreatitis, short-bowel syndrome, Crohn disease)	Use an oligomeric formula until absorption improves; use a relatively isotonic and advance slowly; use a formula low in long-chain fatty acids when fat is malabsorbed and/or consider pancreatic enzymes.
	Hypertonic formula	Change to a lower osmolarity formula.
	Dumping syndrome	See dumping syndrome entry in this table.
	Rapid advancement of formula volume	Temporarily reduce rate or volume, then advance slowly; consider enteral pump for better control of administration rate.
	Lactose intolerance	Change to lactose-free formula if previously using lactose-containing formula; evaluate lactose content of medications and supplemental foods, if patient is not strict NPO.

Complication	Cause/Contributing Factor	Treatment/Prevention
	Contaminated formula	Hang fresh formula every 4–6 hours when using an open administration system; do not add fresh formula to volume remaining in the feeding container; change the formula container and tubing daily; follow clean/aseptic technique when working with the formula or feeding tube; minimize manipulation of the feeding tube; consider changing to a closed enteral system; avoid powdered formulas requiring reconstitution.
Gastrointestinal Complications		
	Medications; antibiotics; magnesium-containing antacid; high-osmolarity liquid dosage forms	Check stool for *Clostridium difficile* and treat if present; consider probiotic agent; administer antidiarrheal if not contraindicated; consider alternative therapy such as histamine-2 blocking agent or proton-pump inhibitor; use calcium-based antacid; reduce dose or divide dose into 3–4/day, when feasible to do so; dilute medication with water before administrations; consider alternative dosage form (transdermal, IV); change to crushed tablet and use appropriate precautions to avoid tube occlusion.
Constipation	Inadequate fluid or free-water intake	Increase volume and/or frequency of tube flushes to increase fluid intake; change to a formula with lower caloric density, if possible.
	Inadequate fiber intake	Change to a formula with fiber or with a higher fiber content; administer fruit juice or bulk-forming laxative (eg, psyllium) using caution to prevent tube occlusion.
	Fecal impaction	Administer stool softener daily using caution to prevent tube occlusion if administered via the tube.

Complication	Cause/Contributing Factor	Treatment/Prevention
	Poor gastric/GI motility	Encourage ambulation; consider promotility agent.
	Medications, especially narcotics and anticholinergics	Use lowest effective dose of medication and transition to an alternative medication with fewer constipating effects, if possible.
Metabolic Complications		
Hyperglycemia, glycosuria (can lead to dehydration, coma, or death)	Stress response; diabetes mellitus	Monitor finger-stick glucose every 6 hours, use sliding scale insulin plus appropriate routine insulin (eg, insulin drip in critically ill).
	High-carbohydrate formula	Change formula.
	Drug therapy (steroids)	Monitor intake and output accurately.
Excess CO_2 production (high RQ)	High percentage of carbohydrate calories or excess calories from any source	Reduce total calories to avoid overfeeding; consider formula with higher fat calories.
Hyponatremia	Dilutional (fluid excess, SIADH); inadequate sodium intake; excess GI losses	Use full-strength formula or change to 1.5–2 kcal/mL formula; add salt to tube feeding (1 tsp–2 g Na—90 mEq); use diuretics if appropriate; replace GI losses.
Hypernatremia	Inadequate free-water intake	Use 1 kcal/mL formula; monitor intake and output accurately; temperature and weight daily; increase flush volume.
	Excess water losses (diabetes insipidus, osmotic diuresis from hyperglycemia, fever)	Correct hyperglycemia and the cause of fever or diabetes insipidus.

Complication	Cause/Contributing Factor	Treatment/Prevention
Hypokalemia	Medications (diuretics, antipseudomonal penicillins, amphotericin B)	Monitor serum potassium; give PO or IV potassium replacement PRN.
	Intracellular or extracellular shifts (insulin therapy, acidosis)	Correct underlying problem.
	Excess GI losses (NG suction, small-bowel fistula, diarrhea)	Routinely provide potassium in replacement fluid.
Hyperkalemia	Potassium-sparing medications (triamterene, amiloride, spironolactone, ACE inhibitors); potassium-containing medications (penicillin G potassium)	Monitor serum potassium; change to medications without potassium-sparing effect or without potassium salts.
	Renal failure	Monitor renal function; change to formula with lower potassium content.
Hypercoagulability	Warfarin antagonism owing to formula	Hold formula 1 hour before and after warfarin dose; monitor coagulation status; check vitamin K content and change to lower vitamin K, if appropriate (most EN formulas are not high in vitamin K).

ACE, angiotensin-converting enzyme; EN, enteral nutrition; GI, gastrointestinal; IV, intravenous; NG, nasogastric; NPO, nothing by mouth; PO, oral; PRN, as needed; RQ, respiratory quotient; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Mechanical Complications

The major mechanical complications are EAD occlusion and aspiration. Mechanical complications often can be avoided with good nursing technique and careful observation of feeding tolerance. Adequate flushing is essential to prevent EAD occlusion. Flushing with 30 mL of water every 4 hours during continuous feeding or before and after intermittent feedings is recommended.[21] Flushing must also occur before and after medication administration and after withdrawal of gastric contents. T.L.'s EAD should be flushed using these guidelines. Frequent assessment of tube placement by auscultation and location of markings on the EAD is important to prevent pulmonary aspiration of the formula secondary to displacement of the tube into the esophagus or pharynx. Tube placement should be evaluated every 4 to 6 hours with continuous feeding, or before each intermittent or bolus feeding.[3,21,22]

Withdrawal of gastric contents through a gastric tube using a syringe allows evaluation of volume in the stomach (gastric residual volume [GRV]). The reliability of GRV measurements has been questioned, and data for effectiveness as a monitor for aspiration risk are conflicting.[21,22] In combination with other parameters, such as vomiting, sedation, sepsis, and use of vasopressor agents, high GRVs may correlate with worse patient outcomes. Conversely, measurement of GRVs is associated with increased risk of EAD occlusion and reduced EN delivery because of inappropriate stopping of EN. Routine GRV measurement is no longer performed in many settings, including in ICUs; however, it may be appropriate in conjunction with other indicators of EN intolerance for some patients based on risk versus benefit.

When GRV is used, EN should not be held unless residuals are somewhere from 250 to 500 mL per CCP guidelines, or >500 mL per SCCM-ASPEN Critical Care guidelines.[4,9,21] A recent systematic review found no increase in GI complications with GRVs of 500 mL compared to that of 250 mL, but nutrient delivery was better using 500 mL GRV.[44] Jejunal feeding tube placement should be considered when GRV is consistently >500 mL. In addition, use of a

promotility agent, preferably metoclopramide (10 mg IV four times daily), should be considered when GRV is >250 mL after a second check.[4,9,21] These agents may improve feeding tolerance and formula delivery, and the risk of aspiration may be decreased, although the benefit of these agents has been questioned. If the feeding is held because of a high GRV, hourly evaluation of the GRV is recommended until the volume is <200 to 250 mL, and the feeding is restarted. The fluid withdrawn for GRV assessment may be infused through the tube back into the stomach to minimize electrolyte imbalances; however, CCP guidelines suggest either discarding GRV or feeding back up to 250 mL may be acceptable.[9] Elevating the head of the bed to 30 to 45°, with 45° preferred in patients who are critically ill, during and after feedings also is recommended to reduce the risk of aspiration.[4,9,21,22] Methylene blue or blue food coloring should not be added to the formula to evaluate reflux or aspiration of formula because of reports of mortality associated with this practice.[4,21,22] The use of glucose oxidase test strips to detect the presence of enteral formula in tracheobronchial secretions lacks sensitivity and specificity, and the results have not been shown to correlate with aspiration; thus, it is not a recommended practice.[22] The small bowel does not serve as a reservoir for residuals; therefore, GRV should not be checked through EADs placed in the postpyloric region, such as T.L.'s jejunal feeding tube.

Metabolic Complications

Major metabolic complications of EN include hyperglycemia, electrolyte abnormalities, and fluid imbalance. Although rigorous studies evaluating monitoring frequency are lacking, regular biochemical determinations similar to those used for PN are recommended to identify and correct metabolic abnormalities before severe abnormalities occur. Baseline values for serum glucose, SCr, BUN, and electrolytes should be available to guide selection of the enteral formula. The few baseline laboratory results available for T.L.

may be adequate as a baseline, but additional laboratory parameters will be necessary as part of the monitoring regimen once EN starts.

Capillary glucose measurements every 6 hours or an insulin protocol is recommended before EN starts in patients with diabetes or hyperglycemia or if hyperglycemia is anticipated. Given T.L.'s history of diabetes and a baseline glucose >200 mg/dL, diligent monitoring and treatment of her hyperglycemia is warranted even before EN starts. T.L. will require long-term glucose monitoring; however, routine glucose monitoring in patients who are not diabetic can be stopped once a stable euglycemic state is established with EN at the goal volume and infusion regimen.

A basic metabolic panel ([BMP]; serum glucose, sodium, potassium, chloride, bicarbonate, calcium, BUN, and SCr) is generally checked daily after feeding starts in critically ill patients and those at risk for electrolyte abnormalities or renal dysfunction. More stable patients may have serum glucose and electrolytes (sodium, potassium, chloride, bicarbonate) monitored rather than a BMP. During the first week of EN, whether initiated in the hospital or alternate site (SNF or at home), a BMP, phosphorus, and magnesium should be monitored a minimum of two to three times weekly in patients with weight loss; once or twice weekly may be adequate if there is no weight loss. Monitoring frequency can be reduced once tolerance to tube feeding is established and there are no metabolic abnormalities. Daily BMP for a minimum of 4 to 5 days is probably best for T.L. considering her recent dehydration. Daily phosphorus and magnesium also should be considered for a few days in T.L. because of her significant weight loss and risk of refeeding syndrome (see Chapter 38, Adult Parenteral Nutrition, for a more detailed discussion of refeeding syndrome). Despite being obese, T.L. is at risk for electrolyte abnormalities associated with refeeding syndrome.[15] Failure to monitor T.L. and replace electrolytes as necessary could result in serious electrolyte abnormalities. Once T.L.'s BMP, phosphorus, and magnesium are stable, the frequency of monitoring could be reduced to once or twice weekly. Critically ill patients generally require daily or every other day monitoring while in the ICU. For patients receiving long-

term EN, the frequency of laboratory monitoring gradually is decreased. Laboratory monitoring should be done once or twice yearly in stable patients without significant medical problems. Patients who have medical problems that can affect nutrient, electrolyte, or trace element requirements or tolerances should be monitored as appropriate to the medical condition.

Weight and fluid status are important parameters to monitor throughout EN therapy, especially in patients with unusual fluid or nutrient losses, an inability to recognize thirst, or inability to voluntarily adjust their oral fluid intake. For hospitalized patients, weight is primarily a reflection of fluid status, and total fluid can typically be adjusted by the number of times the feeding tube is flushed daily and the volume of each flush. In long-term patients, fluid is an important parameter for adequacy of caloric intake. Consistent increases or decreases from the required enteral formula volume can have significant effects on weight. For example, a weight loss of 12.5 pounds (5.67 kg) over the course of a year can be expected if the daily intake of a 1-kcal/mL formula is <120 mL required. Changing caloric density of the formula may be a potential option to help manage fluid when altering the number or volume of flushes is not adequate for fluid control. For patients with a stable fluid status, the week-to-week weight change can be used as an indicator of appropriate caloric intake. An upward trend in weight (eg, ≥3 consecutive weeks with an increase) may indicate a need for fewer calories unless weight gain is a goal. A downward trend may indicate a need to increase caloric intake, unless weight loss is desired. A plan that includes gradual weight loss is appropriate for T.L. based on her obesity.

Nursing protocols for patients receiving EN should include monitoring of respiratory status. Coughing or respiratory distress may be indications of aspiration or other developing respiratory problems. Vital signs also may provide clues to aspiration or other problems, such as dehydration, fluid overload, or infection.

In addition to monitoring for complications, routine monitoring for response to EN and changes in nutritional status is necessary for patients who are receiving EN for both short term and long term.

Chapter 35, Basic Nutrition and Patient Assessment, discusses parameters used for nutrition assessment and ongoing monitoring of nutritional status.

Gastrointestinal Complications

Assessment of GI symptoms is important for determining EN tolerance because GI complications are frequently associated with tube feeding. Abdominal distension and bloating should be evaluated at least every 8 hours while T.L. is hospitalized. Abdominal distension may be an indication of accumulating formula. Gas formation secondary to lactose intolerance or rapid increases in fiber intake, and poor gastric emptying secondary to a high-fat formula, medications, recent surgery, critical illness, or an underlying disease such as diabetes are among the conditions associated with distension. When considerable distension is present, the formula should be held temporarily, and the patient evaluated further to rule out a contraindication to EN.

Nausea, vomiting, abdominal cramping, diarrhea, and constipation are other GI symptoms monitored as indicators of EN tolerance. T.L. has some of these symptoms associated with her gastroparesis, and disease-associated symptoms should not be confused with feeding intolerance. Vomiting creates the most immediate concern because tube displacement and pulmonary aspiration can occur. Nausea and vomiting commonly occur with severe gastric distension, poor gastric emptying during gastric feeding, GI tract obstruction, or poor GI motility. The prevalence of diarrhea in patients receiving EN differs considerably depending on the definition used, but diarrhea is one of the most difficult problems for patients and caregivers to address.[21,22] Predisposing illnesses, including diabetes mellitus, GI infections, pancreatic insufficiency, and malabsorption syndromes, are more likely to cause diarrhea in patients receiving EN than does the formula itself.[3,21,22] Concurrent drug therapy is another major contributor to diarrhea in tube-fed patients; up to 25% of patients treated with antibiotics experience diarrhea.[22] T.L. has type 2

diabetes; however, at this time, diarrhea has not been reported as a problem.

Formula-related GI infections could occur from contamination of an opened can or package. Sources of contamination include the water used for reconstitution or dilution, transfer to the delivery bag, formula kept in the delivery bag for a prolonged period, and poorly cleaned feeding bags or administration sets. Water used to flush the tube can also be a source of contamination; therefore, sterile water is recommended as the flush solution for patients who are immunocompromised.[21] Closed enteral feeding systems using ready-to-hang bags of formula decrease contamination by reducing manipulation of the bag and formula, and are commonly used in the hospital setting.

Bolus feeding into the jejunum can lead to diarrhea and abdominal cramping, as well as nausea and vomiting. Because T.L. is being fed into the jejunum, she should remain on a continuous infusion protocol. Initiation of EN with a hypertonic formula, a rapid rate of infusion or a large volume, and use of formula at refrigerator temperature are other factors often cited as causing GI symptoms. Although controlled studies have not supported these factors as significant contributors to GI intolerance, subjective evidence suggests they are important. Constipation is most likely to occur with long-term tube feeding in nonambulatory patients. Inadequate fluid intake and lack of fiber may be factors associated with constipation. Diabetic EN formulas contain fiber. However, if the decision is to use a very high-protein formula rather than a diabetic formula for T.L., a fiber-containing formula would be reasonable to use based on her known history.

MEDICATIONS AND NUTRITION BY ENTERAL ACCESS DEVICE

Patients receiving EN often receive medications through the same EAD. Adverse effects caused by changes in pharmaceutical dosage forms, and alteration of medication pharmacokinetics and pharmacodynamics are among the potential problems, as is EAD occlusion.[16,45–48] Interactions related to pharmacologic or physiologic effects of medications or enteral nutrients also may occur. For this reason, oral medication administration should be considered unless a strict NPO status is required. T.L. has severe gastroparesis, a diagnosis not requiring a strict NPO status; however, the medical team is concerned that medications administered by mouth may have erratic absorption and poor efficacy because of delayed gastric emptying. Medications are ordered to be administered through T.L.'s EAD.

Case 37-4, Question 3: T.L. has been receiving EN for 5 days and has been at goal rate for 2 days. Laboratory evaluation today shows the following:

Sodium, 137 mEq/L
Potassium, 2.8 mEq/L (decreased from 3.7 mEq/L yesterday, 4.1 mEq/L the previous day, and 4.8 mEq/L when tube feeding started)
Chloride, 97 mEq/L
Calcium, 7.8 mg/dL
Magnesium, 1.3 mEq/L (decreased from 2.5 mEq/L 2 days ago)
Phosphorus, 2.5 mg/dL (decreased from 4.7 mg/dL 2 days ago)
Albumin, 2.4 g/dL

Micro-K® (10 mEq KCl/capsule) has been ordered as five capsules via feeding tube along with calcium carbonate (260-mg elemental calcium/tablet) as two tablets twice daily via feeding tube. Orders were also placed in the chart for warfarin. She was placed on a heparin drip yesterday for a newly diagnosed deep vein thrombosis (DVT) in her left leg, despite prophylactic heparin therapy since admission. Home medications are to be restarted, including enteric-coated aspirin, 81 mg daily; famotidine tablet, 20 mg twice daily; simvastatin tablet, 20 mg daily; metoprolol succinate tablet, 95 mg daily; and verapamil capsule, 240 mg daily. How should T.L.'s medications be administered when she is receiving EN?

Medication Selection

Solid dosage forms are a challenge to administer by EAD. Crushing a medication and mixing the powder in water results in an altered pharmaceutical dosage form, and this may affect its efficacy or patient tolerance. Liquid dosage forms are generally recommended for administration through an EAD, but they are not without problems, and a liquid dosage form may not always be the best choice. For example, liquid dosages may contain sorbitol, which is used as a sweetening excipient but is also an approved laxative. Liquids should be diluted at a minimum of 1:1 with water before administration to avoid coating the tube interior. High-viscosity liquids, such as suspensions, should be diluted 3:1 with water, and up to 10:1 if hyperosmolar.[16,45] Pharmaceutical syrups with a pH of ≤4 must be used with caution because immediate clumping and tackiness of formulas mixed with the syrups have been reported.[45] For medications not available in liquid form, a therapeutically equivalent medication in a liquid form can be considered. Extemporaneous preparation of a liquid also may be considered, but can increase cost significantly. Medications in a soft gelatin capsule are best avoided for administration through an EAD. If there is no alternative, the capsule can potentially be dissolved in warm water, but dissolution is slow and must be complete to avoid EAD occlusion. The safety and efficacy of simple compressed tablets are typically not affected by crushing and dissolving in water immediately before use; however, this is an off-label use of the medication.[16] The U.S. Food and Drug Administration (FDA) does not require data on EAD delivery of medications, nor the effects of enteral formula on a medication before drug approval. Simple compressed tablets can be crushed to a fine powder, then dissolved or suspended in water for administration. Powder in hard gelatin capsules can be poured into a container (eg, medicine cup, capped EAD-compatible syringe), then diluted with water, and mixed thoroughly before administration through an EAD. Failure to adequately suspend or thoroughly dissolve any of these dosage forms in water before administration can result in EAD occlusion. Dispersible tablets can be placed into a capped EAD-compatible syringe and dilutant (usually purified water) added to allow dispersion before the medication is administered from

the syringe into the EAD. Some medications appear to be particularly troublesome for administration through an EAD. Calcium salts, iron salts, lansoprazole, omeprazole, multivitamins, pentoxifylline, potassium chloride, phenytoin, protein supplements, sucralfate, and zinc salts were identified by nurses as the products most frequently contributing to EAD occlusion.[46] T.L. has both calcium and potassium ordered today.

Calcium carbonate is a simple compressed tablet that can be crushed, suspended in 30 mL of water, and administered through the EAD. Risk of occlusion from an inadequately crushed tablet may be decreased by use of calcium carbonate suspension (500-mg calcium/5 mL), if available. Administration of either crushed and suspended tablets or commercial suspension requires flushing the EAD with 15 to 30 mL of water before and after medication administration.[21] Diluting the suspension at least 1:1 with water, preferably 3:1, and flushing with 50 to 150 mL may be advisable because suspensions may otherwise coat the tube. The appropriateness of calcium supplementation should be questioned, however, because T.L.'s serum calcium concentration is within normal limits after correction for her low serum albumin concentration; an ionized calcium concentration could be considered if hypocalcemia is truly a concern. Administering any medication via the EAD may occlude the tube; therefore, administering an unneeded medication through the EAD is an unwarranted risk. For calcium, and for electrolytes in general, only oral and IV dosage forms are available, so the easiest and most cost-effective route is an oral dosage form via EAD if T.L. cannot take oral medications by mouth.

Potassium supplementation is ordered because of T.L.'s low serum potassium. Potassium should have been considered yesterday because the serum level has been decreasing since tube feeding began. The selected potassium supplement is inappropriate for administration by EAD because Micro-K® (KV Pharmaceutical for Ther-Rx Corporation., St. Louis, MO) is a slow-release product. Crushing any type of slow-release or sustained-release product destroys slow-release mechanisms, resulting in the immediate

release of several hours' worth of the medication at one time. An exaggerated therapeutic response may be seen initially, followed by a loss of response part way through the dosing interval. Deaths have occurred when sustained-release or long-acting products are crushed before administration; therefore, these dosage forms should not be crushed.[49] Instead, an immediate-release dosage form should be used, with appropriate adjustment of dose and dosing interval, or an alternate administration route (eg, IV, suppository, transdermal patch) may be available. Potassium chloride powder for solution (three packets with 15 mEq KCl/packet) or liquid (10% KCl 35 mL, 15% KCl 25 mL, or 20% KCl 15–20 mL) should be ordered rather than the slow-release product. Dividing the potassium dose into two or three smaller doses and diluting each dose with 60 mL of water may be better tolerated. Giving 50 mEq of potassium as a single dose may cause nausea, vomiting, abdominal discomfort, or diarrhea. These symptoms might be mistaken as intolerance to EN, resulting in the tube feeding being stopped temporarily. The larger fluid volume for administration also may help reduce the GI irritation associated with potassium doses.

Potassium supplementation could also be partially accomplished by changing part of the potassium ordered to potassium phosphate, which is available as a 250-mg capsule that provides 8.1 mmol of phosphate and 14.2 mEq of potassium. T.L. shows signs of refeeding syndrome, with phosphorus and magnesium slightly less than the normal range and having decreased significantly during the past 2 days.[15] Supplements should be started today so that smaller daily quantities can be used before electrolytes are critically low. This may decrease the risk of diarrhea and GI upset caused by the administration of oral phosphate or magnesium. Contents of each potassium phosphate capsule are designed to be dissolved in 75 mL of water for administration, so dissolution is not a concern. One potassium phosphate capsule twice a day plus KCl liquid to provide 20 mEq potassium is therapeutically the same potassium dose as is ordered currently. The liquid KCl dose should be separated from the potassium phosphate to minimize GI effects.

Magnesium supplementation could be accomplished with a magnesium oxide tablet (400 or 500 mg) administered two to four times daily. These are simple compressed tablets that can be crushed and suspended for administration via EAD. An alternative would be magnesium hydroxide suspension 5 mL two to four times daily. Magnesium doses are distributed through the day to reduce the risk of diarrhea. The EAD must be flushed adequately before and after each dose of electrolyte replacement. The flush volume should be a minimum of 15 mL, although 30 mL or more after the magnesium dose may be better to ensure the electrolyte preparation is out of the tube. The volume of other tube flushes can be adjusted to limit the total fluid intake to the estimated requirements. It can be difficult to provide large quantities of potassium, phosphate, and magnesium via EAD secondary to the GI intolerance they cause. Therefore, IV electrolyte replacement may be necessary if intracellular depletion is extensive and T.L. does not tolerate oral electrolyte replacement.

Famotidine is a simple compressed tablet that can be crushed. However, both the verapamil and metoprolol dosage forms ordered for T.L. contain multiple doses intended to be slowly released. The once-daily dosing schedule helps identify these two medications as slow-release products, and, for metoprolol, the succinate salt is also a clue because this is different from other dosage forms of metoprolol. Both verapamil and metoprolol should be changed to immediate-release dosage forms if T.L. cannot take them by mouth. The dose and frequency of dosing will need to be adjusted to reflect the immediate-release dosage form.

Enteric-coated tablets are designed to release medication in the small bowel because the medication is either acid labile or irritates the stomach. Protection for the medication or stomach is lost when enteric-coated tablets are crushed and delivered via EAD into the stomach, resulting in decreased efficacy of the medication or increased gastric irritation. When an irritating medication must be given by tube into the stomach, diluting the medication in at least 60 mL of water is recommended.[45] T.L. has enteric-coated aspirin ordered for administration into a jejunal EAD. The enteric coating is

designed to dissolve in the small bowel, and could be dissolved with bicarbonate solution before administration into the small bowel. However, it would be better to use a noncoated tablet for his aspirin dose. If enteric-coated beads, such as those found in several proton-pump inhibitor dosage forms, are to be administered through an EAD, use of an acidic liquid (eg, fruit juice) helps prevent the enteric coating from becoming sticky and adhering to the inside of the tube. This should only be considered for a large-bore EAD, such as a gastrostomy, or the beads will occlude the tube. Film-coated tablets may also cause problems when crushed because the coating does not crush well and becomes sticky in water; however, thinly coated products may crush and disperse in water. T.L.'s simvastatin has a film coating and may be a problem to crush and administer through her EAD.

Administering buccal or sublingual dosage forms via EAD may result in altered absorption or destruction of the medication by stomach acid. These dosage forms are not intended to be swallowed; thus, a conscious patient who is unable to swallow medications may still be able to use a buccal or sublingual product as intended. If not, therapeutically equivalent medications (eg, isosorbide dinitrate rather than sublingual nitroglycerin) or an alternate route of administration (eg, nitroglycerin ointment or transdermal system rather than sublingual nitroglycerin) should be used. A listing of medications that should not be crushed is available at http://www.ismp.org/recommendations/do-not-crush.[50] Carcinogens, teratogens, or cytotoxic agents that should not be crushed are included in the list.

Pharmacokinetic parameters can be altered when medications are administered by EAD. T.L. has a jejunal tube, and delivering medication into the jejunum could affect bioavailability, although few studies address this issue. Medications taken orally are delivered to the stomach, where dissolution typically occurs for most dosage forms and hydrolysis of some medications may occur. Delivery into the small bowel may alter these processes, thereby affecting bioavailability. For instance, recovery of digoxin from intrajejunal dosing is higher than it is with oral administration, primarily because

of reduced intragastric hydrolysis.[45] Bioavailability of medications also can be affected by the presence of enteral formula in the GI tract. Medications affected by the presence of food are expected to be affected by the presence of formula; however, meal consistency (eg, liquid enteral formula versus solid meal) may alter medication effects, as can meal composition (eg, protein content, nutrient sources).[16] Generally, it is assumed that food effects apply to EN, although studies are seldom available. For example, it is assumed that administration of tetracycline-class medications with formula present will reduce bioavailability because of interactions with divalent cations. A similar interaction is expected between ciprofloxacin and enteral formula, although some evidence suggests that a mechanism other than binding with divalent cations is responsible for reduced ciprofloxacin concentrations with enteral feeding.[45] Numerous medications have been reported to be potentially troublesome when administered with EN; several are listed in **Table 37-6**.[16,45,46] The mechanism of such troubles/interactions are often poorly understood, but can include the EAD (binding of drug with the EAD), the enteral formula (chelation or complexation of drug with formula components such as divalent cations), or drug characteristics (solubility, pH). Without a clear understanding of the mechanism of interaction, various and sometimes conflicting methods of managing the interactions may be reported. The interaction of phenytoin and warfarin with EN is described in further detail in the following paragraphs.

Table 37-6

Examples of Drugs Frequently Reported to Interact With Enteral Nutrition

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]
Carbamazepine	Slow and variable GI absorption owing to solubility issues without EN; better absorption expected with food and slower gastric emptying (allows more time for dissolution). Jejunal administration may result in poorer absorption, likely related to solubility issues in the higher pH of the small intestine.	Data currently available do not support holding EN before or after drug administration. Suspension must be diluted a minimum of 1:1, although 3:1 is preferable.
Dolutegravir	Chelation or complexation with cations in EN or in water used for dilution	Dilute with mineral-free water. Hold EN for 2 hours before and after administration. Handle as a hazardous drug.

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]
Fluoroquinolones	Unclear if chelation or complexation with cations in EN is the primary reason for decreased drug concentrations. Interaction may not be class related, but, rather, depend upon individual drug hydrophilicity. Reduced bioavailability of ciprofloxacin and norfloxacin appears to be most significant with EN, followed by moderate reduction for levofloxacin, and slight reduction with ofloxacin. Bioavailability of gatifloxacin and moxifloxacin does not appear to be reduced in the presence of EN.	Data supporting holding of EN is limited. Holding EN for a minimum of 1 hour before and 2 hours after norfloxacin and ciprofloxacin does appear to minimize effects on bioavailability; some experts suggest holding EN for 2 hours both before and after drug administration. Data for holding EN for levofloxacin is conflicting; consider holding EN the same as for ciprofloxacin given moderate reduction in bioavailability with EN. Current data do not support holding EN for gatifloxacin or moxifloxacin. Ciprofloxacin suspension labeling states “Should not be administered through feeding or NG (nasogastric) tubes.”
Isoniazid	Isoniazid should be taken on an empty stomach (at least 1 hour before or 2 hours after a meal) to avoid decreased drug concentrations.	Limited data for EN; however, should consider holding EN for a minimum of 30 minutes before and 1 hour after drug administration. Based on limited data with other drugs, continuous tube feeding has effects on drug absorption similar to the nonfed state; thus, it may be possible to hold drug administration for a shorter time than with food to achieve the “empty stomach” effect. With bolus EN, it may be preferable to follow recommendations of no feedings for 1 hour before and 2 hours after drug administration.

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]
Levodopa	Protein content of formula may contribute to reduced drug efficacy/bioavailability owing to amino acid transport competition.	Hold EN for 2 hours before and after drug administration. When feasible, consider cyclic EN with formula administration overnight and drug administration during waking hours when therapeutic effects of the drug are most necessary.
Levothyroxine	Dissolution of tablets is poor. Drug may bind/adsorb to EAD. Different EAD materials (silicon, PVC, polyurethane) and drug exposure time (length and size of tube) could contribute to conflicting study results if binding/adsorption occurs.	Monitor for signs/symptoms of hypothyroidism and monitor thyroid stimulating hormone (sensitive thyrotropin test) concentration after starting or stopping EN therapy.

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]
Phenytoin	Drug has variable absorption because of solubility issues without EN. Proposed mechanisms of interaction: (1) pH-associated issues, which include: • dosage form issues (suspension, chewable tablets, capsule, IV formulation) • chemical form (phenytoin acid vs phenytoin sodium) • solubility (2) phenytoin binding to an EN component (3) phenytoin binding to the tubing/EAD	Data currently available do not support withholding EN around the phenytoin dose, although holding EN for an hour or more (commonly 2 hours) before and after phenytoin is still a common practice. Holding EN for 2 hours or more before and after the phenytoin dose does not reliably improve phenytoin concentrations. Suspension must be diluted a minimum of 1:1, although 3:1 is preferable. Therapeutic drug monitoring should be more frequent than without EN administration.
Voriconazole	Take on an empty stomach (at least 1 hour before or 2 hours after a meal) to reduce the risk of decreased drug concentrations. Maximum serum concentration and area under the curve are significantly reduced with high-fat meals.	Hold EN for a minimum of 1 hour before and after drug administration. Carefully weigh risk vs benefit of high-fat EN formulas such as pulmonary formulas and diabetic formulas.

Drug[a,b]	Potential Mechanism(s) of Interaction With EN	Recommendations Related to EN[c,d]
Warfarin	Several mechanisms have been proposed: (1) reversal of warfarin anticoagulation by vitamin K in EN (2) physicochemical interaction from binding or complexation of drug with a macromolecular component of EN, likely protein (3) binding/adsorption of drug to the EAD, particularly polyurethane feeding tubes	Data do not support vitamin K content of EN as a contributor to warfarin failure, or vitamin K restriction as a method to improve warfarin effect. Hold EN for at least 1 hour before and after drug administration. Limit exposure time to the EAD by diluting the drug in a small volume and administering rapidly, followed quickly by tube flushing. Monitor therapeutic response with INR when EN is started, stopped, or changed significantly.

EAD, enteral access device; EN, enteral nutrition; GI, gastrointestinal; INR international normalized ratio; IV, intravenous; PVC, polyvinylchloride.

[a]This is not an exhaustive list of drugs interacting with enteral nutrition (EN), but represents interactions more commonly reported in the literature. Caution is advised for any drug known to interact with cations such as calcium, magnesium, iron, zinc, selenium, and aluminum. Consider that effects of EN may differ from those of food, although effects with food may provide some guidance.

[b]When feasible, therapeutic alternatives should be considered. When the problematic drug is not changed, frequent monitoring for clinical signs/symptoms related to altered drug efficacy should occur when enteral nutrition (EN) is started, stopped, or changed. More frequent therapeutic drug monitoring should occur where feasible.

[c]Recommendations are in addition to the general recommendations for drug administration via enteral access device (EAD), including drug dilution and tube flushing (minimum of 15–30 mL of water before and after drug administration; 5–15 mL between drugs).

[d]When recommendations include holding enteral nutrition (EN) before or after the drug, it is imperative that EN administration directions account for the time EN is held and ensure the prescribed volume of EN is delivered. Volume-based protocols should be considered.

Phenytoin is troublesome to manage in patients receiving EN, but erratic absorption occurs without EN administration. Among the various methods suggested for managing reduced phenytoin concentrations, stopping formula delivery for 1 to 2 hours before and after the phenytoin dose has been widely used. Stopping EN around the phenytoin dose increases the risk of inadequate nutrient delivery. Stopping EN is not supported by current data.[16] Adequate dilution and flushing before and after medication administration have also been advocated to reduce loss of the medication. Both of these actions are important and may improve phenytoin delivery. No method, however, clearly prevents low phenytoin concentrations; thus, monitoring of serum concentrations is important whenever EN is started or altered. Large-scale, controlled trials are needed to determine the most appropriate method for managing the phenytoin–EN interaction. When appropriate, changing to a therapeutic alternative to phenytoin avoids the interaction; however, carbamazepine has also been reported to be a problem with EN.

Warfarin can also be problematic to manage in patients receiving their medications via an EAD, and T.L. is to start warfarin for a newly diagnosed DVT. Reversal of warfarin anticoagulation by vitamin K is an important pharmacologic interaction. Although enteral formulas do contain vitamin K, the content of most enteral formulas is about the same as that found in a mixed diet. This amount is unlikely to interfere with anticoagulation, and the consistent vitamin K dose may improve maintenance of anticoagulation. Binding of warfarin to a macular molecular component of enteral formula (eg, protein) has been proposed to explain warfarin resistance with formulas containing low vitamin K content; others suggest that binding to the feeding tube itself may occur.[16,45] Stopping formula administration for an hour before and after warfarin administration appears to prevent this type of interaction. Flushing the EAD with at least 15 mL of water before and after warfarin administration, along with use of a small volume of water for dilution and rapid administration is also advisable.[16] Unfortunately, rigorous, randomized studies to provide evidence-based guidance for the management of this potential interaction are lacking. The risks, benefits, and cost of alternative

anticoagulation therapy should be evaluated if T.L. is not achieving anticoagulation goals within the expected warfarin dosage range.

Liquid dosage forms are often hypertonic. Diarrhea is a potential problem related to physiologic effects of hypertonic medications. Diluting hypertonic medications (eg, potassium chloride) with 30 to 60 mL of water before administration is usually adequate; however, the necessary volume to achieve a desired osmolality (eg, 300 mOsm/kg) can be calculated using medication osmolality, concentration, and dose.[16] Dividing the medication dose and separating doses by about 2 hours also decrease GI effects of hypertonic medications. In addition, selection of brands and dosage forms with minimal sorbitol can reduce the risk of diarrhea. Sorbitol is a nonabsorbed sugar alcohol found in many liquid dosage forms. Cumulative sorbitol doses >5 g can cause bloating and flatulence, whereas larger doses may act as a cathartic.[45]

Enteric Access Device Occlusion

Case 37-4, Question 4: T.L.'s EAD has occluded (clogged). What are the causes of EAD occlusion and how can occlusions be managed? What can be done to avoid occluding T.L.'s EAD in the future?

The incidence of EAD occlusion is 12.5% to 40%.[6,51] Pump malfunction, lack of periodic tube flushing, formula characteristics, and tube characteristics are non–medication-related factors affecting EAD occlusion. Important EAD characteristics include the inner diameter (bore size), tube material, and the arrangement and number of delivery holes (ports) at the distal end. The most important formula characteristic appears to be the protein source. In vitro studies suggest formulas with intact protein, particularly caseinates or soy, coagulate, and clump when exposed to an acidic pH, whereas formulas with hydrolyzed protein do not.[45]

Medication-related factors influencing EAD occlusion include the administration method, dosage form, pH, and viscosity. Medications must be crushed to a fine powder, mixed with water to form a smooth

slurry, and adequately diluted before administration. Medications admixed with formula have the greatest potential for occluding EADs owing to alteration of the texture, viscosity, or physical form of the medication or formula. Therefore, medications should not be admixed directly with formula. The enteral formula infusion should be stopped, and the EAD flushed with a minimum of 15-mL water before and after medication administration and with 15 mL between each medication.[21,45,51] Contact between medications and formula within the tube lumen should be limited to decrease the risk of occlusion. Each medication should be administered separately to reduce the risk of interactions.

When an EAD occludes, it must be replaced unless patency can be restored. Frequent EAD replacement disrupts nutrient delivery and increases patient discomfort as well as the cost of care. The initial treatment for EAD occlusion is to flush the tube with warm water using a large syringe, at least 20 mL but preferably 50 mL, to avoid generation of excessive pressure that could rupture the tube. When a specific cause for occlusion can be identified (eg, a specific medication) and physiochemical characteristics of the responsible product are known (eg, solubility, pH), it may be possible to select a more appropriate flush preparation than water. In most cases, however, use of an acidic or basic flush preparation could worsen the occlusion. Acidic liquids (eg, cranberry juice, diet soda, regular soda) may perpetuate or extend the occlusion, especially when coagulated proteins are the cause.[45,51] When water fails to restore patency, activated pancreatic enzymes may be effective. A product containing multiple enzymes, buffers, and antibacterial agents in a powder form (Clog Zapper™, Halyard Health, Inc. Alpharetta, GA) is commercially available. Alternatively, one crushed uncoated pancreatic enzyme tablet and one sodium bicarbonate tablet (325 mg) can be dissolved in 5 mL of warm water just before instillation into the occluded tube.[21,45,51] Several mechanical declogging devices are also commercially available.[51] Adherence to flush protocols and proper medication administration techniques are essential to maintain patency once tube patency is restored.

Transfer to Home on Enteral Nutrition

CASE 37-5

Question 1: J.B., a 77-year-old male, was admitted 2 days ago from an SNF for evaluation after he fell. He receives intermittent feedings through his PEG. The volume is 1680 mL (seven cans) daily. J.B.'s history indicates he was hospitalized ~7 weeks ago with an ischemic stroke and was discharged to an SNF (see Case 37-2, Question 1, 7). J.B.'s tube-feeding volume has increased from 1440 mL on discharge, but the formula remains the same (1.06 kcal/mL, 0.044 g protein/mL, 15 g fiber/1000 kcal polymeric formula). His weight has increased 4.41 pounds (2 kg) since hospital discharge, and his overall status has improved. Bone fractures have been ruled out, and J.B. is able to participate in physical therapy (PT). The PT consult indicates J.B. is appropriate for outpatient PT after hospital discharge. The swallow study performed this morning indicates J.B. must continue NPO for at least another 4 months when the swallow study will be repeated. J.B.'s daughter has made arrangements for him to move in with her family. She is concerned about insurance coverage for the EN therapy and states that J.B. has Medicare insurance, including a Part D prescription plan.

Will Medicare cover EN?

Based on the PT assessment, J.B. is considered appropriate for discharge home, providing he will have some supervision and assistance available. Typically, a case manager or social worker is involved in arranging appropriate discharge facilities; however, the health care professional managing nutrition support in the hospital setting should facilitate the nutrition support portion of discharge, as necessary. The pharmacist should review the medication regimen to assure it is appropriate for administration through the EAD.

Strict guidelines exist for home EN coverage. Medicare Part B (not Part D) will cover 80% of the cost if criteria are met.[52] EN must be medically necessary to "maintain weight and strength commensurate with overall health status" and there must be a functional disability of the GI tract (eg, dysphagia, swallowing disorder) that is expected to be "permanent." The formula must be delivered by feeding tube (ie, not oral supplements) and must provide most of the patient's nutritional requirements (ie, not supplemental nutrition). Approval is on an individual basis, requires a physician's written order, and

sufficient documentation must be available to support the need for EN. Calories <20 kcal/kg/day or >35 kcal/kg/day require additional documentation. The duration of therapy must be ≥90 days to meet the test of permanence. J.B.'s therapy falls within these guidelines. In addition, the formula J.B. receives is in a category that does not require him to meet additional eligibility criteria related to the formula itself. Additional documentation would be needed to justify a pump if J.B. was receiving EN via pump.

Adult enteral formulas are divided into five categories for reimbursement purposes by Medicare Part B (**Table 37-7**). Formula manufacturers typically list the Medicare category on the product label. Most polymeric formulas containing intact (whole) protein and 1 to 1.2 kcal/mL are in category I. These products do not require documentation of medical necessity for the specific formula itself, but still require documentation of the need for EN. Clear documentation of medical need for formulas in specific categories (eg, categories III and IV) is required for their higher reimbursement rates. The company selected to provide home care services should review all necessary documentation and assist with J.B.'s transition to home EN therapy.

Table 37-7
Medicare Categories for Enteral Formulas

Category and Codea	Description	Examples from Abbott Laboratories, Abbott Park, IL	Examples from Nestle Health Sciences, Vevey, Switzerland
Category I BA 150	Semlsynthetic intact protein or protein isolates (general purpose formulas)	Jevity® 1 0 Cal, Osmollte® 1 2 Cal	Boost®, Isosource* HN, Nutren® 1.0 Fiber
Category II BA 152	Intact protein or protein isolates; calorically dense (≥ 1.5 kcal/ml)	Ensure® Rus HN, Jevity® 1.5 Cal	Boost® Plus, Isosource® 1 5 Cal, Nutren® 2.0, Resource* 2.0
Category 111° BA 153	Hydrolyzed protein or amlno acids	Perative®, Promote", Vital® AF *1.2* Cal®	Peptamen® 1.5, Peptamen* AF
		Documentation that may provide justification for use: dumping syndrome, uncontrolled diarrhea, evidence of malabsorption on appropriate semisynthetic formulas (eg, isotonic, low long-chain fat content, lactose free) that resolves wlth an oligomerlc formula or documentation of the disease process causlng malabsorption	
Category IV" BAI 5A	Defined formula for special metabollc need (ie, disease-specific formulas)	Glucerna* 1.0, Glucerna® 1.5, Impact®, Nepro® with CARBSTEADY, Oxepa®, Pulmocare®, Suplena® with CARBSTEADY	Boost® Glucose Control, Glytrol®, Novasource® Renai, Nutren® Pulmonary, NutriHep®, Renalcal®
		Documentation that may provide lustification for use: evidence of inability to meet nutritional goals with category I or II products without compromising patient safety and documentation of the specific diagnosis for which a formula is intended	
Category V" BA 155'	Modular components for protein, fat, carbohydrate, and individual amino acids	*Protein*: ProMod* *Amino Acids*: ARG, GLU: Juven*	*Protein*: Beneprotein® *Amino Aads*: ARG: Arginaid* GLU: Glutasolve® *Protein and Fot*: Benecalorie® *Fat*: MCT oil*, Microlipid®
		Documentation that may provide justification for use: inability to meet specific nutrient requlrements (ie, protein, carbohydrate, or fat) with a commercially available formula	

ARG, arginine; GLU, glutamine; MCT, medium-chain triglyceride.

[a]Code refers to the Health Care Procedure Code System (HCPCS) billing code used by providers billing the Center for Medicare and Medicaid.

[b]Failure to provide adequate documentation of medical necessity for the specific formula will likely result in denial of claim or payment at the lower category I rate for Medicare Part B insurance coverage.

[c]There are several other suppliers of B4155 products in addition to Abbott and Nestle products given as examples here.

CASE 37-5, QUESTION 2: J.B.'s daughter asks about using blenderized food rather than his current enteral formula to feed her father through the PEG. Can a blenderized diet be used for patients with an EAD?

Blenderized, real-food diets are viewed by some as more natural than are commercial enteral formulas. Blenderized formulas containing real foods (eg, peaches, green beans, peas, carrots, tomato) are commercially available and may be covered by insurance when documentation supports the need for such a

specialized product.[53,54] Home-prepared products are not typically covered by insurance, and nutritional balance may be compromised unless a dietitian is working with the patient/family. The Oley Foundation, an education, advocacy, and networking organization for home nutrition support, provides information on home blenderized tube feeding.[54] An adequate-size EAD is required for these products. J.B. has been tolerating his current EN; therefore, it is unlikely that he would qualify for insurance coverage of a commercial blenderized formula.

CASE 37-6

Question 1: J.N., a 27-year-old male, was admitted to the hospital 70 days ago after a motor vehicle crash. He sustained multiple traumatic injuries and exhibited multiple complications requiring several exploratory laparotomies. He has been treated for multiple infections, including pneumonia, sepsis, and wound infection. Treatment for *Clostridium difficile* diarrhea was completed 3 weeks ago, and he has not had diarrhea since then. Lysis of adhesions, closure of an enterocutaneous fistula, and placement of a feeding jejunostomy tube (J tube) were done during the last laparotomy 9 days ago. Enteral feedings were started through his J tube 4 days ago at 50 mL/hour and advanced to the goal rate of 90 mL/hour within 24 hours. The EN lactose-free and fiber-free, 460 mOsm/kg, contains 15% of calories from a 50% MCT–50% long-chain triglycerides fat mix, and provides 35 kcal/kg/day and 1.6 g protein/kg/day, which is less than his protein goal. The product is ready to use in a closed-system bag. J.N. has received PN for nutrition during most of his hospitalization, and the PN rate was decreased as EN increased. J.N. now has diarrhea, which started ~12 hours after his EN was increased to goal rate.

What is the likely cause of diarrhea? What other information related to the EN regimen would be helpful to determine whether the EN should be stopped and the PN formulation restarted?

Evaluation of Tube-Feeding Intolerance

Diarrhea develops in 12% to 32% of hospitalized patients; and in up to 80% of high-risk patients, a point preference of 12.4% has been reported.[55] In patients receiving EN, 15% to 40% develop diarrhea, which is multifactorial. Factors associated with diarrhea, but not related to EN, include medications, partial small-bowel obstruction or

fecal impaction, bile salt malabsorption, intestinal atrophy, hypoalbuminemia, malnutrition, infections such as *C. difficile*, and underlying conditions affecting the GI tract.[4,22,45,55–57] Tube-feeding–related causes of diarrhea include high-fat content, lactose content, and bacterial contamination. Formula temperature, caloric density, osmolality, formula strength, lack of fiber content, and method of delivery have been associated with diarrhea, although these factors are not shown to affect diarrhea in some studies, making a cause-and-effect relationship unclear.[56]

J.N.'s hospitalization has been unusually long and complicated. Many factors could contribute to diarrhea; however, the diarrhea coincides relatively closely with initiation and advancement of tube feeding. He may have intestinal atrophy and impaired absorptive function because of his prolonged period without GI tract stimulation. He has had multiple surgeries, including GI surgeries, and may have reduced absorptive capacity, bile salt malabsorption, dumping syndrome, or reduced pancreatic enzyme availability related to his complications and surgeries. At least theoretically, an oligomeric formula would be better absorbed if any of these conditions exist. The SCCM-ASPEN Critical Care guidelines recommend a standard formulation for those not meeting guidelines for an immune-modulating product.[4] The CCP guidelines recommend considering use of a polymeric (intact nutrient) formula, although clinical outcomes do not appear to differ between polymeric and oligomeric formulas.[9] However, studies have not evaluated patients without use of the GI tract for weeks before EN initiation. Formula selection is often determined by physician preference and the calorie, protein, and fat content of formulas on the institution's formulary. Because J.N. had been >2 months without significant use of the GI tract, he was started on an oligomeric peptide formula.

The EN formula selected for J.N. is only slightly more than isotonic. Risk of diarrhea from fat malabsorption should be minimal with the low-fat content and MCT mix. Increasing EN to goal rate within 24 hours may have contributed to diarrhea. Based on consensus rather than evidence from well-designed studies, it may have been preferable to initiate feeding for J.N. at 10 to 40 mL/hour

and advance by 10 to 20 mL every 8 to 12 hours because he was critically ill and had not used his GI tract for >2 months.[3,15,22] The jejunum adapts slowly to changes in volume or concentration, and formula volume was increased <24 hours before diarrhea started. Also, an enteral infusion pump should be used to maintain consistent flow. Changing to a lower volume should decrease stool output within 24 hours if the volume change was responsible. If J.N. does not respond to decreasing formula volume, the formula may be held for 24 hours to assess whether diarrhea decreases or stops. Diarrhea related directly to EN usually is an osmotic diarrhea that stops within 24 hours of stopping the formula. A more objective approach than stopping the formula is to measure stool osmolality. Enteral formula–induced diarrhea is associated with a large osmotic gap, whereas secretory diarrhea (eg, infectious diarrhea) is associated with a low or negative osmotic gap.

The selected oligomeric formula is ready to use and in a closed-system bag; therefore, bacterial contamination from mixing technique is not of concern. Cleanliness during formula transfer to the delivery bag, the period of time the formula is in the bag, and methods of cleaning the delivery bag may contribute to bacterial contamination of formula. J.N. is receiving formula from a closed enteral system (ie, ready-to-hang formula-filled containers), and this virtually eliminates transfer-related contamination when proper technique is used. Any addition (eg, medication, carbohydrate, fat or protein module, MCT oil) to the prefilled container before hanging can contaminate the system, and guidelines (eg, hang time, set changes) for an open enteral system then apply. Even when administered separately from the formula, modular components are a potential contributor to diarrhea because of their osmolarity and potential contamination during preparation and administration. The selected formula does not meet J.N.'s protein requirement; therefore, a modular protein is needed to supplement the enteral formula. The nutrition plan includes addition of a modular protein component; however, on review of the medication administration record, this has not been started and is ordered as separate flushes (not added to the EN container).

Medications are a major contributor to diarrhea in tube-fed patients.[3,22,55] J.N. currently receives antibiotics and has for some time. However, the prevalence of diarrhea with antibiotic therapy is difficult to determine because of failure to report stool frequency and consistency as well as lack of a clear definition of diarrhea. *C. difficile* may have relapsed after his previous treatment. Stool specimens should be sent for culture and/or *C. difficile* toxin. Evaluation of J.N.'s medications may reveal medications associated with diarrhea (eg, sorbitol-containing products, antacids, oral magnesium, potassium chloride, phosphate supplements, H_2 receptor antagonists) for which therapeutic alternatives or different routes of administration could be considered.[16,45] High-osmolality liquid medications should be diluted before administration to reduce GI side effects.[21,45]

J.N.'s GI tract should continue to be used to the extent possible. EN appears to be better than is PN for maintaining the GI tract barrier and host immunologic function.[4,9] Both the CCP and SCCM-ASPEN Critical Care guidelines recommend use of EN over PN in critically ill patients whenever feasible.[4,9] Both guidelines also recognize the need for PN at some point when EN cannot meet the patient's nutritional requirements; however, neither guideline addresses patients with long-term, chronic critical illness such as J.N. The risk of sepsis increases without enteral stimulation of the GI tract. Whether this occurs through bacterial translocation, an unproved process in humans in which enteric bacteria or endotoxin crosses the GI mucosa into mesenteric lymph nodes and portal circulation, or through another mechanism is unclear. In addition, the GI tract serves an immune function, especially with respect to immunoglobulin (Ig)A secretion. Respiratory tract infections, such as pneumonia, may increase without proper stimulation of the GI tract, owing to less effective protection from IgA. Compared with PN, EN attenuates catabolism in highly stressed patients, although initiation of feedings soon after the stressing event may be required to obtain this response. Before a decision is made to stop J.N.'s EN, all possible causes of diarrhea should be investigated. Possible benefits

of improved fluid and electrolyte balance from stopping EN should be weighed against the potential benefits of reduced infections from continued use of the GI tract. Combined EN plus PN can also be considered, especially if J.N. tolerates partial EN but cannot advance to goal rate. Full PN should be provided if EN is stopped for more than 1 or 2 days.

Adult Parenteral Nutrition

Susan L. Mayhew and Richard S. Nicholas

CORE PRINCIPLES		CHAPTER CASES
1	Parenteral nutrition (PN) is indicated in patients with a nonfunctioning gastrointestinal (GI) tract. Patients should be assessed for appropriate indications of the use of PN.	**Case 38-1 (Question 1)** **Case 38-2 (Question 1)**
2	Calories, protein, fluid, electrolytes, vitamins, and minerals are based on the patient's individual needs and are determined by baseline nutritional status, medical history, clinical presentation, and intravenous (IV) access.	**Case 38-1 (Questions 1–3, 5)** **Case 38-2 (Questions 2, 4)** **Case 38-3 (Questions 1, 4, 6, 9)**

CORE PRINCIPLES		CHAPTER CASES
3	Before PN is initiated, the practitioner must be aware of potential metabolic and respiratory complications, including refeeding syndrome, increased carbon dioxide production, and hyperglycemia. Appropriate fluid, macronutrient, and micronutrient adjustments to specialized nutrition support must be implemented to avoid or diminish the expected complications.	**Case 38-1 (Question 6)** **Case 38-2 (Question 3)** **Case 38-3 (Questions 2–4)** **Case 38-4 (Question 3)**
4	PN formulations are complex IV admixtures that require strict adherence to safe compounding practices.	**Case 38-1 (Question 4)** **Case 38-2 (Questions 5–8)** **Case 38-3 (Question 8)** **Case 38-4 (Question 7)**
5	Appropriate monitoring of the patient's vital signs, body weight, temperature, serum chemistries, hematologic indices, nutrition intake, and fluid intake and output is essential to determine the success of PN therapy and to make changes in therapy.	**Case 38-2 (Question 9)** **Case 38-3 (Question 7)** **Case 38-4 (Question 1)**
6	Fluid requirements, macronutrient selections, electrolyte quantities, and vitamin and mineral alterations may be warranted in patients presenting with hepatic or renal failure, short bowel syndrome, obesity, diabetes, pancreatitis, and respiratory failure.	**Case 38-3 (Questions 2, 4–7)** **Case 38-4 (Questions 2–4)**

CORE PRINCIPLES		CHAPTER CASES
7	Practitioners should be aware of the additional complications associated with home (or long-term) delivery of PN, including hepatobiliary complications, metabolic bone disease, and catheter-related complications.	**Case 38-4 (Questions 8, 9)**
8	Advancements in the delivery of home PN (HPN) have increased patients' acceptance and empowered engagement in self-care. An understanding of the patient's fluid and nutrient needs is essential for optimal delivery of HPN, to help ensure positive outcomes and the best quality of life for the patient.	**Case 38-2 (Question 6)** **Case 38-4 (Questions 5, 6)**

INTRODUCTION

Nutritional status directly affects recovery from illness or injury. Malnutrition may stem from acute or chronic illness, injury, or starvation. Regardless of its origin, malnutrition is associated with multiple complications, including poor wound healing, infection, prolonged hospital stays, and increased mortality.[1,2] A nutritional assessment should occur for all patients admitted to a hospital or diagnosed with a chronic disease (see Chapter 35, Basics of Nutrition and Patient Assessment). For patients identified as high risk, a nutrition care plan should be initiated.

The preferred method of providing nutritional support is through the gastrointestinal (GI) tract unless there is a contraindication to oral or enteral nutrition (EN). Absolute contraindications to feeding into

the GI tract include active GI bleed, bowel trauma, intestinal obstruction, and ischemic bowel with hemodynamic instability. Other conditions such as GI infection or inflammation, malabsorption, severe acute pancreatitis, or small bowel fistulas may hinder the ability to feed into the GI tract safely. If using the GI tract is not feasible, a patient may be classified as having intestinal failure and intravenous (IV) feeding may be warranted depending on the patient's nutritional status and disease severity. Parenteral nutrition (PN) is a sterile liquid nutrition formula administered IV that generally contains a combination of protein, carbohydrate, fat, electrolytes, vitamins, and trace elements. PN may be given to neonates, infants, children, and adults and can be specifically formulated to meet individual patient needs. Some patients require PN for a short period (1–3 weeks), whereas others may require home PN (HPN) for months, years, or even a lifetime.[3]

VASCULAR ACCESS

For centuries, clinicians attempted IV feeding using crude IV cannulas and nutritional substances ranging from olive oil to cow's milk. Unfortunately, historical attempts at using the vascular system for nutritional support were fraught with challenges. Clinicians were limited by the amount of calories administered, lack of reliable IV access, and risk of infection because of the lack of sterility.[4]

The advent of central venous catheters (CVCs) in the 1960s ushered in the contemporary practice of IV feeding—PN therapy. CVCs allow the administration of concentrated nutritional admixtures that are rapidly diluted in the systemic circulation. Before the development of central catheters, peripheral catheters were used, which limited the amount of calories and nutrients that could be safely administered.[5]

Today, PN formulations are administered through peripheral or central veins. The type of venous access utilized primarily depends

on the anticipated duration of therapy and nutrient requirements of the patient.[7,8]

Peripheral Venous Access

Peripheral venous access, typically in a forearm vessel, may be used for peripheral PN (PPN) administration. PPN is used for short-term therapy, generally <7 days in patients who are not fluid restricted. Because PN formulations are hypertonic and irritating to fragile peripheral veins, low final concentrations of dextrose (<10%) and amino acids (AAs) (<5%) are necessary to maintain the osmolarity of the PPN <900 mOsm/L (normal serum osmolality 280–300 mOsm/L). The dilute nature of the PPN solutions limits the amount of deliverable calories (<1 kcal/mL) such that a large volume (~2–3 L/day) of PPN may be necessary to approach nutritional goals. The addition of lipid emulsion increases the caloric density of the PPN and may help protect the vein against irritation through dilution and by a buffering effect.[6]

Central Venous Access

Central venous access is the preferred route of administration of PN formulations for patients who have a nonfunctional GI tract, require bowel rest for >7 days, have limited peripheral venous access, or have energy and protein needs that cannot be met with peripheral nutrient formulations.[7,8] Traditionally, the CVC is percutaneously inserted into the subclavian vein and threaded through the vein so that the tip rests in the upper portion of the superior vena cava (SVC) just above the right atrium. Another technique involves the use of a peripherally inserted central catheter (PICC), which is inserted in the antecubital vein and advanced until the end of the catheter reaches the upper SVC.[7,9] The internal and external jugular veins may also be used to thread a catheter into the SVC; however, maintaining a sterile dressing on these sites is more difficult.

The SVC is an area of rapid blood flow, which quickly dilutes concentrated parenteral nutrient formulations, thereby minimizing phlebitis or thrombosis. Some patients are not the candidates for placement of catheters in the SVC and require a femoral vein insertion of the catheter with the tip in the inferior vena cava. There may be a higher risk for infection with catheters placed using this technique.[7,8] Placing catheters via the jugular vein is associated with a higher risk of infection.[49]

Differing from PPN, parenteral nutrient formulations designed for administration through central veins often contain relatively high final concentrations of dextrose (20%–35%) and AAs (5%–10%), plus lipids. The central PN (CPN) formulation typically provides a caloric density >1 kcal/mL and an osmolarity >2000 mOsm/L. CPN formulations are often termed *total PN* (TPN) because complete nutrient requirements of the patient may be achieved by this route.

COMPONENTS OF PARENTERAL NUTRIENT FORMULATIONS

PN formulations are complex mixtures containing 30 or more nutrients, including energy substrates such as carbohydrate (dextrose), protein (AAs), and fat (lipid, lipid emulsion, or intravenous fat emulsion [IVFE]), along with a variety of electrolytes, vitamins, and trace minerals. Various combinations of these components are prepared under aseptic conditions based upon individual patient needs.[10,11] The three macronutrients used in PN formulations are available in various concentrations from manufacturers. Sterile water for injection is used to dilute the macronutrients to achieve the prescribed final concentrations of dextrose, AAs, and lipids, as well as the final volume of the PN formulation.

PN formulations may be prepared in one of two ways, a dextrose–AA (2-in-1) mixture in which the lipid emulsion is administered separately as a piggybacked infusion or a total nutrient admixture

(TNA or 3-in-1) in which the dextrose, AAs, and lipids are combined in solution in the same PN bag.

Premixed PN solutions are also available commercially in different percentages of dextrose and AA preparations. Premixed PN solutions are sterile products that have a longer shelf life and are formulated to meet the standard nutrient requirements in noncritically ill patients. These formulations limit the ability to customize the final product to meet individual patient needs. However, the use of premixed formulas may be advantageous by reducing costs and the risk of bloodstream infections.[12] This may be a viable option for small institutions without a nutrition support service (**Table 38-1**).

Table 38-1

Ready to Use, Premixed Parenteral Nutrition Formulas

Product Name	Manufacturer	Formula	Volume	Comments
ProCalamine®	B. Braun Medical	Amino acids 3% Glycerin 3% Electrolytes	1000 mL	B. Braun discontinued production. Supplies depleted by May 2021
Clinimix®	Baxter	Amino acids%/dextrose% 4.25%/5% 4.25%/10% 5%/15% 5%/20% 6%/5% 8%/10% 8%/14%	1000 mL 2000 mL	Sulfite free Dual-chambered bag 6%/5% for peripheral administration 24-month shelf life
Clinimix E®	Baxter	Amino acids%/dextrose% 2.75%/5% 4.25%/5% 4.25%/10% 5%/15% 5%/20% 8%/10% 8%/14% Electrolytes with Ca	1000 mL 2000 mL	Sulfite free Dual-chambered bag 24-month shelf life
Kabiven®	Fresenius Kabi	Amino acids 3.31% Dextrose 9.8% Lipid emulsion 3.9% Electrolytes 0.7%	1026 mL 1540 mL 2053 mL 2566 mL	Specialized three-chamber bag Central TPN
Perikabiven®	Fresenius Kabi	Amino acids 2.4% Dextrose 6.8% Lipid emulsion 3.5% Electrolytes 0.5%	1440 mL 1920 mL	Specialized three-chamber bag Central or peripheral TPN

Errors have occurred in preparing and managing this complex therapy, resulting in patient harm and death. A responsibility of the pharmacist is to ensure safe, accurate, and sterile preparation of the PN formulation. Guidelines for safe practices have been developed

for situations in which inconsistent practices have the potential to cause harm. Pharmaceutical problem areas that are addressed in the Safe Practices for Parenteral Nutrition Formulations are compounding, formulas, labeling, stability, and filtering of PN formulations.[13]

PN is a costly therapy. Costs associated with PN therapy include not only the admixture itself but also the cost of obtaining venous access, human resource administration, laboratory monitoring, and treatment of complications of therapy. Because of the cost and complexity of PN therapy, its use should be scrutinized and reserved for patients who will benefit from it.

Carbohydrate

Dextrose in water is the most common carbohydrate for IV use. It is available commercially in concentrations ranging from 2.5% to 70%. Dextrose solutions are mixed with other components of the PN formulation and diluted to various final concentrations with sterile water for injection. Dextrose in its hydrated form provides 3.4 kcal/g, compared with dietary carbohydrate, which provides 4 kcal/g.

Lipid

Lipid emulsion or IVFE is the most calorically dense macronutrient for infusion and a source of essential fatty acids (FAs). For decades, soybean oil and soybean/safflower oil lipid emulsions (n-6 FAs) have been the mainstay in lipid-containing PN regimens in the United States. FAs, a component of IVFE, are classified based on carbon chain length, degree of saturation, and location of the first double bond from the ω carbon. The optimal composition of FAs within IVFE has been a focus of clinical debate because of the potential to influence immune function, inflammatory response, and liver function. This has prompted research into the development of alternative lipid formulations in which part of the n-6 polyunsaturated fatty acids (PUFAs) has been replaced by less bioactive FAs, such

as coconut oil (rich in medium-chain saturated FAs), olive oil (rich in n-9 monounsaturated FA oleic acid), or fish oil (rich in n-3 PUFA).[14-16] Emerging literature highlights benefits of these alternative lipid products as having less inflammatory properties, higher antioxidant content, and improved clinical outcomes in some patient populations.[17]

Plant-based fat emulsions contain phytosterols. When consumed orally, phytosterols are poorly absorbed; however, when administered IV, phytosterols are eliminated via the hepatobiliary system. It is thought that phytosterols are involved with cholestasis associated with chronic lipid emulsion administration. This is especially seen in pediatric populations.

Because of the bioactivity of n-6 PUFAs and liver complications associated with phytosterols, research has been conducted in the development of new lipid formulations (structured lipids). The n-6 PUFA has been reduced or replaced by less bioactive FAs, such as coconut oil (rich in medium-chain saturated FA), olive oil (rich in n-9 monounsaturated FA oleic acid), or fish oil (rich in n-3 PUFA)—challenging the traditional soybean oil and soybean/safflower oil emulsions (n-6 FA).[18] While structured IVFEs have been used for years outside the United States, the U.S. Food and Drug Administration (FDA) has approved IVFE formulations with a 4:1 combination of olive oil and soybean oil[14] and another IVFE formulation containing soybean oil, medium-chain triglycerides (MCT), olive oil, and fish oil.[14,18] Most recently, a fish oil–based fat emulsion has been approved for pediatric patients.

The traditional soybean oil IVFEs continue to be available commercially as 10% (1.1 kcal/mL), 20% (2.0 kcal/mL), and 30% (3.0 kcal/mL) concentrations. The newer IVFE products are available in 10% or 20% concentrations. While each gram of fat provides 9 kcal, the caloric density of the IVFE is increased slightly because of the glycerol within the IVFE such that each milliliter of 10% IVFE provides 1.1 kcal, and each milliliter of 20% and 30% IVFE provides 2.0 and 3.0 kcal/mL, respectively. Other components of the IVFE include glycerol to make the formulation isotonic, egg phospholipid as an emulsifier, vitamin K, and sodium hydroxide to adjust the final

pH. The 10% and 20% IVFEs may be administered concurrently (IV piggyback) alongside the dextrose/AA solutions or mixed with dextrose and AAs as a TNA formulation. The 30% IVFE is used exclusively for compounding TNA formulations that combine dextrose, AAs, and lipid in the same container.[15] **Table 38-2** summarizes available lipid products approved by the FDA.

Table 38-2
Intravenous Lipid Emulsion (IVFE)

Product Name	Percentage	Manufacturer	Composition	Fatty Acid Composition
Clinolipid®	20%	Baxter	Olive oil Soybean oil Egg phospholipid	Linoleic acid 13.8%–22.0% Oleic acid 44.3%–79.5% Palmitic acid 7.6%–19.3% Palmitoleic acid 0.0%–3.2% Linolenic acid 0.5%–4.2% Stearic acid 0.7%–5.0%
Intralipid®	10%, 20%, 30% 20% Bulk	Baxter	Soybean oil Egg phospholipid	Linoleic acid 44%–62% Oleic acid 19%–30% Palmitic acid 7%–14% Linolenic acid 4%–11% Stearic acid 1.4%–5.5%
Nutrilipid®	20%	B. Braun Medical	Soybean oil Egg phospholipid	Linoleic acid 48%–58% Oleic acid 17%–30% Palmitic acid 9%–13% Linolenic acid 4%–11% Stearic acid 2.5%–5%
Omegaven®	10%	Fresenius Kabi	Fish oil Egg phospholipid	Linoleic acid 1.5% Oleic acid 4%–11% Palmitic acid 4%–12% Palmitoleic acid 4%–10% Linolenic acid 1.1% Eicosapentaenoic acid (EPA) 13%–26% Docosahexaenoic acid (DHA) 14%–27% Myristic acid 2%–7% Arachidonic acid 0.2%–2%

Amino Acids

Synthetic crystalline AAs serve as the source of protein and nitrogen. Nitrogen is the building block of cell structure and is used to produce enzymes, peptide hormones, and structural and serum proteins.

When oxidized for energy, protein yields 4 kcal/g. Historically, protein calories have not always been included in the calculation of energy needs for patients receiving PN formulations. Ideally, AAs are used to stimulate protein synthesis and tissue repair and are not oxidized for energy; however, the human body cannot compartmentalize energy metabolism in such a manner. Today, conventional wisdom is to include protein calories in the total calorie calculations. **Table 38-3** summarizes available nutrients and their caloric density.

Table 38-3
Caloric Density of Intravenous Nutrients

Nutrient	kcal/g	kcal/mL

Medium-chain triglycerides	8.3	

AA concentrations of 3% to 20% are available commercially and vary slightly from one product to another in specific amounts of each AA, electrolyte content, and pH. Generally, AA products are characterized as standard mixtures or specialty mixtures. Standard AA products provide a balanced mix of essential, nonessential, and

semiessential AAs, whereas specialty AA products are modified for specific disease states.

Specialty AA mixtures are available for neonatal patients and for adult patients with hepatic encephalopathy, renal failure, or critical illness. Specialty AA formulations designed for patients with hepatic failure contain increased amounts of branched-chain amino acids (BCAAs) and decreased amounts of aromatic amino acids (AAA) compared to standard AA products. These formulations are thought to counter the imbalance between AAA and BCAA that can occur in hepatic failure. Elevations in AAA may lead to altered mental status. There is no evidence to suggest that formulations enriched with BCAA improve patient outcomes compared with standard formulas.[19–21] Formulas enriched with BCAA should be reserved for patients with hepatic encephalopathy, which is refractory to standard treatment with luminal acting antibiotics and lactulose.[19,20] Specialty AA products used in renal failure are predominantly composed of essential AAs.[22] Their use is based upon the theory that nonessential AAs can be recycled from urea and essential AAs. Indications for renal AA formulations are limited.[23] Standard AAs should be used in acute kidney injury (AKI).

Modified AA formulations are also available for critically ill patients with hypercatabolic conditions, such as trauma or thermal injury. These formulations contain increased amounts of the BCAAs (leucine, isoleucine, and valine) to address the increased skeletal muscle catabolism that can be seen in severe metabolic stress. Although these BCAA enriched products may slightly improve nitrogen balance, improved patient outcomes have not been demonstrated.[24,25] For a summary of the various AA formulas, see **Table 38-4**.

Table 38-4
Amino Acid Formulas

Description	Product Name	Available Concentrations
Standard Formulations		

Description	Product Name	Available Concentrations
Contain essential and nonessential amino acids	Aminosyn II Clinisol (sulfite free) FreAmine III Plenamine Premasol ProSol Travasol	10%, 15% 15% 3%, 8.5%, 10% 15% 10% 20% 5.5%, 8.5%, 10%
Standard Formulations with Electrolytes		
Contain essential amino acids, nonessential amino acids and electrolytes	FreAmine III	3%, 8.5%
Pediatric Formula		
Contain essential and nonessential amino acids	Aminosyn-PF Trophamine (non-DHEP)	7%, 10% 6%, 10%
Hepatic Failure Formulation		
Contain essential and nonessential amino acids with a proportion of branched-chain amino acids (leucine, isoleucine, valine)	HepatAmine (B. Braun Medical)	8%
Renal Failure Formulations		
Contain primarily essential amino acids	NephrAmine (B. Braun Medical) Aminosyn-RF (Hospira)	5.4% 5.2%
High Metabolic Stress Formulations		
Contain percentages of leucine, isoleucine, and valine, as well as all essential and nonessential amino acids	FreAmine HBC Aminosyn HBC	6.9% 7.0%

Micronutrients

Micronutrients are electrolytes, vitamins, and trace minerals needed for metabolism. These nutrients are available from various

manufacturers as either single entities or in combinations. For example, the trace element zinc is available commercially as a single trace element product or as a combination product with copper, chromium, manganese, and selenium. Likewise, electrolytes are available as either individual salts or a combination product to facilitate ease of admixing PN. Commercially available vitamins for PN formulations are generally prescribed as a combination multivitamin regimen, although some vitamins are available as single additives. It is important to be aware of the specific products available in each institution to avoid providing inadequate or excessive amounts of various micronutrients.

PARENTERAL NUTRITION

Patient Assessment: Population-Based Formulation

CASE 38-1

QUESTION 1: A.A. is a well-developed and well-nourished 70-year-old male brought to the emergency department with left-sided facial palsy and left-sided muscle weakness in his upper and lower extremities. He was admitted to the hospital 8 days ago with a diagnosis of ischemic stroke. Evaluation of swallowing with modified barium swallow showed him at an increased risk of aspiration. Enteral tube feedings were initiated, but repeated attempts of advancement of the enteral regimen were unsuccessful. A GI consult was requested. He has been receiving maintenance IV fluids containing 5% dextrose/0.45% sodium chloride with potassium chloride (KCl) 10 mEq/L infusing through a peripheral catheter at 125 mL/hour to provide hydration since admission. His weight today is 165 pounds (74.84 kg); his height is 70 inches (177.80 cm).

Nutrition laboratory panel values are as follows:

Sodium (Na), 142 mEq/L
Potassium (K), 4.1 mEq/L
Chloride (Cl), 100 mEq/L
Bicarbonate (HCO_3^-), 25 mEq/L

Blood urea nitrogen (BUN), 10 mg/dL
Creatinine, 1.0 mg/dL
Glucose, 91 mg/dL
Calcium (Ca), 9.4 mg/dL
Magnesium (Mg), 2.1 mg/dL
Phosphorus (P), 3.4 mg/dL
Total protein, 6.0 g/dL
Albumin, 3.6 g/dL
Prealbumin, 14 mg/dL
White blood cell (WBC) count, 8800/mL

After evaluation of A.A.'s nutritional status, GI function, IV fluid regimen, and other clinical findings, is PN an option for A.A.?

A.A. is a well-developed, well-nourished male before admission. Although PN support is rarely necessary for mildly stressed, well-nourished patients, A.A. has been without sustenance for 8 days and attempts at EN has been unsuccessful. A.A.'s visceral proteins (albumin and prealbumin) are in the low-normal range. Although both albumin and prealbumin have been used as nutritional markers, a low serum albumin is more reliable at indicating risk for morbidity and mortality than it is for assessing acute changes in nutritional status. The half-life of albumin is ~3 weeks, whereas the half-life for prealbumin is 2 to 3 days, making prealbumin more reflective of acute changes in nutritional status in convalescing patients. In critically ill patients, neither prealbumin nor albumin concentrations correlate with calorie and protein adequacy.[26] See Chapter 35, Basics of Nutrition and Patient Assessment, for a more detailed description of evaluation of patients with nutritional deficiencies. The principles from Chapter 35 will be applied to this and all others cases throughout this chapter.

A.A. has a peripheral IV catheter, and his peripheral access appears to be adequate. With good peripheral access, A.A. meets one of the criteria for PPN. Furthermore, he is not fluid restricted and should be able to tolerate the volume of PPN necessary to meet the majority of his nutritional needs. A common complication (up to 70% incidence) of PPN is thrombophlebitis, which generally occurs within 72 hours.[6,27] Phlebitis is usually attributed to the acidic pH or

hyperosmolarity of the PPN formulation. The osmolarity of typical peripheral parenteral feedings ranges from 600 to 900 mOsm/L compared with a normal osmolarity of 280 to 300 mOsm/L for plasma. Osmolarity of a dextrose–AA formulation can be approximated quickly by multiplying the final dextrose concentration (%) by 50 and the final AA (%) concentration by 100 (eg, final AA concentration of PPN of 3.5% × 100 = 350 mOsm/L from the AA component). Approximately 150 to 200 mOsm/L should be added to account for the contribution of electrolytes, vitamins, and trace elements. Although the concurrent administration of fat emulsions decreases osmolarity, buffers the pH, and improves peripheral vein tolerance, it does not eliminate the risk of thrombophlebitis.[28] If PPN therapy is anticipated to be >2 weeks for A.A., then central venous access should be obtained.

Case 38-1, Question 2: Based on the simplistic weight-based calculation, what is the calorie and protein goal range for A.A.?

A.A. has a minimal stress level, and his baseline electrolytes are within normal limits. A.A.'s calorie goals should meet energy expenditure needed for basal metabolism and account for mild stress associated with recovery. A.A. falls into the category of "hospitalized patient, mild stress" requiring 20 to 25 kcal/kg/day (see Table 35-3 in Chapter 35, Basics of Nutrition and Patient Assessment). For this calculation, A.A.'s actual body weight of 165 pounds (74.84 kg) is slightly higher than his ideal body weight [IBW] and should be used to calculate both energy and protein requirements. The caloric goal for A.A. is 1500 to 1875 kcal/day. Using IBW or usual body weight to calculate caloric requirements in patients who have experienced significant weight loss may result in overfeeding and should be avoided.

Protein requirements are estimated based on weight, degree of stress, and disease state. Because A.A. has had a stroke and his metabolic stress is mild, his protein goal should be based on the desire to maintain his current lean body mass. Using the guidelines

provided in Table 35-4 of Chapter 35, Basics of Nutrition and Patient Assessment, A.A. should receive a protein dose of ~1.0 g/kg/day (range 1.0–1.2 g/kg/day) or 75 g/day. As with energy expenditure, calculation of protein needs are estimates; the patient's clinical course should be monitored and the protein dose adjusted accordingly. The protein source for PN is synthetic crystalline AAs. Generally, 1 g of protein is equivalent to 1 g of AAs. A.A. will need 75 to 90 g/day of AAs.

In patients with acute and chronic kidney disease, protein intake should be adjusted to account for catabolic rate, renal function, and possible protein losses from dialysis.[29-31] AKI rarely occurs outside the critical care setting. For most critically ill patients with AKI, protein intake should fall within 1.4 to 1.6 g/kg/day.[32,33] Protein intake for patients receiving continuous renal replacement therapy should range between 1.8 and 2.5 g/kg/day.[29-31] The recommended protein intake for patients who receive maintenance hemodialysis is 1.2 g/kg/day,[34,35] whereas patients who receive chronic ambulatory peritoneal dialysis should receive 1.3 g/kg/day.[36]

Case 38-1, Question 3: What is A.A.'s daily maintenance fluid requirement?

Maintenance fluid requirements can be estimated using several methods. The simplest method uses 30 to 40 mL/kg/day (35 mL/kg/day for average adult) as the basis. Another time-tested method of estimating fluid requirements that was originally developed for the pediatric population, yet remains widely used for both adults and children, is to provide 1500 mL for the first 20 kg body weight plus an additional 20 mL/kg for actual weight beyond the initial 20 kg. Both methods provide estimates of fluid needs for basic maintenance. Additional fluid must be provided for increased losses from vomiting, nasogastric (NG) tube output, diarrhea, or large open wounds. A.A.'s fluid needs are estimated as follows:

$$\begin{aligned} \text{mL/day} &= 1500\ \text{mL} + ([20\ \text{mL/kg}][75\ \text{kg} - 20\ \text{kg}]) \\ &= 1500\ \text{mL} + (20\ \text{mL/kg})\ (55\ \text{kg}) \\ &= 1500\ \text{mL} + 1100\ \text{mL} = 2600\ \text{mL} \end{aligned}$$ **(Eq. 38-1)**

CASE 38-1, QUESTION 4: The institution uses a 2-in-1 system for PN and piggybacked lipids through a Y-site in the IV catheter. Based on the calorie and protein goals determined previously for A.A., what PPN regimen will you design?

A logical place to start when initiating a PPN regimen is to assess the patient's current IV fluids and compare that to the estimated daily maintenance fluid requirements (calculated for A.A. in Question 3). A.A.'s IV fluids are infusing at 125 mL/hour (3000 mL/day). Because of the aforementioned osmolality limitation of peripheral veins, PPN solutions are formulated with relatively low final concentrations of dextrose (<10%) and AAs (<5%). Therefore, a relatively large volume of PPN is required in order to approach nutrient goals. PPN solutions will be formulated for a total volume typically ranging from 2000 to 3000 mL/day depending on patient needs. While final concentrations of dextrose and AAs within PN regimens may vary slightly from patient to patient, the final concentration of dextrose for PPN will typically be 6% to 8% and AAs at 3% to 3.5%.

For A.A., a reasonable PPN regimen will be 100 mL/hour (2400 mL/day), with a final concentration of dextrose at 7% and AAs of 3.5%. Lipid emulsion will be Y-sited into the IV catheter at a dose of 250 mL of 20% lipids. This 2-in-1 regimen will provide a combined volume of 2650 mL/day (2400 mL PN + 250 mL from lipids) and will replace A.A.'s IV fluid volume. It is important to note that A.A.'s IV fluids will either need to be discontinued once the PPN starts or reduced to the minimum rate needed to keep the vein open (KVO), which is typically between 10 and 30 mL/hour. Failure to discontinue or decrease the IV fluids to KVO upon initiation of PN will pose a risk of volume overload to the patient.

Case 38-1, Question 5: Check to see if the PPN regimen for A.A. will meet the majority of his caloric and protein goals. How many total calories and grams of protein per day will the regimen above provide?

The caloric and protein goals for A.A. were previously determined to be 1500 to 1875 kcal/day and 75 to 90 g protein/day. His PPN regimen is 100 mL/hour (2400 mL/day), with a final concentration of dextrose at 7% (7 g/100 mL) and AAs of 3.5% (3.5 g/100 mL). The lipid emulsion will be Y-sited into the IV catheter at a dose of 250 mL of 20% lipids. The PPN volume (2400 mL) plus the lipid volume (250 mL) will total 2650 mL/day.

To calculate the amount of protein and dextrose provided by the 2-in-1 solution, multiply the final concentration of AAs (3.5% or 3.5 g/100 mL) and dextrose (7% or 7 g/100 mL) by the volume of the solution (exclude lipid volume since this is a 2-in-1 solution). Each gram of AA provides 4 calories. Each gram of IV dextrose will provide 3.4 cal/g.

$$
\begin{aligned}
&= 2400\ \text{mL} \times 3.5\%\ \text{AAs} \\
&= 2400\ \text{mL} \times 0.035\ \text{g/mL} \\
&= 84\ \text{g} \times 4\ \text{cal/g} \\
&= 336\ \text{calories} \\
&= 2400\ \text{mL} \times 7\%\ \text{dextrose} \\
&= 2400\ \text{mL} \times 0.7\ \text{g/mL} \\
&= 168\ \text{g} \times 3.4\ \text{cal/g} \\
&= 571\ \text{calories}
\end{aligned}
\qquad \textbf{(Eq. 38-2)}
$$

The regimen provides A.A. 250 mL of 20% lipid emulsion at a caloric density of 2 cal/mL. Therefore, 250 mL of 20% lipid emulsion will provide 500 calories from fat. The calories from fat, dextrose, and AAs are added together to determine total calories. Fat calories are added to dextrose calories (571 cal/day) and protein calories (336 cal/day) to provide a total of 1407 cal/day for A.A. (~19 cal/kg/day).

$$336 \text{ protein calories} + 571 \text{ dextrose calories} + 500 \text{ fat calories} = 1407 \text{ total calories} \quad \text{(Eq. 38-3)}$$

This regimen will provide A.A. with protein intake well within his targeted range and meet the majority of his caloric goal (>75%). If a more aggressive nutritional regimen is desired, then central venous access will need to be considered for A.A. Typically, lipids account for ~30% to 40% of total calories in PPN solutions. In A.A.'s PPN regimen, the lipids account for 35% (eg, 500 fat calories divided by 1407 total calories) of his total calories.

Case 38-1, Question 6: What are the benefits of using a mixed-fuel system, combining dextrose and fat to meet energy needs?

Providing a portion of calories as fat may reduce the metabolic consequences of excessive dextrose administration. The maximal rate of dextrose metabolism in adults is estimated at 5 to 7 mg/kg/minute, or ~7 g/kg/day. In doses >7 g/kg/day, dextrose is used inefficiently and converted to fat.[37] The conversion to fat may be associated with respiratory compromise and hepatic dysfunction.[38–40] Hyperglycemia, another complication of excessive dextrose infusion, is associated with electrolyte and acid–base disturbances, osmotic diuresis, increased risk of infections, and altered phagocyte and complement function. Furthermore, using a mixed-fuel system allows the administration of a small amount of IVFE daily to prevent essential fatty acid deficiency (EFAD). Rapid administration of IVFE has been associated with alterations in the reticuloendothelial system that are not observed with continuous administration of small doses.[18] IVFE should be infused at a rate of <0.11 g/kg/hour to prevent adverse effects, which include impaired hepatic, pulmonary, immune, and platelet function.[18] A typical daily dose of IVFE is ≤1 g/kg/day.

Administration of essential FAs as 1% to 4% of total caloric intake (eg, 250 mL of 20% lipid twice a week) is necessary to prevent EFAD. The essential FAs linoleic acid and α-linolenic acid are those

that cannot be synthesized by humans. Of these, linoleic acid appears to be the only one required by adults. Clinical symptoms of EFAD are dry, thickened, scaly skin, hair loss, poor wound healing, and thrombocytopenia, which may be observed after a few weeks to months of lipid-free parenteral feedings.[36] Biochemical evidence of EFAD, determined by a triene-to-tetraene ratio of >0.4, may be seen after 1 week of lipid-free parenteral feedings. The continuous infusion of hypertonic dextrose from the PN is associated with high circulating concentrations of insulin. Because insulin promotes lipogenesis rather than lipolysis, linoleic acid cannot be released from adipose tissue.[37]

Patient Assessment: Moderate Stress With Malnutrition

CASE 38-2

Question 1: B.B. is a 64-year-old female diagnosed with ovarian cancer 4 years ago. The cancer was treated with a combination of chemotherapy and external beam radiation therapy. Subsequently, B.B. developed chronic radiation enteritis. She was admitted to the hospital with an increasing abdominal pain with eating. She has consumed little oral intake for 7 days, and no stool output for 5 days. Questioning reveals that over the past week, she has been drinking only liquids due to nausea and vomiting, and her weight has decreased 7 pounds (3.18 kg) during that time. On physical examination, B.B. appears thin and her abdomen is distended. Vital signs are notable for a temperature of 101.30 °F (38.50 °C), heart rate of 88 beats/minute, and a blood pressure of 102/68 mm/Hg. She is 66 inches (167.64 cm) tall and weighs 110 pounds (49.90 kg). Her medical record indicates that 1 month ago, she weighed 117 pounds (53.07 kg), and 6 months ago, her weight was 124 pounds (56.25 kg). Admission laboratory values are as follows:

Na, 133 mEq/L
K, 4.5 mEq/L
Cl, 100 mEq/L
HCO_3^-, 25 mEq/L
BUN, 15 mg/dL
Creatinine, 0.6 mg/dL
Glucose, 103 mg/dL
Ca, 9.3 mg/dL

Mg, 2.2 mg/dL
P, 4.5 mg/dL
Albumin, 3.1 g/dL
WBC count, 11,800/mL
Hematocrit, 46%
Alanine aminotransferase, 31 units/L
Aspartate aminotransferase, 27 units/L
Alkaline phosphatase, 65 units/L
Total bilirubin, 0.6 mg/dL

An abdominal computed tomography (CT) scan shows bowel obstruction with a stricture distal to the obstruction and signs of chronic inflammation. B.B. is admitted with complications from chronic radiation enteritis.

After assessing B.B.'s nutritional status and other clinical data, is she a candidate for PN?

B.B. does not have a functioning GI tract and has eaten little in the past week. Patients are considered at risk for nutritional depletion when intake is <50% to 75% of requirements for 5 to 7 days or when weight loss exceeds 5% or more in 1 month, 7.5% or more in 3 months, or 10% or more of usual body weight (preillness) within a 6-month period.[41,42] B.B. falls within these categories and is considered nutritionally at risk.

Assessment of weight loss should include evaluation of hydration status, especially because B.B.'s vomiting and minimal oral intake for the past week place her at risk of dehydration. Loss of lean body mass is probably less than that reflected by the decrease in weight. In addition, B.B.'s admission serum albumin concentration is low at 3.1 g/dL. Her hydration status should be considered when evaluating this visceral protein, because B.B.'s serum albumin concentration will probably decrease further upon rehydration.

B.B. is not expected to resume oral intake soon because her radiation enteritis is being managed conservatively with bowel rest. Therefore, PN is indicated for B.B.

Case 38-2, Question 2: What type of malnutrition does B.B. have?

The origin of malnutrition may be from starvation, acute or chronic illness, or both. B.B. exhibits some loss of fat and muscle, as well as depletion of visceral proteins. She has components of both chronic and acute malnutrition. Refer to Chapter 35, Basics of Nutrition and Patient Assessment, for a more robust discussion of types of malnutrition.

Case 38-2, Question 3: Members of the medical team are anxious to have B.B. gain weight and are concerned by her malnourished appearance. What potential complications may occur from initiating an aggressive feeding regimen for B.B.?

B.B. may be at risk of refeeding syndrome because of poor oral intake and progressive weight loss over the past 6 months. Chronic malnutrition may lead to intracellular depletion of phosphorus, potassium, and magnesium that may not be evident when measuring serum electrolyte concentrations. Refeeding syndrome may occur as phosphorus, potassium, and magnesium shift from the extracellular space into the cells upon consumption of concentrated sources of calories. Carbohydrate calories are converted to glucose, which triggers the secretion of insulin, which, in turn, facilitates the uptake of glucose, water, phosphorus, and other intracellular electrolytes. This phenomenon was first reported in World War II when chronically malnourished survivors were given normal food and liquid diets. Complications coinciding with refeeding included hypertension, cardiac insufficiency, seizures, coma, and death. These complications were reported later in the 1970s and 1980s, with the introduction of PN in chronically ill, essentially starved hospitalized patients. Knowing a patient's history of weight loss and diet will help assess the risk of refeeding syndrome.

To minimize the risk of refeeding syndrome in B.B., the PN should be initiated conservatively (~50% of total dextrose calories for the first 1–2 days) and advanced to goal slowly (over 5–7 days as tolerated). Electrolyte abnormalities should be corrected before nutrition support is initiated. Because B.B.'s electrolytes are within normal range, no baseline adjustments are necessary. Close

electrolyte monitoring is warranted to avoid potentially serious electrolyte abnormalities and the cardiovascular consequences thereof. Laboratory values including phosphorus, potassium, magnesium, and glucose should be monitored at least daily for the first week. Vitamin administration should be routine. Thiamine 100 mg and folate 1 mg are commonly supplemented during the PN advancement period.[43,44] Consensus recommendations for patients at risk for refeeding syndrome include supplementation of 100 mg thiamine before feeding is initiated, and, if at high risk, continuing for 5 to 7 days during feeding.[45]

For adults, current literature supports a daily lipid dose up to 1 g/kg/day (or up to 30% of TPN calories) for soy-based lipid products, with a maximum dose of 2.5 g/kg/day. For lipid products containing other combinations of oils, the usual daily dose for adults is 1 g/kg/day, with a maximum of 2 g/kg/day. The recommended rate of infusion of lipid emulsions varies between products and should strictly follow manufacturer's recommendations. During PN therapy, it is also important to monitor serum triglyceride concentrations weekly to assess lipid tolerance, being mindful to keep triglyceride concentrations <400 mg/dL during PN therapy to decrease the risk of adverse effects.[46] Lipoprotein lipase hydrolyzes lipid particles to release FAs, which are either used for energy, metabolized by the liver, or stored in adipose tissue. In metabolically stressed patients, lipoprotein lipase activity is decreased, leading to hyperlipidemia that may result in alterations in pulmonary gas exchange, immune response, and, in rare cases, acute pancreatitis.

Case 38-2, Question 4: After rehydration with IV fluids, B.B.'s weight climbs to 113.54 pounds (51.50 kg). The initiation of PN therapy was delayed because B.B. experienced severe abdominal pain and distension and required surgery shortly after admission. An exploratory laparotomy was performed and a 25-cm ileum was resected from an area of bowel with severe disease and a stricture that was causing the obstruction. Bowel sounds are absent. She has a right port-a-cath CVC, and PN is to begin on postoperative day 1. What are the energy and protein goals for B.B.?

Energy requirements may be estimated with predictive equations, simplistic weight-based formulas (eg, 25–30 kcal/kg/day), or measured by indirect calorimetry, which is the most accurate method of assessment. The advantage that weight-based equations offer is simplicity. Over 200 predictive equations to estimate energy requirements have been published in the literature, including the Harris–Benedict equation. Using the Harris–Benedict equation for females (see Table 35-3 in Chapter 35, Basics of Nutrition and Patient Assessment) and her current weight of 113.54 pounds (51.48 kg), height of 65.98 inches (167.60 cm), and age of 64 years, B.B.'s basal energy expenditure (BEE) is 1158 kcal/day. To estimate her total energy expenditure, the BEE should be modified with an activity factor of 1.2 for being confined to bed and a stress factor of 1.1 to 1.2 for surgery. These modifications result in an estimated energy expenditure of 32% to 44% greater than her BEE, or 1528 to 1668 kcal/day. Using a target midway within this range, a goal of 1600 kcal/day is reasonable. In a similar manner, her protein goal (see Table 35-4 in Chapter 35, Basics of Nutrition and Patient Assessment) for moderate stress is estimated at 1.5 to 2.0 g/kg/day or 77 to 103 g/day of protein.

Case 38-2, Question 5: Now that calorie and protein requirements have been estimated for B.B., a goal PN regimen can be designed for her. Keep in mind that PN is initiated conservatively, particularly with patients at risk of refeeding syndrome, and advanced to the goal regimen after several days and as tolerated. To begin designing the PN formulation, the bulk macronutrients available on formulary for compounding the PN must be identified. For this case, the bulk macronutrients are 70% dextrose, 30% lipid emulsion, and 10% AAs. How will you design a TNA parenteral nutrient formulation as a single-daily PN bag for B.B. that provides 1600 kcal and 80 g of AAs with a non–protein calorie distribution of 75% carbohydrate and 25% lipid?

1. AAs calculation

$$80\ \text{g} \times 4\ \text{kcal/g} = 320\ \text{kcal} \qquad \textbf{(Eq. 38-4)}$$

$$\text{mL of 10\% AAs} = 80\ \text{g}/0.1\ \text{g/mL} = 800\ \text{mL}$$

2. Dextrose calculation

$$\begin{aligned}\text{Calories from dextrose} &= (1600 - 320)\,(0.75) = 960\text{ g}\\ \text{of dextrose} &= 960\text{ kcal}/3.4\text{ kcal/g}\\ &= 282\text{ g/mL of 70\% dextrose}\\ &= 282\text{ g}/0.7\text{ g/mL}\\ &= 403\text{ mL}\end{aligned}$$

(Eq. 38-5)

3. Lipid emulsion calculation

$$\begin{aligned}\text{Calories from lipid} &= (1600 - 320)\,(0.25)\text{ or }(1280 - 960)\\ &= 320\text{ kcal/mL of 30\% lipid emulsion}\\ &= 320\text{ kcal}/3.0\text{ kcal/mL}\\ &= 107\text{ mL}\end{aligned}$$

(Eq. 38-6)

4. Calculation of final volume of energy substrates

$$\begin{aligned}&800\text{ mL of AA 10\% +}\\ &403\text{ mL dextrose 70\% + 107 mL lipid emulsion 30\%}\\ &= 1310\text{ mL total volume}\end{aligned}$$

(Eq. 38-7)

B.B.'s goal of PN formulation will provide 282 g of dextrose and 32 g of lipids daily. If the PN is infused continuously over 24 hours, B.B. will receive 3.8 mg/kg/minute of dextrose and ~0.6 g/kg/day of lipids. Both dextrose and lipid doses comply with the limitations recommended in Case 38-2, Question 4. Other additives such as electrolytes, vitamins, trace elements, and sterile water are included in the parenteral nutrient formulation and increase the final volume to 1680 mL/day (~1 kcal/mL). The infusion rate for this formulation can be calculated as follows:

$$\begin{aligned}&= 1680\text{ mL/day}/24\text{ hours}\\ &= 70\text{ mL/hour}\end{aligned}$$

(Eq. 38-8)

B.B.'s parenteral nutrient formulation of 1680 mL/day will not meet her maintenance fluid needs of 2130 mL/day (see Case 38-1, Question 3). She will require extra fluid to meet the remainder of her maintenance daily fluid needs. Additional hydration is generally provided through IV fluids, although volume may be supplemented by adding more sterile water for injection into the TNA.

CASE 38-2, QUESTION 6: What are the advantages and disadvantages of combining the dextrose, fat, and AAs in one TNA container?

PN formulations may be prepared in one of the following two ways: a dextrose–AA (2-in-1) mixture in which IVFE is administered separately as a piggybacked infusion or a TNA (3-in-1) in which the dextrose, AAs, and IVFE are combined in solution in the same bag.[41]

Although the use of TNAs has been widely embraced by home care providers and many institutions for convenience and cost advantages, the addition of IVFE to the traditional mixture of dextrose and AAs converts the mixture into a complex emulsion with physiologic differences that alter the stability of the product.[48] The differences between these two methods of compounding PN formulations must be considered. Specific advantages and disadvantages of each are summarized in **Table 38-5**.

Table 38-5

Advantages and Disadvantages of 2-in-1 and 3-in-1 Parenteral Nutrition

	2-in-1	3-in-1

	2-in-1	3-in-1
Advantages	▪ Improved overall stability ▪ Increased flexibility in concentrating dextrose and amino acids ▪ Allows more flexibility to add higher concentrations of electrolytes ▪ Better medication compatibility ▪ Reduced risk of bacterial growth because of high osmolarity and acidic pH ▪ Better visualization of precipitant of particulate matter. Enables the use of bacterial retention filter (0.22-μm) ▪ Lower risk of catheter occlusion if IVFE is not used daily	▪ All components are aseptically compounded by the pharmacy ▪ Simplified regimen for the patient, especially at home ▪ Less supply and equipment costs ▪ Less nursing time needed for administration ▪ Decreased preparation cost ▪ Decreased risk of contamination ▪ Inhibited bacterial growth versus separate IVFE ▪ Minimize infusion-related reactions from IVFE because of slower infusion rate ▪ May improve lipid clearance because of slower infusion rate ▪ Decreased risk of phlebitis with PPN
Disadvantages	▪ Increased administration costs and time when lipids are infused separately ▪ Increased risk of touch contamination ▪ Increased risk of phlebitis, particularly if PPN is not co-infused with IV lipid emulsion ▪ IVFE given in a piggyback manner is limited to a maximum hang time of 12 hours.	▪ Impaired visualization of particulate matter or precipitate because of opacity of IVFE admixture ▪ IVFE is less stable—more prone to lipid separation. Admixture is less stable with concentrated electrolyte additives ▪ Larger particle size of IVFE admixture. Must use 1.2-μm. Cannot use 0.22-μm bacterial retention filter. ▪ Limited compatibility with medications ▪ Containers with diethylhexyl phthalate should be avoided because this toxic material may be extracted by the lipid and may harm patients.

CASE 38-2, QUESTION 7: How stable are the TNA parenteral feeding formulations compared to 2-in-1 formulations? Why is an infusion filter necessary?

IVFE gradually deteriorates over time because of increased formation of free FAs and a resultant decrease in pH. When lipids are mixed with dextrose and AAs, this process is accelerated. IVFE consists of an interior oil phase dispersed within an external water phase. Stability of the IVFE is maintained by polar and nonpolar regions on the same fat droplet. The surface of the polar region of the fat droplet is negatively charged and repels other lipid droplets of the same charge. When the surface loses its negativity, fat droplets aggregate into larger globules and the emulsion becomes unstable and unsafe for use, risking occlusion of pulmonary vasculature. Commercially available IVFEs in the United States use an anionic egg yolk phosphatide emulsifier to stabilize the lipid droplets and maintain dispersion. Destabilization of the emulsion occurs in phases that begin with creaming and end with the coalescence of the lipid particles, or "cracking" of the emulsion. A decrease in pH and the addition of divalent cations (Mg^{2+}, Ca^{2+}) alter the electrical charge on the fat droplet surface and pose a risk to the integrity of the emulsion. Although dextrose decreases the pH, the addition of AAs provides an adequate buffer for this variable. The amount of divalent cations added to TNAs should be limited to minimize the risk of emulsion instability. Trivalent cations such as iron should never be added to a TNA parenteral nutrient formulation. PN formulations containing lipid must be assessed visually for signs of phase separation, in which the instability of the emulsion is manifested by "oiling out," indicated by a continuous layer of oil or individual fat droplets. Fat emulsion particles have an average size of 0.5 mm. A destabilized emulsion is not visibly apparent until the lipid particles are 40 to 50 mm. Fat particles as small as 5 mm may occlude pulmonary capillaries.[47,48] Therefore, the use of a 1.2-mm filter is

recommended to protect against the infusion of enlarged lipid particles.[13,48]

Using dual-chamber bags may extend the shelf life of TNAs because they allow the lipid to be physically separated from the dextrose, AAs, and other additives until it is time to administer the feeding. The use of dual-chamber PN bags has the greatest advantage for home care settings, where a 1-week supply of parenteral feedings may be prepared at a time.[47]

After preparation, TNAs should be refrigerated 39.2 °F (4.00 °C) to preserve stability. Once the bag is removed from the refrigerator, it may be warmed to room temperature and the contents mixed well before administration. Mixing is best accomplished by gently inverting the container up and down to ensure top-to-bottom transfer of the fluid. Vigorous shaking should be avoided because it introduces air, which can destabilize the emulsion.[47,48]

Case 38-2, Question 8: How does microbial growth differ between 2-in-1 and TNA (3-in-1) formulations?

Dextrose–AA PN formulations are not conducive to growth of most organisms because of the high osmolarity (>2000 mOsm/L) and acidic pH. Lipid emulsion, however, is isotonic and has a physiologic pH that provides an optimal growth medium for organisms. Combining these three substrates in a TNA provides a formulation with a microbial growth potential that is intermediate between the two.[47,48] The number of CVC manipulations correlates strongly with the incidence of catheter-related infections. From an infection control perspective, the use of a single-daily bag of PN formulation limits the number of manipulations of the CVC to one per day, thereby minimizing touch contamination. The Centers for Disease Control and Prevention guidelines allow TNA formulations to hang for up to 24 hours. However, because of concerns about the potential of lipid emulsions to support microbial growth, the suggested hang time for IVFE when administered alone in a piggyback manner with 2-in-1 PN formulations is 12 hours.[49]

Case 38-2, Question 9: How will you determine the adequacy of B.B.'s specialized nutrition support?

Routine monitoring and evaluation of nutritional status and the metabolic effects of therapy are required for patients receiving PN therapy. Nutritional goals established in the patient care plan are estimates of a patient's nutritional requirements and must be evaluated regularly to assess adequacy of therapy. Daily monitoring parameters include vital signs, body weight, temperature, serum chemistries, hematologic indices, nutrition intake, and fluid intake and output.[24]

The adequacy of nutrition therapy should be assessed weekly. This may be accomplished through measuring serum concentrations of visceral proteins (see Table 35-2 in Chapter 35, Basics of Nutrition and Patient Assessment), such as prealbumin and albumin. Because prealbumin has a half-life of only 2 to 3 days, serum concentrations of this protein should increase weekly with adequate nutrition and improving clinical status. In convalescing patients, an increase in prealbumin of 4 to 7 mg/dL/week is indicative on an anabolic response to nutritional support. Albumin has a much longer half-life of 14 to 20 days, rendering that it is less useful in reflecting an anabolic response to PN therapy.[26,50] Indirect calorimetry, if performed correctly, is the most accurate way to reassess energy expenditure.

A method to assess adequacy of protein intake is to evaluate nitrogen balance, which compares the amount of nitrogen administered to the amount of nitrogen excreted (amount "in" vs amount "out"). The nitrogen "in" is provided by the AA component of the PN formulation. Each commercially available AA formulation has a slightly different amount of nitrogen per gram of amino, so the manufacturer's product information should be consulted to obtain this value. On average, about 16% of AA is nitrogen or 1 g of nitrogen for every 6.25 g of protein. Most of the nitrogen is excreted in the urine as urea, a byproduct of protein breakdown for energy. Renal excretion of urea nitrogen increases with increasing stress. To

determine the nitrogen balance, urine must be collected for 24 hours and the amount of urine urea nitrogen (UUN) measured. Some laboratories have the capability of measuring total urine nitrogen, which measures all nitrogen entities in the urine. In addition, some nitrogen lost via skin, respiration, and stool is not measurable but is estimated to be between 2 and 4 g/day.

Achieving a positive nitrogen balance is difficult, if not impossible, in critically ill patients; therefore, the calculation may result in a negative number or zero. For convalescing patients, a nitrogen balance of >2 to 4 g is acceptable and indicates a positive nitrogen balance. A negative nitrogen balance prompts a reevaluation of the amount of protein and energy a patient is receiving. For patients with a negative nitrogen balance, it may be helpful to increase intake of both calories and protein.

As with all tests, assessment should include monitoring several parameters, including the patient's clinical status. Most important is the identification of trends that may alert clinicians to impending complications. A suggested schedule for monitoring is provided in **Table 38-6**.

Table 38-6

Routine Monitoring Parameters for Parenteral Nutrition

	Suggested Schedule for TPN Monitoring					
Parameter	**Initial**	**Daily (Critically Ill)**	**2–3× Weekly (Stable)**	**Weekly**	**Monthly (Home Health)**	**As Indicated**
Weight	X	X	X			
BUN, creatinine, glucose	X	X	X			
Na, K, Cl, HCO_3^-, Ca, P, Mg	X	X	X			
Albumin, AST, ALT, LDH, alkaline phosphatase, total bilirubin, conjugate bilirubin	X			X		X
Prealbumin	X			X		X
Triglycerides	X			X		X
RBC count, Hgb, Hct, WBC count, platelets	X			X		X

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Hct, hematocrit; Hgb, hemoglobin; LDH, lactate dehydrogenase.

CASE 38-3

QUESTION 1: C.C., a 33-year-old male, is admitted to the hospital because of increasing shortness of breath, productive cough, wheezing, fever, abdominal pain, and vomiting. He reports consuming mainly fluids over the past week. His severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) antibody test for COVID-19 is positive. His past medical history is significant for occasional binge ethanol abuse, asthma, pancreatitis, and type 2 diabetes. His social history is significant for 2 packs/day smoking history.

During the next 48 hours, his clinical status deteriorates requiring transfer to the intensive care unit (ICU). An NG tube is inserted to decompress the bowel. He is febrile, his WBC count has increased to 21,000/mL, and he is hypotensive, requiring large volumes of IV fluids. His respiratory distress requires endotracheal intubation and mechanical ventilation. C.C.'s clinical presentation is consistent with COVID-19 pneumonia, complicated by acute pancreatitis, and paralytic ileus. Because of C.C.'s critical condition and nonfunctional GI tract, the decision is made to begin PN. C.C. is 74 inches (187.96 cm) tall, and his usual weight is 275 pounds (124.74 kg).

What are C.C.'s energy and protein goals?

It is important to recognize that C.C. is an obese, critically ill patient. The prevalence of obesity in adults and children is steadily increasing nationwide. Clinicians can expect to see the growing numbers of patients with obesity. In 2013, the American Medical Association recognized obesity as a disease that requires medical treatment. In obese ICU patients, a nutritional assessment should be conducted to determine actual body weight, usual body weight, and IBW. Body mass index (BMI) should be calculated and obesity classified. Obesity is defined as a BMI of >30 kg/m^2 or actual body weight exceeding 120% of IBW. C.C. weighs 275 pounds (124.74 kg), which is 152% of his IBW of 180.78 pounds (82 kg) and a BMI of 35.3 as shown by Eq. 38-9. Assessment should also consider preexisting and emerging comorbidities, such as diabetes, hyperlipidemia, hypertension, and end-organ function.[51]

Guidelines from the American Society for Parenteral and Enteral Nutrition (ASPEN) support the use of high-protein hypocaloric feeding in critically ill patients with obesity in efforts to preserve lean body mass, mobilize adipose stores, and minimize metabolic complications. Obese ICU patients are more likely to experience complications and fuel utilization challenges compared to leaner

patients. ASPEN guidelines go a step further to support that if BMI is in excess of 30, goal caloric intake should not exceed 60% to 70% of target energy requirements or 11 to 14 kcal/kg actual body weight per day (or 22–25 kcal/kg IBW per day). Protein should be provided at 2.0 g/kg IBW for BMI between 30 to 40 and 2.5 g/kg IBW for BMI > 40.[24,52] In the case of C.C., his BMI is 35.3 (BMI Class II), so his energy goal is estimated at 22 kcal/kg of IBW or ~1804 kcal/day and protein goal of 2 g/kg IBW or 164 g/day.

Case 38-3, Question 2: Given the critical condition of C.C. and his diagnosis of acute pancreatitis, is the use of lipid emulsion (IVFE) contraindicated in C.C.?

Although consensus has not been reached regarding the optimal composition of lipid emulsions, recent guidelines from the Society of Critical Care Medicine (SCCM) and the ASPEN suggest that soybean oil–based lipid emulsion be withheld or limited to a dose necessary to prevent EFAD (100 g/week) during the first week of stay within an ICU.[24] It is important to note that this recommendation did not receive a consensus vote among the authors of the guidelines. The addition of n-3 FAs, eicosapentaenoic acid and docosahexaenoic acid, to lipid emulsions is recommended because of positive effects on cell membranes and inflammatory processes.[53]

Several observations have raised concern about the use of IVFE in patients with pancreatitis. Available data suggest that IVFE is a safe and efficacious form of calories for most patients with pancreatitis.[55] Although hyperlipidemia has been well described in patients with alcohol-induced pancreatitis, it is unlikely that it is primarily responsible for initiating the pancreatitis.

Acute pancreatitis associated with hypertriglyceridemia is most often seen in patients with hereditary or acquired defects in lipid metabolism (such as type I, IV, or V dyslipidemia) and in the presence of a comorbidity, such as uncontrolled diabetes or excessive alcohol use.[54] Patients with hypertriglyceridemia-associated pancreatitis often experience a more severe clinical course and higher rates of complications—warranting a lipid-free PN

formulation should parenteral feedings be necessary. Lipid emulsion should be avoided or used with caution in patients with severe hyperlipidemia, disorders of lipid metabolism, recent cardiac infarction, stroke, embolism, severe liver disease, and in critically ill patients with shock. Lipids are contraindicated in patients with any known hypersensitivity to any active ingredient with the various lipid products (eg, egg, olive, soy, fish, or peanut protein).[17]

Monitoring serum triglyceride concentrations should be part of routine management for patients with pancreatitis and those receiving parenteral nutrient formulations containing lipids. Serum triglyceride concentrations should be maintained at <400 mg/dL with a continuous infusion of lipids and <250 mg/dL when checked at least 4 hours after the infusion for patients receiving intermittent IVFE infusions.[46,55] If serum triglyceride concentrations exceed these parameters, consideration must be given to decreasing or withholding the IVFE or transitioning to an alternative lipid product.

Case 38-3, Question 3: Given C.C.'s past medical history and current clinical condition, what metabolic complication of PN therapy should be anticipated?

Hyperglycemia is the most common metabolic complication of PN therapy, especially in stressed or critically ill patients. Metabolic stress increases gluconeogenesis and glycogenolysis. This increase in endogenous glucose production coupled with the administration of hypertonic dextrose in PN formulations increases the potential for hyperglycemia.[56] C.C. is at particular risk for hyperglycemia because he is diabetic, experiencing pancreatitis, and critically ill. Stress-induced hyperglycemia may develop as a result of insulin resistance, suppressed insulin secretion, and increased gluconeogenesis and glycogenolysis.[57]

Case 38-3, Question 4: What is an appropriate initial dextrose dose in C.C.'s PN?

With a history of diabetes, coupled with acute pancreatitis, it is anticipated that C.C. will experience hyperglycemia and will need supplemental insulin when his parenteral nutrient regimen is infused. His dextrose should be limited to no >150 g during the first 24 hours of therapy and should not be increased until serum glucose concentrations are consistently <180 mg/dL. Standard practice for administering PN formulations containing hypertonic dextrose in patients with euglycemia or for those with no history of glucose intolerance is to limit the initial dextrose dose to <250 g of dextrose during the first 24 hours. Capillary blood glucose concentrations should be monitored frequently and should be consistently maintained below 180 mg/dL.[58] If C.C.'s serum glucose level consistently remains <180 mg/dL, the dextrose dose within the PN may be increased daily as tolerated and the PN formulation regimen gradually advanced over 2 to 3 days toward his energy goal.

Insulin therapy may be administered subcutaneously, IV with an insulin infusion, or directly in the PN formulation.[59,60] Regular insulin may be added to the PN formulation at a dose of 0.1 units per gram of dextrose as a reasonable starting point and should be adjusted to achieve serum glucose levels between 140 and 180 mg/dL.[62] Alternatively, a separate insulin infusion may be used for more aggressive glucose control. Capillary glucose monitoring is required during PN therapy at least every 6 hours and more frequently in patients with hyperglycemia.[60–62] An insulin administration protocol is recommended before PN starts and for the duration of therapy.

Persistent hyperglycemia may lead to glucosuria and osmotic diuresis, resulting in dehydration and electrolyte abnormalities. Hyperglycemia compromises the immune response altering chemotaxis and phagocytosis and impairing complement function, thereby increasing risk of infection. In extreme cases, hyperglycemia progresses to hyperosmolar, nonketotic acidosis and coma, a condition associated with 40% mortality.

Hyperglycemia can be minimized by limiting the goal dextrose infusion rate to <4 mg/kg/minute (20 kcal/kg/day).[63] Clinical evidence suggests that treatment of hyperglycemia and maintenance of

euglycemia may reduce morbidity and mortality, length of stay, and hospital costs.[60,61,64–66]

Furthermore, overfeeding should be avoided in all patients, especially those with respiratory concerns (ie, mechanically ventilated, chronic obstructive airway disease). Overfeeding with carbohydrates is particularly detrimental because of the amount of carbon dioxide produced relative to the amount of oxygen consumed. This may results in carbon dioxide retention, which may lead to alterations in acid–base balance. Complete oxidation of carbohydrate is demonstrated at dextrose infusions of 4 to 5 mg/kg/minute (20–25 kcal/kg/day). Dextrose infusions exceeding this rate may increase carbon dioxide production and negatively affect respiratory function and may cause respiratory distress in patients at risks.[39]

Case 38-3, Question 5: C.C.'s current laboratory values are as follows:

Na, 137 mEq/L
K, 4.5 mEq/L
Cl, 102 mEq/L
HCO_3^-, 22 mEq/L
BUN, 9 mg/dL
Creatinine, 0.8 mg/dL
Glucose, 218 mg/dL
Ca, 8.9 mg/dL
Mg, 1.9 mg/dL
P, 2.8 mg/dL
Albumin, 3.0 mg/dL

Which electrolytes should be included in C.C.'s parenteral nutrient formulation?

Once macronutrient goals are achieved and tolerance is established, the daily management of PN therapy revolves around maintaining the patient's fluid and electrolyte needs. All concurrently administered IV fluids and medications must be considered and accurate records of volume intake and output reviewed. Typical electrolytes added to PN formulations are sodium, potassium, chloride, acetate (which is metabolized to bicarbonate), magnesium,

calcium, and phosphate. Electrolyte requirements can vary widely and should be added to the PN formulation based on individual patient needs. However, patients without significant fluid and electrolyte losses, hepatic or renal dysfunction, or acid–base disturbances do well with standard maintenance doses of electrolytes. Electrolytes may be added individually or as commercially available combination products for maintenance doses. General guidelines for electrolyte requirements for parenteral feedings are included in **Table 38-7**.

Table 38-7
Recommended Adult Daily Electrolyte Requirements

Electrolyte	Amount
Sodium	80–100 mEq
Potassium	60–80 mEq
Chloride	50–100 mEq[a]
Acetate	50–100 mEq[a]
Magnesium	8–20 mEq
Calcium	10–15 mEq
Phosphorus (phosphate)	20–40 mmol

[a]As needed to maintain acid–base balance.

Case 38-3, Question 6: What doses of multiple vitamins and trace elements should C.C. receive in his parenteral nutrient formulation?

Vitamins and trace elements should be included in PN regimens and are essential for normal metabolism and effective nutrient utilization. ASPEN along with ASPEN and European Society of Parenteral and Enteral Nutrition (ESPEN) has provided consensus recommendations for daily micronutrient administration[67] (**Table 38-8**).

Table 38-8

Recommended Adult Daily Doses of Parenteral Vitamins

Vitamins	Dose
Fat-Soluble Vitamins	
A	3300–3500 IU (990–1050 µg retinol equivalents)
D	200 IU (5 µg cholecalciferol)
E	10 mg/dL α-tocopherol
K	Individual assessment
Water-Soluble Vitamins	
Thiamine (B_1)	3–6 mg
Riboflavin (B2)	3.6–5 mg
Niacin (B3)	40–47 mg
Pantothenic acid (B5)	15–17 mg
Pyridoxine (B6)	3–6 mg
Cyanocobalamin (B12)	5–6 µg
Folic acid	400–600 µg
Biotin	60 µg
Ascorbic acid (C)	110–200 mg

Source: Blaauw R, Osland E, Sriram K, et al. Parenteral provision of micronutrients to adult patients: an expert consensus paper. *JPEN J Parenter Enteral Nutr*. 2019;43(S1):S5–S23. doi:10.1002/jpen.1525.

Guidelines for daily doses of the trace elements, such as chromium, copper, manganese, and zinc, have also been developed.[67,68] In addition to these trace elements, many practitioners provide selenium on a daily basis. Recommended doses of the trace elements are listed in **Table 38-9**. As with vitamins, trace elements are available as single entities or combination products. Molybdenum and iodine are also available commercially.

Table 38-9

Recommended Daily Adult Doses of Parenteral Trace Elements

Trace Element	Dose
Chromium	10–15 µg
Copper	300–610 µg
Manganese	55–100 µg
Selenium	20–100 µg
Zinc	2.5–6.5 mg
Iron	1–1.2 mg
Molybdenum	No recommendation
Iodine	70–150 µg

Source: Blaauw R, Osland E, Sriram K, et al. Parenteral provision of micronutrients to adult patients: an expert consensus paper. *JPEN J Parenter Enteral Nutr*. 2019;43(S1):S5–S23. doi:10.1002/jpen.1525.

Case 38-3, Question 7: A comparison of C.C.'s intake and output reveals an overall negative fluid balance because a high volume of gastric fluid is being removed via the NG tube. Laboratory values at this time are the following:

Na, 138 mEq/L
K, 3.1 mEq/L
Cl, 91 mEq/L
HCO_3^-, 33 mEq/L
BUN, 28 mg/dL
Creatinine, 0.9 mg/dL
Glucose, 279 mg/dL
Ca, 7.8 mg/dL
Mg, 1.4 mg/dL
P, 1.8 mg/dL
Albumin, 2.8 g/dL

Arterial blood gas (ABG) results are pH, 7.46; PO_2, 95 mm Hg; PCO_2, 35 mm Hg; and HCO_3^-, 30 mEq/L.

What factors contribute to these metabolic abnormalities?

PN therapy may be associated with multiple metabolic complications. The most common abnormalities are hypokalemia, hypomagnesemia, hypophosphatemia, and hyperglycemia. The plan for PN therapy should include routine monitoring of these serum

chemistries to identify complications early and institute methods to manage or prevent complications.

HYPOKALEMIA

Hypokalemia, a common metabolic abnormality associated with the initiation of PN, usually occurs within the first 24 to 48 hours. Potassium moves, along with dextrose, from the extracellular to the intracellular space. Furthermore, building lean body mass (ie, anabolism) requires ~3 mEq of potassium per gram of nitrogen provided by the AAs. Administering dextrose promotes repletion of glycogen stores, which also requires potassium.[44,69]

C.C.'s decreased serum potassium concentration is compounded by metabolic alkalosis. With metabolic alkalosis, the renal excretion of potassium is increased. Additional potassium should be administered and can be provided in C.C.'s parenteral feeding or through another IV.

HYPOMAGNESEMIA

Magnesium, like potassium, is primarily an intracellular cation and is considered an anabolic electrolyte. It is common to observe decreases in magnesium serum concentrations during the administration of parenteral nutrient formulations. Synthesis of lean tissue requires 0.5 mEq of magnesium per gram of nitrogen.[44,69] Additional magnesium can be added to the PN formulation. However, when a TNA formulation is used, the amount of magnesium must stay within the guidelines for the cation content to maintain the stability of the lipid emulsion.

HYPOPHOSPHATEMIA

Hypophosphatemia occurs when phosphorus moves into the cells for the synthesis of adenosine triphosphate (ATP), an important energy carrier. Phosphorus is depleted quickly with the administration of hypertonic dextrose, especially in patients who are malnourished (see Case 38-2, Question 3, for discussion of refeeding syndrome). Phosphorus is used for ATP synthesis, primarily in the liver and

skeletal muscle. Alkalosis also decreases phosphate stores by stimulating the phosphorylation of carbohydrates. As a component of 2,3-diphosphoglycerate, found in red blood cells (RBCs), phosphorus is necessary for the disassociation of oxygen from hemoglobin.[69]

Clinical signs and symptoms of hypophosphatemia usually occur when serum concentrations fall to <1.0 mg/dL, including lethargy, muscle weakness, impaired WBC function, glucose intolerance, rhabdomyolysis, seizures, hemolytic anemia, reduced diaphragmatic contractility, and death. Moderate-to-severe, complicated hypophosphatemia can be managed by administering up to 0.625 mmol/kg of phosphate IV.[44,69–71] Although C.C.'s serum phosphorus is not <1.0 mg/dL, it is low (1.8 mg/dL), and he should receive 15 to 30 mmol of phosphate in the parenteral nutrient formulation per day. Additional supplements may be necessary to replete his phosphorus stores.[70]

METABOLIC ALKALOSIS

C.C. has evidence of a metabolic alkalosis based on his ABG results, hypochloremia, and elevated bicarbonate level. The continued loss of fluid and hydrochloric acid from the NG tube is the most probable cause of his metabolic alkalosis. Management of this type of metabolic alkalosis is to replace the fluid and chloride through another IV. Because acetate is converted to bicarbonate and can further contribute to the alkalosis, the acetate salts in the parenteral nutrient formulation can be changed to chloride salts.[69] Nevertheless, the PN formulation generally is not the primary vehicle for adjusting and supplementing electrolytes and fluids. Instead, the fluid and electrolyte balance may be adjusted with maintenance IV fluid and electrolyte supplements.

A complete metabolic panel (CMP) is typically order before PN initiation and at least weekly during PN therapy. A CMP generally includes a serum glucose, sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphorus, BUN, serum creatinine (SCr), liver function tests, albumin, and triglyceride. A basic metabolic panel

(BMP), which includes a serum glucose, sodium, potassium, chloride, bicarbonate, calcium, BUN, and SCr, is usually checked daily in critically ill patients and for those at risk of electrolyte abnormalities or renal dysfunction. More stable patients may have a BMP plus phosphorus and magnesium monitored two to three times a week rather than daily.

Case 38-3, Question 8: In response to these serum chemistries, the electrolytes in C.C.'s parenteral nutrient formulation are changed to the following per liter: NaCl, 160 mEq; KCl, 140 mEq; phosphate as K salt, 60 mmol; $MgSO_4$, 54 mEq; and calcium gluconate, 30 mEq. After analyzing the PN electrolyte content (above), what concerns to you have regarding the calcium and phosphate content of the TNA PN formulation?

Calcium and phosphate solubility is a safety concern with PN formulations. The dose of calcium ordered for C.C. is more than three times the usual maintenance dose (Table 38-7). This amount of calcium is not necessary because the observed hypocalcemia merely reflects C.C.'s low serum albumin concentration; therefore, less calcium is bound to albumin. C.C. probably does not have true hypocalcemia because his free (or ionized) calcium, which is critical for physiologic function, has not changed. If available, obtaining an ionized calcium concentration is advised. However, some laboratories do not have this test available. In this situation, a "corrected" calcium formulation may be used. For every 1 g/dL decrease in serum albumin concentration, there will be about a 0.8 mg/dL reduction in the serum calcium concentration.[72] For C.C., a serum calcium of 7.8 mg/dL will correct to a serum concentration of 8.8 mg/dL ([4.0 − 2.8 g/dL albumin][0.8] + 7.8 mg/dL calcium).

The amount of phosphate prescribed for C.C. at this time exceeds the usual recommended dose of 20 to 40 mmol/day (Table 38-8). Although C.C. has a low serum phosphorus concentration and needs additional phosphate, increasing the dosage in the parenteral nutrient formulation to 60 mmol/day may be incompatible with the calcium content, resulting in calcium phosphate precipitation.

Numerous factors affect calcium phosphate solubility, and caution is warranted when preparing PN formulations to ensure that solubility limits are not exceeded. If solubility is compromised, microprecipitates can occur and may cause diffuse pulmonary emboli, resulting in respiratory distress or death. Calcium and phosphate precipitation curves have been developed to assist practitioners in safe compounding practices. These guidelines help predict the points at which calcium phosphate precipitation is likely to occur. The solubility of calcium and phosphate must be determined based on the volume of the formulation at the time the calcium and phosphate are mixed together, not the final volume. For example, if the electrolytes including calcium and phosphate are added to 1000 mL of a dextrose–AA mixture and then 300 mL of IV fat is added, the calcium phosphate solubility is based on the 1000 mL, not the final 1300 mL volume. In addition, some AA products contain phosphate ions, and these should be considered when determining calcium phosphate solubility.[13,73]

The in vitro precipitation of calcium phosphate depends on the type of calcium salt used in compounding, concentrations of calcium and phosphate, AA concentration, temperature, pH of the formulation, and infusion time. Calcium gluconate rather than the chloride salt offers enhanced calcium phosphate solubility. In solution at equimolar concentrations, calcium chloride dissociates more than calcium gluconate, thereby increasing the yield of free calcium available for binding with phosphate. Calcium and phosphate should not be added to the PN formulation in close sequence. It is recommended to add phosphate first and calcium last, thereby taking advantage of the maximal parenteral volume. The PN formulation should be agitated periodically during preparation and inspected for precipitates.[74] Other guidelines for improving the solubility of calcium are a final AA concentration of >2.5% and a pH <6.0. An increase in the ambient temperature, such as that found in the heated isolettes within neonatal ICUs, can facilitate the precipitation of calcium phosphate. PN formulations should be infused within 24 hours after compounding if stored at room temperature; if refrigerated, it should be infused within 24

hours after rewarming. Increasing temperature and slow infusions may result in calcium phosphate precipitation in the IV catheter, even if precipitation has not occurred in the infusion container.[13]

The amount of divalent cations, calcium (20 mEq) and magnesium (30 mEq), exceeds the general guidelines for maximal amounts that can be added safely to a TNA without disrupting the stability of the lipid emulsion. A limit of 20 divalent cations per liter is a general guideline. The amount prescribed for C.C.'s regimen is excessive because it provides 50 divalent cations in 1.8 L (28 divalent cations/L) and may result in a potentially unstable admixture.

Lastly, a 1.2-mm air-eliminating filter should be used when infusing TNA PN formulations, and a 0.22-mm air-eliminating filter should be used for non–lipid-containing admixtures.[13]

Case 38-3, Question 9: As C.C. recovers and GI tract function returns, a small-bore nasojejunal enteral feeding tube is inserted. Tube feeding is considered because he cannot eat by mouth because of the endotracheal tube and mechanical ventilation. How should he be transitioned from parenteral to enteral feedings?

The EN regimen will depend on the site of feeding (eg, gastric or jejunal) and the condition of the patient's GI tract. EN should begin with a full-strength formula at a continuous infusion rate. Because C.C. has had no oral intake for over a week and is in critical condition, EN is typically started at 10 to 40 mL/hour and advanced by 10 to 20 mL/hour every 8 to 12 hours. For noncritically ill patients, continuous EN is commonly initiated at goal rate, or at 50 mL/hour with advancement by 15 mL/hour every 4 hours until goal is reached —usually within 24 to 48 hours (see Chapter 37, Adult Enteral Nutrition). Concurrently, the PN formulation should be decreased to avoid fluid overload and to keep the calorie and protein intake constant. It can be anticipated that C.C. can transition from parenteral to enteral feedings in 24 to 48 hours.

Long-Term, Chronic Parenteral Nutrition

CASE 38-4

Question 1: D.D. is a 43-year-old male with a 17-year history of Crohn disease (CD). He has had several hospital admissions over the past 2 years with exacerbations of CD. D.D. has experienced an unintentional weight loss of 12% over the past year. He is admitted to the hospital for increasing abdominal pain, nausea, and vomiting for 9 days, and no stool output. Before admission, D.D.'s condition was managed with vedolizumab 300 mg IV every 2 months and prednisone 10 mg qd. On physical examination, D.D. appears thin and his abdomen is distended. Baseline labs are as follows:

Na, 142 mEq/L
K, 4.2 mEq/L
Cl, 99 mEq/L
HCO_3^-, 15 mEq/L
BUN, 12 mg/dL
Creatinine, 0.9 mg/dL
Glucose, 114 mg/dL
Ca, 9.1 mg/dL
Mg, 1.9 mg/dL
P, 5.8 mg/dL
Albumin, 2.8 g/dL
Prealbumin, 28 g/dL

How do you interpret D.D.'s prealbumin concentration?

Although D.D.'s prealbumin concentration appears to be within the desired range, caution must be exercised with its interpretation. In the 1960s, it was shown that prednisone administration may elevate prealbumin levels.[75] Corticosteroid therapy is commonly used in patient populations likely to receive PN, such as patients with inflammatory bowel disease, cancer, and critical illness. In D.D., it is reasonable to think that his prealbumin is falsely elevated given the other indicators of his diminished nutritional status, which include chronic disease, low albumin level of 2.8 g/dL, unintentional weight loss of 12 pounds (5.44 kg) over the past year, and thin appearance.

Case 38-4, Question 2: D.D. has a prolonged hospital course complicated by intra-abdominal abscesses, poor wound healing, and necrotic bowel, requiring removal of all but 82 cm of his small intestine but leaving his ileocecal valve and colon intact. D.D. is given a diagnosis of short bowel syndrome (SBS) requiring

PN. What is the clinical significance of the presence of D.D.'s ileocecal valve and colon?

The presence of the terminal ileum and colon following small bowel resection is critical in nutritional and hydrational management as the patient may be able to tolerate a very short small intestine without TPN support. The presence of the ileocecal valve is thought to prolong intestinal transit time and serve as a barrier to bacterial reflux into the small intestine. Deficiencies of electrolytes, trace elements, and vitamins are common in CD and influenced by the presence of the terminal ileum and colon. Deficiencies are often reflective of chronic blood loss (eg, iron deficiency), chronic diarrhea (eg, magnesium, selenium, zinc deficiencies), or loss of specific absorptive sites (eg, vitamin B_{12}). There is a high prevalence of vitamin D deficiency in patients with CD.

Case 38-4, Question 3: What issues should be addressed in the nutrition and metabolic management of this patient?

SBS occurs from extensive intestinal resection that results in inadequate bowel function to support nutrient and fluid requirements. SBS becomes clinically apparent when about 75% of the small bowel is removed. Studies suggest that the average length of the small intestine may be shorter than previously thought (~11 feet), so SBS is best defined using a patient's symptoms rather than solely on remaining length of small bowel.[76] Patients with SBS frequently experience diarrhea, dehydration, and nutritional deficiencies of minerals, trace elements, and vitamins. In adults, this syndrome is commonly seen in CD, radiation enteritis, mesenteric artery infarction, adhesive obstruction, and trauma.[77] Severe malnutrition will develop without adequate nutrition support.

To maintain adequate nutritional status, D.D. will require PN until his remaining intestine begins to adapt. This adaptive period may take several weeks to months to years, with the majority of intestinal adaptation occurring within the first 2 years following massive bowel

resection. Gut adaptation is enhanced by stimulation of the enterocytes with nutrients, which is best provided by small, frequent oral meals or tube feeding.[78,79] The remaining intestine may never adapt, and SBS may necessitate lifelong PN therapy for survival.

A potential complication of SBS is hypersecretion of gastric fluids.[80-82] The volume and acid content of gastric secretions is directly proportional to the amount of bowel resected.[80–82] The patient can experience symptoms of reflux similar to a Zollinger–Ellison syndrome with epigastric pain and burning. Medications that decrease GI tract motility (antidiarrheals) and secretions (histamine type 2 [H2] blockers and proton-pump inhibitors) are frequently necessary to reduce the volume of gastric secretions and minimize the damaging effects of hypersecretion of gastric acid. These agents are also important in the management of fluid and electrolyte imbalances because of excessive GI fluid losses. Patients with extensive small bowel resection and an intact colon, such as D.D., may experience diarrhea as a result of bile salt depletion.[78,79]

Octreotide may help in decreasing diarrhea in patients with SBS. Octreotide reduces a variety of GI secretions and slows jejunal transit, but the effects are often short lasting and have not shown improved nutrient absorption.[83] It is important to be mindful that most oral medications are absorbed within the first 19.68 inches (50 cm) of the jejunum. Delayed-release medications should be avoided.

Patients with SBS are at risk for having vitamin and mineral deficiencies, especially folate, vitamin B_{12}, vitamin D, selenium, and zinc. These patients should receive supplemental vitamin B_{12} and IV parenteral or oral liquid multivitamin supplements. GI losses of trace minerals, particularly zinc and selenium, are increased in SBS, and these minerals should be supplemented.[78,79]

D.D. should be continued on PN support and will most likely need PN therapy at home to sustain his nutrient and fluid requirements. Because oral ranitidine in not an option, the treatment team orders ranitidine 150 mg to be added to D.D.'s PN formula to manage hypersecretion of gastric fluids and diarrhea. D.D.'s fluid status must be monitored and evaluated daily for clinical signs of dehydration or

fluid overload. Electrolyte abnormalities, including hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and metabolic acidosis, should be anticipated.[79]

Case 38-4, Question 4: On hospital day 10, he presents with a fever and green, purulent fluid draining from his abdominal incision site. He is diagnosed with an enterocutaneous (EC) fistula. The fluid loss from D.D.'s fistula is about 600 mL/day. How will losses from D.D.'s fistula affect his PN?

EC fistulas are an abnormal communication between the intestine and the skin. Most EC fistulas occur 7 to 10 days following surgery and are classified by site of origin, output volume, etiology, and the number of fistulas. Fluid, electrolyte, and trace element losses from the EC fistula will vary depending on the origin of the fistula. For patients with a high-output fistula (>500 mL/day), PN may be required to meet fluid, electrolyte, and nutrient needs and to support spontaneous or surgical closure.[84] Losses must be accounted for and incorporated into the PN formulation or replaced through a separate IV fluid infusion.

Case 38-4, Question 5: D.D. has stabilized and his physician plans to discharge him home in a few days with the plan to continue PN at home. D.D. is 68 inches (172.72 cm) tall and weighs 141 pounds (63.96 kg) at discharge. How will you design an appropriate PN therapy for home infusion?

HPN has allowed patients, such as D.D., to be discharged from the hospital sooner. Candidates for home therapy must be physically and medically stable, have a strong support network in the home setting to assist with care, have an appropriate home environment, and must be educated regarding the prescribed therapy.[85]

The first step in designing an HPN regimen is to estimate the patient's energy and protein needs (see Chapter 35, Basics of Nutrition and Patient Assessment). D.D. is 10 days out from surgery, and his estimated energy requirements are 25 to 30 kcal/kg/day or ~1600 to 1920 kcal/day. Protein goals must include adequate nitrogen (protein) for wound healing and replacement for losses from

the EC fistula. A goal of 1.5 to 2.0 g/kg/day (96–127 g) is reasonable. Long-term systemic corticosteroid therapy is commonly seen in patients with CD and may cause muscle wasting. Losses of lean body mass from corticosteroids may increase AA requirements.

To simplify his nutrition and fluid regimen, all of D.D.'s fluids, including parenteral nutrients, electrolytes, vitamins, trace minerals, and water, should be provided in one TNA container per day. D.D.'s maintenance fluid needs are estimated to be 2380 mL/day (see Case 38-1, Question 5) plus an extra 600 mL/day from the EC fistula brings his total daily fluid requirement to ~3000 mL/day for his HPN regimen. While his daily doses of protein, dextrose, and fat may vary slightly from prescriber to prescriber, a typical PN regimen for D.D. will include ~100 g (96–127 g/day) providing 400 kcal, 264 g of dextrose providing 898 kcal/day, and 50 g of lipid providing 500 kcal/day plus electrolytes, vitamins, and minerals. Total caloric intake for D.D.'s PN regimen is 1798 kcal/day, which falls within his desired caloric range of 1600 to 1920 kcal/day. Initially, daily intake and output must be monitored; therapy should be adjusted based on this information and D.D.'s clinical status.

Adjustments in fluids and electrolytes may be needed. The fluids secreted by the GI tract are rich in electrolytes, including sodium, potassium, chloride, and bicarbonate. Measurement of the electrolyte content of the fistula fluid will determine those that must be replaced and in what quantities. Both fluid and electrolytes should be replaced to prevent dehydration and electrolyte and acid–base imbalances.

In addition to losses of fluids and electrolytes, the trace element zinc is lost in fluid from the small intestine. Approximately 12 mg of zinc is lost in each liter of small bowel fluid and should be replaced to prevent zinc deficiency. Furthermore, zinc may play a role in wound healing.[86] Somatostatin or a somatostatin analog may be used to manage a high-output EC fistulas (>500 mL/day). A typical regimen may be octreotide 100 µg given subcutaneously three times daily or lanreotide 30 mg intramuscularly every 10 days to decrease fistula output and enhance spontaneous closure.[84,87],

A home infusion pharmacy will be responsible for preparing D.D.'s PN formulations. Typically, a 7-day supply of PN therapy (seven bags) is prepared and delivered to the patient's home. These formulations must be refrigerated until administration; however, formulations should be warmed to room temperature and visually inspected for particulate matter before being administered. Because some additives such as multivitamins are not stable for long periods, the patient or caregiver must add these to the PN formulation just before administration.

Patients and caregivers preparing for HPN therapy must be taught how to manage home therapy. This includes assessment of fluid status, care of a CVC, infection, and the technical aspects of administering parenteral feeding formulations.[85] Preparation for HPN includes placement of a central venous access device for long-term TPN therapy.[7,8]

Case 38-4, Question 6: What other measures can be used to simplify D.D.'s PN regimen and encourage ambulation?

PN is generally administered as a 24-hour continuous infusion. However, when PN is needed long term or administered on an outpatient basis, there are advantages of transitioning from a continuous to a cyclic infusion. Cycling means that the PN formulation is infused for <24 hours per day (typically over 10–14 hours), so that there is time free from PN therapy each day. Once the patient has demonstrated stability on a continuous 24-hour PN regimen, a transition to a cyclic regimen may begin several days before hospital discharge. The cyclic PN is typically advance daily toward the goal infusion time (usually a 10- to 16-hour infusion). Advancement of the cyclic regimen is dependent on the patient's ability to tolerate the changes in fluid and nutrient intake that occur when the PN is infused over a shorter time frame each day. For example, the 24-hour PN infusion is decreased to a 20-hour infusion (eg, 8:00 pm to 4:00 pm) on cyclic PN day 1 and then the next day is decreased to a 16-hour infusion (eg, 8:00 pm to 12:00 noon), and the

next day a 12-hour infusion (eg, 8:00 pm to 8:00 am). With each incremental decrease in time, the infusion rate should be increased such that the TPN volume (previously administered in the 24-hour infusion) is infused each day. The infusion rate of the PN regimen is generally tapered up over 1 to 2 hours during PN initiation to avoid hyperglycemia and tapered down over 1 to 2 hours during PN discontinuation to avoid hypoglycemia. For example, a 16-hour cyclic PN infusion with a 1-hour taper up and down can be calculated (see Eq. 38-9) by taking the total TNA volume divided by the infusion time minus 1 hour, to estimate the goal infusion rate. The goal infusion rate is then divided by 2 to get the 1-hour taper up and down rate. For D.D.'s 3000 mL TNA, the regimen would start at 8:00 pm at 100 mL/hour for 1 hour, then at 9:00 pm the rate would increase 200 mL/hour for 14 hours. At 11:00 am the following day, the TNA rate would taper back down to 100 mL/hour and then at noon it would stop. Most infusion pumps used at home can automatically make these adjustments in the infusion rate. Eventually, the nutrient formulation can be infused for 10 to 12 hours during the night, leaving D.D. free from his PN infusion during the day.

$$\begin{aligned}\text{Cyclic PN goal infusion rate} &= \text{TNA volume}/(\text{infusion time} - 1\text{ hour})\\ &= 3000\text{ mL}/16\text{ hours} - 1\text{ hour}\\ &= 200\text{ mL/hour}\\ \text{Cyclic PN taper up and down rate} &= \text{Goal infusion rate}/2\\ &= 200\text{ mL/hour}/2\\ &= 100\text{ mL/hour}\end{aligned}$$

(Eq. 38-9)

Vital signs, fluid intake and output, serum electrolytes, and glucose concentrations should continue to be monitored. The serum glucose concentration should be evaluated 30 minutes to 1 hour after the PN infusion is completed to be sure that hypoglycemia does not occur.

Case 38-4, Question 7: In addition to his PN formula and ranitidine 150 mg IV, D.D. is receiving hydrocortisone 100 mg IV every 8 hours, and he now needs insulin. Can these medications or any other medications be mixed with his PN formula to simplify his medication regimen?

Adding medication to PN is not advised owing to the complexity of the PN formulation and the potential for physiochemical interactions with various drug–nutrient combinations. Patients receiving PN therapy often require concomitant drug therapy. Most patients have adequate venous access or have multiple-lumen CVCs, so that mixing medications with the parenteral nutrient formulation is not necessary. However, for some patients with limited venous access, directly adding medication to the PN or co-infusing medication through the same IV tubing may be considered if stability and compatibility with the PN can be assured and there is no other reasonable medication delivery alternative. Examples of medications that may occasionally be added to PN is regular human insulin and H2-receptor antagonists. Often times, there are requests to add other medications to a PN admixture. Specific criteria for drug admixture with PN are listed as follows[88]:

1. Stability and compatibility of the drug with the specific parenteral admixture over a 24-hour period must be determined before adding the medication.
2. The medication must have appropriate pharmacokinetics and proven efficacy for continuous infusion.
3. The medication dose must have remained constant throughout the previous 24-hour period before admixture in PN.
4. There should be a stable PN infusion rate for at least 24 hours before the medication is added.
5. PN should include appropriate labeling to avoid pharmacotherapeutic problems associated with abrupt discontinuation of PN.

Case 38-4, Question 8: After receiving HPN for 4 weeks, D.D.'s liver function tests are found to be elevated. Current values are as follows:

Bilirubin, 0.8 mg/dL
Aspartate aminotransferase, 70 units/L
Alanine aminotransferase, 90 units/L
Alkaline phosphatase, 100 units/L

Could his PN be contributing to the abnormalities in liver function tests?

Elevations in liver function tests are common in children and adults receiving long-term PN therapy and may be seen as early as 2 to 3 weeks after beginning therapy.[89] The abnormalities are usually mild and transient and do not progress to significant liver dysfunction in adults. The predominant type of hepatobiliary dysfunction is steatosis (fatty liver), whereas other patients develop cholestasis or cholelithiasis (biliary obstruction). Liver-associated enzyme elevations usually resolve when PN therapy is discontinued. Although it is uncommon for PN-associated liver disease to progress to hepatic failure, it remains a feared life-threatening complication of long-term PN therapy.[40,90] ω-6 PUFAs and phytosterols in soybean oil IVFE have been thought to contribute to hepatotoxicity. Recent data suggest that IVFE containing fish oil, high in ω-3 FAs with minimal phytosterols, has a hepatoprotective effect.[91]

There are few options to prevent or manage PN-associated liver abnormalities. Some strategies include avoiding overfeeding with carbohydrate and lipid transitioning from a soybean oil to fish oil (ω-3 FAs) IVFE, and utilizing metronidazole and supplements of ursodeoxycholic acid, choline, and carnitine. In addition, transitioning the PN from a 24-hour continuous infusion to a cyclic regimen may decrease the risk of liver dysfunction for patient requiring long-term PN therapy. Patients with progressive liver disease may be the candidates for liver and small bowel transplantation.[90]

The elevations in D.D.'s liver enzymes are not of concern at this time because they are less than three times normal. However, because D.D. has been on HPN for 4 weeks and his wounds have healed, it is time to decrease his energy and protein intake to

maintenance requirements (20–25 kcal/kg/day and 0.8–1.0 g/kg/day of protein). Liver enzymes should be monitored weekly. Because he may not need lifelong PN therapy, the mild elevations are likely to resolve.

It is important to keep in mind that the liver is the primary organ involved with digestion, metabolism, and storage of nutrients. When the functional capacity of the liver is compromised (eg, cirrhosis), macronutrient intolerance and imbalances may occur. The patient may experience hyperglycemia, hypoglycemia, variations in blood lipid levels, and accumulation of AA metabolites (ammonia).

Case 38-4, Question 9: After 10 months of receiving home TPN, D.D. suffers a fall and fractures his wrist. Fracture of the wrist from a fall raises suspicions of compromised bone density. Subsequent dual-energy x-ray absorptiometry (DEXA) scan reveals a bone density T-score of −3.1. Can these results be caused by long-term PN? What are other complications of long-term parenteral therapy?

Long-term complications of PN are adverse effects associated with PN lasting >3 months. The most common complications include central catheter complications (infection or occlusion), metabolic bone disease, and hepatobiliary disease.[92]

The incidence of hepatobiliary complications associated with long-term PN ranges from 19% to 75%. These complications are variable, with patients experiencing chronic elevations in liver enzymes to advanced liver disease (fibrosis and cirrhosis). Liver disease associated with PN is termed intestinal failure–associated liver disease (IFALD). IFALD is divided into non-nutrient and nutrient-related causes. Non-nutrient causes of IFALD can include medications, biliary obstruction, bacterial overgrowth, and intrinsic liver disease. Nutrient-related IFALD can be caused by overfeeding, nutrient toxicities, and deficiencies. Nutrient toxicities associated with IFALD include manganese, aluminum, and soybean oil. Some nutrient deficiencies associated with IFALD are taurine, choline, carnitine, and essential FAs. The most common histologic finding in IFALD is steatosis followed by cholestatic stasis, fibrosis, and, finally,

cirrhosis. Hepatic steatosis is associated with both underfeeding and overfeeding, so the importance of ensuring the correct amount of calories is of utmost importance.[93]

The exact cause of metabolic bone disease in long-term PN is unknown; however, its origins appear to be multifactorial. The predominant risks factors for metabolic bone disease in D.D. include CD, the medications used to manage it (eg, corticosteroids) coupled with the use of long-term PN therapy.[93] Both osteoporosis and osteomalacia have been associated with long-term PN use. Osteoporosis is the most common form of metabolic bone disease and is because of loss of bone mass. Osteomalacia is the softening of bones and generally occurs as the result of vitamin D deficiency. A combination of both osteoporosis and osteomalacia may occur. Deficiencies in micronutrients such as calcium, magnesium, and vitamin D are risk factors. Historically, bone abnormalities were thought to be caused by aluminum toxicity. However, as aluminum has been nearly eliminated from TPNs, metabolic bone disease remains an issue. High AA concentrations and TPN cycling cause increased renal calcium excretion. Other factors include abnormalities in the handling of calcium, phosphorus, and vitamins D and K.[93]

Central catheter–related complications can vary from occlusion to central catheter–related sepsis. Both of these complications are related to CVC care and are a surrogate measure of overall catheter care.[94] Occlusion develops from fibrin and/or lipid deposits. The consequences of catheter occlusion range from diminished flow to complete occlusion, necessitating removal of the catheter. Central catheter infections are associated with the amount of times the catheter is accessed for PN administration and blood sample removal. Patients with CVC infections usually present with symptoms and signs such as pyrexia and tachycardia during PN infusion. The causes of central catheter infections are bacterial and are usually because of skin flora, *Staphylococcus epidermis* and *Staphylococcus aureus*. If CVC-related sepsis is suspected, then the CVC being used should be discontinued and peripheral and central

cultures taken, while antimicrobial therapy is started pending culture results.[94]

SECTION 8

Dermatologic Disorders

Section Editor: Katie Kiser

39

Dermatotherapy and Drug-Induced Skin Disorders

Daniel R. Malcom and Lynn Z. Fuller

CORE PRINCIPLES		CHAPTER CASES
1	Accurate assessment of dermatologic conditions is primarily based on the appearance and location of the skin lesion, plus age, sex, symptoms, and current and past medical and family histories.	**Case 39-1 (Question 1), Figure 39-1, Tables 39-1–39-3**
2	The selection of topical corticosteroid is based on the nature of the lesion (wet vs dry), the concentration of the corticosteroid, the nature of the vehicle, the corticosteroid potency, the location of the lesion, and the thickness of the epidermis.	**Case 39-2 (Question 1, 2), Figure 39-1, Tables 39-1–39-5**
3	Topical corticosteroids can cause a	**Case 39-3 (Question 1–3), Tables 39-4–39-6**

	variety of adverse effects and adverse reactions that may require adjustment of therapy, including changing products or discontinuing their use.	
4	Dry skin (xerosis) is a common condition that may occur alone or with a variety of dermatologic disorders and requires appropriate treatment depending on geographic location.	**Case 39-4 (Question 1)**
5	Atopic dermatitis is a common dermatologic condition characterized by eczematous lesions, dry skin, and intense pruritus. It is primarily treated with topical corticosteroids and emollients.	**Case 39-5 (Question 1–5), Tables 39-1, 39-3, 39-4, 39-7**
6	Allergic contact dermatitis is one of the most common dermatologic conditions seen by pharmacists. Treatment consists of removal of the antigen and use of topical or systemic corticosteroids.	**Case 39-6 (Question 1), Case 39-7 (Question 1), Tables 39-1, 39-3, 39-4, 39-7**
7	Medications are a common cause of a variety of dermatologic disorders. Timing relative to medication ingestion and principles of dermatologic assessment are important to identify potential life-threatening adverse reactions.	**Case 39-8 (Question 1), Table 39-5**

INTRODUCTION

Anatomy and Physiology of the Skin

The skin is the largest organ in the body and constitutes, on average, nearly one-fifths of a person's body weight. **Figure 39-1** shows a cross section of the anatomy of human skin. Physiologically, the major function of skin is to protect the underlying structures from trauma, temperature variations, mechanical penetrations, moisture, humidity, radiation, and invasion of microorganisms. There are three layers of skin: epidermis, dermis, and subcutaneous tissue.[1–5]

Stratum spinosum
Stratum lucidum
Stratum corneum
Stratum germinativum
Epidermis
Capillary network
Hair shaft
Sebaceous gland
Arrector pili muscle
Dermis
Apocrine (sweat) gland
Hair follicle
Hypodermis (subcutaneous tissue)
Blood vessel

k

Figure 39-1 Cross section of the anatomy of human skin.

EPIDERMIS

The major function of the epidermis is to serve as a barrier. The *stratum corneum*, which is the outermost layer of the epidermis, provides the greatest resistance to the percutaneous absorption of chemicals and drugs. It behaves as a semipermeable membrane through which drugs are absorbed by passive diffusion. Skin hydration and damage to the stratum corneum can enhance drug absorption. Skin diseases affecting only the epidermis typically heal without scarring.[1–5]

DERMIS

The dermis is composed of collagen fibers and provides capillary, lymphatic, and nerve supply to the skin. The dermis contains large amounts of water, thus serving as a water storage organ as well. Importantly, all but the most superficial injuries to the dermis generally result in scarring as the wound heals.[1–5]

Drugs passing through the epidermis penetrate directly into the dermis and may be absorbed into the general circulation through the capillary network. Only small amounts of topically applied drugs enter the dermis via the sweat glands or the pilosebaceous units.

SUBCUTANEOUS LAYER

The subcutaneous layer supports the dermis and epidermis and serves as a fat storage area. This layer helps regulate temperature and provides nutritional support and cushioning to the outer skin layers.[1–5]

DERMATOLOGIC DRUG DELIVERY SYSTEMS

Dermatologic formulations are available in a variety of forms: solutions, suspensions or shake lotions, powders, lotions, emulsions, gels, creams, ointments, and aerosols. Each dermatologic delivery vehicle has specific characteristics and uses based on the type, relative acuteness, and location of the lesion.

Selection of a Delivery System

Dermatologic vehicles should be matched to the type of lesion for which they will be used. Acute lesions (ie, immediately following presentation, often weeping or oozing) require aqueous vehicles until the lesions become dry. Subacute lesions (ie, after initial healing has started and crusting has occurred) also benefit from aqueous vehicles, but for shorter periods before switching to creams or gels. Chronic lesions usually require ointments because of their dry, lichenified characteristics.

Solutions

Solutions provide evaporative cooling and vasoconstriction, with resultant mild antipruritic effects. Aqueous solutions are most useful for acutely inflamed, oozing lesions and are often applied as wet dressings. The most commonly used solutions are normal saline (0.9% NaCl) and aluminum acetate 5% solution (Burow solution) diluted 1:10 to 1:40.

The most important component of a solution is water. Although active or inert substances may be added to solutions, the cleansing, drying, and cooling effect of water provides the major therapeutic benefit. Some products (eg, Burow solution) also have *astringent* properties that alter the skin surface and interstitial spaces to cause contraction and wrinkling. Water penetration is reduced to minimize edema, inflammation, and exudation.[6]

Powders

Powders can be medicated or nonmedicated, although even nonmedicated powders can have therapeutic benefit. They are drying and cooling, absorbing moisture and creating more surface area for evaporation. They are used mainly in intertriginous areas where skin touches the skin (eg, groin, under the breasts, or in skin folds) to decrease friction and irritation. Powders are useful in the treatment of chafing, tinea pedis (athlete's foot), tinea cruris (jock itch), and diaper dermatitis (diaper rash). Contrary to what may be thought given their drying effect, powders should not be applied to oozing lesions because they tend to cake into hard granules, making them difficult and painful to remove and promoting maceration. The most commonly used powder is talc.

Lotions

Lotions are suspensions or solutions of powder in a water vehicle. They are usually cooling and drying, but may provide some lubrication, depending on the formulation. Lotions are used to treat superficial dermatoses, especially if there is slight oozing. They are useful if large or intertriginous areas are affected, and they are especially advantageous in the treatment of conditions characterized by significant inflammation and tenderness.[6]

Liquid Emulsions

Liquid emulsions can be divided into two classes: *oil-in-water* (o/w) and *water-in-oil* (w/o) emulsions. Creams are generally oil-in-water emulsions, whereas ointments are water-in-oil emulsions. The indications for liquid oil-in-water emulsions (eg, Keri Lotion, Cetaphil) are similar to those for lotions and creams, except that this dosage form provides greater occlusion and is more useful in conditions in which dry skin predominates. Liquid water-in-oil emulsions (eg, Nivea, Eucerin, or Lubriderm) have similar indications to ointments, except that they can be applied more easily than ointments. Water-in-oil emulsions are most useful in conditions in which dry skin

predominates; application to hairy or intertriginous areas should be avoided.[7]

Gels

Gels are a form of ointment (semisolid emulsion) that contain propylene glycol (a drying agent) and carboxypolymethylene (a thickening agent). They are clear, nongreasy, nonstaining, nonocclusive, and quick drying. They are thixotropic (ie, become thinner with rubbing and may sting on application). Gels are most useful when applied to hairy areas or other areas such as the face or scalp, where it is considered cosmetically unacceptable to have the residue of a vehicle remain on the skin. Because of their ingredients, gels tend to be more drying.

Creams

Creams are the most commonly used vehicle in dermatology. Most are oil-in-water emulsions and are intended to be rubbed in well until they vanish. Because creams are drying and do not provide much occlusiveness, they are most often recommended for subacute lesions and occasionally for chronic lesions without significant lichenification.

Ointments

Ointments are made of inert bases such as petrolatum or may consist of droplets of water suspended in a continuous phase of oleaginous material (ie, water-in-oil emulsions such as Aquaphor® or Polysorb®). Ointments are most useful on chronic lesions, relieving dryness, brittleness, and protecting fissures owing to their occlusive properties. They should not be used on acutely inflamed lesions. Ointments should not be applied to intertriginous, burns, or hairy areas because they tend to trap heat and promote maceration. Ointments are greasy and may be cosmetically unacceptable.

Aerosols

Aerosols are the most expensive and inefficient way to apply dermatologic medications. Their only advantage over other dosage forms is that they do not require direct mechanical contact with the skin and may be useful if application causes intolerable pain for the patient. If an aerosol is used, it should be shaken well before use, and the patient should be cautioned not to spray the product around the face where it could get into the eyes or nose or be inhaled. Generally, aerosols should be sprayed from approximately 6 inches (15.24 cm) above the skin in bursts of 1 to 3 seconds. Aerosols are also useful for application to hairy areas if a special application nozzle is used. Aerosols have a drying effect and should not be used for a long period. Because aerosols contain a propellant, patients may have reactions to this dosage form.

PATIENT ASSESSMENT

CASE 39-1

QUESTION 1: C.B., a 23-year-old, 145.50 pounds (66-kg) female, with rashes. What types of questions should C.B. be asked to help determine the appropriate diagnosis and treatment?

The diagnosis of dermatologic conditions can be simplified by considering six primary factors: appearance (what the lesions look like, pattern of the lesions); location or distribution of the lesions on the body; symptoms, both local and systemic; history of the present condition as well as related conditions; age of the patient; and biologic sex. Direct observation of the skin lesion, plus C.B.'s responses to questions about these factors, will allow an appropriate diagnosis and treatment plan.

Appearance (Morphology)

Table 39-1 provides a listing of common dermatologic lesions, their respective definitions, and some well-known clinical examples. Lesions may also be classified as either primary (first appearing on the skin) or secondary (developing from primary lesions). Early and accurate recognition of lesions can be critical to achieving optimal therapeutic outcomes.

Table 39-1
Dermatologic Lesions, Definitions, and Clinical Examples

Name	Definition	Examples
Primary Lesions		
Macule	Nonpalpable, flat, change in color, <0.39 inches (1 cm)	Freckles, flat moles
Patch	Nonpalpable, flat, change in color, >0.39 inches (1 cm)	Vitiligo, “café au lait” spots, chloasma
Papule	Palpable, solid mass, may have change in color, <0.39 inches (1 cm)	Verrucae, noninflammatory acne (comedone), raised nevus
Nodule	Palpable, solid mass, most often below the plane of the skin, 0.39–0.78 inches (1–2 cm)	Erythema nodosum, severe acne
Tumor	Palpable, solid mass, >0.78 inches (2 cm), most often above and below the plane of the skin	Neoplasms
Plaque	Flat, elevated, superficial papule with surface area greater than height, >0.39 inches (1 cm)	Psoriasis, seborrheic keratosis
Wheal	Superficial area of cutaneous edema, fluid not confined to cavity	Urticaria (hives), insect bite
Vesicle	Palpable, fluid-filled cavity, <0.39 inches (1 cm), filled with serous fluid (blister)	Herpes simplex, herpes zoster, contact dermatitis
Bulla	Palpable, fluid-filled cavity, >0.39 inches (1 cm), filled with serous fluid (blister)	Pemphigus vulgaris, second-degree burn

Name	Definition	Examples
Pustule	Similar to vesicle, but filled with purulent fluid	Acne, impetigo, folliculitis
Special Primary Lesions		
Comedone	Plugged opening of sebaceous gland	Acne, blackhead, whitehead
Cyst	Palpable lesion filled with semiliquid material or fluid	Sebaceous cyst
Abscess	Accumulation of purulent material in dermis or subcutaneous layers of skin; purulent material not visible on surface of skin	
Furuncle	Inflammatory nodule involving a hair follicle, following an episode of folliculitis	Small boil
Carbuncle	A coalescence of several furuncles	Large boil
Secondary Lesions		
Erosion	Loss of part or all the epidermis	Ecthyma
Ulcer	Loss of epidermis and dermis	Stasis ulcer
Fissure	Linear crack from epidermis into dermis	Tinea pedis
Excoriation	Self-induced linear, traumatized area caused by intense scratching	Atopic dermatitis, extreme pruritus
Atrophy	Thinning of skin with loss of dermal tissue	Striae
Crusts	Dried residue of pus, serum, or blood from a wound, pustule, or vesicle	Impetigo, scabs
Lichenification	Thickening of epidermis, accentuated skin markings, usually induced by scratching or chronic inflammation	Atopic dermatitis, allergic contact dermatitis

Many lesions present in a particular distribution or pattern. Poison ivy lesions are commonly distributed linearly. Herpetic lesions are so typical that the term “herpetiform” is used for lesions caused by other conditions that have a herpes-like distribution. The specific size of the lesion is also important in assessing a patient’s condition. Dermatologic terms related to lesion distribution or pattern are shown in **Table 39-2**. The lesion’s consistency (firm vs soft), borders, and color are also important diagnostic considerations.

Table 39-2
Descriptive Dermatologic Terms

Term	Characteristics	Examples
Annular	Ring-shaped	Tinea
Acneiform	Acne-like	Acne vulgaris
Arcuate	Shaped like an arc	Syphilis
Circinate	Circular	Tinea
Confluent	Lesions run together	Psoriasis, tinea
Discrete	Lesions remain separate	Psoriasis, tinea
Eczematous	General term for dry, red flaky, or lichenified skin without clear border	Chronic allergic contact dermatitis, atopic dermatitis
Geographic	Shaped like islands or continents; map-like	Generalized psoriasis
Grouped	Lesions clustered together	Herpes
Herpetiform	Appears like herpes simplex	Herpes simplex
Intertrigo	Irritant dermatitis in skin folds	Diaper dermatitis
Iris	Looks like a bull's-eye, lesion within a lesion, target lesion	Erythema multiforme
Keratotic	Horny thickening	Psoriasis, corn, callus
Linear	Shaped in lines	Poison ivy
Multiform	More than one type or shape of lesion	Erythema multiforme
Papulosquamous	Papules with desquamation	Psoriasis
Serpiginous	Snake-like lesions	Cutaneous larva migrans
Zosteriform	Appears like herpes zoster	Herpes zoster

Location

Certain lesions or conditions usually occur in specific body locations, usually because of physiologic reasons. **Table 39-3** provides a list of anatomic sites with common dermatoses occurring in those locations. For example, diseases of the sebaceous glands (eg, acne,

seborrheic dermatitis, rosacea) occur only in sites with high concentrations of sebaceous glands, such as the scalp, head, neck, chest, and umbilicus. Atopic dermatitis shows a predilection for the flexor surfaces of the body (ie, antecubital and popliteal fossae).

Table 39-3
Common Skin Diseases by Body Location

Location	Skin Diseases
Scalp	Seborrheic dermatitis, dandruff
Face	Acne, rosacea, seborrheic dermatitis, perioral dermatitis, impetigo, herpes simplex, atopic dermatitis
Ears	Seborrheic dermatitis
Chest or abdomen	Tinea versicolor, tinea corporis, pityriasis rosea, acne, herpes zoster
Back	Tinea versicolor, tinea corporis, pityriasis rosea
Genital area	Tinea cruris, scabies, pediculosis, condyloma acuminate (venereal warts)
Extremities	Atopic dermatitis (cubital and popliteal fossa)
Hands	Tinea manuum, scabies, primary irritant contact dermatitis, warts
Feet	Tinea pedis, contact dermatitis, onychomycosis
Generalized or localized	Primary irritant or contact dermatitis, photodermatitis

Symptoms

Most skin conditions have only localized symptoms with the most common symptom being pruritus. Occasionally, localized burning or pain is the predominant symptom.

History

Although a diagnosis may often be made from morphology, location, and symptoms, the patient history provides useful diagnostic and therapeutic information. Similar to the historical information obtained

for any acute medical problem, the following questions should always be asked:

1. When and how did the problem start?
2. How has it progressed or changed since its onset? How have the lesions changed in size, color, appearance, or severity?
3. What is the patient's past and current medical history? What other symptoms might indicate that this is a dermatologic manifestation of a systemic disease?
4. What are the patient's other symptoms?
5. What kind of allergies does the patient have?
6. What makes the condition worse or better?
7. What events or happenings have occurred with the onset or worsening of the condition (eg, increased stress, exposure to new products, recent travel, and changes in climate)?
8. What have you used to treat the condition, and how have the treatments worked?
9. How did the patient use any previous therapy, and for how long did they use it?

Age

Certain conditions occur predominantly among certain age groups, such as acne in neonates and adolescents, seborrheic dermatitis in neonates and those ages 11 to 12 years, rosacea in those older than 30 years, and atopic dermatitis primarily in children younger than 6 years. In fact, atopic dermatitis begins and ends before age 6 years in 95% of patients. It is equally important to realize that many conditions, such as primary irritant and allergic contact dermatitis, occur independent of age. In addition, the skin of children and patients older than 65 years is more penetrable, thus more responsive and more susceptible to adverse effects from therapy with topical agents. Topical therapeutic agent potency and delivery systems must be carefully evaluated before usage.

Sex

Although most dermatologic conditions occur in both sexes, sometimes frequency and severity are sex-dependent. Rosacea occurs more frequently in females but is often more serious in males.

TOPICAL CORTICOSTEROIDS

Table 39-4 lists the most common topical corticosteroid preparations by their degree of potency according to the Stoughton–Cornell classification system. When equal amounts of a corticosteroid are incorporated into ointments, gels, creams, and lotion bases, the gel and ointment preparations are generally more active than creams and lotions.[8–12] However, with the increased use of optimized vehicles, that rule is not as true as in the past. The addition of certain substances enhances penetration and potency. Using these principles, pharmaceutical manufacturers have increasingly developed optimized vehicles that maximize diffusion of individual corticosteroids into the stratum corneum. Unfortunately, these optimized bases may be labeled as ointments, creams, or gels. Therefore, for new products, the only reliable way to ascertain potency is to consult the manufacturer's literature for its Stoughton–Cornell classification. Increasing the concentration of a corticosteroid in a preparation also increases its potency, but not in a linear fashion.

Table 39-4
Selected Topical Corticosteroid Preparations by Stoughton–Cornell Classification of Potency

Corticosteroid	Example Brand Name(s)	Vehicle
1 (Most Potent) No >2 Weeks' Use		
Betamethasone dipropionate, augmented	Diprolene 0.05%	Gel, lotion, ointment (optimized)

Corticosteroid	Example Brand Name(s)	Vehicle
Clobetasol propionate	Temovate 0.05%	Cream, gel, ointment, solution (scalp)
Fluocinonide	Vanos 0.1%	Cream
Halobetasol propionate	Ultravate 0.05%	Cream, lotion, ointment
2		
Betamethasone dipropionate, augmented	Diprolene AF 0.05%	Cream
Betamethasone dipropionate	Diprosone 0.05%	Ointment
Diflorasone diacetate	Florone, ApexiCon 0.05%	Ointment
Fluocinonide	Lidex 0.05%	Cream, gel, ointment, solution
Halobetasol propionate	Bryhali® 0.01%	Lotion
Mometasone furoate[a]	Elocon 0.1%	Ointment
3		
Betamethasone dipropionate	Diprosone 0.05%	Cream, hydrophilic ointment
Betamethasone valerate	Valisone 0.1%	Ointment
Diflorasone diacetate	Florone 0.05%	Cream
Fluocinonide	Lidex-E 0.05%	Cream aqueous emollient
Triamcinolone acetonide	Aristocort HP, Kenalog, Triderm 0.05%	Cream, ointment
4		
Betamethasone dipropionate	Sernivo 0.05%	Spray
Fluocinolone acetonide	Synalar 0.025%	Ointment
Hydrocortisone valerate[a]	Westcort 0.2%	Ointment
Mometasone furoate[a]	Elocon 0.1%	Cream
Triamcinolone acetonide	Kenalog, Triderm 0.1%	Cream, ointment
5		

Corticosteroid	Example Brand Name(s)	Vehicle
Betamethasone dipropionate	Diprosone 0.05%	Lotion
Betamethasone valerate	Beta-Val, Valisone 0.1%	Cream
Fluocinolone acetonide	Synalar 0.025%	Cream
Hydrocortisone butyrate[a]	Locoid 0.1%	Cream, ointment, solution
Hydrocortisone valerate[a]	Westcort 0.2%	Cream
Triamcinolone acetonide	Kenalog 0.25%	Ointment
6		
Betamethasone valerate	Valisone 0.1%	Lotion
Desonide[a]	Desowen 0.05%	Cream
Fluocinolone acetonide	Synalar 0.01%	Cream, solution
Triamcinolone acetonide	Kenalog 0.025%	Cream, lotion
7 (Least Potent)		
Hydrocortisone[a] (base, ≥2%)	Hytone, Nutracort 2.5%	Cream, ointment
Hydrocortisone[a] (base, <2%)	Cortaid, Cortizone 1%	Cream, gel, ointment
Hydrocortisone[a] acetate	MiCort™ HC 2.5%	Cream

[a]Nonfluorinated corticosteroid.

Indications

A topical corticosteroid is often the drug of choice for many inflammatory and pruritic eruptions. In addition, topical corticosteroids are useful with hyperplastic and infiltrative disorders. The following conditions generally respond well to topical corticosteroids: allergic contact dermatitis, atopic dermatitis, psoriasis, and seborrheic dermatitis.

Contraindications

The following conditions (predominantly infectious etiologies) are worsened by topical corticosteroids: acne vulgaris, ulcers, scabies, warts, molluscum contagiosum, fungal infections, and viral infections.

CASE 39-2

QUESTION 1: A.J. is a 54-year-old male who has suffered intermittently from plaque psoriasis for almost 20 years. Most lesions have been coin-sized in various locations (mostly elbows and knees). Normally, gentle removal of the scales and application of 1% hydrocortisone ointment has been effective over several weeks during which it disappears. He has averaged less than a lesion a year. He saw a dermatologist once 18 years ago. Six weeks ago, a much larger hand-sized lesion developed on his elbow. The usual treatment has been ineffective.

What are the relevant biopharmaceutic considerations for selecting a topical corticosteroid for A.J.?

Topical corticosteroids are classified into potency categories (see Table 39-4). The relative potency assigned to a topical corticosteroid is determined by the ability of the preparation to penetrate the skin after release from the vehicle, the intrinsic activity of the corticosteroid at the receptor, and the rate of clearance from the receptor.[10] Activity of corticosteroids may be enhanced by the use of a more occlusive vehicle, the addition of penetration-enhancing substances (eg, petrolatum, propylene glycol), and pharmacologic structure modifications of the steroid molecule itself. For example, hydrocortisone has been modified at the structural level in several ways to alter its activity. The addition of a fluorine atom at the 6, 9, and 21 positions protects the steroid ring from metabolic conversion, resulting in more potent activity. The addition of a double bond between the first and second carbon atoms slows metabolism, increasing duration of action. The introduction of an acetonide bond or lipophilic ester groups increases skin penetration. Many newer topical corticosteroids have incorporated one or more of these molecular changes, resulting in increased-potency agents and a growing armamentarium of agents.[8–12]

Topical corticosteroids penetrate the stratum corneum by passive diffusion, which varies considerably, depending on thickness of the stratum corneum over the part of the body to which the preparation is applied. When a standard hydrocortisone preparation was applied to various parts of the body, absorption was found to be 0.14% on the plantar surface of the foot, 1% on the forearm, 4% on the scalp, 7% on the forehead, 13% on the cheeks, and 36% on the scrotum. Because penetration is high in the groin, axillae, and face, lower-potency nonfluorinated topical preparations such as hydrocortisone 0.5% to 1% should be used on these areas.[8–12] In areas where penetration is poor, owing to thicker stratum corneum, such as the elbows, knees, palms, or soles, higher-potency preparations should be used.[8–12]

The stratum corneum acts as a reservoir, precluding the need for more than twice daily application. In low-potency preparations, this reservoir effect persists for several days, and with the most potent preparations under occlusion, the effects may persist for up to 14 days.[8–12] The clinical implication of this reservoir effect on chronic conditions is a cumulative effect with repeated application of topical corticosteroids. As a result, the number of applications per day can be reduced, and less potent preparations can be used after the acute inflammatory process has been brought under control. It also allows less frequent administration to maintain remission.

For A.J., a high-potency cream (class 2 or 3 as listed by Stoughton–Cornell classification of corticosteroid potency in Table 39-4) should be used because the thicker stratum corneum over the elbow, the presence of scales, and a raised plaque decreases penetration.

Case 39-2, Question 2: Given A.J.'s larger lesion and the failure of his usual therapy, should occlusive therapy be used? What complications could develop from occlusion? How should the use of occlusion be explained to A.J.?

Occlusion

Occlusion increases the hydration of the skin and resultant absorption of corticosteroid preparations, thus producing a heightened therapeutic effect. Generally, occlusion can be accomplished by the following: (a) selecting an ointment-based corticosteroid, (b) applying a nonmedicated ointment base over a corticosteroid preparation (gel, cream, lotion, or aerosol), 30 minutes after applying the corticosteroid, or (c) by enveloping the medicated area with plastic (eg, plastic wrap, gloves, or plastic suit). Occlusion is best used for chronic lesions that are thick and scaly, in which drug absorption is impaired, such as psoriasis. Increasing the hydration of the skin (with a shower or bath) also increases the effects of medications immediately applied after the bath or shower. An appropriate recommendation for A.J. would be fluocinonide ointment 0.05% applied twice daily to only the psoriatic plaques.[4,6,8–12] For other conditions, for example, atopic dermatitis, several hours of occlusion are all that are necessary to increase potency, these relatively short periods of occlusion can be clinically useful. Occlusion can be uncomfortable and can lead to sweat retention and an increased risk of bacterial and fungal infections. To reduce these problems and the chances of systemic adverse effects, occlusion should not be maintained for more than 12 hours in a 24-hour period. Occlusion should not be used for acute lesions, which already have increased absorptive capability and need the vasoconstrictive effects of cooling first.

The powerful occlusive properties of cloth and disposable diapers tend to be underappreciated. Therefore, only lower-potency nonfluorinated topical corticosteroids such as hydrocortisone valerate or mometasone should be used in the diaper area for no more than 24 to 48 hours in the rare instances of severe diaper dermatitis not responding to conservative treatment. Use of topical corticosteroids to enhance the effectiveness of antifungals to treat diaper dermatitis complicated by fungal infection is only theoretic and does not enhance the efficacy of anticandidal antifungals. However, use of topical corticosteroids does increase the risk of potentially irreversible disfiguring local adverse effects, including scarring.

Adverse Drug Effects

Although relatively infrequent, both localized (ie, at the application site) and systemic adverse effects (from percutaneous absorption) can be caused by topical corticosteroids. The risks for adverse reactions are influenced by the potency of preparation used, frequency of application, duration of use, anatomic site of application, and individual patient factors. Any of the previously discussed factors that increase potency, such as inflammation and occlusion, increase the chances of adverse effects.[8]

CASE 39-3

QUESTION 1: K.L. is a 54-year-old male, recently diagnosed with mild Parkinson disease, who presents with a severe case of seborrheic dermatitis involving the ears, scalp line, forehead, and nasal labial folds. The areas are quite inflamed and red with yellow greasy scales. K.L. is upset with the way it looks. Because suppressing the cause of the disease, the yeast, *Malassezia furfur*, will take some time, it is decided to initially use a topical corticosteroid to reduce the redness and improve K.L.'s appearance.

What would be an appropriate choice of topical corticosteroid for K.L.?

The biggest concern for K.L. is the potential for epidermal and dermal atrophy (thinning of the skin), telangiectasia (small red or purple clusters of dilated capillaries), localized fine hair growth, bruising, hypopigmentation, and striae. These local complications can result from repeated application of topical corticosteroids.[11] Epidermal changes consisting of a reduction in cell size may begin within several days of therapy and are generally reversible after the therapy is stopped.[9] Exposed areas (face) and thin-skinned areas (groin) are most vulnerable to dermal and epidermal atrophy.

Dermal atrophy generally takes several weeks to occur and can be reversed in some cases, depending on how long the patient has used the corticosteroid, and on individual host factors such as skin age. Dermal atrophy can be reversible within 2 months after stopping the corticosteroid.[11]

Telangiectasia, which occurs most often on the face, neck, groin, and upper chest, may not be reversible after stopping corticosteroid therapy. Striae, which occur most commonly in the cubital and popliteal fossa, groin, axillary, and inner thigh areas, are usually permanent.[11] Fine hair growth may be particularly bothersome to female patients using corticosteroid preparations on the face. This problem is generally reversible after stopping therapy. Hypopigmentation, predominantly a problem of dark-skinned patients, is generally reversible after therapy is discontinued.[11]

Especially in thin-skinned areas such as the face, fluorinated corticosteroids are more likely to cause these localized reactions because of their increased potency than are nonfluorinated corticosteroids. Therefore, whenever possible, only nonfluorinated topical corticosteroids should be used in thin-skinned areas for the shortest possible time. Because the use of corticosteroids is expected to last less than a week, the risk of developing local complications is minimal with a nonfluorinated product.

Because the lesions are on the face, a nonfluorinated corticosteroid such as hydrocortisone valerate or mometasone should be used to minimize the potential for adverse effects in this thin-skinned area. Although there is minimal oozing and weeping, his sensitivity to appearance would indicate a cream might be more appropriate.

Case 39-3, Question 2: K.L. calls the next day and presents with a burning sensation lasting for about 30 minutes after each application. He wants to know whether potentially is this an allergic reaction?

Because of the time course of the burning sensation in K.L. (starting the first day and lasting only 30 minutes), it is doubtful that he is allergic to this product and the cream is likely the cause. To remedy this situation, K.L. should continue to apply the cream and if the burning sensation continues for the next 24 hours to call again. Creams applied to inflamed areas can cause burning initially. Because the inflammation lessens, the burning generally subsides. If

the burning persists, an ointment can be substituted for the cream. If the reaction continues with a new product, an allergy workup may be necessary and patch testing could be considered.

Cortisol is endogenously secreted by the adrenal gland and is essential to life. As a result, allergic reactions to topical corticosteroid preparations are rare. When allergic symptoms do occur, they are generally not caused by the corticosteroid, but rather the preservatives (eg, paraben) or other ingredients in the formulation or the base (eg, lanolin). Allergic sensitization can occur within 2 weeks of therapy, but may be difficult to diagnose because the corticosteroid can modify the allergic reaction.[13] One should suspect an allergic reaction if lesions change appearance after starting therapy, if healing does not occur within the expected time, or if the condition improves and then abruptly gets worse. In atopic dermatitis, most case reports of allergic reactions (dryness, itching, burning, or irritation) to topical corticosteroids are nonspecific reactions.[13] The use of creams or gels may cause excessive dryness, burning, and irritation, and switching to an ointment can alleviate those symptoms.

ACNE

Case 39-3, Question 3: After several weeks of continuous corticosteroid and adjuvant therapy, K.L.'s seborrheic dermatitis has disappeared, but he has developed four pustules and two closed comedones on his forehead and multiple pustules on his nasal labial folds. What problems from the use of topical corticosteroid therapy on the face or around the eyes does this represent?

The face is particularly vulnerable to corticosteroid adverse effects because of enhanced skin penetration.[11] Acne, acne rosacea, and perioral dermatitis can develop after several weeks to months of application. Corticosteroid-induced conditions can generally be distinguished from naturally occurring disorders because lesions are uniform at the same level of development throughout the affected area and are present only in areas treated with the corticosteroid.

Generally, steroid acne and perioral dermatitis resolve after discontinuing the drug. Although not specifically relevant to K.L.'s case, application of corticosteroid preparations (particularly the potent preparations) to areas around the eye can lead to increased intraocular pressure, glaucoma, cataracts, increased risk of ocular mycotic infections, and exacerbation of preexisting herpes simplex infections.[11]

Because K.L.'s original disorder was also treated with topical selenium sulfide shampoo to the face and the scalp to suppress the cause of his seborrheic dermatitis, the corticosteroid can be discontinued.

ADRENAL AXIS SUPPRESSION AND RISK OF INFECTION

Systemic adrenal axis suppression from topically applied corticosteroids appears to be more of a theoretic risk than a practical one in adults, except when the highest-potency preparations are used,[14] or other risk factors are present (**Table 39-5**). Although suppression has been reported with use of mild to moderately potent agents, these cases can be attributed to excessive use or to application of corticosteroids over large areas of the body for prolonged periods under occlusion. If suppression does occur, it reverses within 2 to 4 weeks after application is stopped. Patients using more than 45 g/week of a high-potency corticosteroid are at risk for adrenal axis suppression.[14] Therefore, the use of preparations such as clobetasol should be limited to no more than 45 g/week for 2 weeks or less. In addition, these preparations should not be used under occlusion and should be reserved for dermatoses that are unresponsive to less potent preparations.

Table 39-5

Risk Factors for Systemic Adverse Effects from Topical Corticosteroids

Duration of Application
Prolonged application (more than 3–4 weeks)
Potency of Corticosteroid

Weak or moderately strong, 100 g/week without occlusion
Very potent, >45 g/week without occlusion
Application Location
Thin stratum corneum results in easier penetration (eyelids, forehead, cheeks, armpits, groin, and genitals)
Age of Patient
Very young children and elderly people have very thin epidermis
Manner of Application
Occlusion
Presence of penetration-enhancing substances (propylene glycol, salicylic acid, urea)
General Factors
Compromised liver function
Uremia

Because young children absorb corticosteroids to a greater extent than adults, they have a greater risk of developing adrenal axis suppression and other systemic adverse effects.[14] To reduce this risk, low-potency topical preparations should be used in children, and their use should be limited to short periods. Patients whose corticosteroid clearance is impaired (eg, liver failure) should also use hydrocortisone and be monitored closely for signs of systemic toxicity.[11]

The risk of developing an Addisonian crisis during surgery or at other times of stress secondary to adrenal suppression from topical steroids is extremely low. Patients who have used potent topical corticosteroids over large areas of their bodies (>30%) or those who have used occlusion are at greater risk (see previous discussion) and are often given systemic hydrocortisone prophylactically before surgery.[14]

PROPER APPLICATION OF TOPICAL CORTICOSTEROIDS

Because overuse of topical corticosteroids leads to local and/or systemic effects and underuse results in suboptimal treatment, the

amount of corticosteroid required to treat certain anatomic areas of the body has long been an issue of debate and discussion.[15,16] To prevent overuse in clinical practice, patients are typically given subjective instructions to apply topical products “sparingly” or “in a thin layer or coat” and is left up to the patient or caregiver’s interpretation.

The fingertip unit (FTU) was devised as a means of standardizing the way practitioners and pharmacists alike thought about how to prescribe topical corticosteroids and counsel patients on appropriate use. One FTU is defined as the amount of ointment (or other semisolid topical formulation) squeezed from a tube with a 5-mm diameter nozzle (standard in manufacturing), applied from the first distal skin crease to the tip of the index finger of an adult.[17–19] This amount is roughly equivalent to 500 mg of medication. The FTU can serve as a helpful starting point for how much product is used. Because lesions rarely conform to the exact anatomic areas in **Table 39-6**, adjustments need to be made based on the specific area involved. For example, in an adult with atopic dermatitis on the cubital fossa of both arms, the table does not provide that exact measurement. Because one FTU covers both sides of a hand and the cubital fossa is approximately hand-sized, the patient should be instructed to apply 0.5 FTU to each cubital fossa once or twice daily depending on the specific preparation. Although use of the FTU concept is not a panacea, it does provide a more objective benchmark to help patients more consistently apply the correct amount of product and avoid overuse. Use of the FTU concept must be accompanied by counseling and reinforcement based on the individual medication received, size and location of the lesion, and the desired goals of therapy. In addition, the FTU concept can be used to determine the amount to be dispensed to cover a treatment period.

Table 39-6

Fingertip Unit Charts for Adults and Children

Fingertip Unit Measures for t/se in Adults	
Area of body	FTU per dose
Face and neck	2.5
Torso and abdomen (front of trunk)	7
Back and buttocks (back of trunk)	7
One arm (front and back)	3
One hand	1
One leg (front and back)	6
One foot	2

Adult Fingcrtip Unit Measures for t/se in Children (by Age of Child)				
	3–6 months	1–2 years	3–5 years	6–10 years
Face and neck	1	1.5	1.5	**2**
Arm and hand	1	1.5	1	2.5
Leg and foot	1.5	2	3	A.5
Trunk (front)	1	2	3	3.5
Trunk (back including buttocks)	1.5	3	3.5	5

From Berth-Jones J. Topical therapy. In: Burns DA, Breathnach SM, Cox N, et al, eds. *Rook's Textbook of Dermatology*. 8th ed. Blackwell Scientific; 2010. © 2010 Blackwell Publishing Ltd. Reprinted by permission of John Wiley & Sons, Inc.

Summary of Principles of Topical Corticosteroid Therapy

The following principles are used to guide the choice of agent and application technique (Tables 39-4 and 39-6):

- Because of the reservoir effect of the stratum corneum, topical corticosteroids should be applied no more than twice daily. Increasing the application from twice daily to four times daily does not produce superior responses, is more expensive, and may lead to increased frequency of topical and systemic adverse effects.[9]
- Preparations should be rubbed thoroughly and, when possible, applied while the skin contains optimal moisture (eg, after bathing and drying off).[6] Hydration of the skin increases percutaneous absorption and the resultant therapeutic effect of topical corticosteroids.
- Appropriate-strength preparations should be used to control the condition. For maintenance, most dermatologic conditions requiring topical corticosteroids can be managed with medium- or low-potency corticosteroid preparations (ie, 1% hydrocortisone or a

low-strength fluorinated corticosteroid such as triamcinolone acetonide 0.025%).[9,10]

- Occluded areas and certain, thin-skinned areas of the body, such as the face and flexures, are more prone to the development of adverse effects.[8,10] If corticosteroids must be used on the face flexures or other thin-skinned areas, hydrocortisone or other nonfluorinated topical corticosteroids should be used to reduce the probability of adverse effects. These nonfluorinated corticosteroid products are highlighted in Table 39-4.
- Children, elderly patients, and patients with liver failure are at risk for systemic corticosteroid toxicities. In addition, patients who use the highest-potency preparations for longer than 2 weeks are susceptible to percutaneous absorption and systemic toxicity, including Addison syndrome upon sudden discontinuation.[8–13]
- With chronic conditions such as atopic eczema or allergic contact dermatitis, it is best to discontinue therapy gradually. This reduces the potential for rebound flares of topical lesions.[6]

Xerosis

CASE 39-4

Question 1: C.R., a 64-year-old female, requests something for dry skin on her shoulders and back. She has had this problem for a number of years. It is generally not a problem in the summer, with most symptoms troubling her in the winter. She denies any visible rash. When asked what makes it better, she tells you bathing provides some temporary relief. She has no other medical conditions and only takes an occasional aspirin for "arthritis."

How would you advise C.R. to manage this condition?

C.R.'s represent a common problem of the elderly, xerosis (dry skin). The seasonal cycle described is frequently called "winter itch." Most cases of dry skin are caused by dehydration of the stratum corneum.[7,20] Many factors can dry out the outer layers of the skin, such as decreased indoor humidity during cold temperatures because of increased use of central heating and or living in a low

humidity climate, such as in Arizona. Given the fact that bathing (moisture) provides temporary relief points to xerosis as the most likely cause.[7,20] The location of the itching, the lack of a visible rash, the relief with bathing, and no chronic diseases rule out most other causes of xerosis (eg, atopic dermatitis, diabetes mellitus). However, given her age and sex, hypothyroidism remains a possibility.

Atopic Dermatitis

CASE 39-5

Question 1: P.K., a 17-year-old boy, presents to a dermatology clinic with 5% of his body covered with a pruritic, eczematous rash. There is extensive involvement of popliteal and cubital fossae bilaterally. There is evidence of excoriation with cosmetic disfigurement in the cubital fossae, and on his cheeks, with a history or frequent bouts of impetigo. P.K.'s mother and aunt have asthma. One sister (L.K.), age 15, has seasonal allergic rhinitis and eczema. His father and younger brother, age 11, appear to have no atopic manifestations. A rash was first noted 1 month after birth. The cheeks of the face were the only area affected, and the rash continued with varying degrees of severity until age 2 years, when it spontaneously resolved. A similar rash reappeared at age 12 years, was diagnosed as atopic dermatitis, and has not disappeared since that time. P.K. experienced seasonal allergic rhinitis beginning at age 6 years. He has had a difficult time trying to follow provided nondrug recommendations for eczema. He has used over-the-counter topical hydrocortisone cream to treat flare-ups during the years.

On physical examination, P.K. is a well-nourished, well-developed, adolescent boy with no abnormal physical findings other than marked allergic shiners, pale boggy nasal mucosa, and Dennie–Morgan folds noted near the eyes, plus extensive skin lesions. Oozing, crusted, excoriated areas caused by scratching, with erythematous, eczematous, lichenified eruptions, are on his face and the flexor aspects of both arms and legs. There is some evidence of a secondary bacterial infection in both cubital fossae and on portions of the left leg. The presenting history, symptoms, and signs are characteristics of atopic dermatitis (eczema).

What are the characteristics of atopic dermatitis, and what is the significance of P.K.'s family and medical history as it relates to this disorder?

Atopic dermatitis, a form of eczema, can be acute or subacute, but is more commonly a chronic pruritic inflammation of the epidermis

and dermis. Approximately two-thirds of the patients have a personal or family history of allergic rhinitis, eczema, or asthma. Sixty percent of patients are affected within the first year of life, 30% by 5 years of age, with the remaining 10% experiencing atopic dermatitis between 6 and 20 years of age. Atopic dermatitis in infants may be a prelude to the development of other atopic disorders later in life (eg, allergic rhinitis or asthma). Presence of these disorders many times is the key to differential diagnosis. About 80% of patients with atopic dermatitis have a type I (immunoglobulin E [IgE]–mediated) hypersensitivity reaction occurring because of the release of vasoactive substances from both mast cells and basophils that have been sensitized by the interaction of the antigen with IgE. An allergy workup is rarely helpful in determining the allergen. The disorder affects 0.5% to 1% of the general population, although its prevalence in children is 5% to 10%. In infants and young children, dermatitis often occurs on the face and sternal area of the chest. In older children and adults, it tends to localize to the flexural areas, especially the cubital and popliteal fossae with the neck and face involved in more severe cases.[21]

Pruritus is the hallmark of atopic dermatitis. Atopic dermatitis has been described as “the itch that rashes, rather than the rash that itches.” In other words, the itching precedes the rash. The constant scratching leads to a vicious cycle of itch-scratch-rash-itch, with bacterial colonization and infections intertwined. Chronically, untreated atopic dermatitis leads to lichenification of the affected areas. Wool, detergents, soaps, a change in room temperature, and mental or physical stress can precipitate itching. Patients tend to have dry skin (xerosis) all over the body. This is attributable to a reduced water-binding capacity and a higher transdermal water loss. Xerosis is worsened during periods of low humidity, such as winter in northern latitudes. Treating the xerosis can prevent or control the disease in mild or episodic cases.[21,22]

P.K.’s family and medical history are classic for atopic dermatitis. His family history is significant for asthma, allergic rhinitis, and atopic dermatitis. He had his initial outbreak at the age of 1 month and then experienced seasonal allergic rhinitis after his dermatitis went into
