Vasodilatory Hormones While RAAS and SNS activation contributes to disease progression in HF, a number of counterregulatory hormones are upregulated and exert beneficial effects on the heart, kidney, and vasculature. These include the natriuretic peptides (atrial natriuretic peptide [ANP] and B-type natriuretic peptide [BNP]), prostaglandins (prostaglandin E_1 [PGE_1] and prostacyclin [PGI_2]), bradykinin, adrenomedullin, and nitric oxide. ANP and BNP are stored and released primarily from the atria and ventricles, respectively, in response to increased stretch or pressure. Beneficial actions are mediated through stimulation of guanylate cyclase and include systemic and pulmonary vasodilation, increased sodium and water excretion, inhibition of renin and aldosterone, and baroreceptor modulation. Bradykinin and natriuretic peptides are inactivated by neprilysin, a membrane-bound peptidase, which explains in part the beneficial clinical impact of angiotensin receptor–neprilysin inhibition in HF **(Chap. 265)**. As described below, natriuretic peptide levels can be used to assist in the diagnosis and risk stratification of patients with HF.

Endothelin, Inflammatory Cytokines, and Oxidative Stress Endothelin is a potent vasoconstrictor peptide with growth-promoting effects that may play an important role in pulmonary hypertension and right ventricular failure. Endothelin is released from a variety of vascular and inflammatory cells within the pulmonary circulation and myocardium in response to increased pressure and has direct deleterious effects on the heart, leading to myocyte hypertrophy and interstitial fibrosis. Unlike RAAS and SNS inhibition, however, endothelin blockade has not been shown to slow the progression of clinical HF due to left ventricular failure but is beneficial for treatment of pulmonary arterial hypertension and consequent right HF **(Chap. 294)**. Other factors that have the potential to cause or contribute to ventricular remodeling in HF include inflammatory cytokines such as tumor necrosis factor (TNF) α and interleukin (IL) 1β and reactive oxygen species such as superoxide and peroxynitrite. Potential sources of these biologically active substances are the liver and gastrointestinal tract, as described below. The role of anti-inflammatory and antioxidant therapies remains unproven.

Novel Biologic Targets Sodium-glucose cotransporter 2 (SGLT-2) is a protein located on the proximal tubule of the kidney that is responsible for reabsorption of up to 90% of filtered glucose. In patients with HF, activity of SGLT-2 contributes to sodium and water retention, endothelial dysfunction, abnormal myocardial metabolism, and impaired calcium handling. Inhibitors of SGLT-2 were developed for the treatment of type 2 diabetes mellitus to take advantage of their glycosuric and metabolic effects **(Chap. 416)**. Subsequent large clinical trials in cardiovascular disease including HF (with or without diabetes mellitus) have demonstrated not only safety of these agents (as required by the U.S. Food and Drug Administration) but also, more importantly, beneficial effects on morbidity and mortality. Whether benefits of SGLT-2 inhibitors in HF are due primarily to diuretic effects or to effects on cardiac and vascular remodeling, proarrhythmia, renal function, and/or metabolic function, inflammation or dysregulated autophagy remains to be conclusively determined. Another pathway that is downregulated in HF and contributes to endothelial dysfunction involves cyclic guanosine monophosphate (cGMP). Oral soluble guanylate cyclase stimulators enhance the cGMP pathway and exert beneficial myocardial and vascular effects in experimental and clinical HF.

Dyssynchrony and Electrical Instability In up to one-third of patients with HF, disease progression is associated with prolongation of the QRS interval. Electrical dyssynchrony in the form of left bundle branch block (LBBB) or intraventricular conduction delay results in abnormal ventricular contraction. As discussed in **Chap. 265**, correction of electrical dyssynchrony with left or biventricular pacing can improve contractile function, decrease mitral regurgitation, and reverse ventricular remodeling. In patients with symptomatic HFrEF and LBBB on guideline-directed medical therapy, cardiac resynchronization therapy or LBBB (or His bundle) pacing is suggested to reduce morbidity and mortality. Other forms of electrical instability, including atrial fibrillation with inadequate rate control and frequent premature ventricular complexes, can also contribute to worsening HF. In addition to the direct impact of tachycardia and irregular rhythm on disease progression, the link between these arrhythmias and cardiac

TABLE 264-3 Mechanisms of Ventricular Remodeling

Changes in Myocyte Biology
Abnormal excitation-contraction coupling and crossbridge interaction
Fetal gene expression (e.g., β-myosin heavy chain)
β-Adrenergic receptor desensitization

Impaired cytoskeletal proteins
Changes in Myocardial Composition
Myocyte necrosis, apoptosis, and autophagy
Interstitial and perivascular fibrosis
Matrix degradation
Changes in Ventricular Geometry
Ventricular dilation and wall thinning
Increased sphericity and displacement of papillary muscles
Atrioventricular valve regurgitation

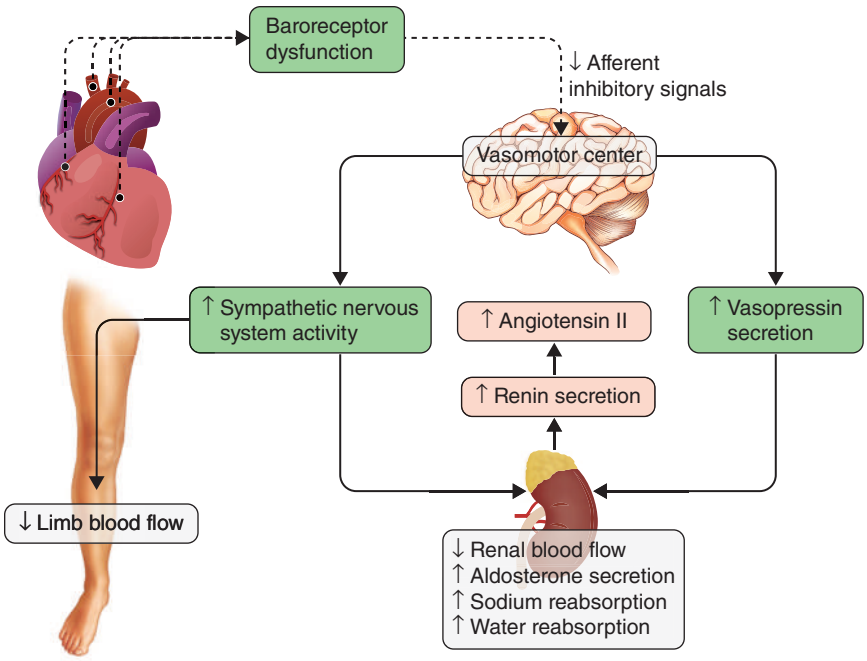

FIGURE 264-7 Activation of neurohormonal systems in heart failure. Decreased cardiac output in heart failure (HF) results in an "unloading" of high-pressure baroreceptors (*circles*) in the left ventricle, carotid sinus, and aortic arch, which in turn causes reduced parasympathetic tone. This decrease in afferent inhibition results in a generalized increase in efferent sympathetic tone and nonosmotic release of arginine vasopressin from the pituitary. Vasopressin is a powerful vasoconstrictor that also leads to reabsorption of free water by the kidney. Afferent signals to the central nervous system also activate sympathetic innervation of the heart, kidney, peripheral vasculature, and skeletal muscles. Sympathetic stimulation of the kidney leads to the release of renin, with a resultant increase in circulating levels of angiotensin II and aldosterone. The activation of the renin-angiotensin-aldosterone system promotes salt and water retention, peripheral vasoconstriction, myocyte hypertrophy, cell death, and myocardial fibrosis. Although these neurohormonal mechanisms facilitate short-term adaptation by maintaining blood pressure and organ perfusion, they also result in end-organ changes in the heart and circulation. *(Modified from A Nohria et al: Atlas of Heart Failure: Cardiac Function and Dysfunction, 4th ed, WS Colucci [ed]. Philadelphia, Current Medicine Group, 2002, p. 104, and J Hartupee, DL Mann: Nat Rev Cardiol 14:30, 2017.)*

remodeling (atrial and ventricular) involves increased wall stress, neurohormonal activation, and inflammation.

Secondary Mitral Regurgitation A large number of patients with HFrEF demonstrate evidence of mitral regurgitation. This occurs due to a distortion in the mitral valve apparatus and includes the effects of various pathophysiologic mechanisms including reduced contractile force, which leads to decreased coaptation of the leaflets, a spherical shape of the ventricle that influences length and function of the chordal-papillary muscle structure, increased dimension of the mitral annulus (and inability of the annulus to contract during systole) with reduced leaflet alignment, and dilation of the posterior wall of the left atrium, which distorts the posterior leaflet of the valve. This worsening in regurgitant volume contributes to progression in HF and adversely influences prognosis. Ensuring that this vicious cycle is interrupted is now a therapeutic target in HF. Some success has been noted by treating the mitral valve using transcatheter techniques when patients are carefully selected after exposure to optimal medical therapy when residual and significant secondary mitral regurgitation persists. Similarly, progressive tricuspid regurgitation can result from and promote adverse right ventricular remodeling. Current interventional studies are underway to assess the impact of transcatheter tricuspid valve repair or replacement in patients with advanced HF.

CARDIORENAL AND ABDOMINAL INTERACTIONS

An important concept underlying the pathophysiology of HF recognizes the systemic nature of disease. Thus, while the primary hemodynamic problem in HF is related to abnormalities in myocardial function (preload, afterload, and contractility), many of the presenting signs and symptoms are related to end-organ failure, including dysfunction of the kidneys, liver, and lungs. The heart and kidney interaction increases circulating volume, worsens symptoms of HF, and results in disease progression, referred to as the cardiorenal syndrome. Traditionally, this relationship was deemed to be a consequence of an impairment in forward flow (cardiac output) leading to a decrease in renal arterial perfusion, worsening renal function, and neurohormonal activation with release of arginine vasopressin, resulting in water and sodium retention. However, evidence has emerged that renal dysfunction may not be adequately explained simply by arterial underfilling and a decline in cardiac output. Systemic venous congestion in HF with increased backward pressure may be operative in determining the development of the cardiorenal syndrome, and relief of venous congestion is associated with significant improvement in renal function in HF. Increased intraabdominal pressure, as noted in right-sided HF, and a rise in abdominal congestion are correlated with renal dysfunction in worsening HF. The interaction is not only confined to the renal component of the abdominal compartment but also involves the liver and spleen. The splanchnic veins serve as a blood reservoir and actively function in regulation of cardiac preload during changes in volume status, regulated by transmural pressure changes or mechanisms of systemic sympathetic activation. The liver and spleen participate in determining volume regulation in HF in addition to several additional interactive pathways. Splanchnic congestion results in portal vein distension and activation of the hepatorenal reflex as well as the splenorenal reflex, which induces renal vasoconstriction. Thus, decongestion in HF by diuretic therapy or mechanical means such as ultrafiltration reduces volume, but also facilitates a decrease in pressure within the abdominal compartment, and this combination of therapeutic effect may serve to improve or stabilize renal function in HF.

GUT CONGESTION, THE MICROBIOME, AND INFLAMMATION

As noted above, circulating levels of proinflammatory cytokines are elevated in a number of cardiovascular disease states, including HF, and have been associated with disease progression. While the primary source of inflammation is unknown, emerging evidence suggests that an alteration in gut microbial composition and loss of microbial diversity may play an important role. The potential role of gut congestion

and also altered gut microbial composition may propagate the chronic state of inflammation and immune system dysregulation, eventually leading to progression of HFrEF. Lipopolysaccharide (LPS) is a gram-negative bacterial cell wall product whose levels are increased in patients with HF in the setting of increased intestinal permeability during periods of congestion, which is reduced with diuretic treatment. LPS is a strong stimulator of the immune system and can lead to dysregulated systemic inflammation via macrophage activation. Resulting increases in cytokines such as TNF-α, IL-1, and IL-6 in these pathways can cause progressive loss of cardiac function and also contribute to cardiac cachexia. A mechanistic link has been shown between gut microbe–dependent generation of trimethylamine *N*-oxide derived from specific dietary nutrients such as choline and carnitine and poor outcomes in patients with both acute and chronic HF. Microbe-generated uremic toxins, such as indoxyl sulfate, may play an important role in the development of HF, particularly in interaction with renal insufficiency. Thus, bowel ischemia and/or congestion depending on HF severity may be associated with morphologic and functional alterations in the intestines and result in bacterial endotoxemia and a proinflammatory state.

HIGH-OUTPUT STATES

Although most patients with HF, with either reduced or preserved EF, have low or normal cardiac output (CO) accompanied by elevated systemic vascular resistance (SVR), a minority of patients with HF present with a high-output state with low SVR (Table 264-2). High-output states by themselves are seldom responsible for HF, but their development in the presence of underlying cardiovascular disease can precipitate HF. For example, chronic anemia is associated with high CO when hemoglobin reduces significantly, for example, to a level that is ≤8 g/dL. An increase in vasodilatory metabolites and arteriolar vasodilation in response to decreased oxygen-carrying capacity of the blood in addition to a decrease in blood viscosity contributes to low SVR. Even when severe, anemia rarely causes high-output HF in the absence of a specific cardiac abnormality such as ischemic or valvular heart disease. Patients with end-stage renal disease **(Chap. 323)** are at particular risk of developing high-output HF when chronic anemia is exacerbated by increased flow through an arteriovenous fistula. In a recent analysis of the National Readmission Database, the most common causes of high-output HF included pulmonary disease (19.8%), severe obesity (9.9%), sepsis (9.6%), cirrhosis (8.9%), myelodysplastic syndrome (7.9%), hyperthyroidism (5.5%), and sickle cell disease (3.3%).

EVALUATION

HISTORY

Symptoms of Congestion: Pulmonary Versus Systemic The most common symptoms of HF are related to volume overload with elevation in pulmonary and/or systemic venous pressures. Shortness of breath is a cardinal manifestation of left HF and may arise with increasing severity as exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and dyspnea at rest. Mechanisms of dyspnea include pulmonary venous congestion and transudation of fluid into the interstitium and/or alveoli, leading to decreased lung compliance, increased airway resistance, hypoxemia, and ventilation/perfusion mismatch. Stimulation of juxtacapillary J receptors leading to an increased ventilatory drive and reduced blood flow to respiratory muscles may cause lactic acidosis and a sensation of dyspnea. The New York Heart Association (NYHA) functional classification **(Table 264-4)** may be used to categorize patients based on the amount of effort required to provoke breathlessness. Notably, however, NYHA class does not correlate well with other objective measures of cardiac structure (e.g., left ventricular size, EF) or function (e.g., peak oxygen consumption).

Shortness of breath when bending forward (e.g., to put on socks or tie a shoe) has been associated with an increase in cardiac filling pressure, especially in the presence of a low CO, a symptom referred to as "bendopnea." Orthopnea refers to dyspnea that occurs in the recumbent position and is due to redistribution of fluid from the abdomen and lower body into the chest, increased work of breathing due to decreased lung compliance, and, in patients with ascites or hepatomegaly, an elevation of the diaphragm. Orthopnea typically occurs in the awake patient within 1–2 min of lying down and may be relieved by raising the head and chest with pillows or an adjustable bed. With more severe HF, patients may end up sleeping in a recliner chair or sitting up, although for some, orthopnea may diminish as symptoms of right HF appear. Orthopnea may be accompanied by nocturnal cough related to pulmonary congestion.

TABLE 264-4 New York Heart Association Functional Classification

FUNCTIONAL CLASS	LIMITATION	CLINICAL ASSESSMENT
Class 1	None	Ordinary physical activity does not cause undue fatigue, dyspnea, palpitations, or angina.
Class II	Mild	Comfortable at rest. Ordinary physical activity (e.g., carrying heavy packages) may result in fatigue, dyspnea, palpitations, or angina.
Class III	Moderate	Comfortable at rest. Less than ordinary physical activity (e.g., getting dressed) leads to symptoms.
Class IV	Severe	Symptoms of heart failure or angina are present at rest and worsen with any activity.

Paroxysmal nocturnal dyspnea (PND) refers to episodes of shortness of breath that awaken a patient suddenly from sleep with feelings of anxiety and suffocation and require sitting upright for relief. In contrast to orthopnea, PND usually occurs after prolonged recumbency, is less predictable in occurrence, and may require 30 min or longer in the upright position for relief. Episodes are often accompanied by coughing and wheezing (so-called cardiac asthma) thought to be due to increased bronchial arterial pressure leading to airway compression and interstitial pulmonary edema causing increased airway resistance. Acute pulmonary edema, due to marked elevation of the pulmonary capillary wedge pressure, is manifested by severe shortness of breath and pink, frothy sputum **(Chap. 316)**. Cheyne-Stokes respiration and central sleep apnea may precipitate episodes of PND in HF and are related to increased sensitivity of the respiratory center to arterial PCO_2 and a prolonged circulatory time. Unlike obstructive sleep apnea, which can be treated with positive airway pressure, oral appliance, or surgical therapy, central sleep apnea has no proven therapy beyond the directed treatment of HF **(Chap. 308)**.

In contrast to symptoms of left HF due to pulmonary venous congestion, symptoms of right HF are typically related to systemic venous congestion. Weight gain and lower extremity edema may be the initial manifestations followed by a range of gastrointestinal symptoms due to edema of the bowel wall and hepatic congestion. Abdominal bloating, anorexia, and early satiety are common. Some patients develop right upper quadrant pain related to stretching of the hepatic capsule with consequent nausea and vomiting. When these symptoms are associated with abnormal liver function tests (see below), misdiagnosis of biliary tract disease may occur. For patients with refractory right HF, the development of massive edema involving the entire body with recurrent pleural effusions and/or ascites is termed *anasarca*.

Symptoms of Reduced Perfusion Some patients with advanced HF present with symptoms related to decreased CO, sometimes referred to as *low-output syndrome*. Fatigue and weakness, particularly of the lower extremities, are nonspecific symptoms that can occur with exertion or at rest. Pathophysiology includes reduced blood flow to exercising muscles with endothelial dysfunction and increased SVR from neurohormonal activation. Chronic alterations in skeletal muscle structure and metabolism have also been demonstrated. In older patients with HF and cerebrovascular disease, reduced systemic perfusion may result in mental dullness, depressed affect, and confusion. In addition to low CO, fatigue may be caused by volume depletion, hyponatremia, iron deficiency, and medication effect (e.g., beta blockers).

Other Symptoms Patients with HF may present with mood disturbances and poor sleep, both of which may be exacerbated by nocturnal

TABLE 264-5 Precipitating Factors in Heart Failure

Patient-Related
Excess exertion or emotional stress
Excess fluid and/or sodium intake
Nonadherence with medications
Heavy alcohol use
Provider-Related
Use of medications that cause salt and water retention (e.g., NSAIDs)
Prescribed use of medications with negative inotropic properties (e.g., CCBs)
Unrecognized congestion and inadequate use of diuretics
Heart Failure–Related
Uncontrolled hypertension
Myocardial ischemia or infarction
Atrial or ventricular arrhythmias
Pulmonary embolism
Other Disease States
Systemic infection
Worsening renal or hepatic failure
Hyperthyroidism
Untreated sleep apnea
Anemia or iron deficiency syndrome

Abbreviations: CCB, calcium channel blocker; NSAID, nonsteroidal anti-inflammatory drug.

TABLE 264-6 Diagnostic Criteria for Cachexia in Adults

- Underlying disease and body weight loss ≥5% in ≤12 months (or BMI <20 kg/m^2)
- Plus at least three of the following five criteria
  - Decrease in muscle strength
  - Fatigue
  - Anorexia
  - Low fat-free mass index
  - Abnormal biochemistry: inflammation, anemia, low serum albumin levels

Abbreviations: BMI, body mass index.

dyspnea and obstructive and/or central sleep apnea. Nocturia due to improved CO and renal perfusion in the supine position, in addition to delayed diuretic effects, can also contribute to sleep disturbances. Oliguria due to severe reductions in renal blood flow may be a sign of advanced-stage HF.

Precipitating Factors Patients with HF may be asymptomatic or mildly symptomatic either because the cardiac impairment is mild or because compensatory mechanisms help to balance or normalize cardiac function. Symptoms of HF may develop when one or more precipitating factors increase cardiac workload and disrupt the balance in favor of decompensation. Specific factors may be identified in 50–90% of admissions and can be divided into patient-related factors, provider-related factors, HF-related disease states, and other causes (Table 264-5). Inability to recognize and correct these factors promptly may lead to persistent HF despite adequate treatment.

PHYSICAL EXAMINATION

General Appearance Most patients with mild-moderate HF will appear well nourished and comfortable at rest. Even patients with more advanced disease may be in no distress after resting for a few minutes but may demonstrate immediate dyspnea with limited exertion such as walking across the room. In contrast, patients with severe HF may need to sit upright and appear anxious, diaphoretic, and dyspneic at rest with pallor due to anemia or duskiness due to low output. Other signs of severe HF include cool extremities and peripheral cyanosis. Cardiac cachexia (Table 264-6), defined partially as unintentional edema-free weight loss of >5% over 12 months, may be observed in patients with longstanding, severe HF as bitemporal or upper body muscle wasting. Contributing factors include poor oral intake due to anorexia, decreased fat absorption due to bowel wall edema, and catabolic/metabolic imbalance from activation of inflammatory cytokines (see above) and dysregulation of the growth hormone–insulin-like growth factor 1 pathway. Rarely, scleral icterus and jaundice may result from severe right HF. Others may demonstrate frailty, which can be diagnosed in the presence of sarcopenia and is exemplified by poor hand-grip strength or severely reduced gait speed.

Vital Signs With new-onset HF, heart rate rises and blood pressure may initially be increased due to sympathetic activation. In patients with chronic HF on guideline-directed medical therapy, resting heart rate ideally should be <70–75 beats/min, and blood pressure should be in the normal to low-normal range. An irregular rhythm may be due to atrial fibrillation or flutter or frequent premature atrial or ventricular complexes. Severe HF may be associated with hypotension and narrow pulse pressure along with a rapid, thready pulse. An alternating strong and weak pulse, known as *pulsus alternans*, is attributed to reduced left ventricular contraction in every other cardiac cycle due to incomplete recovery causing reduction in the left ventricular stroke volume with each alternate beat. Respiratory rate may be normal at rest but may increase on lying down or on minimal exertion. Advanced HF may be associated with periodic breathing or Cheyne-Stokes respirations. The patient is usually unaware of the altered breathing pattern, but family members or friends may become alarmed or attribute this incorrectly to anxiety. Oxygen saturation is typically normal on room air unless there is acute pulmonary edema, underlying CHD with shunting, severe pulmonary arterial hypertension, or concomitant acute or chronic lung disease. A low-grade fever resulting from cytokine activation may occur in severe HF and subside when compensation is restored.

Jugular Venous Pulse Examination of the jugular veins provides an estimate of the right atrial pressure. Typically, the patient is examined at a 45° angle, and jugular venous pressure (JVP) is quantified in centimeters of water by estimating the height of the venous column of blood above the sternal angle in centimeters and then adding 5. In patients with mild right HF, JVP may be normal at rest (≤8 cm H_2O) but increase with compression of the right upper quadrant. *Hepatojugular reflux* is elicited by applying firm continuous pressure over the liver for 15–30 s while observing the neck veins. The patient must breathe normally and not strain during the maneuver. Higher levels of venous pressure approaching the angle of the jaw are common in chronic right HF. If significant tricuspid regurgitation is present, prominent V waves and Y descents may be noted. The *abdominojugular test*, defined as an increase in right atrial pressure during 10 s of firm midabdominal compression followed by an abrupt drop on pressure release, suggests elevated left-sided filling pressure. Elevation in JVP during inspiration or Kussmaul's sign may be due to severe biventricular HF and is a marker of poor outcome; it can also be seen with constrictive pericarditis or restrictive cardiomyopathy.

Lung Examination Pulmonary rales result from transudation of fluid from the intravascular space into the alveoli and airways. In general, rales are heard at the lung bases, but in severe HF or acute pulmonary edema, they may be heard throughout the lung fields. Wheezing and rhonchi can occur with congestion of the bronchial mucosa and sometimes lead to a misdiagnosis (and inappropriate treatment) of asthma or chronic obstructive pulmonary disease (COPD). Rales may be absent in patients with longstanding HF and chronically elevated pulmonary capillary wedge pressures due to increased lymphatic drainage, which prevents spillage from the interstitium into the alveoli. In biventricular or predominant right HF, bilateral pleural effusions are recognized as dullness to percussion and decreased breath sounds at the bases. When pleural effusions are unilateral, they typically involve the right side.

Cardiac Examination As discussed above, chronic HF with ventricular remodeling is typically accompanied by cardiac enlargement. The apical impulse is displaced downward and to the left and may be diffuse in dilated cardiomyopathy or sustained in pressure overloaded states such as aortic stenosis. In biventricular or severe right HF, a right ventricular heave or parasternal lift may be palpated along the left sternal border. Uncommonly, a palpable third heart sound may be present. In patients with HFpEF, precordial palpation is often normal. On auscultation, an S_3 gallop is most commonly present in patients with volume overload and tachycardia, suggests severe hemodynamic compromise, and carries negative prognostic significance. An S_4 gallop is not specific to HF but may be present in patients with HFpEF due to hypertension. Holosystolic murmurs of mitral and tricuspid regurgitation are present in the setting of advanced HF, often in the absence of structural valvular abnormalities. In patients with secondary pulmonary hypertension, a loud pulmonary component of the second heart sound may be heard.

Abdomen and Extremities Hepatomegaly is an early sign of systemic venous congestion. The liver edge may be tender due to stretching of the capsule, but with progression of right HF, tenderness may disappear. The liver edge may be pulsatile in patients with tricuspid regurgitation. Longstanding hepatic congestion may result in cardiac cirrhosis with congestive splenomegaly and mild-moderate ascites. The presence of massive ascites should lead to a search for other causes such as constrictive pericarditis or primary liver failure. Dependent lower extremity edema is common in chronic HF and is typically symmetric and pitting. Over time, chronic edema may cause reddening and induration of the skin, become weeping, or lead to cellulitis. Anasarca is used to describe massive, generalized edema involving the legs, sacrum, and abdominal wall. In patients with acute HF or younger adults with chronic HF, lower extremity edema may be absent despite marked systemic venous hypertension. Unilateral lower extremity edema may be due to deep venous thrombosis, prior trauma, or history of vein harvest for bypass surgery. Nonpitting edema that does not respond to increasing doses of diuretics may represent lymphedema that requires alternative diagnostic workup and treatment.

DIAGNOSIS

The diagnosis of HF is relatively straightforward when the patient presents with typical signs and symptoms; however, the signs and symptoms of HF are neither specific nor sensitive. It is therefore important for clinicians to have a high index of suspicion for HF, particularly in patients who are at increased risk, including older patients with underlying cardiovascular disease and those with comorbidities such hypertension, diabetes, and chronic kidney disease. In this setting, additional laboratory testing and imaging should be performed **(Fig. 264-8)**.

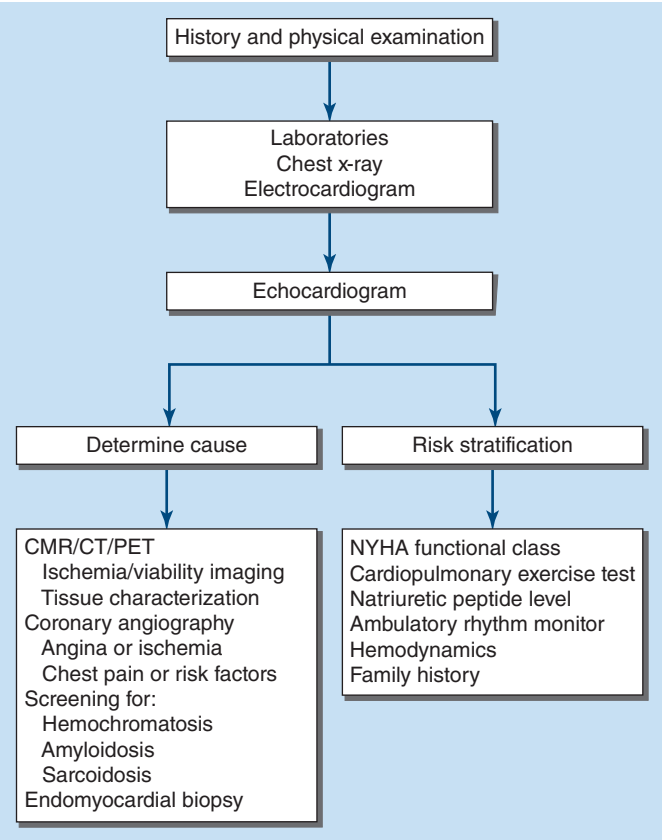

FIGURE 264-8 Initial assessment of patients presenting with heart failure. The initial evaluation starts with a thorough history and physical examination, focusing on detection of comorbidities including hypertension, diabetes, and hyperlipidemia. In addition, identification of valvular heart disease, vascular disease, history of mediastinal radiation, or exposure to cardiotoxins (e.g., chemotherapy, alcohol, or illicit drugs) may help determine underlying cause. A family history of sudden death, heart failure, arrhythmias, or cardiomyopathy is also useful. Routine laboratory evaluation (see text) should also be performed. Chest x-ray is useful to detect cardiomegaly and fluid overload and to rule out pulmonary disease. A 12-lead electrocardiogram should be performed to detect abnormalities of cardiac rhythm and conduction, left ventricular hypertrophy, and evidence of myocardial ischemia or infarction. Two-dimensional echocardiography with Doppler imaging is indicated to assess cardiovascular structure and function and detect abnormalities of the myocardium, heart valves, or pericardium. Further imaging and laboratory studies aimed at identifying a specific cause of cardiomyopathy depend on information obtained from the history and physical examination. In all patients, risk stratification should be performed to assess severity of illness, guide therapy, and provide prognosis to patient and family. CMR, cardiac magnetic resonance imaging; CT, computed tomography; NYHA, New York Heart Association; PET, positron emission tomography.

Routine Laboratories Standard laboratory testing in patients with HF includes a comprehensive metabolic panel, complete blood count, coagulation studies, and urinalysis. Selected patients should have assessment for diabetes, hyperlipidemia, and thyroid function. Blood urea nitrogen and creatinine levels are often elevated in moderate-severe HF due to reduced renal blood flow and/or increased renal venous pressure. Worsening renal function **(Chaps. 321 and 322)** due to diuretics, RAAS inhibitors, and noncardiac medications (e.g., nonsteroidal anti-inflammatory drugs) is also common. Proteinuria may be present in the setting of longstanding hypertension or diabetes or suggest an underlying systemic disease. Chronic right HF with congestive hepatomegaly can lead to modest elevations in transaminases, alkaline phosphatase, and bilirubin that should not be confused with biliary tract disease. Marked elevation in transaminases and lactic acid suggests cardiogenic shock with severe low output. In patients with cardiac cirrhosis, hypoalbuminemia may exacerbate fluid accumulation, whereas hyperammonemia contributes to altered mental status. In general, inflammatory markers such as erythrocyte sedimentation rate, C-reactive protein, and uric acid are nonspecific and do not aid in the diagnosis of HF. Other laboratories, including antinuclear antibodies, rheumatoid factor, serum free light chains, serum protein electrophoresis, ferritin, ceruloplasmin, hepatitis C, and HIV, are reserved for targeted testing.

Electrolyte abnormalities seen in HF include hyponatremia due to sodium restriction, diuretic therapy, and vasopressin-mediated free water retention. Hyponatremia is a negative prognostic indicator at the time of HF hospitalization and predicts decreased long-term survival (Table 264-1). Hypokalemia is most often due to thiazide or loop diuretics given without oral potassium supplementation but may also result from increased aldosterone levels. Hyperkalemia may result from marked reductions in glomerular filtration rate and is exacerbated by use of RAAS inhibitors, potassium-sparing diuretics, and potassium supplements **(Chap. 265)**. Hypo- or hyperkalemia may lead to atrial or ventricular arrhythmias. Hypophosphatemia and hypomagnesemia are commonly associated with chronic alcohol use.

Anemia is not diagnostic of HF, but when present, it may exacerbate underlying ischemic heart disease or decrease quality of life in patients with HF due to any cause and should be corrected. Rarely, severe

anemia may cause high-output HF typically in the presence of underlying cardiovascular disease. The presence of iron deficiency (with or without anemia) is increasingly recognized in patients with chronic HF and has been attributed to decreased gut absorption, impaired hepatic storage, and chronic blood loss. Repletion with IV iron (but not oral iron) results in improved symptoms and exercise capacity and reduced HF hospitalizations, but its effect on survival remains uncertain.

Chest X-Ray Major abnormalities on chest imaging associated with left HF include enlarged cardiac silhouette (cardiothoracic ratio >0.5) and pulmonary venous congestion. Early radiologic signs of acute HF include upper zone venous redistribution and thickening of interlobular septa. When the pulmonary capillary wedge pressure is moderate to severely elevated, alveolar edema can present as diffuse haziness extending downward toward the lower lung fields. The absence of these findings in patients with chronic HF reflects the increased capacity of the lymphatics to remove interstitial and/or pulmonary fluid. Pleural effusions of varying size and distribution are common in biventricular HF. Chest x-ray can also be used to identify noncardiac causes of dyspnea (e.g., pneumonia, COPD).

Electrocardiogram No specific electrocardiographic (ECG) pattern is diagnostic of HF. Rather, the ECG may provide important information regarding presence of underlying cardiac disease. For example, left ventricular hypertrophy and left atrial enlargement suggest HFpEF due to hypertension, aortic stenosis, or hypertrophic cardiomyopathy. The presence of Q waves or infarction is suggestive of ischemic heart disease, whereas Q waves with reduced QRS voltage (pseudo-infarct pattern) may be seen with restrictive or infiltrative cardiomyopathies (e.g., amyloid). Conduction system disease should raise concern for cardiac sarcoid or Chagas cardiomyopathy in the right clinical setting.

Paroxysmal or persistent atrial fibrillation is present in up to 40% of patients with chronic HF and is an indication for anticoagulation. Premature ventricular complexes (PVCs) and nonsustained ventricular tachycardia can reflect worsening HF and are markers of increased risk. Conversely, frequent PVCs can cause cardiomyopathy that may be treated successfully with ablation **(Chap. 260)**. Finally, determination of the QRS width and presence of LBBB is used to ascertain whether the patient may benefit from cardiac resynchronization or left bundle branch (or His bundle) pacing therapy.

Noninvasive Imaging Noninvasive cardiac imaging **(Chap. 248)** is essential for the diagnosis, evaluation, and management of HF. Two-dimensional echocardiography provides an accurate and rapid determination of ventricular size and function and valvular morphology and function and can detect intracavitary thrombi and pericardial effusions. When left ventricular ejection fraction (LVEF) is ≥50%, systolic function is deemed to be normal. Myocardial strain rate imaging using speckle tracking can add incremental value to LVEF and carries prognostic value. Doppler techniques can be used to estimate CO, pulmonary artery pressures, and valve areas, and may detect abnormalities in left ventricular diastolic filling in patients with HFpEF. For patients with end-stage HF, echocardiography is critical for assessment of right ventricular function before and after mechanical circulatory support and heart transplant. Transesophageal echocardiogram (TEE) or cardiac computed tomography (CT) with contrast is indicated to rule out left atrial appendage thrombus prior to cardioversion and can assess aortic or mitral valve pathology in planning for transcatheter valvular replacement or repair. TEE can also be used to assess for endocarditis in patients with bacteremia or acute valvular regurgitation.

Cardiac magnetic resonance imaging (CMR) has emerged as a highly accurate and quantitative tool for evaluation of left ventricular mass, volumes, and function and for determining specific causes of HF (e.g., ischemic cardiomyopathy, myocarditis, amyloidosis, hemochromatosis). CMR is particularly helpful in defining multiple anatomic and functional abnormalities in adults with CHD. Serial CMR studies can assess ventricular remodeling in response to therapy and are useful in clinical research. For patients who cannot undergo CMR (e.g., due to implantable devices), cardiac CT is particularly helpful to rule out pericardial disease or left ventricular apical thrombus. Coronary CT angiography has also emerged as a useful noninvasive test to rule out obstructive coronary artery disease as a cause of HF. While limited by availability and cost, cardiac positron emission tomography (PET) plays a role in evaluating the extent of ischemia, infarction, or hibernating myocardium in patients with coronary artery disease and, in the case of sarcoidosis, can reliably determine the severity and distribution of cardiac inflammation.

Cardiopulmonary Exercise Testing While not routinely performed in HF, cardiopulmonary exercise testing using a symptom-limited, ramp protocol can provide an objective assessment of peak functional capacity in patients being evaluated for mechanical circulatory support or heart transplant **(Chap. 271)**. Several parameters including absolute and percent-predicted peak oxygen consumption (VO_2) and ventilatory efficiency (VE; assessed by the VE/VCO_2 slope) are independent predictors of survival. Additional data including heart rate and blood pressure response to exercise and exercise-induced arrhythmias can also be assessed. This test may also be useful in defining the cause of dyspnea when the diagnosis is uncertain.

Biomarkers Circulating levels of natriuretic peptides are useful, adjunctive tools in the diagnosis of HF. BNP and N-terminal pro-BNP (NT-proBNP) are released from the atria and ventricles in response to increased wall stress. Patients with HFrEF tend to have higher levels than patients with HFpEF, whereas levels may be falsely low in obesity. In ambulatory patients with dyspnea, the measurement of BNP or NT-proBNP is useful to support clinical decision-making regarding the diagnosis of HF, especially in the setting of clinical uncertainty or with concomitant lung disease. Moreover, natriuretic peptide levels can be used to establish disease severity and prognosis in chronic HF and may help to guide optimal dosing of medical therapy in stable outpatients. Importantly, many noncardiac factors, including age, female sex, and chronic kidney disease, increase natriuretic peptide levels. Other cardiovascular diseases including atrial fibrillation, pulmonary embolism, and pulmonary arterial hypertension can also increase BNP levels. Galectin-3 and soluble ST2 (suppression of tumorigenicity 2 protein) are newer biomarkers that have been approved for assessment of prognosis in HF but are not widely used. Biomarkers of renal injury require further study in HF, although use of cystatin C to measure renal function may be more accurate than a creatinine, which can be influenced by muscle mass.

Invasive Studies In the intensive care setting, assessment of cardiac filling pressures and CO may be necessary to differentiate cardiogenic from noncardiogenic pulmonary edema and manage hemodynamic instability. Placement of a pulmonary artery catheter can be performed safely at the bedside and used to determine response to intravenous vasoactive and diuretic therapy in severe HF. Simultaneous measurement of right and left heart filling pressures in the cardiac catheterization laboratory can be used to distinguish restrictive cardiomyopathy from constrictive pericarditis. Coronary angiography is indicated to exclude ischemic heart disease as an underlying, potentially reversible cause of left ventricular dysfunction. The management of coronary artery disease in the setting of chronic HF is discussed in **Chaps. 285–287**. If echocardiographic windows are suboptimal, left ventriculography can provide an assessment of left ventricular size and function and severity of mitral regurgitation. The role of right ventricular endomyocardial biopsy in the management of HF and cardiomyopathy remains controversial. Indications include detection of myocarditis (lymphocytic, eosinophilic, sarcoid, or giant cell), diagnosis of cardiac amyloidosis and chemotherapy- or immunotherapy-related left ventricular failure, and screening for cardiac allograft rejection following heart transplant.

COMORBIDITIES

DIABETES

Type 2 diabetes mellitus is a risk factor for the development of HF **(Table 264-7)** and increases the risk of morbidity and mortality in

TABLE 264-7 Mechanisms That Contribute to Development of Heart Failure in Patients with Type 2 Diabetes Mellitus

patients with established disease. In ambulatory HF cohorts, the prevalence of diabetes ranges from 10 to 40%, with prevalence even higher in patients hospitalized with HF. When the two diseases coexist, patients are at increased risk for adverse outcomes, worse quality of life, and higher costs of care. Recent data from cardiovascular outcomes trials demonstrate that HF is a critical outcome in patients with diabetes and that glucose-lowering therapies can impact morbidity and mortality. As discussed above, SGLT-2 inhibitors in particular have not only been shown to be safe in patients with HF but can also improve renal function, enhance quality of life, increase LVEF, and decrease the risk of hospitalization and death. Use of other guideline-directed medical therapy is indicated in patients with HF regardless of diabetes status.

SLEEP APNEA

Sleep-disordered breathing is common in HF, with increased incidence of both obstructive sleep apnea and central sleep apnea **(Chap. 308)**. The pathophysiologic link between these disorders has been studied in both animal models and humans and includes increased afterload, decreased preload, intermittent hypoxia, and sympathetic activation. Increase in sympathetic tone can provoke ischemia and arrhythmias and complicate blood pressure management. Approximately one-third of patients with HF and sleep-disordered breathing have central sleep apnea, which is associated with increased mortality independent of other known risk factors. In patients with HFrEF and obstructive sleep apnea, continuous positive airway pressure has been shown to improve quality of life, decrease blood pressure and arrhythmias, and increase LVEF. Unlike obstructive sleep apnea, there is no proven therapy for central sleep apnea, although phrenic or hypoglossal nerve pacing may provide benefit in some cases.

OBESITY

Similar to diabetes, obesity is both a risk factor for the development of HF and highly prevalent in patients with HF. In particular, obesity is common in patients with HFpEF and complicates the assessment of volume status in both ambulatory and inpatient settings. Unlike diabetes, the risk of morbidity and mortality in patients with obesity and HF is complex. The obesity paradox refers to the observation that obese patients diagnosed with HF have a more favorable prognosis than patients with low or even normal body mass index. While weight loss has been shown to improve quality of life and exercise capacity and may contribute to reverse ventricular remodeling in patients with HF, the impact on survival is unknown. Large randomized clinical trials are assessing safety and efficacy of glucagon-like peptide-1 (GLP-1) agonists such as semaglutide in patients with heart failure and obesity.

DEPRESSION

Depression is an independent risk factor for adverse outcomes in HF (Table 264-1), especially in older women. The mechanisms underlying this risk remain unknown but may involve neuroendocrine dysfunction and systemic inflammation, as well as contributions from poor sleep, decreased appetite, and adverse effects of medications and alcohol. The AHA recommends screening for depression among patients with cardiovascular disease including HF using validated patient health questionnaires. Selective serotonin reuptake inhibitors are safe for treating depression in HF but do not appear to affect the natural history of disease. The effects of cognitive behavioral therapy and the collaborative care model, as well as newer therapies such as transcranial magnetic stimulation, on HF morbidity and mortality require further study.

TABLE 264-8 Differential Diagnosis of Heart Failure

SYMPTOM OR SIGN	DIFFERENTIAL DIAGNOSIS
Dyspnea	Chronic lung disease Pulmonary arterial hypertension Neuromuscular disease Anemia Iron-deficiency anemia
Edema	Venous insufficiency Nephrotic syndrome Deep vein thrombosis Lymphedema
Ascites	Hepatic cirrhosis Portal vein thrombosis Malignant carcinomatosis
Pleural effusion(s)	Chronic infection Lung cancer Collagen vascular or rheumatologic disease
Jugular venous distension	Constrictive pericarditis Pericardial effusion Superior vena cava syndrome

DIFFERENTIAL DIAGNOSIS

Many symptoms and signs suggesting HF may be caused by other conditions **(Table 264-8)**. In a patient with dyspnea, the clinician must distinguish cardiac from pulmonary causes, although the differentiation may be difficult. For example, orthopnea may be a well-established symptom in some patients with severe chronic lung disease. Patients with underlying pulmonary disease may also experience episodic shortness of breath during sleep that mimics PND. In chronic lung disease, this is usually due to accumulation of tracheobronchial secretions and is relieved by coughing and expectoration, whereas in cardiac disease, the patient has to sit upright. Wheezing caused by bronchoconstriction may be a prominent symptom when left ventricular failure supervenes in individuals with reactive airways disease. Patients with cardiac asthma may be more likely to exhibit diaphoresis and varying degrees of cyanosis compared to patients with bronchial asthma. Differentiating dyspnea related to HF versus pulmonary disease may be impossible when the diseases coexist, a situation that is common in chronically ill older patients with active or prior smoking. Following effective diuresis, pulmonary function tests may help to determine the predominant cause of dyspnea. In ambulatory patients with advanced HF, cardiopulmonary exercise testing can also help to make this distinction. Finally, a very low BNP or NT-proBNP level may be helpful in excluding HF as the cause of dyspnea in nonobese patients.

Apart from pulmonary disease, HF needs to be distinguished from conditions in which congestion results from abnormal salt and water retention but in which cardiac structure and function are normal (e.g., acute or chronic kidney disease) and from noncardiac causes of pulmonary edema (e.g., acute respiratory distress syndrome). Non-HF causes of lower extremity edema such as venous insufficiency, lymphedema, and obesity should also be considered.

265 Heart Failure: Management

Akshay Desai, Mandeep R. Mehra

Clinical management of patients with heart failure (HF) varies widely based on the clinical phenotype at presentation. Those in the earliest stage of disease with asymptomatic ventricular dysfunction (American College of Cardiology [ACC]/American Heart Association [AHA] stage B) may be amenable to treatment with neurohormonal antagonists, including angiotensin-converting inhibitors and β-adrenergic receptor antagonists, with the goal of facilitating ventricular recovery and preventing the development of clinical HF (not further discussed). Those with symptomatic HF (ACC/AHA stage C) comprise a heterogeneous group in whom the approach to therapy is differentiated largely based on measurement of the left ventricular ejection fraction (LVEF). Data from prospective, randomized clinical outcomes trials enrolling patients with symptomatic chronic HF and reduced ejection fraction (HFrEF; LVEF ≤40%) have provided a rich evidence base that supports the efficacy of stepped pharmacologic therapy with renin-angiotensin-aldosterone system (RAAS) antagonists (including angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and mineralocorticoid receptor antagonists), neprilysin inhibitors, β-adrenergic receptor antagonists, and sodium-glucose cotransporter 2 (SGLT-2) inhibitors as a complement to device-based treatment with cardiac resynchronization therapy and implantable cardioverter-defibrillators. By contrast, treatment of patients with symptomatic chronic HF and mildly reduced (HFmrEF; LVEF 41–49%) or preserved ejection fraction (HFpEF; LVEF ≥50%) has, until recently, been symptom-focused owing to the lack of evidence-based therapies but is evolving in the wake of favorable results from recently reported trials of SGLT-2 inhibitors, glucagon-like peptide 1 (GLP-1) agonists, and angiotensin-neprilysin inhibitors. Even with effective therapy, patients with HFrEF, HFmrEF, and HFpEF are at risk for clinical deterioration, typically because of progressive sodium and fluid retention that fuels the development of congestive symptoms and acute decompensated HF (ADHF). Management of these exacerbations (frequently hospital-based) is heavily focused on hemodynamic stabilization, decongestion, and institution of appropriate disease-modifying therapy in the transition back to chronic ambulatory management. Recurrent episodes of ADHF despite careful follow-up and effective treatment may signal the onset of an advanced or refractory HF phenotype (ACC/AHA stage D) in which the risk of mortality from sudden death or end-stage HF is high, and consideration of salvage therapies including cardiac transplant or mechanical circulatory support may be appropriate prior to escalation to palliative measures **(Chap. 271)**.

HEART FAILURE WITH MILDY REDUCED OR PRESERVED EJECTION FRACTION

GENERAL PRINCIPLES

Although clinical trials of RAAS antagonists, digoxin, β-adrenergic receptor blockers, and neprilysin inhibitors have been conducted in patients with HFpEF, none has conclusively demonstrated a mortality reduction. Variable benefits, measured in the form of reduced HF hospitalizations, have been seen with mineralocorticoid receptor antagonists, angiotensin receptor blockers, and angiotensin receptor-neprilysin inhibitors, but benefits are principally confined to those with LVEF below the normal range (<0.60). This has led many to recommend that patients with HFmrEF should be treated with the same therapies as those with HFrEF. Patients with higher ejection fraction (EF) remain a therapeutic challenge. In the absence of specific pharmacologic therapies proven to improve clinical outcomes, management of patients with HFpEF has historically been focused on improving symptoms and effort tolerance through lifestyle modification, control of congestion, stabilization of heart rhythm (particularly in those with atrial fibrillation), control of blood pressure to guideline-recommended targets, and management of comorbidities that may contribute to disease progression (including, for example, obesity, obstructive lung disease, obstructive sleep apnea, diabetes/insulin resistance, anemia, iron deficiency, and chronic kidney disease). More recently, however, targeted pharmacologic therapy is emerging, with clinical trials of SGLT-2 inhibitors supporting use of these agents to reduce cardiovascular mortality and HF hospitalizations in HFmrEF and HFpEF. Trials of angiotensin receptor-neprilysin inhibitors and GLP-1 agonists (in obese patients) also suggest possible benefits in selected HFpEF patients.

CLINICAL TRIALS IN HFPEF

Attempts to export the benefits of drugs that improve clinical outcomes in patients with HFrEF, including angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), β-adrenergic receptor blockers, digoxin, and mineralocorticoid receptor antagonists, to those with HFpEF have generally been unsuccessful. The Candesartan in Heart Failure—Assessment of Mortality and Morbidity (CHARM) Preserved study showed a statistically significant reduction in HF hospitalizations but no difference in all-cause mortality in patients with HFpEF who were treated with the ARB candesartan.

Similarly, the Irbesartan in Heart Failure with Preserved Systolic Function (I-PRESERVE) trial demonstrated no differences in the composite of cardiovascular death or HF hospitalization during treatment with the ARB irbesartan compared with placebo. Apparent early benefits of the ACE inhibitor perindopril on HF hospitalizations and functional capacity in the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) study were attenuated over longer-duration follow-up. The Digitalis Investigation Group (DIG) Ancillary Trial found no impact of digoxin on all-cause mortality or on all-cause or cardiovascular hospitalization among patients with chronic HF, EF >45%, and sinus rhythm, although a modest reduction in HF hospitalizations was noted. While no dedicated study of beta blockers has been conducted in HFpEF, the subgroup of elderly patients with prior hospitalization and HFpEF enrolled in the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS) trial of nebivolol, a vasodilating beta blocker, did not appear to experience significant reductions in all-cause or cardiovascular mortality.

Regarding *mineralocorticoid receptor antagonists*, which have potent antifibrotic effects in HFrEF, the Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) trial explored the potential benefit of spironolactone compared to placebo in HFpEF. This trial demonstrated no improvement in the primary composite endpoint of cardiovascular death, HF hospitalizations, or aborted cardiac arrest but did show a reduction in HF hospitalizations among those allocated to spironolactone. Post hoc analyses of the study suggested significant regional differences in the baseline characteristics, event rates, adverse effects, and adherence to spironolactone among patients randomized in Russia and the Republic of Georgia compared with those randomized in the Americas that raised concerns about study conduct in Russian and Georgian sites. Apparent reductions in cardiovascular death and HF hospitalization associated with spironolactone among the subgroup of patients randomized in the Americas suggest that these study design issues may have obscured a signal of spironolactone benefit. These data have supported a weak recommendation for spironolactone in patients with HFpEF who meet the inclusion criteria for the TOPCAT trial and are at low risk for adverse effects, including hyperkalemia and worsening renal function, in the most recent U.S. and European guidelines. However, the results of the Aldosterone Receptor Blockade in Diastolic Heart Failure (ALDO-DHF) study in which spironolactone improved echocardiographic indices of diastolic dysfunction but failed to improve exercise capacity, symptoms, or quality-of-life (QOL) measures highlight the need for further study. Ongoing trials, including the registry-based Spironolactone Initiation Registry Randomized Interventional Trial in Heart Failure with Preserved Ejection Fraction (SPIRRIT-HFpEF) (SPIRRIT-HFpEF; clinicaltrials.gov identifier NCT02901184) and the randomized Study to Evaluate the Efficacy and Safety of Finerenone on Morbidity and Mortality in Participants with Heart Failure and Left Ventricular Ejection Fraction Greater than or Equal to 40% (FINE-ARTS-HF, *clinicaltrials.gov* identifier: NCT04435626) may provide additional insight in this regard.

Addition of the SGLT-2 inhibitors dapagliflozin and empagliflozin to guideline-directed medical therapy of HFrEF has been associated with reductions in cardiovascular mortality and HF hospitalization among patients with and without diabetes mellitus enrolled in the Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) and Empagliflozin Outcome Trial in Patients with Chronic Heart Failure with Reduced Ejection Fraction (EMPEROR-REDUCED) trials. These benefits have recently been extended to the population of patients with symptomatic HF and LVEF >40% based on observed reductions in the composite of cardiovascular death or HF hospitalization among those assigned to SGLT-2 inhibitors compared to placebo in the Dapagliflozin Evaluation to Improve the Lives of Patients with Preserved Ejection Fraction Heart Failure (DELIVER) and Empagliflozin Outcome Trial in Patients with Chronic Heart Failure with Preserved Ejection Fraction (EMPEROR-PRESERVED) trials. Pooled analysis of the data from these trials is associated with a reduction in the composite or cardiovascular death or HF hospitalization. These results have driven updates to treatment guidelines in the United States and Europe, which now embrace use of SGLT-2 inhibitors as foundational therapy in patients with symptomatic HF regardless of EF. However, cost-effectiveness analyses suggest that these agents may be of low to intermediate economic value, which may limit access until price reductions ensue.

OTHER THERAPEUTIC TARGETS

Beyond pharmacologic therapy, small studies of exercise training and cardiac rehabilitation in patients with HFpEF have suggested benefits on functional capacity and QOL, indicating a possible role for lifestyle interventions to improve cardiorespiratory fitness in this population. For obese patients with HFpEF, aggressive efforts at weight loss (including bariatric surgery) may also be associated with improvements in hemodynamics and exercise capacity. Recently, the randomized STEP-HFpEF trial of the once-weekly GLP-1 agonist semaglutide in obese (body mass index ≥30 kg/m^2) HFpEF patients without diabetes mellitus demonstrated improvements in functional capacity and QOL associated with incremental weight loss of nearly 12% relative to placebo. Several ongoing trials including STEP-HFpEF DM (Semaglutide Treatment Effect in People with Obesity and HFpEF and Type 2 Diabetes; clinicaltrials.gov identifier: NCT04916470) and the SUMMIT trial of the dual GLP-1/glucose-dependent insulinotropic polypeptide (GIP) agonist tirzepatide (*clinicaltrials.gov* identifier: NCT04847557) will provide further data for clinical utility in this population.

A novel paradigm for understanding the pathophysiology of HFpEF has focused on the role of microvascular endothelial inflammation driven by comorbidities that results in impaired nitric oxide (NO) signaling and associated increases in myocardial stiffening. This paradigm has emphasized the potential for improving outcomes in HFpEF by enhancing NO bioavailability and improving downstream protein kinase G–based signaling. In this regard, a small trial demonstrated that the phosphodiesterase-5 inhibitor *sildenafil* improved filling pressures and right ventricular function in a cohort of HFpEF patients with pulmonary venous hypertension. This finding led to the phase 2 trial, Phosphodiesterase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Diastolic Heart Failure (RELAX), in HFpEF patients (LVEF >50%) with New York Heart Association (NYHA) functional class II or III symptoms, who received sildenafil at 20 mg three times daily for 3 months, followed by 60 mg three times daily for another 3 months, compared with a placebo. There was no improvement in functional capacity, QOL, or other clinical and surrogate parameters in those allocated to sildenafil compared to placebo. On the premise that *nitrates*, which are NO donors, might improve preload, coronary perfusion, endothelial function, and exercise tolerance, the Nitrate's Effect on Activity Tolerance in Heart Failure with Preserved Ejection Fraction (NEAT-HFpEF) study was conducted. Isosorbide mononitrate did not improve QOL or submaximal exercise capacity and decreased overall activity levels in treated patients. *Inorganic nitrate* compounds have also been shown to enhance NO signaling but did not improve functional capacity compared to placebo among patients with HFpEF randomized in the Inorganic Nitrite Delivery to Improve Exercise Capacity in Heart Failure with Preserved Ejection Fraction (INDIE-HFpEF) trial.

Neprilysin inhibition is known to increase circulating levels of various vasoactive peptides, including the natriuretic peptides, which may facilitate cyclic guanosine 3′,5′-monophosphate–based signaling, enhance myocardial relaxation, and reduce ventricular hypertrophy. Composite *angiotensin receptor-neprilysin inhibition* (ARNI) with sacubitril-valsartan reduced cardiovascular mortality, overall mortality, and HF hospitalization compared with enalapril among patients with HFrEF randomized in the PARADIGM-HF trial. The PARAGON-HF trial randomized 4822 patients with symptomatic HFpEF (LVEF ≥45%), elevated natriuretic peptides, and structural heart disease to treatment with either sacubitril-valsartan or valsartan with the novel composite primary endpoint of cardiovascular death and total hospitalizations for HF. Although there was a 13% reduction in the rate of the primary composite endpoint in those allocated to sacubitril-valsartan, this result narrowly missed the margin for statistical significance in the

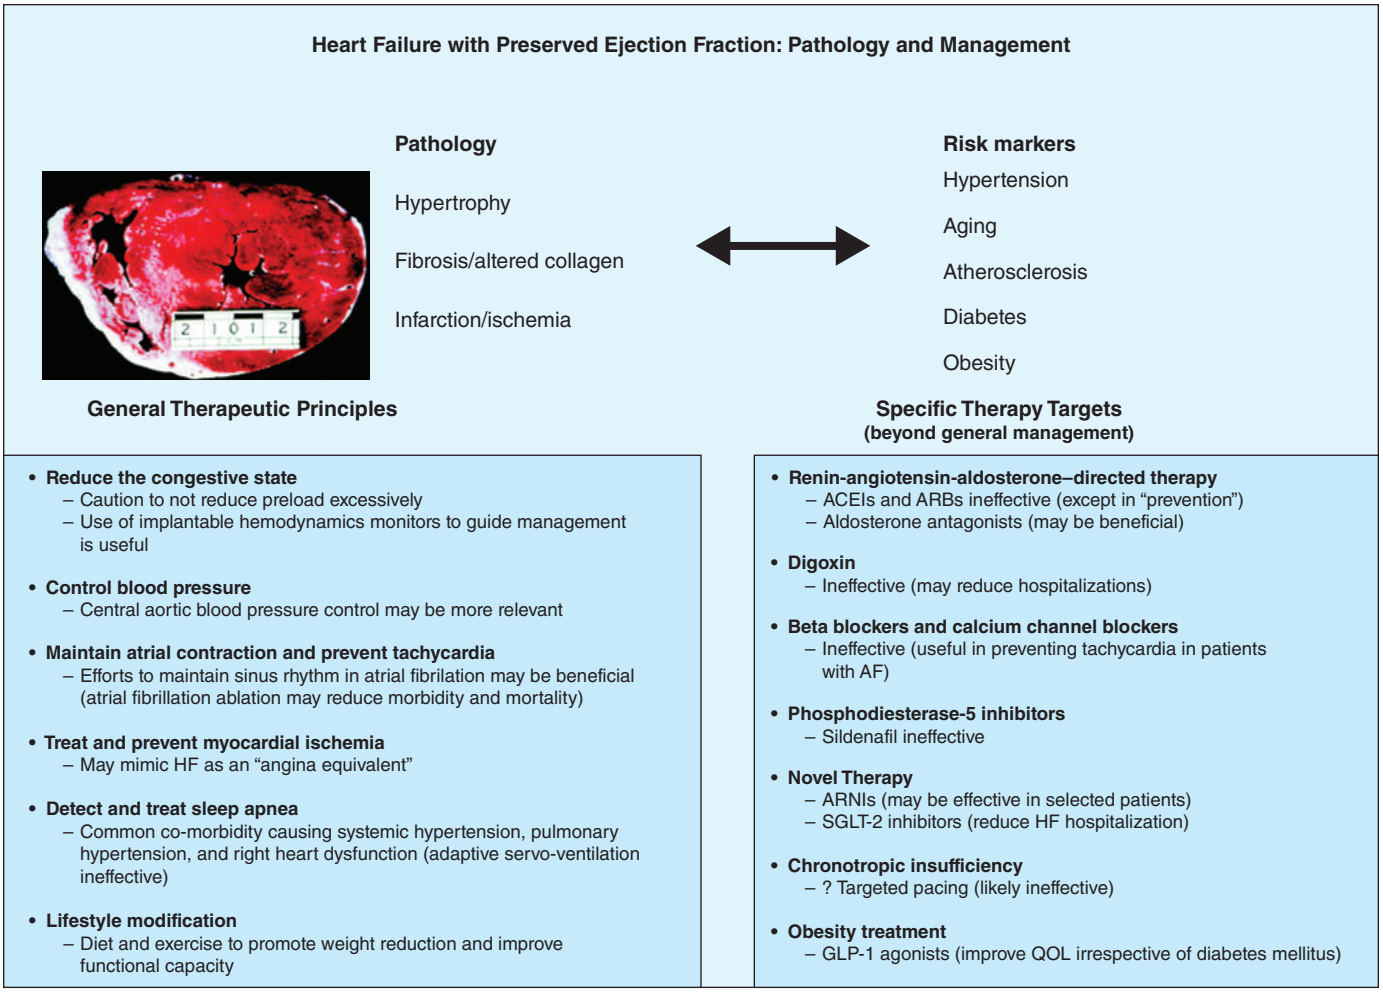

FIGURE 265-1 Pathophysiologic correlations, general therapeutic principles, and results of specific "directed" therapy in heart failure (HF) with preserved ejection fraction. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor; GLP-1, glucagon-like peptide 1; SGLT-2, sodium-glucose cotransporter 2; QOL, quality of life.

primary statistical analysis ($p = .06$). Directional benefits in secondary endpoints including QOL, NYHA class, and renal function favoring sacubitril-valsartan support a possible modest benefit of neprilysin inhibition in this population, particularly among patients with lower (i.e., mildly reduced) EF and in women, subgroups who appeared to derive greater benefit. Based on these data, sacubitril-valsartan has recently been approved in the United States for treatment of symptomatic HF across the full spectrum of EF, with benefits acknowledged to be greatest in those with LVEF below normal. The PARAGLIDE-HF trial randomly assigned patients with HF and EF >40% within 30 days of a worsening HF event to treatment with sacubitril-valsartan or valsartan. Although those assigned to sacubitril-valsartan experienced greater reductions in N-terminal prohormone of brain natriuretic peptide (NTproBNP) at 8 weeks, clinical benefits were modest and appeared to be confined to those with EF ≤60%, suggesting this therapy may be most effective in that subgroup.

CLINICAL GUIDING PRINCIPLES

Beyond disease-modifying therapy, treatment of HFpEF should focus on decongestion, aggressive management of medical comorbidities, and relief of exacerbating factors. A careful diagnostic approach is critical, since patients with HF and a normal or near-normal LVEF compose a heterogenous group that includes patients with infiltrative heart disease (amyloidosis, hemochromatosis, sarcoidosis), storage disease (Fabry's disease, Gaucher's disease), hypertrophic cardiomyopathy, pericardial disease, pulmonary arterial hypertension, valvular heart disease, and primary right ventricular failure who may require a different management approach. For those with true HFpEF, aggressive control of blood pressure to guideline-recommended targets and relief of volume overload with diuretics are critical to symptom relief. Excessive decrease in preload with diuretics and vasodilators may lead to underfilling the ventricle and subsequent azotemia, hypotension, and syncope. For patients at risk for coronary heart disease, deliberate evaluation for ischemia and consideration of coronary revascularization may be important. Since clinical outcomes in HFpEF are worse in the setting of atrial fibrillation, aggressive rate control, anticoagulation, and early consideration of sinus rhythm restoration are important. Comorbidities such as obesity, obstructive lung disease, sleep apnea, chronic kidney disease, and anemia/iron deficiency are increasingly recognized as important contributors to diminished functional capacity and QOL in patients with HFpEF and may be additional targets for therapy. Some investigators have suggested that the exercise intolerance in HFpEF is a manifestation of chronotropic insufficiency. While this hypothesis appears to be supported by small trials randomized trials of beta blocker withdrawal, improving chronotropic response through rate-adaptive atrial pacing did not improve functional capacity in the randomized RAPID-HF trial (Fig. 265-1).

ACUTE DECOMPENSATED HEART FAILURE

GENERAL PRINCIPLES

ADHF is a heterogeneous clinical syndrome most often resulting in need for hospitalization due to confluence of interrelated abnormalities of decreased cardiac performance, renal dysfunction, and alterations in vascular compliance. Admission with a diagnosis of ADHF is associated with excessive morbidity and mortality, with nearly half of these patients readmitted for management within 6 months, and a high short-term (5% in-hospital) and long-term cardiovascular mortality

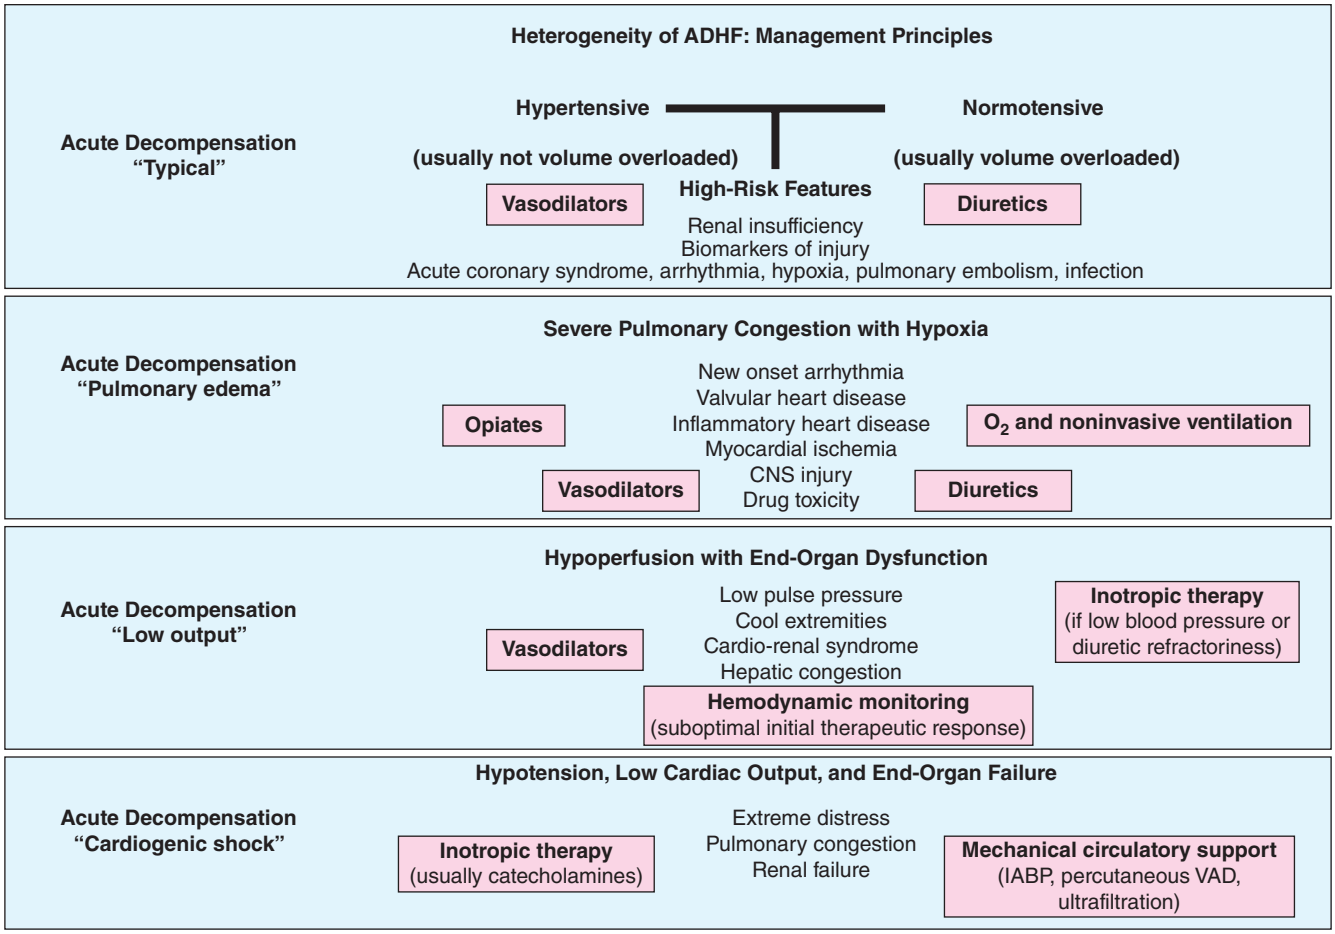

FIGURE 265-2 The distinctive phenotypes of acute decompensated heart failure (ADHF), their presentations, and suggested therapeutic routes. (Unique causes of ADHF, such as isolated right heart failure and pericardial disease, and rare causes, such as aortic and coronary dissection or ruptured valve structures or sinuses of Valsalva, are not delineated and are covered elsewhere.) CNS, central nervous system; IABP, intraaortic balloon pump; VAD, ventricular assist device.

(20% at 1 year). Importantly, long-term outcomes remain poor, with a combined incidence of cardiovascular deaths, HF hospitalizations, myocardial infarction, strokes, or sudden death reaching 50% at 12 months after hospitalization. The management of these patients remains difficult and principally revolves around volume control and hemodynamic optimization to maximize end-organ perfusion.

The first principle of management in ADHF is to identify and address the factors that precipitated decompensation. Important historical factors to consider are nonadherence to medications, dietary salt indiscretion, and usage of medications (including over-the-counter preparations) that may exacerbate HF, including nonsteroidal anti-inflammatory drugs, thiazolidinediones, tumor necrosis factor inhibitors, selected antidepressants, selected cancer therapies, cold and flu preparations with cardiac stimulants, and some herbal preparations. Coronary ischemia frequently drives HF exacerbation in patients with atherosclerotic cardiovascular disease and should be systematically investigated (either invasively or noninvasively) in all patients at risk to identify candidates for revascularization. Atrial and ventricular arrhythmias are common contributors to HF exacerbation and may trigger the need for antiarrhythmic drug suppression, cardioversion, or catheter ablation. Valvular heart disease is increasingly recognized as a target for therapy in patients with recurrent HF exacerbations and can be readily identified through echocardiography. Systemic infection and pulmonary thromboembolism are additional triggers of HF decompensation and should be routinely considered.

Concurrent with the identification of HF precipitants, effective management of ADHF requires pharmacologic therapy directed at hemodynamic optimization, including relief of congestion, reduction in afterload, and maximization of vital organ perfusion. The routine use of a pulmonary artery catheter is not recommended and should be restricted to those who present with features typical of low-output HF or cardiogenic shock who may require vasopressor or mechanical circulatory support, those who are resistant or refractory to diuretic therapy, those with combined cardiorenal dysfunction in whom therapeutic goals are difficult to define at the bedside, and those with known or suspected pulmonary arterial hypertension in whom vasodilator therapy may be appropriate. Analysis of in-hospital registries has identified several parameters associated with worse outcomes: a blood urea nitrogen level >43 mg/dL (to convert to mmol/L, multiply by 0.357), systolic blood pressure <115 mmHg, a serum creatinine level >2.75 mg/dL (to convert to μmol/L, multiply by 88.4), and elevated cardiac biomarkers including natriuretic peptides and cardiac troponins. A useful clinical schema to identify treatment targets for the various phenotypic presentations and management goals in ADHF is depicted in Fig. 265-2.

VOLUME MANAGEMENT

Intravenous Diuretic Agents Intravenous loop diuretic agents rapidly and effectively relieve symptoms of congestion and are essential when oral drug absorption is impaired. When high doses of diuretic agents are required or when the effect of bolus dosing is suboptimal, a continuous infusion may be needed to reduce toxicity and maintain stable serum drug levels. Randomized clinical trials of high- versus low-dose and bolus versus continuous infusion diuresis have not provided clear justification for the best diuretic strategy in ADHF, and as such, the use of diuretic regimens remains an art rather than science. For those refractory to loop diuretic treatment alone, addition of a thiazide diuretic agent such as chlorothiazide or metolazone to provide sequential nephron blockade may enhance natriuresis and facilitate decongestion, but also increases the risk of significant hypokalemia. Addition of acetazolamide to loop diuretic therapy in the randomized ADVOR trial was demonstrated to facilitate greater decongestion but was not associated with reduction in HF readmissions or mortality.

Change in weight is often used as a surrogate for adequate diuresis, but this objective measure of volume status may be surprisingly difficult to interpret, and weight loss during hospitalization does not necessarily correlate closely with outcomes. Effective decongestion may also be confirmed by improvement in clinical symptoms as well as the bedside examination documenting normalization of the jugular venous pressure, clearance of pulmonary rales, suppression of cardiac gallops, and resolution of peripheral edema, hepatomegaly, and abdominal ascites. It is generally advisable to continue diuresis until euvolemia has been achieved, since residual congestion or volume overload is strongly associated with risk for recurrent decompensation. Predischarge measurement of natriuretic peptide levels, which are highly correlated with risk for postdischarge mortality and readmission, may also be useful in assessing the adequacy of therapy and stratifying risk. Chronic oral loop diuretic therapy is appropriate at discharge for most patients to maintain decongestion. The TRANSFORM-HF trial did not demonstrate any mortality or morbidity advantage of torsemide compared to furosemide for this purpose despite its greater oral bioavailability, longer half-life, and other potential beneficial effects on myocardial fibrosis, aldosterone production, sympathetic activation, ventricular remodeling, and natriuretic peptides noted in small studies.

The Cardiorenal Syndrome The cardiorenal syndrome is increasingly being recognized as a complication of ADHF. Multiple definitions have been proposed for the cardiorenal syndrome, but at its simplest, it can be thought to reflect the interplay between abnormalities of heart and kidney function, with deteriorating function of one organ while therapy is administered to preserve the other. Approximately 30% of patients hospitalized with ADHF exhibit abnormal renal function at baseline, and this is associated with longer hospitalizations and increased mortality. However, mechanistic studies have been largely unable to find correlation between deterioration in renal function, cardiac output, left-sided filling pressures, and reduced renal perfusion; most patients with cardiorenal syndrome demonstrate a preserved cardiac output. It is hypothesized that in patients with established HF, this syndrome represents a complex interplay of neurohormonal factors, potentially exacerbated by "backward failure" resulting from increased intraabdominal pressure and impairment in return of renal venous blood flow. Continued use of diuretic therapy may be associated with a reduction in glomerular filtration rate and a worsening of the cardiorenal syndrome when right-sided filling pressures remain elevated. In patients in the late stages of disease characterized by profound low cardiac output state, inotropic therapy or mechanical circulatory support has been shown to preserve or improve renal function in selected individuals in the short term until more definitive therapy such as assisted circulation or cardiac transplantation is implemented.

Ultrafiltration Ultrafiltration (UF) is an invasive fluid removal technique that may supplement the need for diuretic therapy. Proposed benefits of UF include controlled rates of fluid removal, neutral effects on serum electrolytes, and decreased neurohormonal activity. This technique has also been referred to as aquapheresis in recognition of its electrolyte depletion–sparing effects. In an initial study evaluating UF versus conventional therapy, fluid removal was improved, and subsequent HF hospitalizations and urgent clinic visits were reduced with UF; however, no improvement in renal function and no subjective differences in dyspnea scores or adverse outcomes were noted. In the Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) trial, 188 patients with ADHF and worsening renal failure were randomized to stepped pharmacologic care or UF. The primary endpoint was a change in serum creatinine and change in weight (reflecting fluid removal) at 96 h. Although similar weight loss occurred in both groups (~5.5 kg), there was a rise in serum creatinine among patients allocated to the UF group. Deaths and hospitalizations for HF were no different between groups, but there were more adverse events in the UF group, mainly due to kidney failure, bleeding complications, and intravenous catheter-related complications. This investigation argues against using UF as a primary strategy in patients with ADHF who are diuretic-responsive. Whether UF is useful as a rescue strategy in diuretic refractory patients with advanced renal disease remains an open question, and this strategy continues to be employed judiciously in such situations.

VASOACTIVE THERAPY

Vasodilators including *intravenous nitroglycerin, sodium nitroprusside*, and *nesiritide* (a recombinant brain-type natriuretic peptide) are frequently used in ADHF to lower intracardiac filling pressures and reduce systemic vascular tone. Rapid reduction in ventricular preload and afterload with these therapies may be effective in providing symptom relief in patients with pulmonary edema and in restoring end-organ perfusion for those with low cardiac output and high systemic vascular resistance. Nitroglycerine principally impacts venous tone and ventricular preload, whereas sodium nitroprusside is a potent arterial and venous vasodilator with more comprehensive effects on both preload and afterload. While intravenous nitroglycerine is commonly utilized as an adjunct to diuretics for acute management of symptomatic HF and pulmonary edema, nitroprusside is typically reserved for use in those with adequate arterial pressure or invasive hemodynamic monitoring due to the risk for hypotension. The hemodynamic effects of nesiritide are intermediate between those of nitroglycerine and nitroprusside, with head-to-head comparisons with nitroglycerine suggesting more rapid reduction in pulmonary capillary wedge pressure and pulmonary vascular resistance. Clinical utilization of nesiritide has waned due to concerns raised regarding heightened risks of renal insufficiency and mortality identified in early trials. The Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND-HF) randomizing 7141 patients with ADHF to nesiritide or placebo did not confirm this risk but identified no clear clinical benefit regarding subsequent HF admissions, mortality, or symptom relief (reduction in dyspnea). Renal function did not worsen, but increased rates of hypotension were noted. A smaller study of low-dose nesiritide in acute HF (Renal Optimization Strategies Evaluation Acute Heart Failure Study [ROSE-AHF]) also showed no incremental benefit over intravenous diuretics for relief of congestion or preservation of renal function. Despite apparent safety in ADHF, the routine use of nesiritide is accordingly not recommended.

Other novel vasodilators have been explored for the management of ADHF. Recombinant human relaxin-2, or *serelaxin*, is a vasodilatory hormone known to contribute to cardiovascular and renal adaptations during pregnancy. In the Relaxin in Acute Heart Failure (RELAX-AHF) trial, 1161 patients hospitalized with ADHF, evidence of congestion, and systolic pressure >125 mmHg were randomized to treatment with serelaxin or placebo in addition to standard HF therapy. Serelaxin improved dyspnea, reduced signs and symptoms of congestion, and was associated with less early worsening of HF. A positive signal of reduced mortality identified in an exploratory analysis prompted a second study (RELAX-AHF2), which did not confirm an effect on cardiovascular death or worsening HF. Accordingly, this agent was not approved for use in clinical practice.

One hypothesis for the failure of vasodilator therapies to improve clinical outcomes in ADHF despite favorable hemodynamic effects is related to the acute injury hypothesis; in this model, acute HF is analogous to presentation with an acute coronary syndrome, with the initial hours of presentation representing a period of vulnerability to myocardial damage (reflected in a rise in markers of myocyte injury such as cardiac troponins) as a consequence of abrupt increases in ventricular wall stress related to acute plasma volume expansion. To test this hypothesis, the Trial of Ularitide Safety and Efficacy in Acute Heart Failure (TRUE-AHF) randomly allocated 2157 patients with acute HF to early treatment with the synthetic natriuretic peptide *ularitide* (at a dose sufficient to reduce ventricular wall stress) or placebo. Despite a very short duration between initial clinical presentation and pharmacologic intervention (<6 h) and early hemodynamic benefits, no improvement in clinical outcomes was observed in patients allocated to ularitide at 6 months. Ularitide was associated with a higher rate of hypotension and worsening serum creatinine. These data undermine the notion that acute myocardial damage related to ventricular distension associated with HF exacerbation drives subsequent clinical outcomes and argue against the clinical importance of early vasodilator therapy in ADHF.

INOTROPIC THERAPY

Impairment of myocardial contractility often accompanies ADHF, and pharmacologic agents that increase intracellular concentration of cyclic adenosine monophosphate via direct or indirect pathways, such as sympathomimetic amines (*dopamine, dobutamine*) and phosphodiesterase-3 inhibitors (*milrinone*), respectively, serve as positive inotropic agents. Their activity leads to an increase in cytoplasmic calcium. Inotropic therapy in those with a low-output state augments cardiac output, reduces systemic vascular resistance, improves perfusion, and relieves congestion acutely. Although systematic head-to-head comparisons are available to identify a "best" agent, slight variations in the hemodynamic effects of inotropic drugs may condition selection of the appropriate drug for a given clinical context. Dopamine exhibits dose-dependent effects on dopaminergic, α-, and β-adrenergic receptors, with vasodilatory effects predominating at lower doses (<2 μg/kg per min), β-adrenergic (inotropic) effects at moderate doses, and α-adrenergic effects (vasoconstriction) at higher doses (typically >10 μg/kg per min). Low-dose ("renal dose") dopamine has been explored as an adjunctive strategy for preservation of renal function and augmentation of diuresis in acute HF but does not appear to provide incremental advantage over routine therapy with intravenous diuretics (ROSE-AHF).

Milrinone is typically associated with a greater reduction in systemic and pulmonary vascular resistance than dobutamine and, accordingly, carries a higher risk of systemic hypotension. Moreover, because milrinone has a longer half-life and is renally excreted, it requires dose adjustments in the setting of kidney dysfunction. Because milrinone acts downstream from the β_1-adrenergic receptor, it may provide an advantage in patients receiving beta blockers when admitted to the hospital.

Long-term inotropic therapy is associated with a heightened risk of mortality in HF, perhaps due to the increased risk of arrhythmia and sudden death. Routine, short-term use of milrinone in patients hospitalized with ADHF in the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) trial was associated with increased risk of atrial arrhythmias and prolonged hypotension, but no benefit regarding subsequent mortality or HF hospitalization. Accordingly, routine use of inotropic support in ADHF is discouraged, and these agents are currently indicated principally for short-term use as bridge therapy (to either left ventricular assist device support or to transplant) in cardiogenic shock or as selectively applied palliation in end-stage HF.

Novel inotropic agents that leverage the concept of myofilament calcium sensitization rather than increasing intracellular calcium levels have been introduced. *Levosimendan* is a calcium sensitizer that provides inotropic activity but also possesses phosphodiesterase-3 inhibition properties that are vasodilatory. Two trials, the second Randomized Multicenter Evaluation of Intravenous Levosimendan Efficacy (REVIVE II) and Survival of Patients with Acute Heart Failure in Need of Intravenous Inotropic Support (SURVIVE), have tested this agent in ADHF. SURVIVE compared levosimendan with dobutamine, and despite an initial reduction in circulating B-type natriuretic peptide levels in the levosimendan group compared with patients in the dobutamine group, this drug did not reduce all-cause mortality at 180 days or affect any secondary clinical outcomes. The second trial compared levosimendan against traditional noninotropic therapy and found a modest improvement in symptoms with worsened short-term mortality and ventricular arrhythmias. Although levosimendan has been approved for use to support management of HF in several countries worldwide, it is not approved for use in the United States, largely owing to the lack of compelling data for incremental efficacy in comparison with conventional inotropic drugs or standard HF therapies.

(**Table 265-1** depicts typical inotropic, vasodilator, and diuretic drugs used in ADHF.)

OTHER THERAPIES FOR ADHF

Other trials testing unique agents have yielded disappointing results in the situation of ADHF. Adenosine has been implicated as a mediator of worsening renal function and diuretic resistance, and accordingly, treatment with *adenosine receptor antagonists* was postulated to be potentially beneficial in relieving symptoms and preserving renal function in patients with acute HF. Among patients with acute HF and renal dysfunction enrolled in the Placebo-Controlled Randomized Study of the Selective A1 Adenosine Receptor Antagonist Rolofylline for Patients Hospitalized with Acute Decompensated Heart Failure and Volume Overload to Assess Treatment Effect on Congestion and Renal Function (PROTECT) trial, no cardiovascular or renal benefit was observed. Similarly, despite compelling theoretical benefit of vasopressin receptor antagonism in acute HF (based on the central role of vasopressin in mediating the fluid retention that contributes to worsening HF), no benefit of the oral selective vasopressin-2 antagonist *tolvaptan* was seen regarding mortality or HF-associated morbidity in the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) trial.

CLINICAL GUIDING PRINCIPLES

In the absence of data to support specific pharmacologic interventions in ADHF, management is largely goal-directed and focused on decongestion to relieve symptoms, investigation and suppression of triggers for recurrent decompensation, and careful transition to longitudinal HF management. Patients who fail to respond adequately to medical therapy or who develop hemodynamic instability may benefit from pulmonary artery catheter placement to guide titration of vasoactive therapy or inotropic support; in those with hemodynamics suggestive of cardiogenic shock, mechanical assist devices may be required **(Chap. 271)**. Following stabilization, all patients should receive education regarding HF self-management prior to discharge, including guidance regarding diet and lifestyle modification, identification of worsening HF symptoms, and whom to contact in the event of clinical deterioration. Early postdischarge follow-up of patients following hospitalization for management of worsening HF is associated with lower rates of hospital readmission. For patients with HFrEF hospitalized with ADHF, data suggest that institution of appropriate guideline-directed medical therapy prior to hospital discharge is associated with higher rates of adherence to appropriate pharmacologic treatment in longitudinal follow-up and may be associated with improved outcomes in the early postdischarge interval. In the Comparison of Sacubitril-Valsartan Versus Enalapril on Effect on NTproBNP in Patients Stabilized from an Acute Heart Failure Episode (PIONEER-HF) study of patients with HFrEF stabilized after hospital admission for ADHF, predischarge initiation of sacubitril-valsartan compared with enalapril was associated with greater reductions in natriuretic peptides as well as lower rates of composite death and HF readmission at 8 weeks. Similarly, in the EMPULSE trial, predischarge initiation of the SGLT-2 inhibitor empagliflozin in hospitalized HF patients across the spectrum of EF was associated with reductions in a hierarchical clinical composite outcome at 90 days. More recently, in the STRONG-HF trial, an intensive postdischarge treatment strategy of frequent follow-up and rapid uptitration of guideline-recommended medical therapy was associated with lower rates of death and HF readmission at 180 days compared with usual care. These results were consistent in those with EF ≤40% and those with EF >40%, underscoring the need for early postdischarge follow-up and medical optimization in high-risk patients following a worsening HF event, regardless of EF.

HEART FAILURE WITH REDUCED EJECTION FRACTION

The past 50 years have witnessed great strides in the management of HFrEF. Treatment of symptomatic HF has evolved from a renocentric (diuretics) and hemodynamic therapy model (digoxin, inotropic therapy) to an era of disease-modifying therapy with neurohormonal antagonism. In this regard, RAAS blockers (including ARNIs), β-adrenergic receptor blockers, and, most recently, SGLT-2 inhibitors form pillars of pharmacotherapy and facilitate stabilization and even improvement in cardiac structure and function with consequent reduction in symptoms, improvement in QOL, decreased burden of hospitalizations, and a decline in mortality from both pump failure and arrhythmic deaths **(Fig. 265-3)**.

TABLE 265-1 Vasoactive Therapy in Acute Decompensated Heart Failure

DRUG CLASS	GENERIC DRUG	USUAL DOSING	SPECIAL CAUTION	COMMENTS
Inotropic therapy				Use in hypotension, end-organ hypoperfusion, or shock states
	Dobutamine	2–20 μg/kg per min	Increased myocardial oxygen demand, arrhythmia	Short acting, an advantage; variable efficacy in presence of beta blockers (requires higher doses); clinical tolerance to prolonged infusions; concerns with hypersensitivity carditis (rare)
	Milrinone	0.375–0.75 μg/kg per min	Hypotension, arrhythmia	Decrease dose in renal insufficiency; avoid initial bolus; effectiveness retained in presence of beta blockers
	Levosimendan	0.1 μg/kg per min; range, 0.05–0.2 μg/kg per min	Hypotension, arrhythmia	Long acting; should not be used in presence of low blood pressure; similar effectiveness as dobutamine but effectiveness retained in presence of beta blockers
Vasodilators				Use in presence of pulmonary congestion for rapid relief of dyspnea, in presence of a preserved blood pressure
	Nitroglycerin	10–20 μg/min, increase up to 200 μg/min	Headache, flushing, tolerance	Most common vasodilator but often underdosed; effective in higher doses
	Nesiritide	Bolus 2 μg/kg and infusion at 0.01 μg/kg per min	Hypotension	Decrease in blood pressure may reduce renal perfusion pressure; bolus may be avoided since it increases hypotension predilection
	Nitroprusside	0.3 μg/kg per min titrated to 5 μg/kg per min	Thiocyanate toxicity in renal insufficiency (>72 h)	Requires arterial line placement for titration for precise blood pressure management and prevention of hypotension
	Serelaxin	N/A (tested at 30 μg/kg per d)	Baseline blood pressure should be >125 mmHg	Not widely commercially available; ineffective in confirmatory trials
	Ularitide	15 ng/kg per min (48 h)	Baseline blood pressure >116 mmHg	Excess hypotension and increased serum creatinine
Diuretics				First line of therapy in volume overload with congestion; may use bolus or continuous dosing; initial low dose (1 × home dose) or high dose (2.5 × home dose) equally effective with higher risk of renal worsening with higher dose
	Furosemide	20–240 mg daily	Monitor for electrolyte loss	In severe congestion, use intravenously and consider continuous infusion (not trial supported)
	Torsemide	10–100 mg daily	Monitor for electrolyte loss	High bioavailability, can be given orally; anecdotally more effective in advanced heart failure states if furosemide less bioavailable (due to gut congestion)
	Bumetanide	0.5–5 mg daily	Monitor for electrolyte loss	Can be used orally; intermediate bioavailability
	Adjuvant diuretics for augmentation	N/A	Metolazone, chlorthalidone, spironolactone, acetazolamide	Acetazolamide is useful in presence of alkalosis (bicarbonate level >27mEq/L); metolazone given in 2.5- to 10-mg doses; concomitant use of loop diuretics and thiazides associated with risk for severe hypokalemia, careful laboratory monitoring advised; spironolactone is useful in presence of severe hypokalemia and normal renal function

Abbreviation: N/A, not applicable.

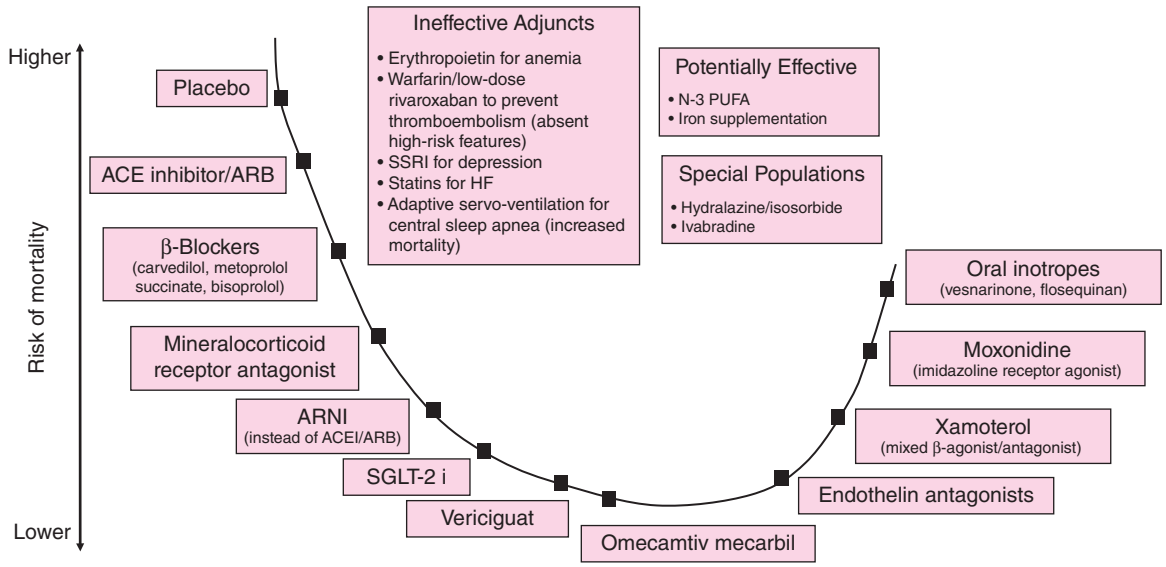

FIGURE 265-3 Progressive decline in mortality with angiotensin-converting enzyme (ACE) inhibitors (ACEIs) or angiotensin receptor blockers (ARBs), angiotensin receptor-neprilysin inhibitors (ARNIs), beta blockers, mineralocorticoid receptor antagonists, sodium-glucose cotransporter-2 (SGLT-2) inhibitors, and balanced vasodilators (*selected populations such as African Americans). Addition of selected therapies (ivabradine, vericiguat) may further reduce heart failure (HF) hospitalization but does not substantially impact mortality. Further stack-on neurohormonal therapy is ineffective or results in worse outcome. Management of comorbidity (e.g., iron deficiency, sleep apnea) is of unproven efficacy. HFrEF, heart failure with reduced ejection fraction; PUFA, polyunsaturated fatty acid; SSRI, selective serotonin reuptake inhibitor.

NEUROHORMONAL ANTAGONISM

Meta-analyses suggest a 23% reduction in mortality and a 35% reduction in the combined endpoint of mortality and hospitalizations for HF in patients with symptomatic HFrEF treated with ACE inhibitors (ACEIs). Addition of β-adrenergic receptor blockers to background therapy with ACEIs provides a further 35% reduction in mortality. Although placebo-controlled studies are lacking, several noninferiority trials have demonstrated comparable efficacy of ARBs and ACEIs in patients with HFrEF, making ARBs a suitable alternative for patients who are intolerant to ACEIs due to cough or angioedema. Abundant data support the efficacy across the full spectrum of HF severity (including those with NYHA class III–IV functional capacity), as well as the safety data of these agents. These observations demonstrate the basis for the tolerability of these agents even in subgroups at higher risk for adverse effects such as those with mild-moderate chronic kidney disease. In diabetes mellitus and chronic obstructive lung disease, these agents have been established as foundational therapy for HFrEF as directed by consensus guidelines. Both agents are generally recommended for all patients with HFrEF, independent of symptom burden, and should be titrated to the doses proven to provide clinical benefit or to the maximally tolerated dose. The inability to tolerate initiation or dose titration of neurohumoral antagonists due to hypotension, worsening HF, or progressive renal insufficiency is a poor prognostic marker and may be a cardinal manifestation of transition to an advanced HF phenotype.

Class Effect and Sequence of Administration ACEIs and ARBs exert their beneficial effects in HFrEF as a class; however, the beneficial effects of beta blockers are thought to be limited to specific drugs. Beta blockers with intrinsic sympathomimetic activity (xamoterol) and other agents, including bucindolol, have not demonstrated a survival benefit. Based on the available data, beta blocker use in HFrEF should ideally be restricted to carvedilol, bisoprolol, and metoprolol succinate—agents tested and proven to improve survival in clinical trials. Whether beta blockers or ACEIs should be started first was answered by the Cardiac Insufficiency Bisoprolol Study (CIBIS) III, in which outcomes did not vary based on the sequence of drug initiation. Thus, it matters little which agent is initiated first; what does matter is that optimally titrated doses of both ACEIs and beta blockers be established in a timely manner.

Dose and Outcome In general, the benefits of neurohumoral antagonists in HFrEF are closely related to the dose achieved, girding the rationale for aggressive titration to target doses as defined by clinical trials. Prospective trials of high- versus low-dose ACEIs (ATLAS), ARBs (HEAAL), and beta blockers (MOCHA) consistently favor the higher dose, with lower rates of death and HF hospitalization seen in the higher-dose group. Clinical experience suggests that, in the absence of symptoms to suggest hypotension (fatigue and dizziness), pharmacotherapy may be uptitrated every 2 weeks in stable ambulatory patients as tolerated. Notably, data from large registries in the United States and Europe suggest that guideline-directed medical therapy for patients with HFrEF is frequently underutilized and underdosed, leaving considerable room for quality improvement.

MINERALOCORTICOID RECEPTOR ANTAGONISTS

Addition of mineralocorticoid receptor antagonists to treatment with ACEI/ARBs and beta blockers in patients with symptomatic HFrEF (NYHA class II–IV) is associated with further reductions in morbidity and mortality. Elevated aldosterone levels in HFrEF promote sodium retention, electrolyte imbalance, and endothelial dysfunction and may directly contribute to myocardial fibrosis. Hyperkalemia and worsening renal function are concerns, especially in patients with underlying chronic kidney disease, and renal function and serum potassium levels must be closely monitored. Spironolactone is the most utilized agent in this class based on efficacy demonstrated in the Randomized Aldactone Evaluation Study (RALES) in patients with HFrEF and NYHA class III–IV symptoms. Eplerenone (studied principally in patients with milder NYHA class II symptoms and those with HF or left ventricular dysfunction complication myocardial infarction) lacks the antiandrogen effects of spironolactone and may be a suitable alternative for patients who experience sexual side effects (gynecomastia, erectile dysfunction, diminished libido).

RAAS THERAPY AND NEUROHORMONAL "ESCAPE"

Since angiotensin II can be generated by non-ACE pathways, levels of angiotensin II may recover to pretreatment levels during long-term ACEI therapy. This phenomenon of neurohormonal "escape" has fueled interest in dual blockade of the RAAS using ACEI and ARBs in combination. In both the Valsartan Heart Failure Trial (Val-HeFT) and the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM-Added) trial, addition of an ARB to an ACEI and other HF therapy was associated with a lower risk of HF hospitalizations. Since neither trial mandated an evidence-based dose of an ACEI, it remains unclear whether combination therapy was clearly superior to a strategy of maximizing a single agent through dose titration. Subsequent data from the Valsartan in Acute Myocardial Infarction (VALIANT) trial suggested that the addition of the ARB valsartan to an evidence-based dose of the ACEI captopril in patients with HF complicating myocardial infarction was associated with an increase in adverse events without any added benefit compared with monotherapy for either group. The findings of the VALIANT trial are also informed by the Aliskiren Trial to Minimize Outcomes in Patients with Heart Failure (ATMOSPHERE), which randomly allocated 7016 patients with HFrEF to treatment with enalapril (targeted dose 10 mg twice daily as recommended by guidelines), the plasma renin inhibitor aliskiren, or the combination on top of standard HF therapy. In that study, combination treatment with aliskiren and enalapril was associated with higher rates of hyperkalemia, hypotension, and worsening renal function, but no incremental benefit regarding HF hospitalization or cardiovascular mortality. Together, these data argue for a ceiling of benefit of angiotensin inhibition in HFrEF, beyond which further inhibition brings more adverse effects without additional efficacy. Guidelines discourage the combination of an ACEI, ARB, and spironolactone in HFrEF due to the risks of hyperkalemia and renal dysfunction, and for patients, treatment with either an ACEI or ARB and spironolactone is deemed most appropriate.

ALTERNATIVE VASODILATORS

The combination of hydralazine and nitrates has been demonstrated to improve survival in HFrEF. Hydralazine reduces systemic vascular resistance and induces arterial vasodilatation by affecting intracellular calcium kinetics; nitrates are transformed in smooth muscle cells into NO, which stimulates cyclic guanosine monophosphate production and consequent arterial-venous vasodilation. This combination improves survival but to a lesser extent than ACEIs. However, in individuals with HFrEF unable to tolerate RAAS-based therapy for reasons such as renal insufficiency or hyperkalemia, this combination is preferred as a disease-modifying approach. A trial conducted in self-identified African Americans, the African-American Heart Failure Trial (A-HeFT), studied a fixed dose of isosorbide dinitrate with hydralazine in patients with advanced symptoms of HFrEF who were receiving standard background therapy including an ACEI and beta blocker. The study demonstrated improvements in survival and hospital admission for HF in the treatment group. Adherence to this regimen is limited by the thrice-daily dosing schedule.

NOVEL NEUROHORMONAL ANTAGONISTS

Despite an abundance of animal and clinical data demonstrating deleterious effects of activated neurohormonal pathways beyond the RAAS and sympathetic nervous system, targeting such pathways with incremental blockade has been largely unsuccessful. As an example, the endothelin antagonist bosentan is associated with worsening HF in HFrEF despite demonstrating benefits in right-sided HF due to pulmonary arterial hypertension. Similarly, the centrally acting sympatholytic agent moxonidine worsens outcomes in left HF. The combined drug omapatrilat hybridizes an ACEI with a neutral endopeptidase (neprilysin) inhibitor, and this agent was tested in the Omapatrilat

TABLE 265-2 Guideline-Directed Pharmacologic Therapy and Target Doses in Heart Failure with Reduced Ejection Fraction

DRUG CLASS	GENERIC DRUG	MEAN DAILY DOSE IN CLINICAL TRIALS (mg)	INITIATION (mg)	TARGET DOSE (mg)
Angiotensin-Converting Enzyme Inhibitors				
	Lisinopril	4.5–33	2.5–5 qd	20–35 qd
	Enalapril	17	2.5 bid	10–20 bid
	Captopril	123	6.25 tid	50 tid
	Trandolapril	N/A	0.5–1 qd	4 qd
Angiotensin Receptor Blockers				
	Losartan	129	50 qd	150 qd
	Valsartan	254	40 bid	160 bid
	Candesartan	24	4–8 qd	32 qd
Aldosterone Antagonists				
	Eplerenone	42.6	25 qd	50 qd
	Spironolactone	26	12.5–25 qd	25–50 qd
Beta Blockers				
	Metoprolol succinate CR/XL	159	12.5–25 qd	200 qd
	Carvedilol	37	3.125 bid	25–50 bid
	Bisoprolol	8.6	1.25 qd	10 qd
Arteriovenous Vasodilators				
	Hydralazine isosorbide dinitrate	270/136	37.5/20 tid	75/40 tid
	Fixed-dose hydralazine/isosorbide dinitrate	143/76	37.5/20 qid	75/40 qid
Angiotensin Receptor-Neprilysin Inhibitor				
	Sacubitril-valsartan	375	100 bid	200 bid
SGLT-2 Inhibitor				
	Dapagliflozin	10	10 qd	10 qd
	Empagliflozin	10	10 qd	10 qd
	Sotagliflozin	200	200 qd	200 qd
Novel Therapies				
	Vericiguat (sGC stimulator)	9.2	2.5 qd	10 qd
	Omecamtiv mecarbil (myosin activator)	Not reported	25 bid	Up to 50 mg bid (based on plasma concentrations)

Abbreviations: sGC, soluble guanylyl cyclase; SGLT-2, sodium-glucose cotransporter 2.

Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) trial. This drug did not favorably influence the primary outcome measure of the combined risk of death or hospitalization for HF requiring intravenous treatment compared with enalapril alone, and notably, the risk of angioedema was increased in patients assigned to omapatrilat.

The risk of angioedema with composite ACE/neprilysin inhibition appears to be related to excessive blockade of bradykinin breakdown by this combination. Blockade of angiotensin at the receptor level with an ARB leaves the ACE pathway for bradykinin breakdown intact and is associated with lower angioedema risk. Recently, a composite ARNI, sacubitril-valsartan (formerly LCZ696), was developed and applied to the treatment of patients with HFrEF. In the PARADIGM-HF trial, 8399 patients with HFrEF treated with guideline-directed medical therapy were randomly allocated to treatment with either enalapril or sacubitril-valsartan after a run-in period designed to ensure tolerability of both drugs at target doses. Compared to those assigned to enalapril, patients assigned to sacubitril-valsartan experienced a dramatic 20% reduction in the composite primary endpoint of cardiovascular death or HF hospitalization and a 16% reduction in all-cause mortality, as well as clinically important improvements in QOL measures. Sacubitril-valsartan was well tolerated and associated with lower rates of hyperkalemia and worsening renal function, but greater rates of symptomatic hypotension, than enalapril. Guidelines now advocate a switch to ARNI for patients with symptomatic HFrEF who tolerate ACEIs and ARBs, and emerging data suggest that up-front utilization of ARNI in patients with de novo HF naïve to ACEIs/ARBs may also be appropriate for those with adequate blood pressure to tolerate it. Given ongoing concern for angioedema, use of ARNI is contraindicated in patients with prior history of angioedema, and those being transitioned from ACEIs should receive ARNI only after a 36-h gap to limit the risk of overlap. Table 265-2 lists the common neurohormonal and vasodilator regimens for HFrEF.

HEART RATE MODIFICATION

Distinct from β-adrenergic receptor blockers, ivabradine, an inhibitor of the I_f current in the sinoatrial node, selectively reduces heart rate without affecting cardiac contractility or vascular tone. The Systolic Heart Failure Treatment with Ivabradine Compared with Placebo Trial (SHIFT) was conducted in patients with NYHA class II or III HFrEF, prior HF hospitalization, sinus rhythm, and heart rate >70 beats/min. Ivabradine reduced the combined endpoint of cardiovascular-related death and HF hospitalization in proportion to the degree of heart rate reduction, which supports the notion that heart rate may be a therapeutic target in patients with HFrEF in sinus rhythm. Importantly, despite a protocol requirement for patients to be treated with a maximally tolerated dose of a beta blocker prior to study entry, 10% of patients randomized were not treated with a beta blocker, and 75% were treated at subtarget doses. Accordingly, it remains unclear whether this agent would have been effective in patients receiving robust, guideline-recommended therapy for HF; however, these data do support the potential value of ivabradine as an adjunct or alternative in those who are intolerant to initiation or dose titration of beta blockers. Clinical guidelines have been adapted

to encourage consideration of ivabradine in patients with HFrEF who remain symptomatic after treatment with guideline-based ACEI/ARB/ARNIs, beta blockers, and mineralocorticoid receptor antagonists; are in sinus rhythm; and have a residual heart rate >70 beats/min.

SGLT-2 INHIBITION

Inhibitors of SGLT-2 have been shown to reduce cardiovascular events and mortality among patients with type 2 diabetes mellitus at high cardiovascular risk or with established atherosclerotic cardiovascular disease. A particular signal of benefit has been seen regarding the incidence of HF hospitalization, which was reduced by 35% in comparison to placebo in the Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOMES) study. Because the cardiovascular benefits of SGLT-2 inhibition appear to be unrelated to the degree of reduction in hemoglobin A_{1c}, it has been postulated that the HF benefits of this therapy might be extended to patients without diabetes mellitus. Recently, the Dapagliflozin in Heart Failure (DAPA-HF) study randomized 4744 patients with symptomatic HFrEF treated with guideline-directed medical therapy (including a beta blocker, ACEI/ARB/ARNI, and spironolactone in >70% of patients) to treatment with either the SGLT-2 inhibitor dapagliflozin (dosage 10 mg daily) or placebo over a median duration of follow-up of 18.2 months. Patients allocated to dapagliflozin experienced a highly significant 26% reduction in the primary composite endpoint of worsening HF or death from cardiovascular causes, an effect that was consistent in both patients with (42%) and without diabetes mellitus at baseline. These results have been reinforced by the results of the EMPEROR-Reduced trial, in which 3730 patients with symptomatic HF and EF of ≤40% were randomized to treatment with empagliflozin (dosage 10 mg once daily) or placebo in addition to recommended therapy. Over a median 16-month follow-up, patients allocated to empagliflozin experienced a 25% reduction in the primary composite endpoint of cardiovascular death or hospitalization for HF, an effect that was again consistent regardless of the presence or absence of diabetes mellitus. Together, these studies have driven consensus guidelines to consider use of SGLT-2 inhibitors as foundational therapy for HF alongside ARNIs, beta blockers, and mineralocorticoid receptor antagonists.

SOLUBLE GUANYLYL CYCLASE STIMULATION

Soluble guanylyl cyclase (sGC) is a key enzyme of the NO signaling pathway that catalyzes synthesis of cyclic guanosine monophosphate (GMP), producing vasodilation. Vericiguat is a novel oral sGC stimulator that enhances cyclic GMP and NO signaling by directly stimulating sGC and sensitizing sGC to endogenous NO. The Vericiguat Global Study in Subjects with Heart Failure with Reduced Ejection Fraction (VICTORIA) randomly assigned 5050 patients with chronic HF, NYHA class II–IV symptoms, LVEF <45%, elevated natriuretic peptide levels, and evidence of worsening HF (requiring recent hospitalization or intravenous diuretic therapy) despite guideline-directed medical therapy to treatment with vericiguat (target dose 10 mg) or matching placebo over a median follow-up of 11 months. The primary study results were notable for a modest 10% relative risk reduction in the primary composite outcome of cardiovascular death or HF hospitalization among those assigned to vericiguat, an effect driven principally by effects on HF hospitalization, rather than cardiovascular death. As vericiguat was generally well tolerated with a low rate of serious adverse events, these data suggest a potential role for sGC stimulation as an adjunct to guideline-directed medical therapy in the high-risk group of HFrEF patients with recent congestive exacerbations requiring treatment, although these data await further review by regulatory agencies and guidelines committees.

MYOSIN ACTIVATION

A novel approach to augmentation of cardiac output is to prolong ventricular systole without increasing myocardial contractility. As a selective myosin activator, *omecamtiv mecarbil* prolongs the ejection period and increases fractional shortening without altering the force of contraction. This agent, distinct from inotropic agents, is not associated with an increase in myocardial oxygen demand. Importantly, the drug is available for oral, rather than intravenous, administration, enabling chronic use in the ambulatory setting. In the COSMIC-HF (Chronic Oral Study of Myosin Activation to Increase Contractility in Heart Failure) trial of 448 patients with chronic HF and left ventricular systolic dysfunction, treatment with omecamtiv mecarbil for 20 weeks was associated with significant improvements in cardiac function and indices of left ventricular remodeling, as well as reductions in natriuretic peptide levels. Notably, the safety profile was comparable to placebo, with no increase in cardiac adverse events despite a modest increase in cardiac troponins in patients allocated to omecamtiv mecarbil. These promising preliminary data fueled a larger clinical outcomes trial (GALACTIC-HF), in which 8256 patients with symptomatic chronic HF and EF of ≤35% were randomized to treatment with omecamtiv mecarbil (25–50 mg twice daily based on plasma levels) or placebo in addition to standard HF therapy. Over a median follow-up of 21.8 months, patients allocated to omecamtiv mecarbil experienced a 14% reduction in the primary composite endpoint of death from cardiovascular causes or first HF event (hospitalization or urgent visit for HF), an outcome driven principally by reduction in HF events (no measurable effect on cardiovascular death alone). A possible signal of greater benefit in patients with features of advanced HF (lower EF, higher natriuretic peptide levels, more severe symptoms) combined with a favorable safety and tolerability profile suggests a possible role for this agent in patients with late-stage disease, although additional study is needed.

DIGOXIN

Digitalis glycosides exert a mild inotropic effect, attenuate carotid sinus baroreceptor activity, and are sympatho-inhibitory. These effects decrease serum norepinephrine levels, plasma renin levels, and possibly aldosterone levels. The Digitalis Investigation Group (DIG) trial demonstrated a reduction in HF hospitalizations in the treatment group (patients with HF and sinus rhythm) but no reduction in mortality or improvement in QOL. Importantly, treatment with digoxin resulted in a higher mortality rate and hospitalizations in women than men. It should be noted that low doses of digoxin are sufficient to achieve any potentially beneficial outcomes, and higher doses breach the therapeutic safety index. Although digoxin levels should be checked to minimize toxicity and although dose reductions are indicated for higher levels, no adjustment is made for low levels. Generally, digoxin is now relegated as late-line therapy for patients who remain profoundly symptomatic despite optimal neurohormonal blockade and adequate volume control.

ORAL DIURETICS

Neurohormonal activation results in avid salt and water retention. Diuretic therapy is typically required in patients with symptomatic HF to remedy congestive symptoms as a prelude to initiation and titration of neurohormonal therapy. Because of their potent effect on renal sodium excretion, loop diuretic agents are the preferred agents, with thiazide diuretics reserved for use in combination with loop diuretics for those with refractory volume overload. Frequent dose adjustments of loop diuretics may be necessary during longitudinal follow-up of patients with HF because of variable oral absorption and fluctuations in renal function. Patients who fail to respond to furosemide at high doses may benefit from transition to torsemide or bumetanide, which have greater oral bioavailability, but recent studies have not confirmed a greater benefit for alternatives to furosemide as a loop diuretic. Importantly, clinical trial data confirming efficacy are limited, and no data suggest that these agents improve survival. Since loop diuretics do enhance neurohumoral activation, dosing should be minimized as possible to maximize the balance of risk and benefit.

CALCIUM CHANNEL ANTAGONISTS

Amlodipine and felodipine, second-generation calcium channel–blocking agents, safely and effectively reduce blood pressure in HFrEF but do not affect morbidity, mortality, or QOL. The first-generation agents, including verapamil and diltiazem, may exert negative inotropic effects and destabilize previously asymptomatic patients. Accordingly, their use should be discouraged in patients with HFrEF.

ANTI-INFLAMMATORY THERAPY

Targeting inflammatory cytokines such as tumor necrosis factor α (TNF-α) for the management of HF by using anticytokine agents such as infliximab and etanercept has been unsuccessful and associated with worsening HF. Use of intravenous immunoglobulin therapy in nonischemic etiology of HF has not been shown to result in beneficial outcomes. Nonspecific immunomodulation has been tested in the Advanced Chronic Heart Failure Clinical Assessment of Immune Modulation Therapy (ACCLAIM-HF) trial where ex vivo exposure of a blood sample from systolic HF patients to controlled oxidative stress was hypothesized to initiate apoptosis of leukocytes soon after intramuscular gluteal injection of the treated sample. The physiologic response to apoptotic cells results in a reduction in inflammatory cytokine production and upregulation of anti-inflammatory cytokines. This promising hypothesis was not proven, although certain subgroups (those with no history of previous myocardial infarction and those with mild HF) showed signals in favor of immunomodulation. Most recently, in the Canakinumab Anti-inflammatory Thrombosis Outcomes Study (CANTOS), treatment of post–myocardial infarction patients with elevated high-sensitivity C-reactive protein using a monoclonal antibody targeted at interleukin 1β was associated with a dose-dependent reduction in hospitalization for HF and HF-associated mortality in post hoc analyses. Whether this approach might have relevance for patients with established HF remains unclear.

HMG-CoA REDUCTASE INHIBITORS (STATINS)

Potent lipid-altering and pleiotropic effects of statins reduce major cardiovascular events and improve survival in non-HF populations. Once HF is well established, this therapy may not be as beneficial and theoretically could even be detrimental by depleting ubiquinone in the electron transport chain. Two trials, Controlled Rosuvastatin Multinational Trial in Heart Failure (CORONA) and Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiac (GISSI-HF), have tested low-dose rosuvastatin in patients with HFrEF and demonstrated no improvement in aggregate clinical outcomes. If statins are required to treat progressive atherosclerotic vascular disease or significant dyslipidemia in the background setting of HF, then they should be employed. However, no clear rationale appears to exist for routine use of statin therapy in nonischemic HF.

ANTICOAGULATION AND ANTIPLATELET THERAPY

HFrEF is accompanied by a hypercoagulable state and therefore a high risk of thromboembolic events, including stroke, pulmonary embolism, and peripheral arterial embolism. Although the value of long-term oral anticoagulation is established in certain groups, including patients with atrial fibrillation, the data are insufficient to support the use of warfarin in patients in normal sinus rhythm without a history of thromboembolic events or echocardiographic evidence of left ventricular thrombus. In the large Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial, full-dose aspirin or international normalized ratio–controlled warfarin was tested with follow-up for 6 years. Among patients with reduced LVEF in sinus rhythm, there was no significant overall difference in the primary outcome between treatment with warfarin and treatment with aspirin. A reduced risk of ischemic stroke with warfarin was offset by an increased risk of major hemorrhage. A recent trial of the direct oral anticoagulant rivaroxaban at low dose (2.5 mg daily) for patients with ischemic heart disease, HFrEF, and sinus rhythm also indicated no reduction in stroke or ischemic events compared with placebo. Aspirin blunts ACEI-mediated prostaglandin synthesis, but the clinical importance of this finding remains unclear. Current guidelines support the use of aspirin in patients with ischemic cardiomyopathy who do not have a contraindication, although the risk-benefit balance in older patients at higher risk for bleeding complications may be less favorable.

FISH OIL

Treatment with long-chain omega-3 polyunsaturated fatty acids (ω-3 PUFAs) has been shown to be associated with modestly improved clinical outcomes in patients with HFrEF. This observation from the GISSI-HF trial was extended to measurements of ω-3 PUFAs in plasma phospholipids at baseline and after 3 months. Three-month treatment with ω-3 PUFAs enriched circulating eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Low EPA levels are inversely related to total mortality in patients with HFrEF.

MICRONUTRIENTS

A growing body of evidence suggests an association between HF and micronutrient status. Reversible HF has been described because of severe thiamine and selenium deficiency. Thiamine deficiency has received attention in HF because malnutrition and diuretics are prime risk factors for thiamine loss. Small exploratory randomized studies have suggested a benefit of supplementation with thiamine in HFrEF with evidence of improved cardiac function. This finding is restricted to chronic HF states and does not appear to be beneficial in the ADHF phenotype. Due to the exploratory nature of the evidence, no recommendations for routine supplementation or testing for thiamine deficiency can be made.

ENHANCED EXTERNAL COUNTERPULSATION

Peripheral lower extremity therapy using graded external pneumatic compression at high pressure is administered in 1-h sessions for 35 treatments (7 weeks) and has been proposed to reduce angina symptoms and extend time to exercise-induced ischemia in patients with coronary artery disease. The Prospective Evaluation of Enhanced External Counterpulsation in Congestive Heart Failure (PEECH) study assessed the benefits of enhanced external counterpulsation in the treatment of patients with mild-to-moderate HF. This randomized trial improved exercise tolerance, QOL, and NYHA functional classification but without an accompanying increase in peak oxygen consumption. A placebo effect due to the nature of the intervention simply cannot be excluded.

EXERCISE

The Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) study investigated short-term (3-month) and long-term (12-month) effects of a supervised exercise training program in patients with moderate HFrEF. Exercise was safe, improved patients' sense of well-being, and correlated with a trend toward mortality reduction. Maximal changes in 6-min walk distance were evident at 3 months with significant improvements in cardiopulmonary exercise time and peak oxygen consumption persisting at 12 months. Therefore, exercise training is recommended as an adjunctive treatment in patients with HF.

MANAGEMENT OF SELECTED COMORBIDITY

Sleep-disordered breathing is common in HF and particularly in HFrEF. A range of presentations exemplified by obstructive sleep apnea, central sleep apnea, and its extreme form of Cheyne-Stokes breathing are noted. Frequent periods of hypoxia and repeated micro- and macro-arousals trigger adrenergic surges, which can worsen hypertension and impair systolic and diastolic function. A high index of suspicion is required, especially in patients with difficult-to-control hypertension or with predominant symptoms of fatigue despite reverse remodeling in response to optimal medical therapy. Worsening of right heart function with improvement of left ventricular function noted on medical therapy should immediately trigger a search for underlying sleep-disordered breathing or pulmonary complications such as occult embolism or pulmonary hypertension. Treatment with nocturnal positive airway pressure improves oxygenation, LVEF, and 6-min walk distance. However, no conclusive data exist to support this therapy as a disease-modifying approach with reduction in mortality. A recent trial using adaptive servo-ventilation triggered by a minute ventilation sensor in patients who had HFrEF and predominantly central sleep apnea increased all-cause and cardiovascular mortality, so this approach should be avoided; however, modification of this approach using lower background pressures and an alternative trigger based on peak airflow appeared to be safe in patients with sleep apnea and HFrEF enrolled in the ADVENT-HF trial, although there was

no discernible benefit with regard to clinical outcomes. Whether this modified approach to adaptive servo-ventilation will be appropriate for management of selected patients with HFrEF and central sleep apnea requires further study.

Anemia is common in HF patients, reduces functional status and QOL, and is associated with increased proclivity for hospital admissions and mortality. Anemia in HF is more common in the elderly, in those with advanced stages of HFrEF, in the presence of renal insufficiency, and in women and African Americans. The mechanisms include iron deficiency, dysregulation of iron metabolism, and occult gastrointestinal bleeding. Intravenous iron using either iron sucrose or carboxymaltose (Ferric Carboxymaltose Assessment in Patients with Iron Deficiency and Chronic Heart Failure [FAIR-HF] trial) has been shown to correct anemia and improve functional capacity. Another trial, CONFIRM-HF, enrolled similar patients with iron deficiency (ferritin <100 ng/mL or 100–300 ng/mL if transferrin saturation <20%) and demonstrated that use of ferric carboxymaltose in a simplified high-dose schedule resulted in improvement in functional capacity, symptoms, and QOL. These symptomatic benefits of iron repletion, however, do not appear to translate clearly to benefits on longer term clinical outcomes. In the AFFIRM-AHF trial of patients with HF, LVEF <50%, and iron deficiency, randomization to ferric carboxymaltose compared with placebo was associated with a lower rate of cardiovascular death and total HF hospitalizations that narrowly missed the margin for statistical significance. Similar results were seen in the IRONMAN trial of another iron polysaccharide, ferric derisomaltose. The results of both of these trials may have been confounded by the coronavirus disease 2019 (COVID-19) pandemic, and pooled data suggested a possible favorable effect on HF hospitalizations. However, the HEART-FID trial, which randomized 3065 ambulatory HF patients with LVEF ≤40% and iron deficiency to treatment with ferric carboxymaltose or placebo, showed no benefit with regard to the primary hierarchical composite of death, hospitalizations for HF, or 6-minute walk distance. Accordingly, it seems that benefits of iron repletion in this population are likely confined to reduction in symptoms, and perhaps HF hospitalizations, particularly among those with iron deficiency. Oral iron supplementation does not appear to be effective in treating iron deficiency in HF. Erythropoiesis-regulating agents such as erythropoietin analogues have been studied with disappointing results. The Reduction of Events by Darbepoetin Alfa in Heart Failure (RED-HF) trial demonstrated that treatment with darbepoetin alfa did not improve outcomes in patients with systolic HF but increased the risk of thromboembolism-related adverse events.

Depression is common in HFrEF, with a reported prevalence of one in five patients, and is associated with a poor QOL, limited functional status, and increased risk of morbidity and mortality in this population. However, the largest randomized study of depression in HFrEF, the Sertraline Against Depression and Heart Disease in Chronic Heart Failure (SADHART-CHF) trial, showed that although sertraline was safe, it did not provide greater reduction in depression or improve cardiovascular status among patients with HF and depression compared with nurse-driven multidisciplinary management.

Atrial arrhythmias, especially atrial fibrillation, are common and serve as a harbinger of worse prognosis in patients with HF. When rate control is inadequate or symptoms persist, pursuing a rhythm control strategy is reasonable. Rhythm control may be achieved via pharmacotherapy or by percutaneous or surgical techniques, and referral to practitioners or centers experienced in these modalities is recommended. Antiarrhythmic drug therapy should be restricted to amiodarone and dofetilide, both of which have been shown to be safe and effective but do not alter the natural history of the underlying disease. The Antiarrhythmic Trial with Dronedarone in Moderate-to-Severe Congestive Heart Failure Evaluating Morbidity Decrease (ANDROMEDA) studied the effects of the novel antiarrhythmic agent dronedarone and found an increased mortality due to worsening HF. Given the potential adverse effects and limited efficacy of pharmacologic strategies for maintenance of sinus rhythm, catheter ablation has been explored as an alternative. In the CASTLE-AF trial, among 363 patients with HF, LVEF ≤35%, and paroxysmal or persistent atrial fibrillation randomized to treatment with catheter ablation or medical therapy, those assigned to catheter ablation experienced a significantly lower rate of death or hospitalization. These results are supported by similar outcomes in the CASTLE-HTX trial, which sought to include patients with advanced HF; however, this aspect is disputed. These data argue for consideration of restoration of sinus rhythm with catheter ablation as a preferred strategy to antiarrhythmic drugs in patients with HF and reduced EF.

Diabetes mellitus is a frequent comorbidity in HF. Prior studies using thiazolidinediones (activators of peroxisome proliferator-activated receptors) have been associated with worsening HF. GLP-1 agonists such as liraglutide have also been tested and do not lead to worsening in HF but require more study. The role of SGLT-2 inhibitors in HF has been previously discussed, and they represent an important disease-modifying therapy in diabetic patients with HF.

NEUROMODULATION USING DEVICE THERAPY

Autonomic dysfunction is common in HF, and attempts at using devices to modulate the sympathetic and parasympathetic systems have been undertaken. Broadly, devices that achieve vagal nerve stimulation, baroreflex activation, renal sympathetic denervation, spinal cord stimulation, or left cardiac sympathetic denervation have been employed. While small preclinical and clinical studies have demonstrated benefits, large, randomized trials, when conducted, have failed. The INOVATE-HF study tested vagal nerve stimulation versus optimal medical therapy among individuals with stable HF. Vagus nerve stimulation did not reduce the rate of death or hospitalization for HF. However, functional capacity and QOL were favorably affected by vagus nerve stimulation. The ANTHEM-HFrEF trial, which enrolled only half its intended population, did not show a signal for benefit of vagal nerve stimulation.

CARDIAC CONTRACTILITY MODULATION

Cardiac contractility modulation (CCM) is a device-based therapy for HF that involves nonexcitatory electrical stimulation to the right ventricular septal wall during the absolute myocardial refractory period to augment the strength of subsequent myocardial contraction. A series of small, randomized, prospective clinical trials, as well as several real-world observational registries, have suggested that application of CCM to selected patients with HF may improve symptoms, functional capacity, and QOL, although no effect on hard clinical outcomes such as HF hospitalization or mortality has been established. The predominant benefits of CCM appear to accrue to those with symptomatic HFrEF (EF 25–45%) and narrow QRS duration (for whom cardiac resynchronization therapy is not an option), and the approach can be combined with an implantable defibrillator. The device is not currently endorsed for routine use by clinical treatment guidelines in the United States or Europe and is deemed to require more evidence prior to widespread adoption.

CARDIAC RESYNCHRONIZATION THERAPY

Nonsynchronous contraction between the walls of the left ventricle (intraventricular) or between the ventricular chambers (interventricular) impairs systolic function, decreases mechanical efficiency of contraction, and adversely affects ventricular filling. Mechanical dyssynchrony results in an increase in wall stress and worsens functional mitral regurgitation. The single most important association of extent of dyssynchrony is a widened QRS interval on the surface electrocardiogram, particularly in the presence of a left bundle branch block pattern. With placement of a pacing lead via the coronary sinus to the lateral wall of the ventricle, cardiac resynchronization therapy (CRT) enables a more synchronous ventricular contraction by aligning the timing of activation of the opposing walls. Early studies showed improved exercise capacity, reduction in symptoms, and evidence of reverse remodeling. The Cardiac Resynchronization in Heart Failure Study (CARE-HF) trial was the first study to demonstrate a reduction in all-cause mortality with CRT placement in patients with HFrEF on optimal therapy with continued moderate-to-severe residual symptoms of

NYHA class III or IV HF. More recent clinical trials have demonstrated disease-modifying properties of CRT in even minimally symptomatic patients with HFrEF, including the Resynchronization–Defibrillation for Ambulatory Heart Failure Trial (RAFT) and Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT), both of which sought to use CRT in combination with an implantable defibrillator. Most benefit in mildly symptomatic HFrEF patients accrues from applying this therapy in those with a QRS width of >149 ms and a left bundle branch block pattern. Attempts to further optimize risk stratification and expand indications for CRT using modalities other than electrocardiography have proven disappointing. Echocardiographically derived measures of dyssynchrony vary tremendously, and narrow QRS dyssynchrony has not proven to be a good target for treatment. Uncertainty surrounds the benefits of CRT in those with ADHF, a predominant right bundle branch block pattern, atrial fibrillation, and evidence of scar in the lateral wall, which is the precise location where the CRT lead is positioned. His-Purkinje conduction system or left bundle branch area pacing are evolving alternatives to biventricular pacing; however, the evidence supporting their benefits over conventional CRT remains less certain.

TABLE 265-3 Principles of ICD Implantation for Primary Prevention of Sudden Death

PRINCIPLE	COMMENT
Arrhythmia–sudden death mismatch	Sudden death in heart failure patients is generally due to progressive LVD, not a focal arrhythmia substrate (except in patients with post-MI HF with scar)
Diminishing returns with advanced disease	Intervention at early stages of HF most successful since sudden death incidence diminishes as cause of death with increasing severity of HF
Timing of benefits	LVEF should be evaluated on optimal medical therapy or after revascularization before ICD therapy is employed; no benefit to ICD implant within 40 days of an MI (unless for secondary prevention)
Estimation of benefits and prognosis	Patients and clinicians often overestimate benefits of ICDs; an ICD discharge is not equivalent to an episode of sudden death (some ventricular arrhythmias terminate spontaneously); appropriate ICD discharges are associated with a worse near-term prognosis; recent trials with uncertain benefit in nonischemic cardiomyopathy (especially in those >68 years old)

Abbreviations: HF, heart failure; ICD, implantable cardioverter-defibrillator; LVD, left ventricular disease; LVEF, left ventricular ejection fraction; MI, myocardial infarction.

SUDDEN CARDIAC DEATH PREVENTION IN HEART FAILURE

Sudden cardiac death (SCD) due to ventricular arrhythmias is the mode of death in approximately half of patients with HF and is particularly proportionally prevalent in HFrEF patients with early stages of the disease. Patients who survive an episode of SCD are at very high risk and qualify for placement of an implantable cardioverter-defibrillator (ICD). Although primary prevention is challenging, the degree of residual left ventricular dysfunction despite optimal medical therapy (≤35%) to allow for adequate remodeling and the underlying etiology (post–myocardial infarction or ischemic cardiomyopathy) are the two single most important risk markers for stratification of need and benefit. Currently, patients with NYHA class II or III symptoms of HF and an LVEF <35%, irrespective of etiology of HF, are appropriate candidates for ICD prophylactic therapy. In patients with a myocardial infarction and optimal medical therapy with residual LVEF ≤30% (even when asymptomatic), placement of an ICD is appropriate. A recent Danish trial suggested that prophylactic ICD implantation in patients with symptomatic systolic HF not caused by coronary artery disease was not associated with a significantly lower long-term rate of death from any cause than was usual clinical care. In this trial, benefits were noted in those aged <60 years. In patients with a terminal illness and a predicted life span of <6 months or in those with NYHA class IV symptoms who are refractory to medications and who are not candidates for transplant, the risks of multiple ICD shocks must be carefully weighed against the survival benefits. If a patient meets the QRS criteria for CRT, combined CRT with ICD is often employed **(Table 265-3)**.

SURGICAL THERAPY IN HEART FAILURE

Coronary artery bypass grafting (CABG) is considered in patients with ischemic cardiomyopathy with multivessel coronary artery disease. The recognition that hibernating myocardium, defined as myocardial tissue with abnormal function but maintained cellular function, could recover after revascularization led to the notion that revascularization with CABG would be useful in those with living myocardium. Revascularization is most robustly supported in individuals with ongoing angina and left ventricular failure. Revascularizing those with left ventricular failure in the absence of angina remains controversial. The Surgical Treatment for Ischemic Heart Failure (STICH) trial in patients with an EF of ≤35% and coronary artery disease amenable to CABG demonstrated no significant initial benefit compared to medical therapy. However, patients assigned to CABG had lower rates of death from cardiovascular causes and of death from any cause or hospitalization for cardiovascular causes over 10 years than among those who received medical therapy alone. An ancillary study of this trial also determined that the detection of hibernation (viability) before revascularization did not materially influence the efficacy of this approach, nor did it help to define a population unlikely to benefit if hibernation was not detected. Notably, a strategy of percutaneous coronary revascularization in patients with ischemic left ventricular dysfunction in the REVIVED-BCIS2 study did not show clinical benefit.

Surgical ventricular restoration (SVR), a technique characterized by infarct exclusion to remodel the left ventricle by reshaping it surgically in patients with ischemic cardiomyopathy and dominant anterior left ventricular dysfunction, has been proposed. However, in a 1000-patient trial in patients with HFrEF who underwent CABG alone or CABG plus SVR, the addition of SVR to CABG had no disease-modifying effect. However, left ventricular aneurysm surgery is still advocated in those with refractory HF, ventricular arrhythmias, or thromboembolism arising from an akinetic aneurysmal segment of the ventricle. Other remodeling procedures, such as use of an external mesh-like net attached around the heart to limit further enlargement, have not been shown to provide hard clinical benefits, although favorable cardiac remodeling was noted.

Functional (or secondary) mitral regurgitation (MR) occurs with varying degrees in patients with HFrEF and dilated ventricles, and its severity is correlated inversely with prognosis. Annular dilatation and leaflet noncoaptation related to distorted papillary muscle geometry in the context of ventricular remodeling is typically responsible, although in patients with ischemic heart disease and prior myocardial infarction, leaflet tethering and displacement may contribute. The primary approach to management of functional MR is optimization of guideline-directed medical therapy, followed by CRT in eligible patients, but relief may be incomplete for many patients with advanced HF. In these patients with HF and severe left ventricular dysfunction who are not candidates for surgical coronary revascularization, surgical mitral valve repair (MVR) to remedy functional MR carries significant risk and remains controversial. The development of percutaneous approaches to edge-to-edge MVR has provided a less invasive approach that enables reduction in functional MR at lower risk than conventional surgery. Recently, two large, randomized trials of transcatheter MVR using this approach have been conducted in patients with symptomatic HFrEF and moderate-severe functional MR. In the Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional Mitral Regurgitation (COAPT) study, patients allocated to MVR versus standard HF therapy experienced a marked reduction in both HF hospitalizations and mortality at 2 years, supporting the efficacy of this approach. In the second trial, Percutaneous Repair with the MitraClip Device for Severe Functional/Secondary Mitral Regurgitation (MITRA-FR), which employed a similar design, the rates of

death or HF hospitalization did not differ between the percutaneous MVR and medical therapy groups. The precise reason for discrepant results between these studies remains unclear but may be related to differences in background utilization of guideline-directed medical therapy, procedural success rates, and patient selection (particularly whether the severity of MR is proportionate or disproportionate to the degree of left ventricular cavity dilation). Because mortality rates at 2 years remain high even with percutaneous MVR, patients with advanced symptoms of HF in whom MR severity is driven principally by end-stage left ventricular remodeling should also be considered for advanced therapies such as mechanical circulatory support if symptoms remain refractory to medical therapy.

CELLULAR AND GENE-BASED THERAPY

The cardiomyocyte possesses regenerative capacity, and such renewal is accelerated under conditions of stress and injury, such as an ischemic event or HF. Investigations that use either bone marrow–derived precursor cells or autologous cardiac-derived cells have gained traction but have not generally improved clinical outcomes in a convincing manner. More promising, however, are cardiac-derived stem cells. Two preliminary pilot trials delivering cells via an intracoronary approach have been reported. In one, autologous c-kit–positive cells isolated from the atria obtained from patients undergoing CABG were cultured and reinfused. In another, cardiosphere-derived cells grown from endomyocardial biopsy specimens were used. These small trials demonstrated improvements in left ventricular function but require far more work to usher in a clinical therapeutic success. Efforts to utilize mesenchymal stem cells to facilitate left ventricular recovery and weaning from mechanical circulatory support in patients with left ventricular assist devices have also been disappointing. The appropriate route of administration, the quantity of cells to achieve a minimal therapeutic threshold, the constitution of these cells (single source or mixed), the mechanism by which benefit accrues, and short- and long-term safety remain to be elucidated.

Targeting molecular aberrations using gene transfer therapy, mostly with an adenoviral vector, has been tested in HFrEF. A cellular target includes calcium cycling proteins such as inhibitors of phospholamban such as SERCA2a, which is deficient in patients with HFrEF. Primarily responsible for reincorporating calcium into the sarcoplasmic reticulum during diastole, this target was tested in the CUPID (Efficacy and Safety Study of Genetically Targeted Enzyme Replacement Therapy for Advanced Heart Failure) trial. This study used coronary arterial infusion of adeno-associated virus type 1 carrying the gene for SERCA2a and initially demonstrated that natriuretic peptides were decreased, reverse remodeling was noted, and symptomatic improvements were forthcoming. However, a confirmatory trial failed to meet its primary efficacy endpoint. The DREAM-HF trial was a randomized, double-blind, multicenter study of a single transendocardial administration of mesenchymal precursor cells in patients in HFrEF. The primary and secondary endpoints of the trial were negative.

More advanced therapies for late-stage HF such as left ventricular assist devices and cardiac transplantation are covered in detail in Chap. 271.

DISEASE MANAGEMENT AND SUPPORTIVE CARE

Despite stellar outcomes with medical therapy, admission rates following HF hospitalization remain high, with nearly half of all patients readmitted to hospital within 6 months of discharge. Recurrent HF and related cardiovascular conditions account for only half of readmissions in patients with HF, whereas other comorbidity-related conditions account for the rest. The key to achieving enhanced outcomes must begin with the attention to transitional care at the index hospitalization with facilitated discharge through comprehensive discharge planning, patient and caregiver education, appropriate use of visiting nurses, and planned follow-up. Early postdischarge follow-up, whether by telephone or clinic-based, may be critical to ensuring stability because most HF-related readmissions tend to occur within the first 2 weeks after discharge. The results of the recent STRONG-HF trial suggest that a strategy of intensive titration of medical therapy to guideline-recommended targets within 2 weeks of hospital discharge and frequent ambulatory follow-up through 2 months is associated with a substantial reduction in all-cause mortality and HF readmission at 180 days, underscoring the importance of timely application of targeted pharmacologic therapy and intensive clinical surveillance in the early postdischarge interval.

Although routinely advocated, intensive surveillance of weight and vital signs with use of telemonitoring has not decreased hospitalizations. Serial measurement of intrathoracic impedance has been utilized to identify early signals of worsening congestion to guide preemptive management to obviate the need for hospitalization. However, when systematically studied in randomized trials, this approach has not been proven to improve outcomes in comparison with routine HF care and may even enhance the rate of hospitalization due to the high frequency of impedance threshold crossings and device alerts. Implantable hemodynamic monitoring systems that directly measure pulmonary artery pressure tend to provide signals for early decompensation, and in patients with HF and moderately advanced symptoms across the full spectrum of EF, such systems have been shown to provide information that can allow implementation of therapy to avoid hospitalizations by as much as 39% (in the CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients [CHAMPION] trial). More recently, in the larger Hemodynamic Guided Management of Heart Failure (GUIDE-HF) Trial, hemodynamic-guided management with the same sensor did not result in a lower rate of composite mortality and total HF events in the primary analysis, the results of which were confounded by the impact of the COVID-19 pandemic on overall hospitalization rates. In a prespecified analysis of patients enrolled prior to the pandemic onset, there was a statistically significant reduction in the composite endpoint driven by lower rates of HF hospitalization in those assigned to the hemodynamic-guided therapy arm. Benefits were consistent across patients with prior HF hospitalization within 12 months and in those with elevated natriuretic peptide levels but no recent hospitalization. These data in aggregate suggest that hemodynamic-guided management is a useful adjunct to routine clinical care in selected high-risk patients with chronic HF across the spectrum of EF. Alternate approaches to longitudinal HF monitoring that leverage multiparameter signals derived from implantable cardiac rhythm devices such as pacemakers and defibrillators to provide a global index of congestion are also being explored as adjuncts to longitudinal HF management.

Once HF becomes advanced, regularly scheduled review of the disease course and options with the patient and family is recommended, including discussions surrounding end-of-life preferences when patients are comfortable in an outpatient setting. As the disease state advances further, integrating care with social workers, pharmacists, and community-based nursing may be critical in improving patient satisfaction with the therapy, enhancing QOL, and avoiding HF hospitalizations. Equally important is attention to seasonal influenza vaccinations and periodic pneumococcal vaccines that may obviate non-HF hospitalizations in these ill patients. When nearing end of life, facilitating a shift in priorities to outpatient and hospice palliation is key, as are discussions around advanced therapeutics and continued use of ICD prophylaxis, which may worsen QOL and prolong death. Small, randomized trials have suggested that systematic integration of palliative care considerations in high-risk HF patients by a specialized team has been demonstrated to improve QOL, anxiety, depression, and spiritual well-being and to facilitate goal-concordant care.

GLOBAL CONSIDERATIONS

Substantial differences exist in the practice of HF therapeutics and outcomes by geographic location. The penetrance of CRT and ICD is higher in the United States than in Europe. Conversely, therapy unavailable in the United States, such as levosimendan, is designated

as useful in Europe, although the usefulness is disputable. Variation in the benefits of beta blockers based on world region remains an area of controversy. In oral pharmacologic therapy trials of HFrEF, patients from southwest Europe have a lower incidence of ischemic cardiomyopathy and those in North America tend to have more diabetes and prior coronary revascularization. There is also regional variation in medication use even after accounting for indication. In trials of HF, disparate effects are noted across populations. As a recent example, in TOPCAT, the drug spironolactone was effective when used in the U.S. population, whereas patients recruited from Russia and contiguous territories showed no difference. Whether this represents population differences or trial conduct disparity remains a serious question. ADHF patients in Eastern Europe tend to be younger, with higher EFs and lower natriuretic peptide levels. Patients from South America tend to have the lowest rates of comorbidities, revascularization, and device use. In contrast, patients from North America have the highest comorbidity burden with high revascularization and device use rates. Given geographic differences in baseline characteristics and clinical outcomes, the generalizability of therapeutic outcomes in patients in the United States and Western Europe may require verification.

266 Classification of Cardiomyopathy

Lynne Warner Stevenson, Neal K. Lakdawala, Joseph Loscalzo

The term *cardiomyopathy* describes primary disease of the heart muscle itself, originally excluding myocardial dysfunction resulting from other cardiovascular disease. Common usage, however, often includes diagnoses of ischemic cardiomyopathy, valvular cardiomyopathy, and hypertensive cardiomyopathy. The traditional morphologic classification defines the three major phenotypes of hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), and restrictive cardiomyopathy (RCM) **(Table 266-1)**.

Left ventricular wall thickness is increased (≥13–15 mm depending on context) and ejection fraction is normal or high with HCM. DCM is defined when the left ventricular ejection fraction (LVEF) is ≤0.50, but most clinical presentations are with LVEF ≤0.40. RCMs typically present with mildly decreased ejection fraction and variably increased wall thickness and are often defined less by morphology than by evidence of abnormal diastolic physiology on echocardiography or invasive hemodynamic measurement.

Although these phenotypes are helpful to guide initial evaluation of clinical disease, the phenotypes increasingly overlap over time as there is increasing recognition that DCMs can respond to recommended therapies with "reverse remodeling" to higher ejection fraction and smaller ventricles, while HCM evolves in ~5% of patients to a reduced ejection fraction (HCM-rEF) with more restrictive physiology. A fourth evolving phenotype with predominantly genetic causes is arrhythmogenic right ventricular cardiomyopathy (ARVC), originally termed *arrhythmogenic right ventricular dysplasia*, characterized by life-threatening arrhythmias and abnormal right ventricular structure and function, with variable expression in the left ventricle. As new phenotype-genotype connections are revealed, the terminology continues to evolve, as arrhythmogenic right ventricular dysplasia may also be termed ACM-RV (arrhythmogenic cardiomyopathy–right ventricle predominant), in line with ACM-LV, in which the arrhythmias and structural changes are predominantly in the left ventricle. If the ACM terminology is expanded to include acquired disease, the granulomatous disease of sarcoidosis and the protozoal myocarditis of Chagas' disease can both cause phenotypes with cardiomyopathy and ventricular arrhythmias that qualify as ACM-RV and ACM-LV.

Reliance upon phenotypic presentation is diminishing as more is learned about the underlying causes of cardiomyopathy. The catalog is rapidly growing of pathogenic genetic variants that can lead to heritable cardiomyopathies, which new imaging techniques can now sometimes identify prior to clinical disease. Expanding knowledge of immune response pathways reveals how some aspects of myocarditis may also be inherited and how they contribute to infectious and noninfectious inflammation that can cause clinical myocarditis and cardiomyopathy. Diagnosis and outcomes of clinical cardiomyopathies are further complicated by the frequent two-hit models where the clinical expression of a genetic predisposition to cardiomyopathy may

TABLE 266-1 Classification of Cardiomyopathies

CARDIOMYOPATHY (CM) PHENOTYPE	DIAGNOSTIC CRITERIA	OTHER MORPHOLOGY	COMMON CHALLENGES IN DIAGNOSIS
Hypertrophic cardiomyopathy (HCM) *Mid-range LVEF includes rare transition to HCM with LV systolic dysfunction* (LVEF <0.50)	Septal thickness in men ≥15 mm, ≥13 mm in women. 13–14 mm may be diagnostic in relatives of proband with known HCM or with positive genetic test. LVEF ≥ normal, usually >0.60 LV chamber volume ≤normal.	Patterns of LV hypertrophy (LVH) in HCM: • Asymmetric septal hypertrophy • Inverse (sigmoid pattern) septal hypertrophy • Concentric LVH • Apical hypertrophy	Distinction from athlete's heart and severe chronic hypertension The storage diseases of *GLA* (Anderson-Fabry), *PRKAG2,* and *LAMP2* (Danon's), which can mimic HCM morphology Exclude aortic stenosis In older patients, exclude amyloidosis, which can also cause asymmetric septal thickening
Restrictive cardiomyopathy (RCM) Least common cardiomyopathy (CM) phenotype	Functional diagnosis based on moderate-severe diastolic dysfunction and/or elevated cardiac filling pressures. Wall thickness often increased but can appear normal. LVEF usually mildly reduced, occasionally normal.	Usually marked atrial enlargement Although both ventricles affected, clinical right heart failure often dominates. Marked wall thickness suggests: • Amyloidosis • Inherited storage diseases • Inborn metabolic diseases	Common etiologies of radiation, scleroderma-type connective tissue diseases, doxorubicin and other medications Some sarcomeric variants and storage diseases can appear with RCM as well as HCM phenotypes Although traditionally listed as restrictive, sarcoidosis more often has morphology of regional wall motion abnormalities, DCM phenotype, or right ventricular (RV) involvement with systolic dysfunction
Mid-range LVEF is often a transition in DCM, either deterioration from early DCM or improvement into DCM remission LV dilated cardiomyopathy (DCM)	• Early: LVEF ≤0.50 and/or LVEDV >112% normal for age/sex or LVEDD >95% predicted sex/height • LVEF ≤0.40: threshold for traditionally recommended therapies for heart failure with low LVEF • Persistent LVEF ≤0.30–0.35: threshold for primary prevention ICD	Can involve LV alone or with RV involvement either from primary cause or from secondary RV failure due to chronically elevated pulmonary artery pressures	Structural heart disease such as coronary artery disease or infarction from other cause, primary valve disease
Arrhythmogenic CM Dominant in LV (ACM-LV) Usually DCM, occasionally RCM	Morphologic criteria generally those for DCM. *Ventricular tachyarrhythmias dominate without or before severely reduced LVEF and heart failure.* Primary prevention ICD considered even when LVEF >0.35.	Suggestive but not necessarily conclusive differences in patterns of late gadolinium enhancement between different variants Occasional ACM-LV with RCM phenotype	For frequent PVCs or NSVT, may be difficult to distinguish PVC-related CM from genetic CM causing both the arrhythmias and the CM
Arrhythmogenic CM Dominant in RV (ACM-RV; also termed ARVC) *Biventricular arrhythmogenic CM*	Modified task force criteria from 2010 include combinations of major and minor criteria *Ventricular arrhythmias and evidence of both ACM-RV and ACM-LV*	Abnormal RV function or structure *Biventricular ACM often diagnosed from LGE in ventricle with less involvement*	Cardiac sarcoidosis can cause predominantly RV involvement with ventricular arrhythmias, RV wall motion abnormalities, aneurysms, and dilation
Trait of LV noncompaction (LVNC) Implications determined by CM phenotype and genotype	Often assessed by maximum ratio of noncompacted/compacted LV myocardium >2.3 and other criteria	Can occur with HCM, DCM, some dystrophies, and other syndromic presentations	Can occur in normal hearts, pregnancy Increased prevalence in athletic hearts

Mid-range LVEF (0.40–0.50)

Abbreviations: ICD, implantable cardioverter-defibrillator; LGE, late gadolinium enhancement; LV, left ventricle; LVEDD, left ventricular end-diastolic dimension; LVEDV, left ventricular end-diastolic volume; LVEF, left ventricular ejection fraction; NSVT, nonsustained ventricular tachycardia; PVC, premature ventricular contraction.

be triggered by acquired conditions such as infections, toxic exposures, pregnancy, or tachycardia.

CLINICAL PRESENTATION AND EVALUATION OF CARDIOMYOPATHY

Early symptoms of cardiomyopathy often reflect exertional intolerance with breathlessness or fatigue. Arrhythmias are often presenting events of unrecognized cardiomyopathy, which can also present with embolic events related to atrial fibrillation or apical ventricular thrombi. Cardiomyopathy may often present first with the syndrome of congestion, with fluid retention and elevated left heart filling pressures causing shortness of breath with minimal activity or even at rest, particularly with orthopnea. It may be accompanied by elevated right-sided filling pressures causing edema and often abdominal symptoms. The nonspecific historical term *congestive heart failure* describes the syndrome of congestion, which is common to diverse cardiac diagnoses such as congenital heart disease, primary pulmonary hypertension, and structural valve disease. "Congestive heart failure" should not be considered a diagnosis or an etiology of cardiomyopathy but a nonspecific syndrome requiring thorough evaluation of possible etiology/ies. Initial evaluation of possible cardiomyopathy begins with a detailed clinical history and examination seeking clues to cardiac, genetic, and systemic causes of heart disease, which help to guide subsequent evaluation (Table 266-2).

Echocardiography remains the initial imaging modality to define morphology and function, with increasing use of magnetic resonance imaging to provide further information on myocardial tissue characterization, patterns of fibrosis indicated by late gadolinium enhancement, and T1 and T2 mapping for evidence of focal and diffuse inflammation.

TABLE 266-2 Initial Evaluation of Cardiomyopathy

Clinical Evaluation
Thorough history and physical examination to identify cardiac and noncardiac disorders
Detailed family history of heart failure, cardiomyopathy, skeletal myopathy, conduction disorders, tachyarrhythmias, and sudden death
History of alcohol, illicit drugs, chemotherapy or radiation therapy
Assessment of changing ability to perform routine and desired activities
Assessment of jugular venous pressure, edema, orthostatic blood pressure, adequacy of perfusion
Laboratory Evaluation
Electrocardiogram
Chest radiograph
Two-dimensional and Doppler echocardiogram
Magnetic resonance imaging for evidence of myocardial inflammation and fibrosis
Chemistry:
Serum sodium, potassium, calcium, magnesium
Fasting glucose (glycohemoglobin in diabetes mellitus)
Creatinine, blood urea nitrogen
Albumin, total protein, liver function tests
Lipid profile
Thyroid-stimulating hormone
Serum iron, transferrin saturation
Urinalysis
Creatine kinase isoforms
Cardiac troponin level
Hematology:
Hemoglobin/hematocrit
White blood cell count with differential
Total eosinophil count if abnormal % on differential
Erythrocyte sedimentation rate
Evaluation When Specific Diagnoses Are Suspected
Respiratory pathogen panel during acute respiratory syndromes
Diagnosis of other specific infections such as:
Human immunodeficiency virus
Chagas' disease (*Trypanosoma cruzi*)
Lyme disease (*Borrelia burgdorferi*) and other tick-borne diseases
Toxoplasmosis
Trichinosis
Genetic counseling and testing with multigene cardiomyopathy panel
Serologies for active rheumatologic disease
Endomyocardial biopsy including sample for electron microscopy when suspecting specific diagnosis with therapeutic implications
Catheterization with coronary angiography in patients who have evidence of ischemia/infarction and are candidates for intervention

267 Genetic Cardiomyopathies

Neal K. Lakdawala, Lynne Warner Stevenson, Joseph Loscalzo

Each of the traditional morphologic forms of cardiomyopathy, hypertrophic, dilated, and restrictive, can be caused or modified by underlying genetic factors (Table 267-1). Estimates for the prevalence of a genetic etiology for cardiomyopathy continue to rise, with increasing availability of genetic testing and attention to the family history. Well-recognized in hypertrophic cardiomyopathy, heritability is also present in at least 30% of dilated cardiomyopathy (DCM) without other clear etiology. Careful family history should elicit information about not only known cardiomyopathy and heart failure, but also family members who have had sudden death, often incorrectly attributed to a "heart attack," who have had atrial fibrillation or pacemaker implantation by middle age, or who have muscular dystrophy.

Most familial cardiomyopathies are inherited in an autosomal dominant pattern, with occasional autosomal recessive, matrilineal (mitochondrial), and X-linked inheritance (Table 267-1). Missense variants with amino acid substitutions and truncating variants are the most common genetic abnormalities in cardiomyopathy. Expressed mutant proteins may interfere with function of the normal allele through a dominant negative mechanism. Variants introducing a premature stop codon (nonsense) or shift in the reading frame (frameshift) may create a truncated or unstable protein, the lack of which causes cardiomyopathy (haploinsufficiency). In some forms of genetic DCM, both haploinsufficiency and the dominant negative effect of a truncated allele may contribute to pathophysiology. Deletions or duplications of an entire exon or gene are uncommon causes of cardiomyopathy, except for the dystrophinopathies.

Many different genes have been implicated in human cardiomyopathy (locus heterogeneity), and many pathogenic or likely pathogenic variants (i.e., variants) within those genes have been associated with disease (allelic heterogeneity). Although most identified variants are "private" to individual families, several specific variants are found repeatedly, either due to a founder effect or recurrent variants at a common residue. While most patients with genetic cardiomyopathy have a single rare, "high effect," disease allele, there is a growing appreciation for the effect of multiple less rare "intermediate effect" alleles on penetrance and expression. While the additive effects of multiple common alleles/variants captured as a polygenic risk score have shown greatest utility in common diseases such as atherosclerosis, they may also provide insight into the subset of patients with primary cardiomyopathy without an identifiable "high effect" allele.

Genetic cardiomyopathy is characterized by age-dependent and incomplete penetrance. The defining phenotype of cardiomyopathy is rarely present at birth and, in some individuals, may never manifest. Related individuals who carry the *same* variant may differ in the severity and rate of progression of cardiac dysfunction and associated rhythm disorders, indicating the important role of other genetic, epigenetic, and environmental modifiers in disease expression. Sex appears to play a role, as penetrance and clinical severity may be greater in men for most cardiomyopathies. The clinical course of a patient usually cannot be predicted based on which variant is present; thus, current therapy is based on the phenotype rather than the genetic defect. Currently, the greatest utility of genetic testing for cardiomyopathy is to inform family evaluations. However, genetic testing can provide risk stratification in some forms of cardiomyopathy and occasionally enables the detection of a disease for which specific therapy is indicated, such as the replacements for defective metabolic enzymes in Fabry's disease and Gaucher's disease. Moreover, clinical trials are interrogating the role of gene therapies for cardiomyopathy, which will provide greater impetus for genetic testing.

TABLE 267-1 Selected Genetic Defects Associated with Cardiomyopathy

	GENE PRODUCT	INHERITANCE	CARDIAC PHENOTYPE	ISOLATED CARDIAC PHENOTYPE[a]	EXTRACARDIAC MANIFESTATIONS
Sarcomere	*ACTC1* (cardiac actin)	AD	HCM, DCM	Yes	
	MYH7 (β myosin heavy chain)	AD	HCM, DCM, LVNC	Yes	Skeletal myopathy
	MYBPC3 (myosin binding protein C)	AD	HCM	Yes	
	TNNT2 (cardiac troponin T)	AD	HCM, DCM, LVNC	Yes	
	TNNI3 (cardiac troponin I)	AD, AR	HCM, DCM, RCM	Yes	
	TTN (Titin)	AD	DCM	Yes	
	TPM1 (α-tropomyosin)	AD	HCM, DCM	Yes	
	TNNC1 (cardiac troponin C)	AD	DCM	Yes	
	MYL2 (myosin regulatory light chain)	AD	HCM	Yes	Skeletal myopathy
	MYL3 (myosin essential light chain)	AD	HCM	Yes	
Z-disk and cytoskeleton	*DES* (desmin)	AD	RCM, DCM	Yes	Skeletal myopathy
	FLNC (filamin C)	AD	DCM	Yes	Skeletal myopathy
	NEXN (nexilin)	AD	DCM	Yes	
	VCL (vinculin)	AD	DCM	Yes	
Nuclear membrane	*LMNA* (lamin A/C)	AD, AR	CDDC	Yes	Skeletal myopathy
	EMD (emerin)	X-linked	CDDC	No	Skeletal myopathy, contractures
Excitation-contraction coupling	*PLN* (phospholamban)	AD	DCM, ARVC	Yes	
	SCN5A (NAV 1.5)	AD	CDDC	Yes	Note other variants associated with Brugada syndrome
	RYR2 (cardiac ryanodine receptor)	AD	ARVC	Yes	
	CASQ2 (calsequestrin 2)	AR	ARVC	Yes	
Cellular metabolism	*PRKAG2* (γ-subunit of AMP kinase)	AD	HCM+	Yes	
	LAMP2 (lysosomal associated membrane protein)	X-linked	HCM+	No[b]	Danon's disease: skeletal myopathy, cognitive impairment
	TAZ (tafazzin)	X-linked	DCM, LVNC	No	Barth's syndrome: skeletal myopathy, cognitive impairment, neutropenia
	FXN (frataxin)	AR	HCM	No	Friedreich's ataxia: ataxia, diabetes mellitus type 2
	TMEM43 (transmembrane protein 43)	AD	ARVC	Yes	
	GLA (α-galactosidase-A)	X-linked	HCM+	No	Fabry's disease: renal failure, angiokeratomas and painful neuropathy
Mitochondria	Mitochondrial DNA	Maternal transmission	DCM, HCM	No	MELAS, MERRF, Kearns-Sayre syndrome, ocular myopathy
Sarcolemmal membrane	*DMD* (dystrophin)	X-linked	DCM	No[b]	Duchenne's and Becker's muscular dystrophy
	DMPK (dystrophica myotonica protein kinase)	AD	DCM	No	Myotonic dystrophy type 1
Desmosome	*DSP* (desmoplakin), *JUP* (plakoglobin)	AD, AR	ARVC, DCM	Yes	Carvajal syndrome (AR), Naxos syndrome (AR), "woolly hair" and hyperkeratosis of palms and soles
	DSG2 (desmoglein 2), *DSC2* (desmocollin 2), *PKP2* (plakophilin 2)	AD	ARVC	Yes	
Other examples	*RBM20* (RNA binding motif 20)	AD	DCM	Yes	
	BAG3 (BCL2-associated athanogene 3)	AD	DCM	Yes	
	ALPK3 (α-kinase 3)	AR	HCM	Yes	

[a]Indicates that the usual clinical presentation is of isolated cardiomyopathy; however, occasionally present extracardiac manifestations are also provided. [b]Indicates that isolated cardiac phenotype can occur in women with the X-linked defects.

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; ARVC, arrhythmogenic right ventricular cardiomyopathy; CDDC, conduction disease with dilated cardiomyopathy; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; HCM+, HCM with preexcitation; LVNC, left ventricular noncompaction; MELAS, (mitochondrial) myopathy, encephalopathy, lactic acidosis, and strokelike episodes syndrome; MERRF, myoclonic epilepsy with ragged red fibers; RCM, restrictive cardiomyopathy.

The genetic architecture of hypertrophic, dilated, arrhythmogenic, and restrictive cardiomyopathy are overlapping, summarized in Table 267-1 and **Fig. 267-1** and detailed in the subsequent sections organized by phenotype.

For any patient with suspected or proven genetic disease, family members should be considered and evaluated in a longitudinal fashion. Screening generally includes both an echocardiogram and electrocardiogram (ECG). The indications and implications for confirmatory specific genetic testing vary depending on the specific variant. The profound questions raised by families about diseases shared and passed down merit serious and sensitive discussion, ideally provided by a trained genetic counselor.

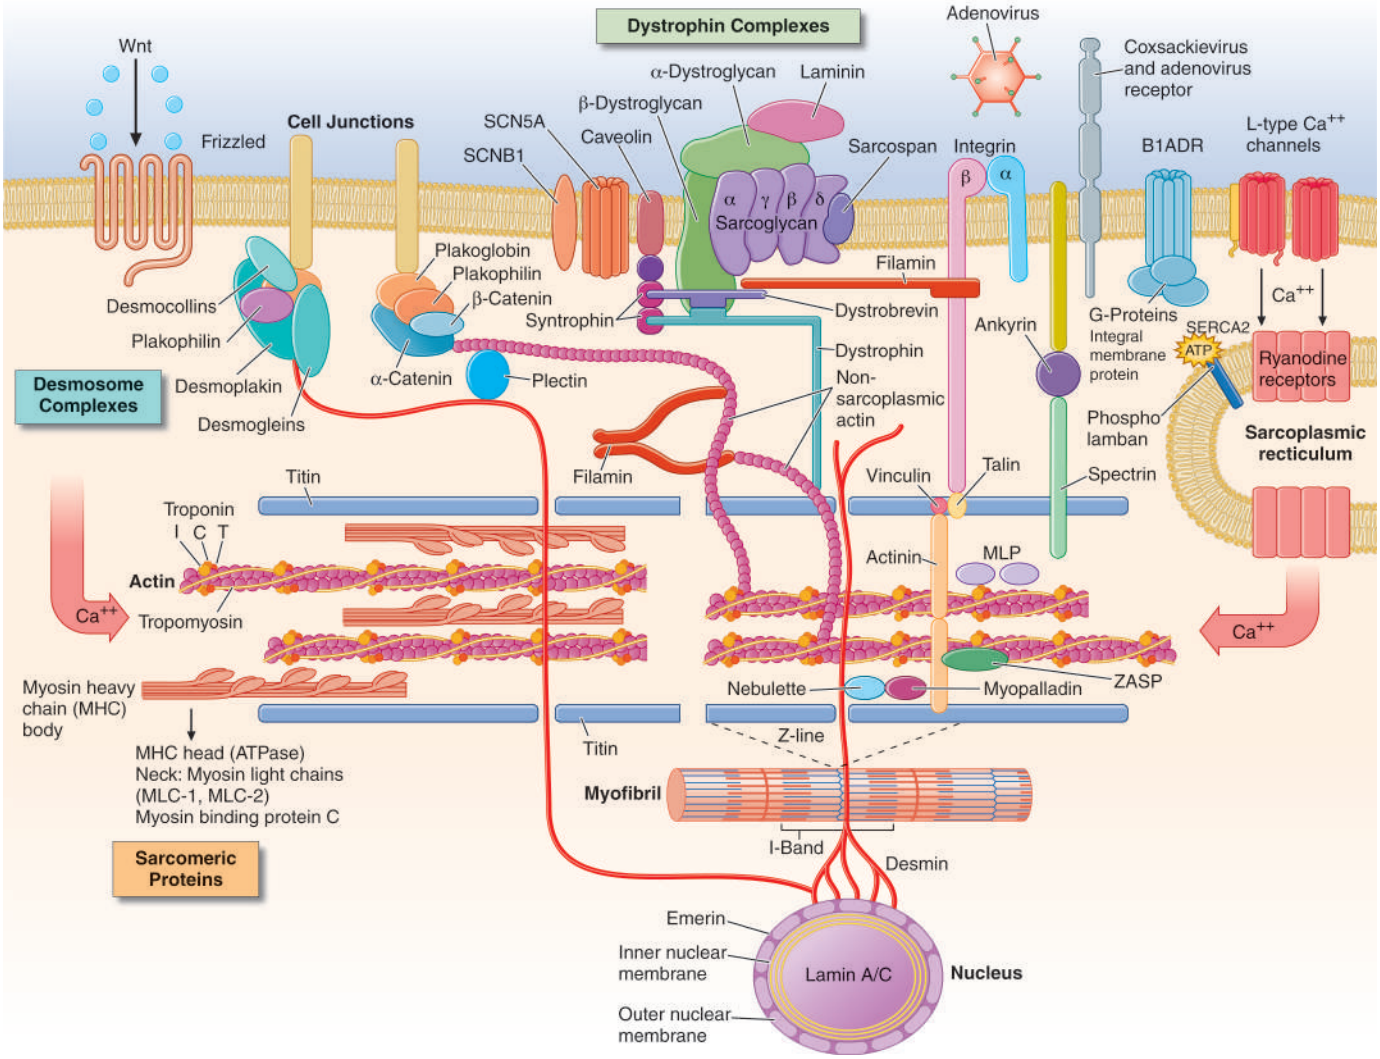

FIGURE 267-1 Drawing of myocyte indicating multiple sites of abnormal gene products associated with cardiomyopathy. Major functional groups include the sarcomeric proteins (actin, myosin, tropomyosin, and the associated regulatory proteins), the dystrophin complex stabilizing and connecting the cell membrane to intracellular structures, the desmosome complexes associated with cell-cell connections and stability, and multiple cytoskeletal proteins that integrate and stabilize the myocyte. ATP, adenosine triphosphate. *(Figure adapted from Jeffrey A. Towbin, MD, University of Tennessee Health Science Center.)*

HYPERTROPHIC CARDIOMYOPATHY

EPIDEMIOLOGY, ETIOLOGY, AND PATHOLOGY

Hypertrophic cardiomyopathy is defined as left ventricular hypertrophy that develops in the absence of causative hemodynamic factors, such as hypertension, aortic valve disease, or systemic infiltrative or storage diseases **(Figs. 267-2 and 267-3)**. It has previously been termed *hypertrophic obstructive cardiomyopathy* (HOCM); however, the accepted terminology is now hypertrophic cardiomyopathy with or without obstruction. Prevalence in North America, Africa, and Asia is about 1:500. It is a leading cause of sudden death in the young and is an important cause of heart failure. Pediatric presentation is associated with increased early morbidity and mortality, and patients diagnosed as adults have decreased survival compared to age-matched individuals without hypertrophic cardiomyopathy.

A sarcomere gene variant is present in ~40–50% of patients with hypertrophic cardiomyopathy and is more common in those with familial disease and characteristic asymmetric septal hypertrophy. More than nine different genes with >1500 variants have been implicated, although ~80% of patients have a variant in either *MYH7* or *MYBPC3* (Table 267-1), which encode the thick myofilament of the sarcomere.

Hypertrophic cardiomyopathy is characterized by age-dependent and incomplete penetrance. The defining phenotype of left ventricular hypertrophy is rarely present at birth and usually develops later in life. Women appear to have lower penetrance of sarcomere variants and an older age at hypertrophic cardiomyopathy diagnosis but subsequently increased rates of heart failure and mortality thereafter. Accordingly, screening of family members should begin in childhood, usually at adolescence, and extend through adulthood. In *MYBPC3* variant carriers, the average age of disease development is ~40 years, while 30% remain free from hypertrophy after 70 years. Related individuals who carry the *same* variant may have a different extent and pattern of hypertrophy (e.g., asymmetric vs concentric), occurrence of outflow tract obstruction, and associated clinical outcomes, although sudden death and progression to heart failure occur more commonly in families with that history.

At the level of the sarcomere, hypertrophic cardiomyopathy variants lead to enhanced calcium sensitivity, maximal force generation, and ATPase activity. Calcium handling is affected through modification of regulatory proteins. Sarcomere variants lead to abnormal energetics and impaired relaxation, both directly and as a result of hypertrophy. Hypertrophic cardiomyopathy is characterized by misalignment and disarray of the enlarged myofibrils and myocytes **(Fig. 267-4)**, which can also occur to a lesser extent in other cardiac diseases. Although hypertrophy is the defining feature of hypertrophic cardiomyopathy, fibrosis and microvascular disease are also present. Interstitial fibrosis is detectable before overt hypertrophy develops and likely results from early activation of profibrotic pathways. In the majority of patients with overt cardiomyopathy, focal areas of replacement fibrosis can be readily

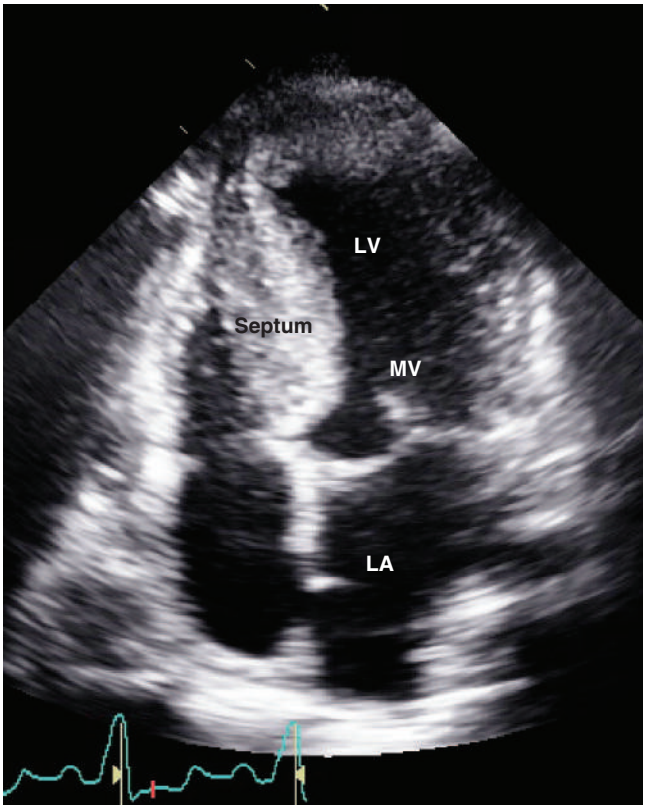

FIGURE 267-2 Hypertrophic cardiomyopathy. This echocardiogram of hypertrophic cardiomyopathy shows asymmetric hypertrophy of the septum compared to the lateral wall of the left ventricle (LV). The mitral valve (MV) is moving anteriorly toward the hypertrophied septum in systole. The left atrium (LA) is enlarged. Note that the echocardiographic and pathologic images are vertically opposite, such that the LV is by convention on the top right in the echocardiographic image and bottom right in the pathologic images. *(Image courtesy of Justina Wu, MD, Brigham and Women's Hospital, Boston.)*

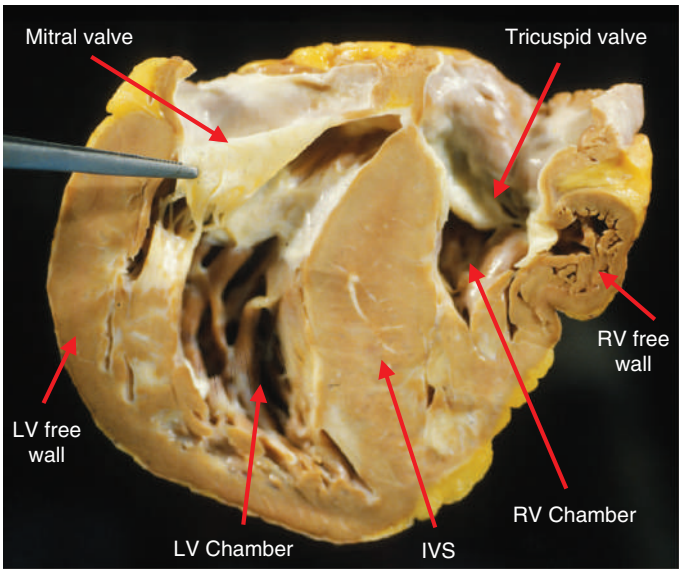

FIGURE 267-3 Hypertrophic cardiomyopathy. Gross specimen of a heart with hypertrophic cardiomyopathy removed at the time of transplantation, showing asymmetric septal hypertrophy (septum much thicker than left ventricular free wall) with the septum bulging into the left ventricular outflow tract causing obstruction. The forceps are retracting the anterior leaflet of the mitral valve, demonstrating the characteristic plaque of systolic anterior motion, manifest as endocardial fibrosis on the interventricular septum in a mirror-image pattern to the valve leaflet. There is patchy replacement fibrosis, and small thick-walled arterioles can be appreciated grossly, especially in the interventricular septum. IVS, interventricular septum; LV, left ventricle; RV, right ventricle. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

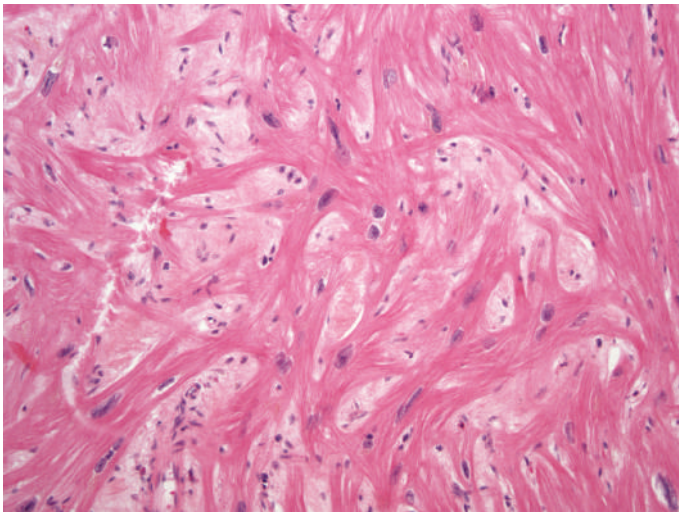

FIGURE 267-4 Hypertrophic cardiomyopathy. Microscopic image of hypertrophic cardiomyopathy showing the characteristic disarrayed myocyte architecture with swirling and branching rather than the usual parallel arrangement of myocyte fibers. Myocyte nuclei vary markedly in size, and interstitial fibrosis is present. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

detected with magnetic resonance imaging (MRI). These areas of "scar" may represent substrate for the development of ventricular arrhythmias. Increased thickness and decreased luminal area of the intramural vessels in hypertrophied myocardium contribute to microvascular ischemia and angina. Microinfarction of hypertrophied myocardium is a hypothesized mechanism for replacement scar formation.

Macroscopically, hypertrophy is typically manifest as nonuniform ventricular thickening (Fig. 267-3). The interventricular septum is the typical location of maximal hypertrophy, although other patterns of hypertrophic remodeling include concentric and midventricular. Hypertrophy confined to the ventricular apex (apical hypertrophic cardiomyopathy) is less often familial and has a different genetic substrate, with sarcomere variants present in only ~15%. Left ventricular outflow tract obstruction represents the most common focus of diagnosis and intervention, although diastolic dysfunction, myocardial fibrosis, and microvascular ischemia also contribute to contractile dysfunction and elevated intracardiac pressures. Obstruction is present in ~30% of patients at rest and can be provoked by exercise in another ~30%. Systolic obstruction is initiated by drag forces, which push an anteriorly displaced and enlarged anterior mitral leaflet into contact with the hypertrophied ventricular septum. Mitral leaflet coaptation may ensue, leading to posteriorly directed mitral regurgitation. To maintain stroke volume across outflow tract obstruction, the ventricle generates higher pressures, leading to higher wall stress and myocardial oxygen demand. Smaller chamber size and increased contractility exacerbate the severity of obstruction. Conditions of low preload, such as dehydration, and low afterload, such as arterial vasodilation, may lead to transient hypotension and near-syncope. The systolic ejection murmur of left ventricular outflow tract obstruction is harsh and late peaking and can be enhanced by bedside maneuvers that diminish ventricular volume and transiently worsen obstruction, such as the Valsalva maneuver or standing from a squatting position.

DIAGNOSIS

The substantial variability of hypertrophic cardiomyopathy pathology is reflected in the diversity of clinical presentations. Patients may be diagnosed after undergoing evaluations triggered by the abnormal physical findings (murmur) or by symptoms of exertional dyspnea, angina, or syncope. Alternatively, diagnosis may follow evaluations prompted by the detection of disease in family members. Cardiac imaging (Fig. 267-2) is central to diagnosis, for which the physical examination and ECG are insensitive. The identification of a disease-causing variant in a proband can focus family evaluations on variant carriers, but this strategy requires a high degree of certainty that the

variant is truly pathogenic and not a benign DNA variant. Biopsy is not recommended to diagnose hypertrophic cardiomyopathy but can be used to exclude infiltrative and metabolic diseases. Rigorous athletic training (athlete's heart) may cause intermediate degrees of physiologic hypertrophy difficult to differentiate from mild hypertrophic cardiomyopathy. Unlike hypertrophic cardiomyopathy, hypertrophy in the athlete's heart regresses with cessation of training and is accompanied by supernormal exercise capacity (VO_{2max} >50 mL/kg per min), mild ventricular dilation, and normal diastolic function.

TREATMENT

Hypertrophic Cardiomyopathy

Management focuses on treatment of symptoms and prevention of sudden death and stroke **(Fig. 267-5)**. Left ventricular outflow tract obstruction can be controlled medically in the majority of patients. β-Adrenergic blocking agents and L-type calcium channel blockers (e.g., verapamil) are first-line agents that reduce the severity of obstruction by slowing heart rate, enhancing diastolic filling, and decreasing contractility. Persistent symptoms of exertional dyspnea or chest pain can be controlled occasionally with the addition of disopyramide, an antiarrhythmic agent with potent negative inotropic properties. The recently introduced small-molecule cardiac myosin inhibitors mavacamten (U.S. Food and Drug Administration approved) and aficamten (under investigation) have shown high efficacy in the treatment of symptomatic obstructive hypertrophic cardiomyopathy, including in patients with persistent symptoms despite treatment with a beta blocker and/or those considering septal reduction therapy. The principal risk of cardiac myosin inhibitors is a transient reduction in left ventricular ejection fraction (LVEF), which warrants frequent echocardiographic monitoring.

Patients with or without obstruction may develop heart failure symptoms due to fluid retention and require diuretic therapies for venous congestion. Severe medically refractory symptoms develop in ~5% of patients, for whom septal reduction therapy with surgical myectomy or alcohol septal ablation may be effective. Developed over 60 years ago, surgical myectomy effectively relieves outflow tract obstruction by excising part of the septal myocardium involved in the dynamic obstruction. In selected patients, perioperative mortality is extremely low with excellent long-term survival free from recurrent obstruction and symptoms. Mitral valve repair or replacement is usually unnecessary as associated eccentric mitral regurgitation resolves with myectomy alone. Alcohol septal ablation in patients with suitable coronary anatomy can relieve outflow tract obstruction via a controlled infarction of the proximal septum, which produces similar periprocedural outcomes and gradient reduction as surgical myectomy. Although head-to-head comparisons between the two septal reduction therapies do not exist, septal ablation is relegated primarily to patients who wish to avoid surgery or who have limiting comorbidities. Neither procedure has been shown to improve outcomes other than symptoms. With both procedures, the most common complication is the development of complete heart block necessitating permanent pacing. However, ventricular pacing as a primary therapy for outflow tract obstruction is ineffective and not generally advised.

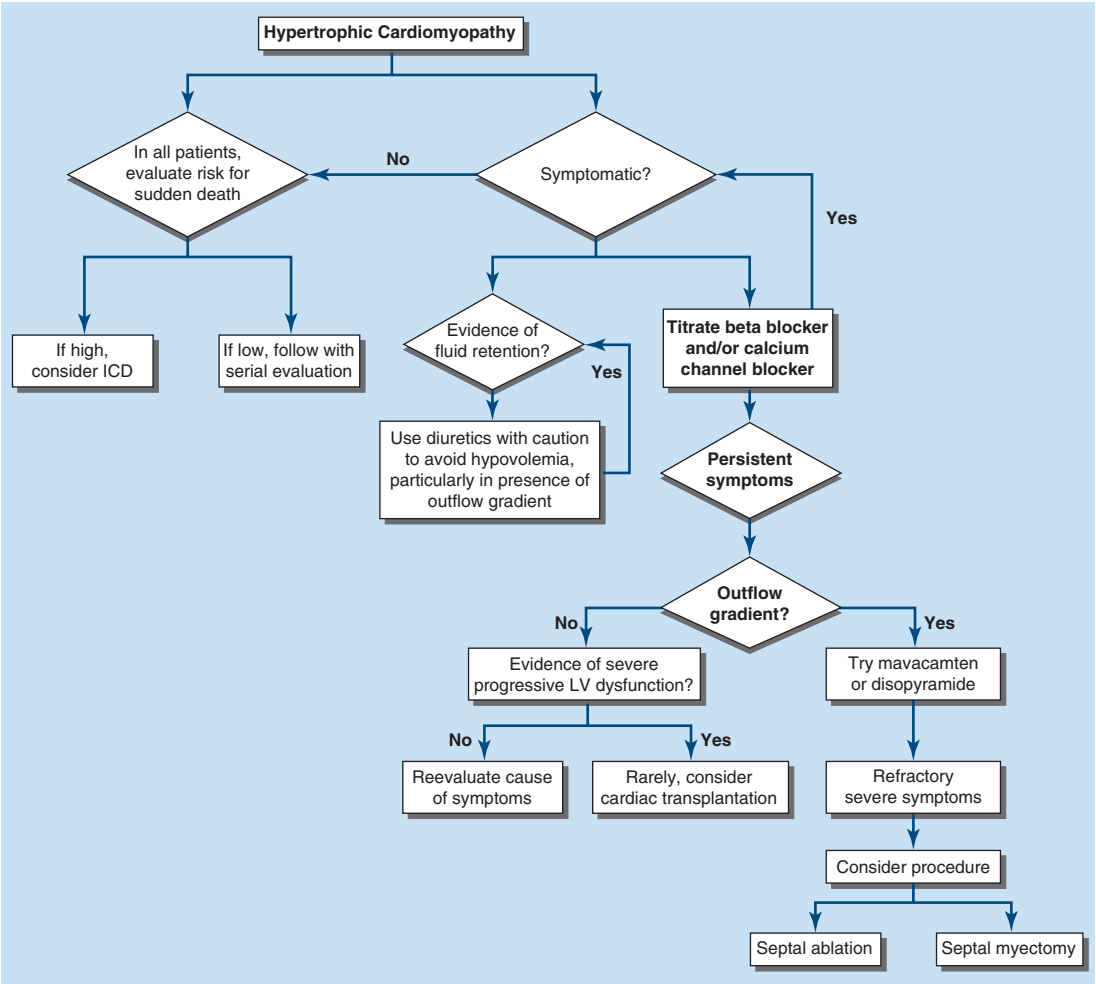

FIGURE 267-5 Treatment algorithm for hypertrophic cardiomyopathy depending on the presence and severity of symptoms and the presence of an intraventricular gradient with obstruction to outflow. Note that all patients with hypertrophic cardiomyopathy should be evaluated for atrial fibrillation and risk of sudden death, whether or not they require treatment for symptoms. ICD, implantable cardioverter-defibrillator; LV, left ventricular.

Patients with hypertrophic cardiomyopathy have an increased risk of sudden cardiac death from ventricular tachyarrhythmias. Vigorous physical activity and competitive sports have been historically prohibited; however, recent studies have failed to identify a relationship between exertion and ventricular arrhythmias in hypertrophic cardiomyopathy, empowering patients and providers to make shared decisions about exercise. Factors that increase the risk of sudden death from a baseline of 0.5% per year are presented in **Table 267-2**. As sudden death has not been reduced by medical or procedural interventions, traditionally an implantable cardioverter-defibrillator has been advised for patients with one or more major risk factors and advised on a selected basis for patient with more than one modifying risk factor. Nevertheless, the positive predictive value of most risk factors is low, and many patients receiving a defibrillator never receive an appropriate device therapy. A complementary approach to sudden death risk stratification and discussion with patients is the application of an externally validated European Society of Cardiology risk score using major criteria from Table 267-2 and continuous variables such as outflow tract gradient and left atrial size. Shared decision-making around implantable cardioverter-defibrillator implantation for primary prevention has emphasized discussions of estimated risk levels rather than dichotomous yes–no criteria. Long-term use of a defibrillator may be associated with serious device-related complications, particularly in young active patients. Refinement of sudden death risk through the application of contemporary technologies such as cardiac MRI is ongoing.

Atrial fibrillation is common in patients with hypertrophic cardiomyopathy and may lead to hemodynamic deterioration and embolic stroke. Rapid ventricular response is poorly tolerated and may worsen outflow tract obstruction. β-Adrenergic blocking agents and L-type calcium channel blockers slow atrioventricular (AV) nodal conduction and improve symptoms; cardiac glycosides should be avoided, as they may increase contractility and worsen obstruction. Even with adequate rate control, symptoms exacerbated by atrial fibrillation may persist due to loss of AV synchrony and may require restoration of sinus rhythm. Disopyramide and amiodarone are the preferred antiarrhythmic agents, with radiofrequency ablation considered for medically refractory cases. Anticoagulation to prevent embolic stroke in atrial fibrillation is recommended.

TABLE 267-2 Risk Stratification for Sudden Death in Hypertrophic Cardiomyopathy

MAJOR RISK FACTOR		SCREENING TECHNIQUE
History of cardiac arrest or spontaneous sustained ventricular tachycardia[a]		History
Syncope	Nonvagal, often with or after exertion	History
Family history of sudden cardiac death		Family history
Left ventricular apical aneurysm	Generally applicable to patients with apical hypertrophy	Echocardiography with contrast, cardiac magnetic resonance imaging
LV thickness >30 mm	Present in <10% of patients	Echocardiography or cardiac magnetic resonance imaging
LV systolic dysfunction (ejection fraction <50%)	Present in <10% of patients	Echocardiography or cardiac magnetic resonance imaging
Variables Utilized in the European Society of Calculator for Estimated Risk of Sudden Death		
LV outflow tract gradient	Peak gradient measured at rest or with the Valsalva maneuver, mmHg	Echocardiography
Left atrial diameter	Diameter measured in the parasternal long axis, mm	Echocardiography
LV thickness	Maximal wall thickness, mm	Echocardiography
Age		
Syncope, family history, nonsustained ventricular tachycardia	As above	As above
Modifying Risk Factors		
Late gadolinium enhancement	As a percentage of myocardial mass	Cardiac magnetic resonance imaging
Spontaneous nonsustained ventricular tachycardia	>3 beats at rate >120	Exercise or 24-h to 48-h ambulatory recording

[a]Implantable cardioverter-defibrillator advised for patients with prior arrest or sustained ventricular tachycardia regardless of other risk factors if life expectancy is estimated to be >1 year. The European Society of Cardiology risk calculator can be found at *https://doc2do.com/hcm/webHCM.html* and provides an estimated 5-year risk of cardiac arrest. Patients with estimated risk of ≥6% are generally advised placement of an implantable cardioverter-defibrillator; those with risk between 4 and 6% can be considered for implant, and implant is not advised when risk is <4%. Emerging risk factors merit further clinical validation.

Abbreviation: LV, left ventricle.

PROGNOSIS

The general prognosis for hypertrophic cardiomyopathy is better than in early studies of referral populations, but mortality remains higher than in an age-matched population without cardiomyopathy. The sudden death risk is <1% per year; however, up to 1 in 20 patients will progress to overt systolic dysfunction with a reduced ejection fraction (<50%) with or without dilated remodeling (i.e., "burned out" or end-stage hypertrophic cardiomyopathy). These patients may suffer from low cardiac output and have an increased risk of death from progressive heart failure and sudden death unless they undergo timely cardiac transplantation.

GENETIC DILATED AND ARRHYTHMOGENIC CARDIOMYOPATHY

EPIDEMIOLOGY, ETIOLOGY, AND PATHOLOGY

As outlined in **Chap. 266**, an enlarged left ventricle with reduced systolic function as measured by LVEF characterizes DCM, which is considered to be present when the LVEF is ≤0.50 and/or the left ventricular diastolic dimension is >95% predicted for age and sex. In some patients with reduced LVEF, the left ventricular dilation is minimal, sometimes referred to as nondilated or minimally dilated cardiomyopathy **(Figs. 267-6, 267-7, and 267-8)**.

While diverse etiologies may cause DCM and arrhythmogenic cardiomyopathy (ACM), familial clustering is present in ~30–40% of cases and monogenic etiologies can be identified in ~25%.

Sarcomere variants are most associated with hypertrophic cardiomyopathy; however, they are also implicated in DCM. The most common genetic causes of DCM are truncating variants of the giant protein titin, encoded by *TTN*, which maintains sarcomere structure and acts as a key signaling molecule.

As cytoskeletal proteins play crucial roles in the structure, connection, and stability of the myocyte, multiple defects in these proteins can lead to dilated cardiomyopathy (Fig. 267-1). For example, desmin forms intermediate filaments that connect the nuclear and plasma membranes, Z-lines, and the intercalated disks between muscle cells. Desmin variants impair the transmission of force and signaling for both cardiac and skeletal muscle and may cause combined cardiac and skeletal myopathy, more commonly with a restrictive phenotype (RCM) than dilated phenotype (DCM).

Defects in the sarcolemmal membrane proteins are associated with DCM. The best known is dystrophin, encoded by the X chromosome gene *DMD*, abnormalities of which cause Duchenne's and Becker's muscle dystrophy. This protein provides a network that supports the sarcolemma and also connects to the sarcomere. The progressive functional defect in both cardiac and skeletal muscle reflects vulnerability

FIGURE 267-6 Dilated cardiomyopathy. This gross specimen of a heart removed at the time of transplantation shows massive left ventricular dilation and moderate right ventricular dilation. Although the left ventricular wall in particular appears thinned, there is significant hypertrophy of this heart, which weighs >800 g (upper limit of normal = 360 g). A defibrillator lead is seen traversing the tricuspid valve into the right ventricular apex. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

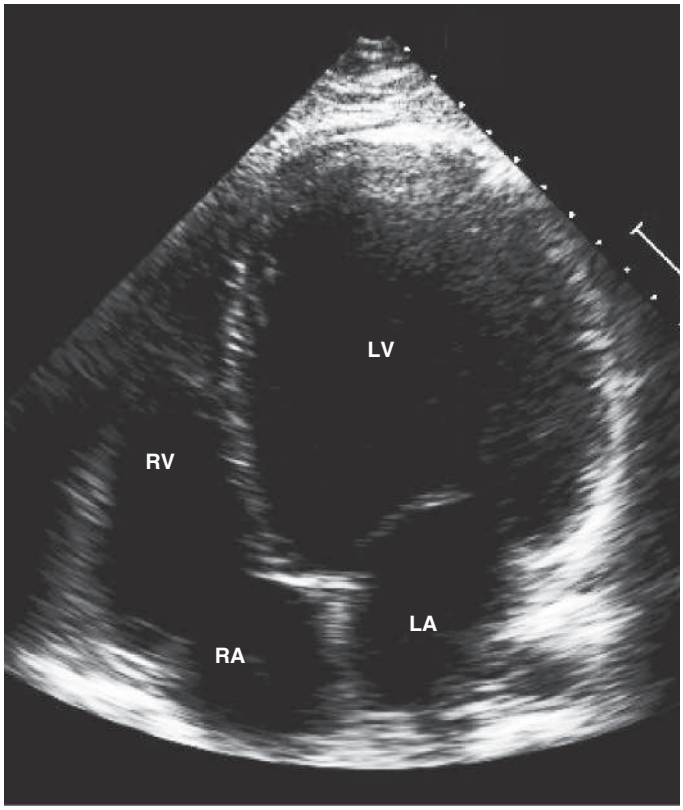

FIGURE 267-7 Dilated cardiomyopathy. This echocardiogram of a young man with dilated cardiomyopathy shows massive global dilation and thinning of the walls of the left ventricle (LV). The left atrium (LA) is also enlarged compared to normal. Note that the echocardiographic and pathologic images are vertically opposite, such that the LV is by convention on the top right in the echocardiographic image and bottom right in the pathologic images. RA, right atrium; RV, right ventricle. *(Image courtesy of Justina Wu, MD, Brigham and Women's Hospital, Boston.)*

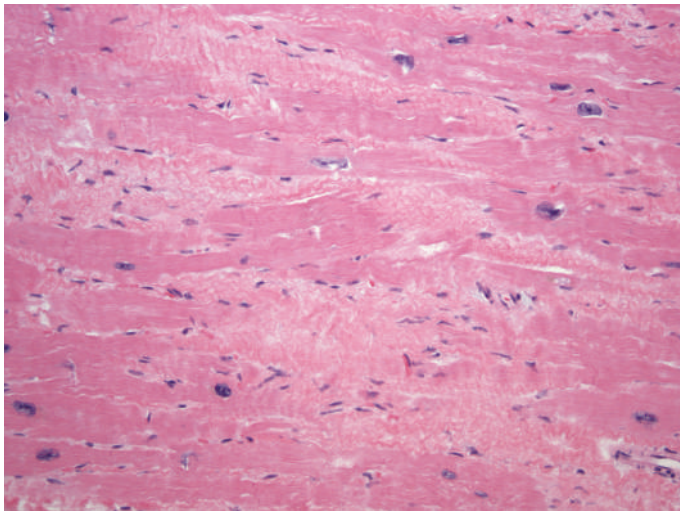

FIGURE 267-8 Dilated cardiomyopathy. Microscopic specimen of a dilated cardiomyopathy showing the nonspecific changes of interstitial fibrosis and myocyte hypertrophy characterized by increased myocyte size and enlarged, irregular nuclei. Hematoxylin and eosin–stained section, 100× original magnification. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

to mechanical stress. Defects in the sarcolemmal channel proteins (*channelopathies*) are generally associated with primary arrhythmias, but variants in *SCN5A*, the α subunit of the Nav 1.5 ion channel protein, distinct from those that cause the Brugada or long QT syndromes, have been implicated in DCM with conduction disease.

Nuclear membrane protein defects in cardiac and skeletal muscle occur in either autosomal (lamin A/C) or X-linked (emerin) patterns. These defects are associated with a high prevalence of atrial and ventricular arrhythmias and conduction system disease, which can occur in some family members without or before detectable cardiomyopathy and underlie gene-specific risk stratification for sudden death and different utilization criteria for primary prevention implantable cardioverter-defibrillators in these patients.

Intercalated disks contribute to intracellular connections, allowing mechanical and electrical coupling between cells and also connections to desmin filaments within the cell. Variants in proteins of the desmosomal complex compromise attachment of the myocytes, which can become disconnected and die via activation of Wnt/β-catenin and proinflammatory signaling pathways, to be replaced by fat and fibrous tissue. These areas are highly arrhythmogenic and may dilate to form aneurysms. Although more often noted in the right ventricle (arrhythmogenic right ventricular cardiomyopathy), this condition can be restricted to the left ventricle (especially when secondary to truncating variants in *DSP*, which encodes desmoplakin) or affect both ventricles and has also been termed "arrhythmogenic cardiomyopathy."

The recognized frequency of familial involvement in DCM has increased to >30%. Truncating variants in *TTN*, encoding the giant sarcomeric protein titin, are the most common cause of DCM, accounting for up to 25% of familial disease. On average, men with *TTN* truncating variants develop cardiomyopathy a decade before women, without distinctive clinical features. Variants in thick and thin filament genes account for ~8% of DCM and may manifest in early childhood.

PROGNOSIS

Prognosis and therapy of DCM and ACM are dictated primarily by the stage of clinical disease and the risk for sudden death, which also varies based on disease gene (higher for patients with variants in *DES, DSP, DSC2, DCG2, FLNC, LMNA, PKP2, PLN, RBM20, SCN5A,* and *TMEM43*). The rate of progression of disease is also heritable, with marked variation based on disease gene observed (e.g., patients with *TTN* truncating variants frequently experience recovery with medical therapy). Medical therapy is generally guided by the phenotype, such that patients with DCM and reduced LVEF are treated with therapies recommended for heart failure with reduced ejection fraction

(Chap. 264). As for HCM, shared decision-making is needed regarding implantable cardioverter-defibrillators. However, the specific genotype plays a greater role in decisions regarding DCM, for which some features may warrant implantable cardioverter-defibrillator placement before the LVEF has declined to 0.35, such as the presence of pathogenic *LMNA* or *FLNC* variants or a family history of sudden death at early ages.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) has an established diagnostic framework (task force criteria) that rests upon identifying and quantifying right ventricular dilation, dyskinesis, and ECG abnormalities (repolarization, depolarization, and arrhythmias) in the context of a suggestive family history of genetic test results. Overlapping with ARVC and DCM is ACM, in which ventricular arrhythmias may precede or supersede the severity of predominantly left ventricular remodeling. Unlike ARVC, consensus diagnostic criteria for ACM are lacking. Early stages of ARVC and ACM may be restricted to ventricular arrhythmias, and over years, ventricular dilation, hypokinesis, and failure may ensue. Patients with an initial presentation of right ventricular cardiomyopathy who progress to include left ventricular dysfunction are at high risk for adverse events.

CARDIOMYOPATHY DUE TO INHERITED DISORDERS OF METABOLISM

Multiple genetic disorders of metabolic pathways can cause myocardial disease, due to infiltration of abnormal products or cells containing them between the myocytes, and storage disease, due to their accumulation within cells (Table 267-1). Hypertrophic cardiomyopathy may be mimicked by the myocardium thickened with these abnormal products causing "pseudohypertrophy," usually with an abnormally short PR interval. The pseudohypertrophic phenotype is most common, but restrictive cardiomyopathy and DCM may occur. Most of these diseases are diagnosed during childhood.

Fabry's disease results from a deficiency of the lysosomal enzyme alpha-galactosidase A caused by variants in *GLA*. This disorder of glycosphingolipid metabolism is an X-linked disorder that may also cause clinical disease in female carriers. Glycolipid accumulation may be limited to the cardiac tissues but usually also involves the skin, peripheral nerve, and kidney. Electron microscopy of endomyocardial biopsy tissue shows diagnostic vesicles containing concentric lamellar figures (Fig. 267-9). Diagnosis can be made through assessment of enzyme activity and/or *GLA* sequencing and is crucial because enzyme replacement can reduce abnormal deposits and improve cardiac and clinical function. The magnitude of clinical impact has not been well established for this therapy, which requires frequent infusions of the enzyme at a cost of >$100,000 a year. The oral chaperone therapy, migalastat, stabilizes mutant forms of alpha-galactosidase, increases enzymatic activity, and was approved for use in a subset of patients with Fabry's disease bearing variants amenable to this therapy.

Carnitine is an essential cofactor in long-chain fatty acid metabolism. Multiple defects have been described that lead to carnitine deficiency, causing intracellular lipid inclusions and restrictive cardiomyopathy or DCM, often presenting in children. Fatty acid oxidation requires many metabolic steps with specific enzymes that can be deficient, with complex interactions with carnitine. Depending on the defect, cardiac and skeletal myopathy can be ameliorated with replacement of fatty acid intermediates and carnitine.

Two monogenic metabolic cardiomyopathies cause increased ventricular wall thickness without an increase of muscle subunits or an increase in contractility. Variants in the gamma-2 regulatory subunit of the adenosine monophosphate (AMP)-activated protein kinase important for glucose metabolism (*PRKAG2*) have been associated with a high prevalence of conduction abnormalities, such as AV block and ventricular preexcitation. Several defects have been reported in an X-linked lysosome-associated membrane protein (*LAMP2*). This defect can be maternally transmitted or sporadic and has occasionally been isolated to the heart, although it often leads to a syndrome of skeletal myopathy, intellectual disability, and hepatic dysfunction referred to as *Danon disease.* Extreme left ventricular hypertrophy appears early, often in childhood, and can progress rapidly to end-stage heart failure with low ejection fraction. Electron microscopy of these metabolic disorders shows that the myocytes are enlarged by multiple intracellular vacuoles of metabolic by-products. Gene therapy using a viral vector to deliver functional *LAMP2* to cardiomyocytes is currently under study in humans with Danon disease.

RESTRICTIVE CARDIOMYOPATHY

Most restrictive cardiomyopathy (RCM) is due to acquired causes, and there is increasing emphasis to diagnose amyloidosis due to transthyretin variants (see Chap. 266). Inherited metabolic and storage diseases can cause RCM, as can variants in *DES* causing combined cardiac and skeletal myopathy and sarcomere variants causing an overlap of RCM and hypertrophic cardiomyopathy.

268 Acute and Chronic Myocarditis

Neal K. Lakdawala, Lynne Warner Stevenson, Joseph Loscalzo

Myocarditis is defined as inflammation of the heart muscle, which may present acutely, subacutely, or insidiously. Outcomes can include resolution, relapsing course, or progression to chronic cardiomyopathy. Myocarditis is generally considered acute when presenting with less than a month of symptoms, often only a few days. The profile of acute myocarditis is changing as the use of sensitive troponin assays and cardiac magnetic resonance imaging (MRI) are increasing recognition of mild cases with good outcomes. Acute myocarditis is most often attributed to active infection but can be caused by multiple types of noninfectious inflammation, such as sarcoidosis, giant cell and eosinophilic myocarditis, and systemic autoimmune disease or immunotherapies. It is uncertain as to how often chronic myocardial inflammation contributes to dilated cardiomyopathy. As with other cardiomyopathies, there is increasing implication of genetic predisposition to inflammatory responses and of independent pathogenic variants as primary cause of myocyte pathology, with almost one in five patients with inflammatory myocarditis harboring genetic variants considered pathogenic for cardiomyopathy.

MODELS OF INFECTIOUS MYOCARDITIS

Infectious agents can injure the myocardium through direct invasion with disruption of normal cellular processes and through activation of different phases of immune responses with or without persistent infection. Although myocarditis has been reported with most types of infectious agents, it is most often associated with viruses and the protozoal disease *Trypanosoma cruzi* (Chagas' disease). The pathogenesis of viral myocarditis has been traditionally portrayed in three phases, arising from extensive study in murine models of enteroviruses, with much less known about human infection. As defined by infection with coxsackie B virus, phase I includes direct invasion of the myocardium. Cellular entry may be enhanced by some genetic variants of the coxsackie/adenovirus receptors. The enteroviral protease A degrades the myocyte structural protein dystrophin and interacts with other proteins to induce apoptosis and interfere with autophagy. Direct myocardial invasion with entry of the viral genome has been shown to occur with the enteroviruses, HIV, and dengue virus. However, most common viruses do not appear to inflict cardiac damage directly. Early cardiac effects may result primarily from cytokine storm and other nonspecific immune responses leading to myocardial depression. This initial immune response appears to be crucial to recovery, as early immunosuppression increased viral replication and worsened cardiac injury in animal models.

The second phase is host response to infection in recognition of common antigenic patterns, triggering macrophage activation and expansion of specific T- and B-cell populations. Myocarditis due to this phase of immune response without direct viral-mediated injury is considered to be virally "triggered" myocarditis, implicated with respiratory viruses including adenovirus, influenza, and COVID-19. Molecular mimicry between viral and cardiac antigens may be the cause of some cases of myocardial injury caused by autoreactive T cells in the absence of ongoing viral infection. There is increasing study of the role of viral "hijacking" of cellular machinery to produce extracellular vesicles containing viral RNA that may then gain protected entry into other cells. A third phase of progression to chronic cardiomyopathy has been demonstrated in animal models of enteroviruses. However, myocarditis is rarely due to enteroviruses in adults. There are limited data providing direct links between chronic cardiomyopathy and previous viral infection (see "Chronic Myocarditis and Cardiomyopathy" below). The MRI pattern of intramyocardial late gadolinium enhancement in chronic cardiomyopathy was previously considered as evidence of prior viral myocarditis, but this pattern is now recognized to be common in genetic cardiomyopathy as well.

ACUTE MYOCARDITIS

PRESENTATION AND DIAGNOSIS

Acute myocarditis in adults typically occurs between 30 and 45 years and is more common in men than women, who tend to present at over 45 years of age. Prodromal symptoms typical of influenza, gastroenteritis, or upper respiratory infection may have occurred days to a few weeks earlier. Fever is present in over half of cases. Chest pain is the most common symptom of acute myocarditis, occurring in >80% of patients, who also often present with dyspnea or arrhythmias. Arrhythmias can manifest as palpitations or syncope but can also cause sudden cardiac death, as in an autopsy series in which inflammatory myocarditis was diagnosed 3–10% of previously healthy young adults. At presentation, about one-fourth of acute myocarditis cases include left ventricular ejection fraction (LVEF) <0.50, ventricular arrhythmias, or clinical shock, which is reported in ~3–9% of cases and termed *fulminant myocarditis*.

Viral titers are not often helpful to guide initial therapy of acute myocarditis. Respiratory viral panels can confirm recent infection with influenza and adenovirus, most implicated in acute myocarditis in adults with a viral prodrome. Finding of COVID-19 may alert to extracardiac involvement. Specific infectious serologies for HIV, Chagas' disease, cytomegalovirus, dengue fever, and Lyme disease and serologies for systemic autoimmune disease should be sent in selected patients. Eosinophil counts should be routinely checked because hypereosinophilia is present in most cases of eosinophilic myocarditis.

The common definition for "probable myocarditis" includes new appearance of least one symptom listed above and at least one supporting finding, which can be elevated troponin levels, consistent ECG findings, or imaging findings of decreased LVEF or obvious wall motion abnormality. Other laboratory findings may include elevated creatine phosphokinase levels, indicating cardiac or skeletal muscle involvement, and elevated C-reactive protein levels. The most common electrocardiogram (ECG) findings are ST elevation suggesting infarction, but also include conduction block, tachyarrhythmias, and nonspecific ST-T changes. Because the combination of chest pain, ECG changes, and elevated troponin is typical of both acute myocarditis and myocardial infarction, the first step in the differential diagnosis is often coronary artery imaging. Subsequent diagnosis of acute myocarditis has been reported in up to one-third of patients with myocardial infarction and nonobstructed coronary arteries (MINOCA).

"Definite myocarditis" previously required positive biopsy findings of typical inflammatory lymphocytic infiltrate on myocardial biopsy **(Fig. 268-1)**.

Newer techniques of immunohistochemistry may increase sensitivity of biopsies and advance our understanding of the inflammatory cell populations. However, the diagnosis can now be confirmed noninvasively when typical symptomatic presentation is accompanied by combination of elevated troponin levels and consistent findings on MRI, which include evidence of both myocardial edema and nonischemic myocardial injury in the absence of other known cause **(Fig. 268-2)**.

Although cardiac MRI may often be sufficient to diagnose acute myocarditis, endomyocardial biopsy should be performed when ventricular arrhythmias, conduction block, elevated eosinophil count, or evidence of systemic autoimmune disease suggests causes of acute myocarditis with specific implications for therapy and prognosis, as discussed below in "Noninfective Inflammatory Myocarditis."

THERAPY AND OUTCOMES

The prognosis is good for "uncomplicated" acute myocarditis, presenting with LVEF ≥0.50 without ventricular arrhythmias or circulatory shock. In the largest series, this low-risk group accounted for about three-fourths of patients with acute myocarditis, in which spontaneous recovery was common without specific therapies other than diuretics and nonsteroidal analgesics for chest pain. Almost all of these patients

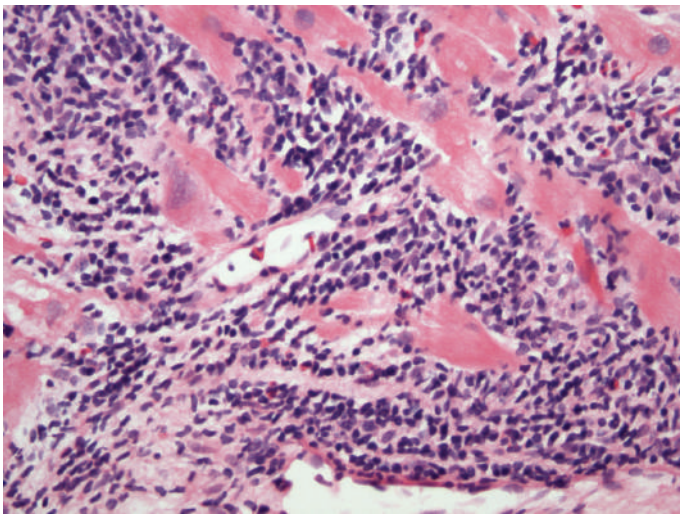

FIGURE 268-1 Acute myocarditis. Microscopic image of an endomyocardial biopsy showing massive infiltration with mononuclear cells and occasional eosinophils associated with clear myocyte damage. The myocyte nuclei are enlarged and reactive. Such extensive involvement of the myocardium would lead to extensive replacement fibrosis even if the inflammatory response could be suppressed. Hematoxylin and eosin–stained section, 200× original magnification. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

still had LVEF ≥0.50 on follow-up imaging and survived without transplantation at 5 years of follow-up. In the one-fourth of patients with complicated presentations, ~18% died or underwent heart transplantation in the next 5 years. Patients with reduced LVEF are generally discharged on the recommended therapies for heart failure with reduced ejection fraction (HFrEF). There are no data supporting routine immunosuppression in patients with acute myocarditis with presumed viral etiology. Fulminant myocarditis requiring high-dose inotropic therapy or mechanical circulatory support occurs in 3–9% of acute myocarditis, with early outcomes of refractory cardiogenic shock but recovery to near-normal LVEF in >50% of affected patients.

CHRONIC MYOCARDITIS AND CARDIOMYOPATHY

Patients with reduced LVEF at the time of presentation with acute myocarditis are at higher risk of developing chronic cardiomyopathy. When the LVEF does not resolve in the initial months after diagnosis, particularly with persistent elevation of troponin, cardiac magnetic resonance imaging (CMRi) or endomyocardial biopsy may reveal ongoing inflammation and developing fibrosis. Evaluation should again be considered for specific etiologies of myocarditis including noninfectious causes of inflammatory disease and for other causes of dilated cardiomyopathy **(Chap. 266, Table 266-2)**.

Evidence of chronic inflammatory disease may also be found in some patients presenting with gradual onset of dilated cardiomyopathy without prior acute myocarditis. Immunosuppression for nonspecific lymphocytic myocarditis in the chronic setting has been tried in multiple series but has not demonstrated convincing benefit. Additional findings of anticardiac antibodies and viral genome fragments are of uncertain significance, as they could be either causes of ongoing cardiac injury or neutral bystanders. Assay for anticardiac antibodies and viral genome analysis in chronic cardiomyopathy continue to be investigated but are not in routine clinical use.

In the past, dilated cardiomyopathy without other cause was generally assumed to result from previously unrecognized viral myocarditis, in part because CMRi patterns of fibrosis suggested prior inflammation. However very similar patterns are typical of genetic cardiomyopathies. The expanding access to genetic testing reveals that 20–40% of patients with dilated cardiomyopathy have pathogenic variants sufficient to cause their cardiomyopathy, and the prevalence and nature of these variants are similar in acute myocarditis. Mapping of the interconnections between genetic predisposition, inflammation, and cardiomyopathy is evolving rapidly.

SPECIFIC CAUSES OF INFECTIOUS MYOCARDITIS

The first viruses implicated in infectious myocarditis were the picornavirus family of RNA viruses, principally the enteroviruses, coxsackie virus, echovirus, and poliovirus. Influenza, another RNA virus, is implicated with varying frequency every winter and spring as epitopes change. Of the DNA viruses, adenovirus, vaccinia, and the herpesviruses (varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, and human herpesvirus 6 [HHV6]) can cause myocarditis but also occur commonly in the healthy population. Polymerase chain reaction (PCR) detects viral genomes in some patients with dilated cardiomyopathy and persistent lymphocytic infiltrates defined as "chronic myocarditis," such as the DNA viruses parvovirus B19 and HHV6, but these are also found in normal "control" hearts, so their contribution to chronic cardiomyopathy is uncertain.

COVID-19 is an RNA virus for which infection was associated with substantial rates of cardiac involvement in patients hospitalized with severe disease, including acute coronary syndrome, thromboemboli, pericarditis, and myocarditis, for which the diagnosis was limited to clinical findings and elevated enzymes rather than demonstration of lymphocytic infiltrates, as biopsies were rarely performed. From broad population data, the rate of myocarditis during the pandemic was estimated at 150/100,000 people, a 15-fold increase over pre-COVID incidence. As for most causes of viral myocarditis, the most common adult patients are young men under the age of 40. As for other viruses, there are multiple potential mechanisms of cardiac injury. Viral particles were identified by PCR in myocardial samples but in low levels at which pathogenicity was uncertain. Other mechanisms include cytokine storm, activated T cells and macrophages, and potential molecular mimicry by which autoimmune reactions may be triggered, as for some animal models of myocarditis with other viruses. As with multiple other viruses, extracellular vesicles containing viral RNA have been identified in myocardium during COVID infection, potentially promoting protected entry into other cells for further injury. In addition, the endothelium is also vulnerable, leading to prothrombotic endotheliopathy that may contribute to myocardial ischemia and stroke, along with the systemic coagulopathy.

HIV was associated with a dilated cardiomyopathy incidence of 1–2%, but this is declining with the availability of highly active antiretroviral therapy. Cardiomyopathy in HIV may also result from other associated viruses, such as cytomegalovirus and hepatitis C. Antiviral drugs to treat chronic HIV can cause cardiomyopathy, both directly

and through drug hypersensitivity. The clinical picture may be complicated by pericardial effusions and pulmonary hypertension. There is an increased frequency of lymphocytic myocarditis found at autopsy; HIV viral particles have been demonstrated in the myocardium in some cases.

For any serious infection, the systemic inflammatory response can cause nonspecific depression of cardiac function, which is generally reversible if the patient survives. Other viruses implicated specifically in myocarditis include mumps, respiratory syncytial virus, the arboviruses (dengue fever and yellow fever), and arenaviruses (Lassa fever).

OTHER INFECTIOUS CAUSES

Parasitic Myocarditis Chagas' disease is the third most common parasitic infection in the world and the most common infective cause of cardiomyopathy. The protozoan *T. cruzi* is transmitted by the bite of the reduviid bug, endemic in the rural areas of South and Central America. Transmission can also occur through blood transfusion, organ donation, from mother to fetus, and occasionally orally. Programs to eradicate the insect vector have decreased the global prevalence from about 18 million in 1990 to 6 million, with the highest number of cases in Brazil and Argentina and increased prevalence also in Spain. It is estimated that >300,000 residents in the United States are infected with Chagas' disease, a minority of whom have acquired it locally.

Initial infection with *T. cruzi* is usually silent but, in 5–10% of cases, can present with systemic illness and acute myocarditis with systemic dense parasitic infiltration in the myocardium forming pseudocysts that rupture and lead to diffuse myocyte necrosis. After initial infection, patients enter an "indeterminate phase," which can last for decades. The silent progression during this phase was at one time attributed to secondary immune activation, but a degree of persistent parasitemia can now be detected and is recognized as the major determinant of ongoing inflammation and progression to chronic heart failure. Depopulation of parasympathetic neurons in the heart and gastrointestinal tract likely contributes to clinical disease. Understanding of the disease patterns has improved in part from the ability to test blood donors for infection. Better detection of the organism has revealed that both the prevalence and survival of patients in the indeterminate phase are higher than previously recognized, with over half of patients remaining asymptomatic.

T. cruzi infection should be considered during evaluation of acute myocarditis or cardiomyopathy in all patients from endemic regions and for other patients with suggestive features. These include sinus and atrioventricular node conduction system disease and right bundle branch block, with frequent atrial and ventricular arrhythmias, some of which may cause sudden death before symptomatic disease. The dilated ventricles are thrombogenic and sometimes have aneurysms. For acute myocarditis, PCR is the most sensitive test and trypomastigotes may also be detected in blood when parasite levels are high. In the chronic phase with low parasite burden, multiple serologic tests may be necessary for diagnosis, but their sensitivity and specificity are improving.

Antiparasitic treatment with nifurtimox or benznidazole is recommended for acute myocarditis with Chagas' cardiomyopathy. During the indeterminate phase prior to clinical symptoms, therapy is widely recommended for children. For the indeterminate phase, there is controversy over the routine use of antiparasitic treatment, which is associated with significant toxicity. Therapy is more often advocated for patients <50 years old, who are more likely to tolerate chronic suppressive therapy. Treatment is recommended for premenopausal women and for patients on immunosuppression, such as after cardiac transplantation. A large multinational trial showed no benefit for benznidazole given to patients with chronic heart failure from Chagas' cardiomyopathy. In these patients, general therapy is as indicated for other HFrEF, with increased indications for anticoagulation and for pacemaker defibrillators. Improvement of LVEF is uncommon and survival is lower than for other cardiomyopathies after the onset of overt clinical heart failure.

Trichinellosis (trichinosis) is caused by the *Trichinella* genus of nematodes (roundworms). The larvae are ingested with undercooked meat, with an initial intestinal phase after which larvae migrate into skeletal muscles, causing myalgias, weakness, and fever. Periorbital and facial edema and conjunctival and retinal hemorrhage may also be seen. Although the larva may occasionally invade the myocardium, clinical heart failure is rare and, when observed, attributed to the eosinophilic inflammatory response. The diagnosis is made from the serologies and is further supported by the presence of eosinophilia. Treatment includes anthelminthic drugs and glucocorticoids if inflammation is severe.

Bacterial Infections Most bacterial infections can involve the heart occasionally through direct invasion and abscess formation but do so rarely. More commonly, systemic inflammatory responses to severe infection and sepsis depress myocardial contractility.

Diphtheria is caused by bacillus *Corynebacterium diphtheriae*, usually presenting with an upper respiratory illness particularly affecting the pharynx, where a pseudomembrane is formed in response to the diphtheria toxin. This toxin interferes with protein synthesis in the heart and may particularly affect the conduction system. Cardiac involvement is the most common cause of death from this infection but rarely occurs with the occasional dominant cutaneous presentation. The prevalence of vaccines has shifted the incidence of diphtheria to countries without routine immunization and to older populations who have lost their immunity. The diagnosis is made from pharyngeal bacterial culture, which requires special culture media and a positive assay for the toxin but can be suspected from gram-positive rods on a Gram stain. Clinical suspicion is sufficient indication for the specific antitoxin, which should be administered as soon as possible, with higher priority than antibiotic therapy.

Streptococcal infection with β-hemolytic streptococci is most commonly associated with acute rheumatic fever and is characterized by inflammation and fibrosis of cardiac valves and systemic connective tissue, but it can also lead to a myocarditis with focal or diffuse infiltrates of mononuclear cells. Other systemic bacterial infections that can involve the heart include brucellosis, legionella, meningococcus, mycoplasma, psittacosis, and salmonellosis, for which specific treatment is directed at the systemic infection.

Tuberculosis can involve the myocardium directly as well as through tuberculous pericarditis but rarely does so when the disease is treated with antibiotics. Whipple's disease is caused by *Tropheryma whipplei.* The usual manifestations are in the gastrointestinal tract, but pericarditis, coronary arteritis, valvular lesions, and occasionally clinical heart failure may also occur. Multidrug antituberculous regimens are effective, but the disease tends to relapse even with appropriate treatment.

Tick-Borne Infections Spirochetal myocarditis has been diagnosed from myocardial biopsies containing *Borrelia burgdorferi*, which causes Lyme disease. Lyme carditis most often presents with arthritis and conduction system disease that resolves within 1–2 weeks of antibiotic treatment and is only rarely implicated in chronic heart failure. Other borrelia species carried by either ticks or lice can cause relapsing fever. Additional tick-borne illnesses associated with febrile illnesses and myocarditis include Rocky Mountain spotted fever, Q fever, and ehrlichiosis, all of which are treated with doxycycline alone or in combination with other agents.

NONINFECTIVE INFLAMMATORY MYOCARDITIS

Myocardial inflammation can occur in the absence of infectious causes. The paradigm of noninfective inflammatory myocarditis is cardiac transplant rejection, from which we have learned that myocardial depression can develop and reverse quickly, that noncellular mediators such as antibodies and cytokines play a major role in addition to lymphocytes, and that myocardial antigens are exposed by prior physical injury and viral infection. In the largest registry of acute myocarditis, chronic systemic inflammatory diseases were implicated in 7% of cases and in 15% of those with high-risk features.

The most commonly diagnosed noninfective inflammatory process affecting the myocardium is sarcoidosis. Sarcoidosis, as discussed in **Chap. 379**, is a multisystem granulomatous disease most commonly affecting the lungs, but involving many organs including skin, eyes, liver, nervous system, and bones, as well as the heart. The epidemiology appears to be changing, now recognized in men and women of all races and ethnic groups, typically between 30 and 50 years old but often after the age of 50 in women. Sarcoidosis is now understood as a combination of foreign antigen presentation and a dysregulated immune response that leads to ongoing inflammation, including activated macrophages. Occupational exposures include agriculture, firefighting, metal-working, and construction work, with silica dust, pesticides, mold, and other inhaled particles as examples of implicated antigens. The occurrence of sarcoidosis is increased in family members, reflecting potential sharing of environments and of genetic variants, which have been identified in loci affecting immune responses.

Cardiac sarcoidosis often accompanies pulmonary sarcoidosis but frequently occurs without detectable lung disease. The time course, burden and activity of cardiac granulomata, and the degree of extracardiac involvement are remarkably variable. Patients may present with rapid-onset heart failure and ventricular tachyarrhythmias, conduction block, chest pain syndromes, or minor cardiac findings in the setting of pulmonary sarcoidosis, ocular involvement, an infiltrative skin rash, or a nonspecific febrile illness. Chronic sarcoidosis may go unrecognized for months or years. When ventricular tachycardia or conduction block dominates the initial presentation of heart failure without coronary artery disease, suspicion should be high for sarcoidosis as a cause of cardiomyopathy. Right bundle branch block should raise suspicion for sarcoidosis but is uncommon with other cardiomyopathies, in which left bundle branch block is more common.

The pathology of cardiac sarcoidosis often shows a spectrum from metabolically active granulomas to bland fibrosis at the sites of previous inflammation. Regional wall-motion abnormalities are common, but global ventricular function may be preserved early during mild disease. When left ventricular function is only mildly reduced, ventricular size may be near normal, sometimes described as "nondilated" or "minimally dilated cardiomyopathy." Although occasionally listed with restrictive cardiomyopathies, sarcoidosis with a reduced ejection fraction generally has the phenotype of dilated or minimally dilated cardiomyopathy. There may be a right ventricular predominance of both dilation and ventricular arrhythmias, in which case potential diagnoses include genetic arrhythmogenic right ventricular cardiomyopathy, with which sarcoidosis shares multiple features.

Diagnosis of cardiac sarcoidosis is easiest in the presence of biopsy-proven sarcoidosis of other organs. Imaging of the heart can show regional wall motion abnormalities or small ventricular aneurysms. MRI of the heart can identify late gadolinium enhancement in a pattern of fibrosis not compatible with myocardial infarction. Computed tomography of the chest often reveals pulmonary lymphadenopathy even in the absence of clinical lung disease. Positron emission tomography (PET) of the whole chest can highlight active sarcoid lesions that are avid for glucose in heart or lung. When metabolically active adenopathy is detected, biopsy is often necessary to rule out malignancy or chronic granulomatous infections such as tuberculosis or histoplasmosis before treating with immunosuppression for sarcoidosis. The scattered granulomata of sarcoidosis are commonly missed on cardiac biopsy **(Fig. 268-3)**.

Immunosuppression for sarcoidosis is generally initiated with glucocorticoids. Initial dosing was traditionally high but now is more often started at 30–40 mg daily or less, with early addition or substitution of steroid-sparing agents like methotrexate or mycophenolate. Third-line treatment may include tumor necrosis factor-alpha inhibitors or other immunomodulators under investigation. The impact of treatment is usually more apparent for suppression of arrhythmias than for improvement of markedly impaired left ventricular dysfunction. Devices are often indicated for tachyarrhythmias or for conduction disease and usually include both pacing and defibrillation capability. Patients with sarcoidosis are immunosuppressed, and their management should be supervised by an experienced multidisciplinary team.

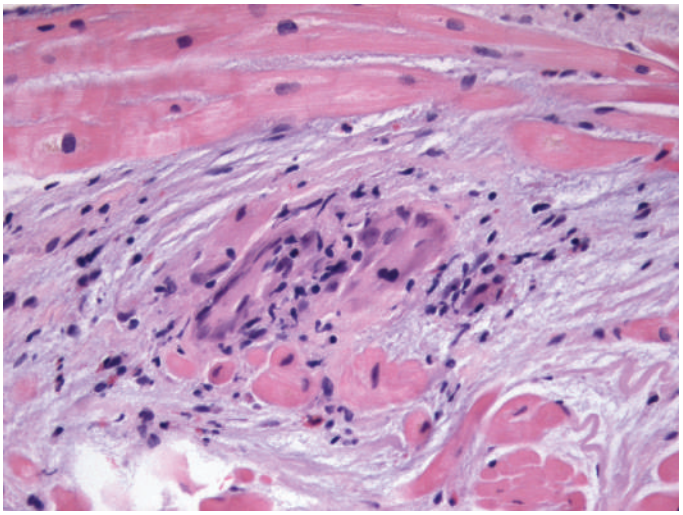

FIGURE 268-3 Sarcoidosis. Microscopic image of an endomyocardial biopsy showing a noncaseating granuloma and associated interstitial fibrosis typical of sarcoidosis. No microorganisms were present on special stains, and no foreign material was identified. Hematoxylin and eosin–stained section, 200× original magnification. *(Image courtesy of Robert Padera, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)*

Cardiac sarcoidosis may respond to the initial immunosuppression course without recurrence, may fluctuate over a chronic course, or occasionally may lead to end-stage heart failure requiring heart transplantation.

Giant cell myocarditis is less common than sarcoidosis, but accounts for 10–20% of biopsy-proven myocarditis, typically presenting acutely with rapidly progressive heart failure and tachyarrhythmias. Giant cell myocarditis occurs equally in men and women, usually of older age than those with acute viral myocarditis, and is more often associated with systemic autoimmune disorders. Unlike sarcoidosis, the more diffuse involvement with giant cell myocarditis usually leads to diagnostic endomyocardial biopsy, revealing granulomatous lesions surrounded by extensive inflammation infiltrate, often with eosinophilic infiltration. However, the occasional finding of giant cell myocarditis in explanted hearts after a previous diagnosis of sarcoidosis suggests that they may share the same disease spectrum. Glucocorticoid therapy alone is rarely effective, but in combination with other immunosuppression therapies similar to those used for severe transplant rejection, the rate of death or heart transplantation has decreased for patients who are stable at the time of presentation. Most patients presenting with cardiogenic shock from giant cell myocarditis progress to need urgent mechanical support or transplantation, for which they may be rendered ineligible by severe infection resulting from intensive immunosuppression.

Eosinophilic myocarditis is one of the causes of fulminant myocarditis but may be missed on milder presentation that does not include assessment for hypereosinophilia, which is present in about three-fourths of diagnosed cases. Myocardial toxicity of eosinophils may lead to apical thrombi on cardiac imaging, and MRI reveals inflammation acutely and subendocardial fibrosis in chronic cases. Endomyocardial biopsies show infiltration with lymphocytes, neutrophils, and a high proportion of eosinophils. Hypersensitivity to chronic medications accounts for up to one-third of cases and is often cured by withdrawal of the agent and acute steroid therapy. Particularly in Mediterranean and African countries, hypereosinophilia can result from chronic parasitic infection, for which treatment may cure the myocarditis. About 12% of cases are due to eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome), which responds to immunosuppression but may have a relapsing course. The hypereosinophilic syndrome (HES) accounts for 10–15% of cases, resulting from myeloproliferative variants or overproduction of eosinophil production, for which combined immunosuppression may soon include therapies under investigation to decrease eosinophil production. About 30% of HES cases are currently

unexplained. Without curative therapy, the initial inflammatory necrosis can lead to thrombosis, valve disease, and progressive endomyocardial fibrosis with restrictive physiology, termed *Loeffler endocarditis*, which presents as a restrictive cardiomyopathy.

Myocarditis is often associated with systemic inflammatory diseases, such as *polymyositis* and *dermatomyositis*, which can affect cardiac as well as proximal skeletal muscle and are usually diagnosed from autoantibodies. Myocarditis with lymphocytic infiltrates on endomyocardial biopsy can be seen in some patients with systemic lupus erythematosus, but multiple cardiac manifestations also include accelerated coronary artery disease, valvular involvement from sterile endocarditis, pericarditis, vasculitis, and chloroquine cardiotoxicity.

Vaccines have occasionally been implicated in myocarditis. This has been best studied after the smallpox vaccine in military populations. As this is a live vaccine, it is unclear whether this is direct injury, but it is generally assumed to be a hypersensitivity response. More recent concern relates to COVID-19 vaccines, after which the overall rate of myocarditis is estimated to be about 1/100,000 vaccine doses (increased to 2–3/100,000 for recipients age 18–39 years). Most cases of vaccine-induced myocarditis resolve without hospitalization. Male adults under 40 are at highest risk of myocarditis from the COVID-19 vaccines, as they are for primary infectious myocarditis after COVID-19 and other viruses. The risk for men under 40 increases after repeat COVID-19 vaccines, for which the benefit/risk for individuals should be considered.

The most dramatic form of noninfectious inflammatory myocarditis is that seen with combined immune checkpoint inhibitors. Targeted monoclonal antibody therapy to unblock the host immune response has produced remarkable remission of multiple advanced tumors. Inhibitory receptors on T lymphocytes (such as CTLA-4 and PD-1) and the programmed death ligands, such as PD-L1, interact in normal self-regulation to inhibit overactivation of immune responses. Tumor cells can upregulate these ligands to hide from immune recognition. Therapeutic antibodies against these inhibitory receptors or ligands can heighten host defenses against the tumor but also unleash immune attack against host tissues expressing PD-L1, which include skeletal and cardiac muscle, endothelial cells, and multiple other organs, such as lung, liver, pancreas, thyroid, and skin. With cardiac involvement, troponin is often elevated, B-type natriuretic peptide may be elevated, and creatine phosphokinase may be high, particularly with skeletal involvement. The diagnosis should be suspected immediately with acute cardiac presentation in patients treated with checkpoint inhibitors. Admission to the coronary care unit is currently recommended for an elevated troponin levels and ECG changes, which may be nonspecific but can also include conduction blocks and bizarre arrhythmias. Echocardiography may suggest myocardial edema, but initial ejection fraction may not be markedly reduced. Initial care should generally not be delayed for endomyocardial biopsy, which typically shows extensive lymphocytic infiltration. Patients may also present initially with other acute organ system involvement, which warrants urgent multidisciplinary management in intensive care. Therapy with high-dose glucocorticoids should be initiated rapidly and may be followed soon by more targeted immune inhibition. Reports of fatality in checkpoint inhibition myocarditis were initially very high, but outcomes are improving with earlier recognition and therapy.

269 Dilated Cardiomyopathies

Neal K. Lakdawala, Lynne Warner Stevenson, Joseph Loscalzo

As described in **Chap. 266**, the phenotype of dilated cardiomyopathy (DCM) is characterized by decreased left ventricular systolic function, typically with increased left ventricular dimensions, although dilation may be minimal in some cases. Multiple causes and contributing factors have been implicated **(Table 269-1)**.

As discussed in **Chaps. 267 and 268**, many cases are attributed to prior myocarditis, and an increasing number are associated with pathogenic genetic variants, but other causes include toxic and metabolic disorders and peripartum cardiomyopathy, which are discussed in this chapter, along with takotsubo cardiomyopathy, which has a distinct presentation and phenotype that often resolves.

Despite the multiple etiologies and variable initial presentations, DCM often progresses into a convergent clinical phenotype similar to that of other injury such as acute myocardial infarction. Some myocytes may die early in the course, while others survive only to have later programmed cell death (apoptosis), and remaining myocytes develop hypertrophy in response to increased wall stress. Local and circulating neurohormonal factors stimulate deleterious secondary responses that contribute to progression of disease. Dynamic remodeling of the interstitial scaffolding affects diastolic function and the amount of ventricular dilation. Mitral regurgitation commonly develops as the ventricle dilates and the valvular apparatus is distorted and is commonly moderate to severe by the time heart failure is advanced. There is increasing evidence for the role of chronic inflammation in disease progression even when not initially implicated. Many cases that present "acutely" have progressed silently through these stages of injury over months to years. Dilation and decreased function of the right ventricle may result directly from the initial injury but more often develop later in response to elevated afterload presented by secondary pulmonary hypertension and in relation to mechanical interactions with the failing left ventricle.

The secondary responses are often modifiable or reversible. Almost a third of patients with recent-onset cardiomyopathy in the absence of coronary artery disease demonstrate substantial spontaneous recovery to normal ejection fraction. Partial recovery to left ventricular ejection fraction (LVEF) >0.40 ("heart failure with improved ejection fraction") is common in chronic DCM during recommended therapy with neurohormonal modulation, cardiac resynchronization therapy for left bundle branch block, and diuretics as needed to maintain fluid balance, as recommended for other heart failure with reduced LVEF **(Chap. 265)** regardless of the initial cause of DCM. Additional aspects of diagnosis, therapy, and outcomes for specific etiologies of DCM other than the infectious, inflammatory, and genetic cardiomyopathies are discussed below.

CARDIOTOXICITY AND CARDIOMYOPATHY

Cardiotoxicity has been reported with multiple environmental and pharmacologic agents. Often these associations are seen only with very high levels of exposure or acute overdoses, in which acute electrocardiographic and hemodynamic abnormalities may reflect both direct drug effect and systemic toxicity. *Alcohol* is the most common toxin implicated in chronic DCM. Although excess consumption may contribute to >10% of cases of heart failure, including exacerbation of heart failure with structural heart disease, alcoholic cardiomyopathy is relatively rare and remains a diagnosis of exclusion. Moreover, Mendelian randomization studies have not identified a link between genetically predicated alcohol consumption and heart failure, suggesting that the population attributable risk of alcohol to the overall heart failure epidemic is modest. Alcoholic cardiomyopathy causes

TABLE 269-1 Major Causes of Dilated Cardiomyopathy (with Common Examples)

Inflammatory Myocarditis (see Chap. 268)
Infective
Viral (coxsackie,[a] adenovirus,[a] COVID-19, HIV)
Parasitic (*Trypanosoma cruzi*—Chagas' disease, trypanosomiasis, toxoplasmosis)
Bacterial (diphtheria)
Spirochetal (*Borrelia burgdorferi*—Lyme disease)
Rickettsial (Q fever)
Fungal (with systemic infection)
Noninfective
Granulomatous inflammatory disease
Sarcoidosis
Giant cell myocarditis
Eosinophilic myocarditis
Polymyositis, dermatomyositis
Collagen vascular disease
Checkpoint inhibitor chemotherapy
Transplant rejection
Toxic
Alcohol
Catecholamines: amphetamines, cocaine
Chemotherapeutic agents (anthracyclines, trastuzumab)
Interferon
Other therapeutic agents (hydroxychloroquine, chloroquine)
Drugs of misuse (testosterone and other anabolic steroids emetine)
Heavy metals: lead, mercury
Occupational exposure: hydrocarbons, arsenicals
Metabolic[a]
Nutritional deficiencies: thiamine, selenium, carnitine
Electrolyte deficiencies: calcium, phosphate, magnesium
Endocrinopathy
Thyroid disease
Pheochromocytoma
Diabetes mellitus
Obesity
Hemochromatosis
Inherited metabolic pathway defects (see Chap. 267)
Familial[a] (see Table 267-1)
Cardiomyopathies without extracardiac involvement
Cardiomyopathy with skeletal myopathy, for example:
Dystrophin-related dystrophy (Duchenne's, Becker's)
Mitochondrial myopathies (e.g., Kearns-Sayre syndrome)
Hemochromatosis
Susceptibility to immune-mediated myocarditis
Associated with other systemic diseases
Miscellaneous (Shared Elements of Above Etiologies)
Arrhythmogenic ventricular cardiomyopathy
Peripartum cardiomyopathy
Left ventricular noncompaction[a]
Tachycardia-related cardiomyopathy
Supraventricular arrhythmias with uncontrolled rate
Very frequent nonsustained ventricular tachycardia or high burden of premature ventricular complexes

[a]Some specific cases can be linked now to specific genetic mutation in a familial cardiomyopathy; others with similar phenotypes that appear to be acquired or idiopathic may represent genetic factors not yet identified.

many more hospital admissions in men than women, but prevalence is similar between men and women with alcoholism, with left ventricular dysfunction detected in about a third of asymptomatic patients. Estimates of the alcohol intake necessary to cause cardiomyopathy have been 3–4 ounces or ≥60–80 g of pure ethanol daily for ≥5 years, about 750 mL of wine, 6 beers, or a half pint of hard liquor, although women may develop cardiomyopathy with lower amounts of consumption. Frequent binge drinking may also be sufficient. Toxicity is attributed both to alcohol and to its primary metabolite, acetaldehyde. Chronic heavy exposure may cause neurohormonal activation and alter metabolism, protein synthesis, substrate utilization, and oxidative stress. Polymorphisms of the genes encoding alcohol dehydrogenase and the angiotensin-converting enzyme may influence the likelihood of alcoholic cardiomyopathy. Superimposed vitamin deficiencies and toxic alcohol additives are rarely implicated currently. Mutations in *TTN* and other DCM disease genes can be identified in ~10% of patients with presumed alcohol cardiomyopathy.

Many patients with alcoholic cardiomyopathy are fully functional in their daily lives without apparent stigmata of alcoholism. The cardiac impairment in severe alcoholic cardiomyopathy is the sum of both permanent damage and a substantial component that is reversible after cessation of alcohol consumption. Atrial fibrillation occurs commonly both early in the disease ("holiday heart") and in advanced stages. Medical therapy includes conventional guideline-directed medical therapies with neurohormonal, mineralocorticoid receptor, and β adrenoreceptor antagonists as well as sodium-glucose cotransporter 2 inhibitors with diuretics as needed for fluid management and careful attention to electrolyte repletion. Withdrawal should be supervised to avoid exacerbations of heart failure or arrhythmias and ongoing support arranged. Even with severe disease, marked improvement can occur within 3–6 months of abstinence, but the prognosis is grim if heavy alcohol consumption continues.

Cocaine, amphetamines, and related catecholaminergic stimulants can produce chronic cardiomyopathy as well as acute ischemia, tachyarrhythmias, malignant hypertension, aortic dissection, and stroke. Cardiac pathology reveals microinfarcts consistent with small vessel ischemia, similar to those seen with pheochromocytoma, and thrombosis secondary to endothelial dysfunction in the case of cocaine. Regular cannabis use has been linked to increased risk of atrial fibrillation, myocardial infarction, and stroke in patients with and without other known risk factors. Cannabis is not specifically implicated as a cause of cardiomyopathy in population studies but is of concern as the potency of both inhaled and edible products continues to increase.

Chemotherapy agents are the most common drugs implicated in toxic cardiomyopathy. Judicious use balances risks of the malignancy and the risks of cardiotoxicity presented not only by the drug regimens but also by the patient's cardiovascular profile and possibly genetic factors influencing myocyte response to injury. Receipt of cardiotoxic drugs or radiation may warrant designation as "stage B" heart failure, with asymptomatic changes in cardiac structure and biomarkers. Clinical recognition can be delayed as some symptoms can overlap with cancer and the prognosis with heart failure may be worse than for the underlying cancer.

Anthracyclines (e.g., doxorubicin) cause characteristic histologic changes of vacuolar degeneration and myofibrillar loss. Multiple mechanisms have been implicated, involving reactive oxygen species and iron compounds, mitochondrial damage, transcription factors such as hypoxia-induced factor, and, most recently, inhibition of topoisomerase II involved in DNA repair. Risk for cardiotoxicity increases with older age, obesity, hypertension, diabetes mellitus, preexisting cardiac disease, higher doses or combination therapies, and left chest irradiation. Systolic dysfunction can occur acutely with symptoms of heart failure noted soon after drug administration, but more often is detected by surveillance echocardiography during the first year after exposure. Doxorubicin cardiotoxicity generally does not result in marked left ventricular dilation, such that stroke volume and systemic perfusion can be low with only a modest reduction of ejection fraction. Therapy

for reduced ejection fraction due to anthracycline therapy includes β-adrenergic receptor blockade and inhibition of the renin-angiotensin system, with conflicting data on whether these agents decrease toxicity when given in parallel with chemotherapy. The use of dexrazoxane, an intracellular iron chelating agent, can prevent anthracycline cardiomyopathy, but there is no consensus on when it should be used owing to concerns that it might attenuate the efficacy of cancer therapies. Once thought to have an inexorable downward course, many patients with symptomatic heart failure can improve to near-normal function with careful management, including prevention of "second-hit" insults such as atrial fibrillation or hypertension. The course differs for some children treated with these agents before puberty, in whom inadequate growth of the heart may lead to refractory heart failure as they reach their twenties.

Trastuzumab (Herceptin) is one of the humanized monoclonal antibodies that interfere with human epidermal growth receptor 2 (HER2), which is crucial for growth of some tumors, such as breast cancer, and for cardiac adaptation. Cardiotoxicity is highest when anthracyclines are administered in conjunction with trastuzumab; however, less toxicity is seen now when these agents are combined compared with the toxicity observed previously with paclitaxel for breast cancer. Although more often reversible than anthracycline cardiotoxicity, trastuzumab cardiomyopathy may persist in about a third of affected patients and can progress to clinical heart failure and death. For cardiotoxicity with anthracyclines or trastuzumab, therapy is recommended as for other causes of reduced ejection fraction.

Cardiotoxicity with *cyclophosphamide and ifosfamide* generally occurs acutely and with very high doses. 5-Fluorouracil, cisplatin, and some other alkylating agents can cause recurrent coronary spasm that occasionally leads to depressed contractility. Acute administration of interferon-α, interleukin 2, and other cytokine-based therapies can cause pericarditis, hypotension, and arrhythmias. Clinical heart failure occurring during their chronic administration usually resolves after discontinuation.

Vascular endothelial growth factor (VEGF), produced endogenously or by tumors, enhances angiogenesis by activating the VEGF signaling pathways. Monoclonal antibodies and many small-molecule *tyrosine kinase inhibitors* that affect VEGF are in use for different malignancies. Although these agents are "targeted" at specific tumor receptors or pathways, the biologic conservation of signaling pathways means that some of these drugs also find targets in the cardiovascular and other organ systems. Blood pressures increase in most patients during therapy, attributed to an imbalance between endogenous vasodilators and vasoconstrictors and alteration of glomerular function. Hypertension and proteinuria can develop with these agents, similar to preeclampsia, and presentation is associated with increased risk of future cardiac disease. Recognition of cardiotoxicity during therapy with these agents is complicated because they occasionally cause peripheral fluid accumulation (ankle edema, periorbital swelling, pleural effusions) due to local factors rather than elevated central venous pressures. Therapeutic approaches include management of associated hypertension, withdrawal of the tyrosine kinase inhibitor (when possible), and conventional treatment for heart failure. Newer tyrosine kinase inhibitors effective against multiple kinases may have more complex off-target effects. This includes the Bruton tyrosine kinase inhibitors (e.g., ibrutinib), which are used as primary therapy for lymphoid malignancies, with predominant cardiovascular risks of atrial and ventricular arrhythmias in addition to heart failure.

Proteasome inhibitors used to treat multiple myeloma are associated with an increased risk of hypertension, ischemic events, thromboembolism, and heart failure. The more potent agent, carfilzomib, appears more cardiotoxic than bortezomib. Other treatments for myeloma include immunomodulatory drugs including lenalidomide and thalidomide, which may cause heart failure in addition to risks of venous thromboembolism. Mitogen-activated extracellular signal regulated kinase (MEK) inhibitors used for metastatic melanoma may cause hypertension and cardiomyopathy, especially when co-administered with rapidly accelerated fibrosarcoma (RAF) inhibitors.

The most dramatic toxicity of contemporary cancer therapy results from combined immune checkpoint inhibitors, which block the natural counterregulatory T-cell suppression and unleash potentially fatal inflammation directed toward multiple organs that can include the heart and vessels. These are discussed in **Chap. 268** on noninfectious myocarditis.

Other therapeutic drugs that can cause cardiotoxicity during chronic use include tumor necrosis factor α antagonists for rheumatologic conditions, and carbamazepine, clozapine, and lithium for neurologic and psychiatric diagnoses. Antiretroviral therapies for HIV have been implicated in cardiomyopathy. Chloroquine and hydroxychloroquine, which are widely used for systemic lupus erythematosus and rheumatoid arthritis, can decrease ejection fraction with either restrictive or dilated phenotype, often in association with conduction block. The presumed mechanism of toxicity is impaired lysosomal function, with accumulation of inclusion bodies that can be seen on cardiac biopsy.

Toxic exposures can cause arrhythmias or respiratory injury acutely during accidents. Chronic exposures implicated in cumulative cardiotoxicity include cobalt, arsenicals, lead, and mercury. Treatment for these disorders includes removing exposure to the toxin and standard medical therapy for heart failure with reduced ejection fraction. Cardiomyopathy secondary to cobalt toxicity may be secondary to impaired myocardial energetics and is more common in the setting of hypothyroidism and dietary protein and thiamine deficiency. Cobalt cardiomyopathy usually presents with polycythemia, hypothyroidism, and goiter due to the effects of cobalt on red cell production and thyroxine. Most historical causes of pathologic cobalt exposure are no longer relevant (e.g., treatment of anemia associated with end-stage disease, beer foam stabilization), and recent cases have been attributed to industrial exposures and cobalt alloy prosthetic hips. Diagnosis occurs in the setting of cobalt exposure and can be confirmed by the presence of electron microscopy dense intramitochondrial particles.

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy (PPCM) develops during the last trimester or within the first 5–6 months after pregnancy, most commonly within the first 2 weeks after delivery. Between 1:1000 and 1:4000 deliveries in the United States are affected. Risk factors include older maternal age, increased parity, twin pregnancy, malnutrition, and tocolytic therapy for premature labor. Up to half of cases occur in the setting of hypertensive disorders of pregnancy, including preeclampsia. Risk of PPCM is fourfold higher in black women, in whom recovery of normal LVEF takes longer and is less likely than in white women.

Several of the risk factors contribute to antiangiogenic signaling through secreted inhibitors of VEGF, such as soluble FLT1 (sFLT1), high levels of which predict worse outcome. An abnormal cleavage fragment of the nursing hormone prolactin has also been implicated in decreased vascular response during oxidative stress, and investigation is ongoing with the prolactin inhibitor bromocriptine after mixed results of small trials. Multiple other hormonal changes of pregnancy and secretory products from the placenta may interact to cause cardiac dysfunction, suggesting a "vasculohormonal model" in the development of PPCM. Genetic contribution has also been recognized. Similar to other DCM populations, truncating mutations in *TTN* are found in ~15% of cases of PPCM and associated with lower rates of recovered systolic function. Pregnancy thus represents another environmental trigger for accelerated phenotypic expression of genetic cardiomyopathy.

PPCM usually presents with evidence of congestion, and criteria generally include an LVEF ≤0.45 presenting toward the end of pregnancy in the absence of another cardiac diagnosis. Pregnancy can unmask previously unrecognized heart disease but usually does so by the second trimester, when the major circulatory changes have already occurred. Toward the end of pregnancy, edema and dyspnea may be mistakenly attributed to the pregnancy itself, but elevated levels of brain natriuretic peptide or troponin or evidence of elevated central venous pressures are clues to cardiac dysfunction, particularly in the setting of hypertension. Echocardiography is usually sufficient for

diagnosis, but in complex cases, cardiac magnetic resonance imaging (MRI) can be considered, but gadolinium should not be used.

Most cases of PPCM present within the first week after delivery, usually with increasing edema and dyspnea when urine output does not keep up with mobilization of fluid. Both atrial and ventricular arrhythmias can occur. It is important to exclude other complications of pregnancy such as pulmonary emboli and coronary artery dissection. Genetic testing should be considered as the results may impact the mother, in whom positive genetic testing predicts less recovery, and also other family members, too.

Initial treatment for PPCM includes loop diuretics as needed to restore normal volume status. Prior to delivery, close collaboration with the maternal-fetal medicine team is necessary to adjust therapies to stabilize the gravid mother while protecting the fetus. Digoxin and beta blockers can be used if needed for arrhythmias, and hydralazine/nitrate combinations can be used for hypertension, but renin-angiotensin system inhibitors should not be given due to adverse fetal effects. Hemodynamic instability may require ongoing hemodynamic monitoring, and plans should be in place for emergency delivery if necessary. When the mother is hemodynamically stable in the postpartum period, metoprolol tartrate, enalapril, and spironolactone have been shown to be compatible with breastfeeding. PPCM with LVEF <0.35 or marked dilation carries increased incidence of left ventricular thrombus and embolic risk, so anticoagulation is usually prescribed for the first 6 weeks once obstetric bleeding has resolved. Breastfeeding was once prohibited but now is generally encouraged in patients in whom fluid balance can be maintained through the high oral fluid intake required. For patients who are not breastfeeding, there is an ongoing large, randomized trial to determine the impact of bromocriptine on PPCM outcomes.

Improvement of LVEF to ≥0.50 occurs in 50–80% of PPCM, often within 6 months, when other cardiac diagnoses have been carefully excluded. Recovery is less likely with LVEF <0.30, left ventricular end-diastolic dimension ≥0.60, black race, and presentation >6 weeks after delivery. Elevated levels of natriuretic peptides, troponin, and sFLT1 have also been associated with less recovery. Patients with LVEF <0.35 have a higher risk of life-threatening arrhythmias during initial presentation and early after discharge, for which consideration of wearable defibrillators is reasonable. This is burdensome both physically and psychologically to a new mother, and more data are needed to help stratify risk. One-year mortality rates after PPCM have ranged in the United States from 4% in one study to 11% in a population of black women, and have been reported as up to twofold higher in Africa.

METABOLIC CAUSES OF CARDIOMYOPATHY

Endocrine disorders affect multiple organ systems, including the heart. *Hyperthyroidism and hypothyroidism* do not often cause clinical heart failure in an otherwise normal heart but commonly exacerbate heart failure. Clinical signs of thyroid disease may be masked, so tests of thyroid function are part of the routine evaluation of cardiomyopathy. Hyperthyroidism should always be considered with new-onset atrial fibrillation or ventricular tachycardia or atrial fibrillation in which the rapid ventricular response is difficult to control. The most common current reason for thyroid abnormalities in the cardiac population is the treatment of tachyarrhythmias with amiodarone, a drug with substantial iodine content. Hypothyroidism should be treated with very slow escalation of thyroid supplements to avoid exacerbating tachyarrhythmias and heart failure. Hyperthyroidism and heart failure create a dangerous combination that merits very close supervision, often hospitalization, during titration of antithyroid medications, during which decompensation of heart failure may occur precipitously and fatally.

Pheochromocytoma is rare but should be considered when a patient has heart failure and very labile blood pressure and heart rate, sometimes with episodic palpitations **(Chap. 399)**. Patients with pheochromocytoma often have postural hypotension. In addition to α-adrenergic receptor antagonists, definitive therapy requires surgical extirpation. Very high renin states, such as those caused by renal artery stenosis, can lead to modest depression in ejection fraction with little or no ventricular dilation and markedly labile symptoms with flash pulmonary edema, related to sudden shifts in vascular tone and intravascular volume.

Controversies remain regarding whether diabetes mellitus and obesity are sufficient to cause cardiomyopathy with reduced ejection fraction. Most heart failure in diabetes mellitus results from epicardial coronary disease, with further increase in coronary artery risk due to accompanying hypertension and renal dysfunction. Cardiomyopathy may result in part from insulin resistance and increased advanced-glycosylation end products, which impair both systolic and diastolic function. However, much of the dysfunction can be attributed to scattered focal ischemia resulting from distal coronary artery tapering and limited microvascular perfusion even without proximal focal stenoses. Diabetes mellitus is a typical factor in heart failure with "preserved" ejection fraction, along with hypertension, advanced age, and female gender.

The existence of a cardiomyopathy due to obesity is generally accepted, but the overlap is not well defined with the syndrome of heart failure with preserved ejection fraction (HFpEF). In addition to cardiac involvement from associated diabetes mellitus, hypertension, and vascular inflammation of the metabolic syndrome, obesity alone is associated with impaired excretion of excess volume load, which, over time, can lead to increased wall stress and secondary adaptive neurohumoral responses. Fluid retention may be aggravated by large fluid intake and the rapid clearance of natriuretic peptides by adipose tissue. In the absence of another obvious cause of cardiomyopathy in an obese patient with systolic dysfunction without marked ventricular dilation, effective weight reduction is often associated with major improvement in ejection fraction and clinical function. Improvement in cardiac function has been described after successful bariatric surgery, although all major surgical therapy poses increased risk for patients with heart failure. Postoperative malabsorption and nutritional deficiencies, such as calcium and phosphate deficiencies, may be particularly deleterious for patients with cardiomyopathy.

Nutritional deficiencies can occasionally cause DCM but are not commonly implicated in developed countries. Beriberi heart disease due to thiamine deficiency can result from poor nutrition in undernourished populations and in patients deriving most of their calories from alcohol and has been reported in teenagers subsisting only on highly processed foods. This disease is initially a vasodilated state with very-high-output heart failure that can later progress to a low-output state; thiamine repletion can lead to prompt recovery of cardiovascular function. Abnormalities in carnitine metabolism can cause dilated or restrictive cardiomyopathies, usually in children. Deficiency of trace elements such as selenium can cause cardiomyopathy (Keshan's disease).

Calcium is essential for excitation-contraction coupling. Chronic deficiencies of calcium, such as can occur with hypoparathyroidism (particularly postsurgical) or intestinal dysfunction (from diarrheal syndromes and following extensive resection), can cause severe chronic heart failure that responds over days or weeks to vigorous calcium repletion. Phosphate is a component of high-energy compounds needed for efficient energy transfer and multiple signaling pathways. Hypophosphatemia can develop during starvation and early refeeding following a prolonged fast and occasionally during hyperalimentation.

Hemochromatosis is variably classified as a metabolic or storage disease **(Chap. 426)**. It is included among the causes of restrictive cardiomyopathy, but the clinical presentation is often that of a DCM. The autosomal recessive form is related to the *HFE* gene. With up to 10% of the population heterozygous for one mutation, the clinical prevalence might be as high as 1 in 500. The lower observed rates highlight the limited penetrance of the disease, suggesting the role of additional genetic and environmental factors such as alcoholism affecting clinical expression. Cardiac siderosis can also be acquired from iron overload due to hemoglobinopathies in patients treated with recurrent transfusions. Excess iron is deposited in the perinuclear compartment of cardiomyocytes, with resulting disruption of intracellular architecture and

FIGURE 269-1 Hemochromatosis. mitochondrial function. A diagnosis of systemic iron overload is made from measurement of serum iron and transferrin saturation, with a threshold of >60% for men and >45–50% for women. MRI is used to quantitate iron stores in the liver and heart. While endomyocardial biopsy tissue can be stained for iron **(see Chap. 270 and Fig. 269-1)**, a diagnosis of cardiac iron overload is made principally by MRI and biopsy is not usually needed. If diagnosed early, hemochromatosis can often be managed by repeated phlebotomy to remove iron. For more severe iron overload, iron chelation therapy with desferrioxamine (deferoxamine) or deferasirox can help to improve cardiac function if myocyte loss and replacement fibrosis are not too severe.

Inborn disorders of metabolism occasionally present with DCM, although they are most often associated with restrictive cardiomyopathy **(Chap. 267, Table 267-1)**.

TAKOTSUBO SYNDROME OR CARDIOMYOPATHY

Apical ballooning or "takotsubo" syndrome, also referred to as stress-induced cardiomyopathy or "broken heart syndrome," is often classified as a cardiomyopathy, although its distinct acute presentation, typical ventricular shape, and frequent rapid recovery differ from most other cardiomyopathies. It occurs typically in older women after sudden intense emotional or physical stress. The ventricle shows global ventricular dilation with basal contraction, forming the shape of the narrow-necked jar (*takotsubo*) used in Japan to trap octopuses. Originally described in Japan, it is well recognized elsewhere during emergency cardiac catheterization and intensive care unit admissions for noncardiac conditions. Presentations include pulmonary edema, hypotension, and chest pain with electrocardiogram (ECG) changes mimicking an acute infarction. The left ventricular dysfunction extends beyond a specific coronary artery distribution and generally resolves within days to weeks. Animal models and ventricular biopsies suggest that this acute cardiomyopathy may result from intense sympathetic activation with heterogeneity of myocardial autonomic innervation, diffuse microvascular spasm, and/or direct catecholamine toxicity. Cardiac MRI **(Fig. 269-2)** demonstrates diffuse myocardial edema without necrosis and abnormal myocardial calcium handling. Coronary angiography may be required to rule out acute coronary occlusion.

A similar picture to takotsubo can also be caused a coronary embolus in the absence of atherosclerotic coronary artery disease. No therapies have been proven beneficial, but reasonable strategies include nitrates for pulmonary edema; combined alpha and beta blockers rather than selective beta blockade if hemodynamically stable; and magnesium for arrhythmias related to QT prolongation. An intra-aortic balloon pump is occasionally employed to improve critically low cardiac output, but only if there is no left ventricular outflow tract obstruction. The long-term prognosis is generally good, with the lowest mortality associated with episodes triggered by emotional rather than physical triggers. In-hospital complications and mortality are similar to those with acute myocardial infarction. Recurrence occurs in 10% of patients at an estimated rate of 2%/year.

270 Amyloidosis and Other Restrictive Cardiomyopathies

Rodney H. Falk, Neal K. Lakdawala, Lynne Warner Stevenson, Joseph Loscalzo

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy (RCM) is dominated by abnormal diastolic function within a noncompliant ventricle, often with mildly decreased contractility and ejection fraction (usually 30–50%). Both atria are enlarged, sometimes massively. Mild left ventricular dilation can be present. End-diastolic pressures are usually elevated in both ventricles, with preservation of resting cardiac output until late in the disease. Subtle exercise intolerance is usually the first symptom but is often not recognized until after clinical presentation with congestive symptoms. The restrictive diseases often present with relatively more right-sided symptoms, such as edema, abdominal discomfort, and ascites, although filling pressures are elevated in both ventricles. The cardiac impulse is less displaced than in dilated cardiomyopathy and less dynamic than in hypertrophic cardiomyopathy. A fourth heart sound is more common than a third heart sound in sinus rhythm, but atrial fibrillation is common. Jugular venous pressures often show rapid Y descents and may increase during inspiration (positive Kussmaul sign).

Most causes of RCM are "infiltrative," due to infiltration of abnormal substances between myocytes, with the amyloidoses being the most common causes of RCM. RCM can also result from storage of abnormal metabolic products within myocytes. RCM due to acquired fibrotic injury is most commonly caused by radiation or connective tissue disease and less commonly by hypereosinophilic injury **(see Chap. 268 and Table 270-1)**.

RCM can also be secondary to genetic causes of primary cardiomyopathy, including variants in *DES* or as a forme fruste of hypertrophic cardiomyopathy caused by sarcomere variants. The most common differential diagnosis is between RCM and constrictive pericardial disease, as both often present with dominant right-sided heart failure.

In the absence of specific therapy for the etiology of RCM, such as is now available for some patients with amyloidosis, general strategies are focused on maintenance of optimal volume status, which is generally a compromise between adequate ventricular filling and systemic decongestion. As ventricular filling and stroke volume are often restricted, therapy with beta blockers can reduce heart rate, contractility, cardiac output, and functional reserve. Vasodilation may not be well tolerated. Other than diuretics, therapies proven effective for dilated cardiomyopathy and other heart failure with reduced ejection fraction are not recommended for routine use in RCM.

TABLE 270-1 Causes of Restrictive Cardiomyopathies (RCM)

Infiltrative (Between Myocytes)
Amyloidosis
Light chain (AL) amyloid
Familial (variant transthyretin)[a]
Wild-type (normal) transthyretin
Inherited metabolic defects[a]
Storage (Within Myocytes)
Hemochromatosis (iron),[a] also with dilated cardiomyopathy phenotype when advanced
Inherited metabolic defects[a]
Fabry's disease
Glycogen storage disease (II, III)
Fibrotic
Radiation
Scleroderma
Endomyocardial
Possibly related fibrotic diseases
Tropical endomyocardial fibrosis
Hypereosinophilic syndrome (Löffler's endocarditis)
Carcinoid syndrome
Radiation
Drugs: e.g., serotonin, ergotamine
Genetic Variants Affecting Cardiomyocyte Function
Occasional RCM due to genetic variants more commonly associated with dilated or hypertrophic cardiomyopathy
RCM and skeletal muscle involvement with desminopathy due to pathogenic *DES* variants

[a]Contribution of genetic background.

AMYLOIDOSIS

Amyloidosis is a systemic disease characterized by the deposition of fibrillar proteinaceous material primarily in the extracellular space of one or more organs. Although there are many precursor proteins that have been shown to cause amyloidosis **(see Chap. 117)**, the unifying feature of all types of amyloid is its staining characteristics. Amyloid is a noncellular material deposited in the extracellular space that stains with Congo red and exhibits "apple-green birefringence" when viewed under polarized light microscopy. When viewed with electron microscopy, amyloid deposits are seen to consist of nonbranching fibrils ~10 nm in diameter and a few micrometers in length. From a cardiac standpoint, there are two main precursor proteins that cause most cases of amyloid cardiomyopathy: transthyretin (TTR), produced in the liver, and light chains produced by abnormal plasma cells. TTR amyloidosis may be caused by a genetic variant of TTR (ATTRv) or by wild-type TTR (ATTRwt), and variant TTR is generally considered to be less stable than wild-type TTR. Once a diagnosis of amyloidosis has been made, it is critically important to determine the precise precursor protein because treatment is specific to the type of amyloid and incorrect typing will lead to inappropriate therapy.

PATHOLOGIC MECHANISMS OF HEART FAILURE IN CARDIAC AMYLOIDOSIS

All forms of cardiac amyloidosis have a similar appearance on gross and microscopic examination **(Figs. 270-1 and 270-2)**.

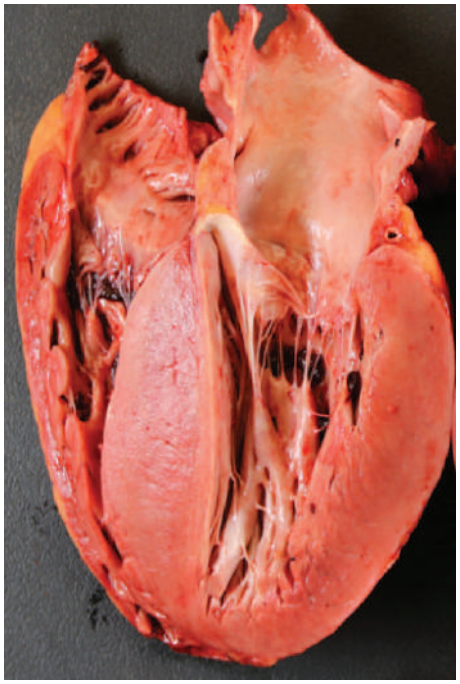

FIGURE 270-1 Gross pathology of the heart in amyloid cardiomyopathy. The left ventricle (LV) is severely thick due to amyloid infiltration. The LV cavity is small with markedly thick walls due to amyloid infiltration. The right ventricle is mildly thickened, and the left atrium (partly excised) is dilated. *(Courtesy of Dr. Richard Mitchell, Brigham and Women's Hospital Department of Pathology.)*

The extracellular deposits of amyloid result in an increase in the mass of the heart, due to expansion of the extracellular space. Both left and right ventricular walls demonstrate increased thickness, and decreased compliance and the left ventricular cavity may be relatively small, leading to a restrictive pathophysiology. The right ventricular cavity is often normal in size but may dilate in advanced disease. The atria are usually dilated due to the chronic elevation of biventricular diastolic filling pressure and may dilate further with the onset of atrial arrhythmias. Histologically, amyloid deposits are widespread throughout the heart so that endomyocardial biopsy is almost always diagnostic in cases of cardiac amyloidosis.

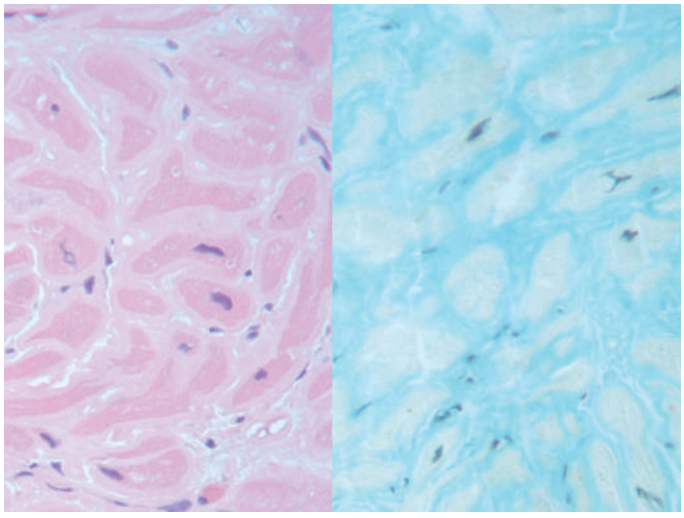

FIGURE 270-2 Histology of amyloid cardiomyopathy. *Left panel:* Hematoxylin and eosin stain showing extensive extracellular cardiac amyloid deposition resulting in separation and distortion of cardiomyocytes. The amyloid stains light pink and the myocytes are nucleated and stain a deeper pink. *Right panel:* Specimen from same patient stained with sulfated Alcian blue. The amyloid stains "sea green," and the myocytes are pale yellow-gray. Magnification ×60. *(Courtesy of Dr. Richard Mitchell, Brigham and Women's Hospital Department of Pathology.)*

CLINICAL FEATURES OF CARDIAC AMYLOIDOSIS

There are some clinical features of light chain (AL) amyloidosis and TTR amyloidosis that suggest one or the other diagnosis, but the cardiac features are similar enough that the final diagnosis of amyloid type often relies upon precise typing of a cardiac or extracardiac tissue biopsy. The most common clinical presentation is congestive heart failure. Although both ventricles are usually heavily infiltrated by the time congestive heart failure occurs, patients tend to present with symptoms of predominant right heart failure, namely peripheral edema and, not infrequently, ascites. Despite the clinical predominance of right ventricular failure, cardiac catheterization will reveal considerable elevation of both left and right ventricular filling pressure. Atrial arrhythmia, particularly atrial fibrillation, is a common presenting feature, particularly in TTR amyloidosis, and may occur at a time when the left ventricle is only mildly thick, precipitating heart failure in a previously asymptomatic patient. The onset of atrial fibrillation may be associated with symptoms of dyspnea, often more severe than is seen in nonamyloid patients with this arrhythmia. Refractory atrial arrhythmia, whether to antiarrhythmic drugs or characterized by failure to maintain sinus rhythm after repeated ablation procedures, should raise the possibility of TTR cardiac amyloidosis, particularly if occurring in a patient in the mid-60s or older without other apparent reason for the atrial fibrillation.

Cardiovascular physical examination in the symptomatic patient with cardiac amyloidosis reveals a normal or low pulse pressure. The apex beat may be difficult to palpate but, if felt, is usually only mildly displaced. The jugular venous pressure is almost always elevated and frequently demonstrates a paradoxical rise on inspiration (Kussmaul sign). The first and second heart sounds tend to be normal. Despite congestive heart failure, a third heart sound is very rarely heard, due to the restrictive pathophysiology and its associated impairment of ventricular relaxation. Similarly, a fourth heart sound is also unusual as the infiltrated atrium is rarely able to generate much contractile pressure. Pleural effusions, primarily caused by heart failure (but occasionally aggravated by associated hypoalbuminemia from nephrotic syndrome or by the presence of pleural amyloidosis) are quite common. Cardiac murmurs due to amyloid-associated valve disease are relatively uncommon, although a tricuspid regurgitation murmur may occasionally be present. There is an association between aortic valve stenosis and TTR amyloidosis, and a murmur of aortic stenosis may be present. Whether amyloid causes aortic stenosis or simply aggravates or precipitates heart failure in a patient with unrelated aortic valve disease is unclear. In addition to the cardiovascular examination, a careful systemic physical examination is mandatory. In advanced heart failure, hepatomegaly due to congestive heart failure is common, but an unusually hard liver may represent amyloid infiltration of the liver—something that occurs in AL amyloidosis but not TTR. The blood pressure should be checked in the supine, seated, and standing positions, seeking an abnormal postural drop. If present, this likely represents associated autonomic neuropathy, which is a feature of AL amyloidosis and some forms of variant TTR amyloidosis but not wild-type TTR amyloidosis. Macroglossia or periorbital bruising, if present, strongly suggest AL amyloidosis, whereas a history of bilateral carpal tunnel syndrome or the finding of a ruptured biceps tendon points toward TTR amyloidosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with biventricular failure manifesting predominantly as edema, in association with a thick left ventricle but without a history of severe hypertension, is small. Hypertensive heart disease is usually associated with left ventricular hypertrophy on the electrocardiogram (ECG), whereas this ECG finding is uncommon in amyloidosis, and it requires several years of severe uncontrolled hypertension to produce the degree of wall thickening equal to that seen in amyloidosis. While amyloidosis, particularly ATTR, can have asymmetric left ventricular thickening, the clinical distinction between hypertrophic cardiomyopathy and amyloidosis is usually fairly clear, since the former rarely presents with peripheral edema and usually has left ventricular hypertrophy (LVH) on the ECG. Other infiltrative cardiomyopathies such as Fabry disease may have typical skin

manifestations and usually LVH on the ECG. The rare mitochondrial cardiomyopathies may have an echocardiographic appearance similar to amyloidosis but have different noncardiac clinical features, such as maternally inherited diabetes, deafness, and recurrent strokes. Patients with advanced diabetes may have heavy proteinuria and heart failure, but their history of diabetes is obvious, and the echocardiogram does not show features suggestive of amyloid heart disease. In the era before echocardiography, constrictive pericarditis, often presenting with edema, ascites, and elevated jugular venous pressure with a Kussmaul sign, was the major differential of amyloid heart disease. Constrictive pericarditis is less common nowadays, and echocardiography can easily distinguish between the two entities.

AL AMYLOIDOSIS OF THE HEART

AL amyloidosis is a plasma cell disorder closely related to multiple myeloma. It is described in detail in **Chap. 117**. An excessive production of abnormal lambda, or (less commonly) kappa, free light chains produced by abnormal clonal bone marrow plasma cells results in amyloid deposits in multiple organs, with heart and kidney being the most common organs involved. AL amyloidosis is closely related to multiple myeloma, with which it may occasionally overlap. It is an aggressive disease, and cardiac involvement, either alone or in combination with other major organ involvement, carries the worst survival, with a median survival from onset of heart failure to death in untreated patients of ~6 months. This short survival underscores the urgency of pursuing a diagnosis of AL amyloidosis once suspected, as therapy can markedly improve duration and quality of life and must be instituted as soon as the diagnosis is made. In addition to the general features of heart failure noted above, there are several clinical noncardiac clues to AL amyloidosis as the etiology of congestive heart failure. These indicate the presence of a multisystem disease and include significant proteinuria, neuropathy, periorbital purpura (virtually pathognomonic of AL amyloidosis and occurring in 20–30% of cases), and macroglossia (~10% of cases).

TTR AMYLOIDOSIS OF THE HEART

Patients with wild-type TTR amyloidosis cardiomyopathy and those with amyloid cardiomyopathy caused by variant TTR may have subtle differences in presentation. The less common variant TTR cardiomyopathy may be associated with amyloid neuropathy, which can vary between mild sensory neuropathy and a rapidly progressive severe sensorimotor neuropathy with or without autonomic nervous system involvement. Myocardial infiltration may be extensive in patients with severe variant transthyretin neuropathy, but cardiac symptoms can be relatively mild in these patients, either because the limitation of physical activity due to the neuropathy masks exercise intolerance or because autonomic neuropathy acts to reduce peripheral resistance, decreasing the work of the heart. If autonomic neuropathy is present, postural hypotension can be highly symptomatic and postural measurements of blood pressure are mandatory. A family history of neuropathy or cardiomyopathy may be elicited in these patients and, when neuropathy is present, may have been misdiagnosed as other neurologic conditions. In the United States, the most common TTR variant causing TTR amyloid cardiomyopathy is the substitution of valine for isoleucine at position 122, Val122Ile. This variant is present in ~3.5% of the U.S. population of African descent and presents as a late-onset restrictive cardiomyopathy usually in the seventh decade onward. The penetrance of clinical disease is incomplete, and the family history is often lacking or unknown. Neuropathy in this mutation is very mild or absent, although carpal tunnel syndrome, often preceding the onset of heart failure by several years, is commonly present. The clinical features of other forms of variant TTR amyloidosis can vary considerably, somewhat dependent on the transthyretin mutation, but in the case of the Val122Ile variant, it tends to be a relatively rapid progressive infiltrative cardiomyopathy with a median survival of 2–3 years following the onset of heart failure in untreated patients.

Once considered a rare form of cardiac amyloidosis, TTR deposition derived from native (wild-type) transthyretin is now considered the most common form of amyloidosis. It affects mainly men in the latter half of their seventh decade and eighth decades but may occasionally present at a younger age and often presents in the ninth decade onward. Men are almost 20 times more likely than women to be diagnosed with wild-type TTR amyloidosis, and when it does occur in women, it tends to present at a later age and to have a more indolent course. On average, the untreated median survival from the onset of heart failure to death is around 4–5 years, with death being due primarily to progressive congestive heart failure rather than to sudden death. Current therapies have slowed the disease progression and improved survival. Both wild-type and mutant TTR cardiomyopathy have a subclinical phase, probably of several years, during which there is a progressive infiltration of the heart with amyloid, and by the time heart failure occurs, 30–50% of the involved heart weight is due to amyloid. Atrial arrhythmias, most commonly atrial fibrillation or atrial flutter, may be the presenting feature of the disease, and when they occur, they often precipitate or worsen heart failure. In contrast to AL amyloidosis, the heart in ATTRwt is the sole major organ to be clinically involved, although histologic examination of the lungs and gut often shows fairly extensive amyloid deposits. TTR also had a predilection for ligaments and tendons, and a history of carpal tunnel syndrome, spinal stenosis, or ruptured bicep tendon, often occurring 5–8 years before heart failure, can be elicited in about half the patients with this disorder.

DIAGNOSIS

The diagnosis of cardiac amyloidosis rests upon a clinical suspicion combined with imaging findings and, in many cases, a confirmatory biopsy. ECG voltage may be abnormally low, particularly in AL amyloidosis, but this is not always the case. Echocardiography is an extremely useful imaging modality. The echocardiogram in all forms of cardiac amyloidosis with heart failure shows increased left ventricular wall thickness without ventricular dilation and, frequently, biatrial enlargement **(Fig. 270-3)**.

The right ventricle may also show increased thickness of the free wall. Diastolic function is abnormal, and a restrictive pattern, consistent with elevated left ventricular diastolic pressures, is often seen. Although the left ventricular ejection fraction may be normal or near-normal, left ventricular longitudinal strain imaging, a tool for measuring the contraction of the left ventricle in the longitudinal plane, often shows a pattern in which strain is relatively preserved at the left ventricular apex and severely impaired at the base of the heart. Color-coding of this pattern results in a "bull's-eye" appearance, which is highly suggestive of cardiac amyloidosis **(Fig. 270-4)**.

Atrial function is often impaired, particularly in AL amyloidosis, and this is characterized by a very small transmitral A wave in patients

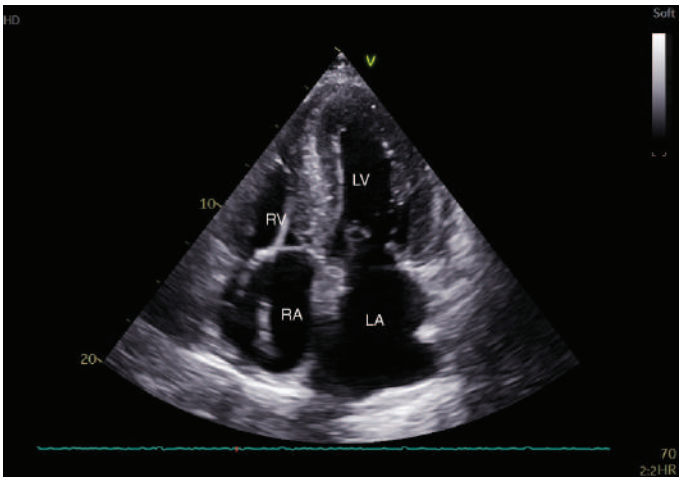

FIGURE 270-3 Echocardiogram (apical four-chamber view) showing typical appearance of amyloidosis. The left ventricular cavity is normal in size with thick walls, and there is biatrial enlargement. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

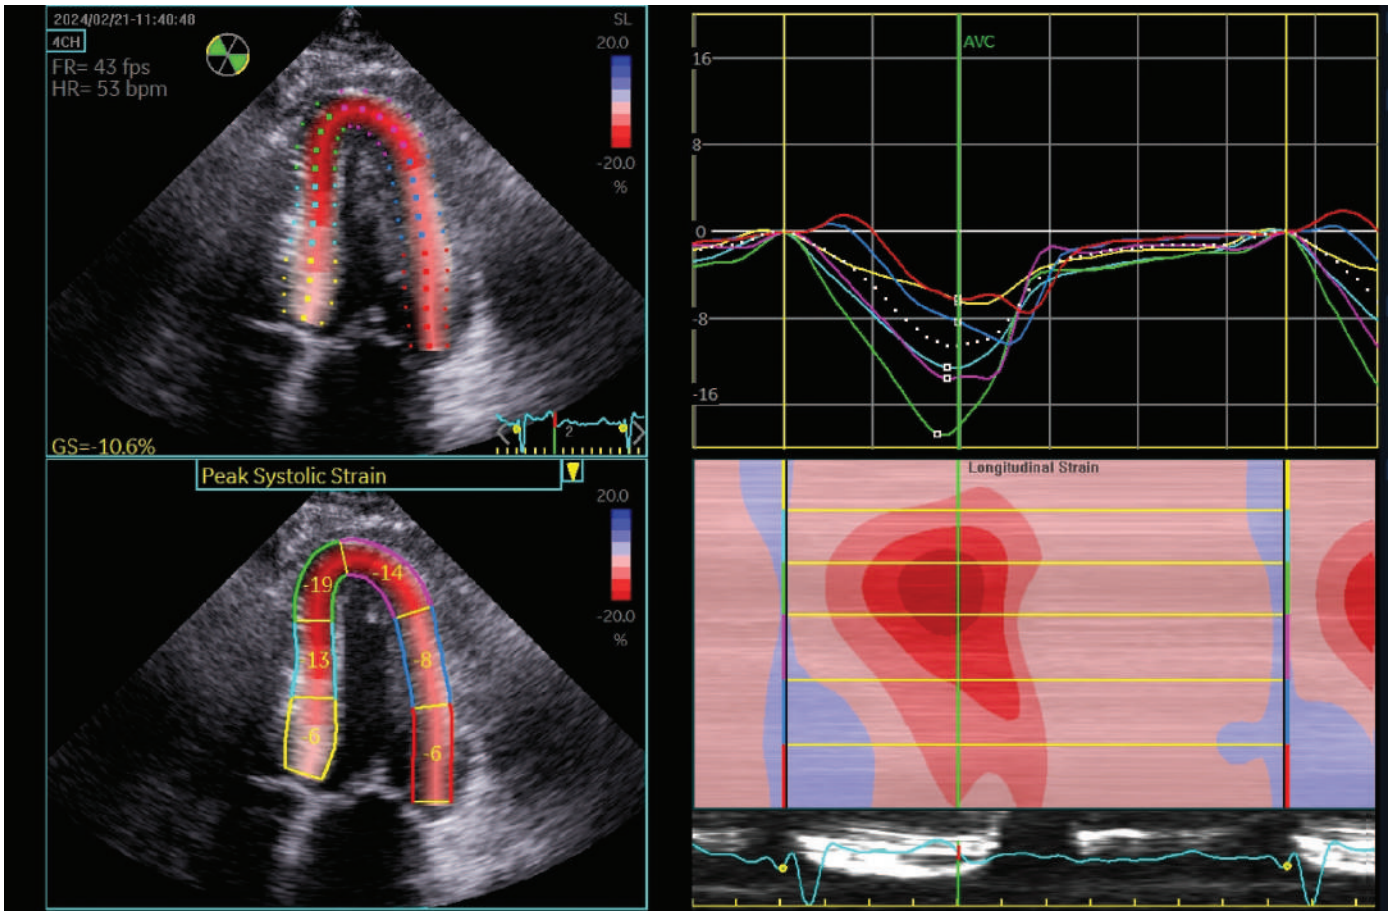

FIGURE 270-4 Left ventricular strain in amyloidosis. *Left panels* show outline of left ventricle divided into seven segments with numbers in bottom panel representing the percentage longitudinal systolic shortening of each segment. *Right top panel* shows corresponding curves for each segment, and *bottom right panel* shows color coding in which the apex codes bright red and base pink due to near-normal apical contraction, resulting in typical "bull's-eye" pattern of amyloidosis.

in sinus rhythm. This appearance may be associated with an increased risk of thromboembolism.

Echocardiography with the typical appearance may be enough to proceed to further laboratory evaluation for amyloidosis, but cardiac magnetic resonance is increasingly used in the diagnosis of suspected cardiomyopathy. The ventricle is seen to be abnormally thick, measurement of extracellular volume demonstrates marked expansion of the extracellular space due to amyloid deposition, and there is often extensive delayed gadolinium enhancement of the myocardium, associated with abnormal nulling of the images **(Figs. 270-5 and 270-6)**.

Taken together, these features are virtually pathognomonic of amyloid cardiomyopathy. Once amyloid cardiomyopathy is suspected, it is critical to determine the specific type of amyloid deposition. Tracers developed for bone imaging (technetium pyrophosphate or technetium 3,3-diphosphono-1,2-propanodicarboxylic acid [DPD]) are not usually taken up by the normal heart or in other forms of cardiac pathology, but there may be avid tracer uptake in patients with transthyretin amyloid cardiomyopathy **(Fig. 270-7)**.

Because patients with AL amyloid cardiomyopathy may occasionally have myocardial uptake of these tracers, it is critically important to measure serum free light chains, serum and urine protein electrophoresis, and serum and urine immunofixation to rule out a plasma cell dyscrasia. If these lab tests are all negative and the nuclear scan is positive, a diagnosis of transthyretin amyloidosis can be confidently made, provided that echocardiography or cardiac magnetic resonance is consistent with this diagnosis. Monoclonal gammopathy of unknown significance not uncommonly coexists with transthyretin amyloidosis and will be associated with abnormalities in testing for plasma cell dyscrasia. Thus, if light chain amyloidosis remains a possibility, despite the presence of a strongly positive pyrophosphate scan, consultation with a hematologist is important to help clarify the diagnosis. If uncertainty remains, an endomyocardial biopsy (or biopsy from other tissue) with definitive tissue typing (ideally by mass spectrometry) is required.

Almost all patients with light chain amyloidosis will have evidence of a plasma cell dyscrasia, and almost all of them will have elevation of either serum free lambda light chains or (less commonly) serum free kappa light chains. If light chain amyloidosis is clinically suspected and serum free light chains are elevated, it is mandatory to obtain a tissue biopsy to confirm the presence of amyloid deposits. Most patients with light chain amyloidosis have widespread systemic involvement, and a subcutaneous fat pad aspirate or deep skin biopsy will show amyloid deposits in the majority of cases, thus avoiding the necessity for a cardiac biopsy. If skin/fat biopsy is negative, it is reasonable to proceed to an endomyocardial biopsy. If amyloid heart disease is present, this will be positive in well over 90% of cases. In all cases, appropriate typing of the amyloid should be done to confirm the appropriate therapy. An algorithm with a suggested workup of suspected amyloidosis is shown in **Fig. 270-8**.

DIAGNOSIS AND TYPING OF CARDIAC AMYLOIDOSIS

Laboratory evaluation in patients with cardiac amyloidosis is generally nonspecific but may give some support to a suspected diagnosis. Electrolytes and complete blood count are usually normal or near normal. N-terminal prohormone of brain natriuretic peptide (NTproBNP) may be higher than anticipated for the degree of congestive heart failure, often in the range of 1000 to 2000 pg/mL even in the presence of relatively mild congestive heart failure. High-sensitivity troponin is frequently mildly elevated and may lead to a misdiagnosis of ischemic heart disease. In AL amyloidosis with renal involvement, heavy

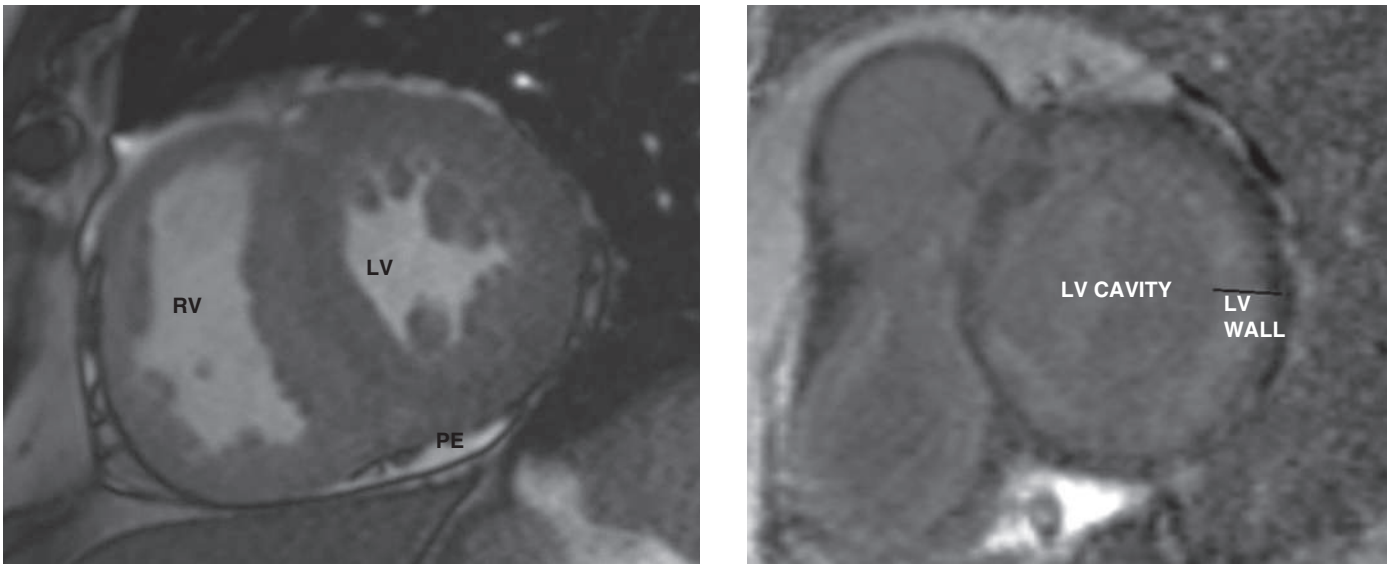

FIGURE 270-5 Typical cardiac magnetic resonance imaging (MRI) in amyloidosis. ***A.*** A typical cardiac MRI appearance in amyloid cardiomyopathy. The left ventricular (LV) cavity is small with a mildly dilated right ventricular (RV) cavity and thick LV walls. ***B.*** The appearance of late gadolinium enhancement after injection of gadolinium in the same patient. Two typical appearances are seen: the distinction between myocardium (*straight line*) and LV cavity is poor, due to delayed nulling of the myocardium, a near pathognomonic feature of cardiac amyloidosis. There is also extensive, transmural delayed gadolinium myocardial uptake due to severe amyloid infiltration. Another aspect of cardiac amyloidosis quantifiable by MRI (not shown) is measurement of extracellular volume, which is markedly increased in cardiac amyloidosis and helps to differentiate amyloid infiltration from true LV hypertrophy. PE, pericardial effusion. *(Image courtesy of Dr. Sarah A. M. Cuddy, Brigham and Women's Hospital, Section of Cardiology.)*

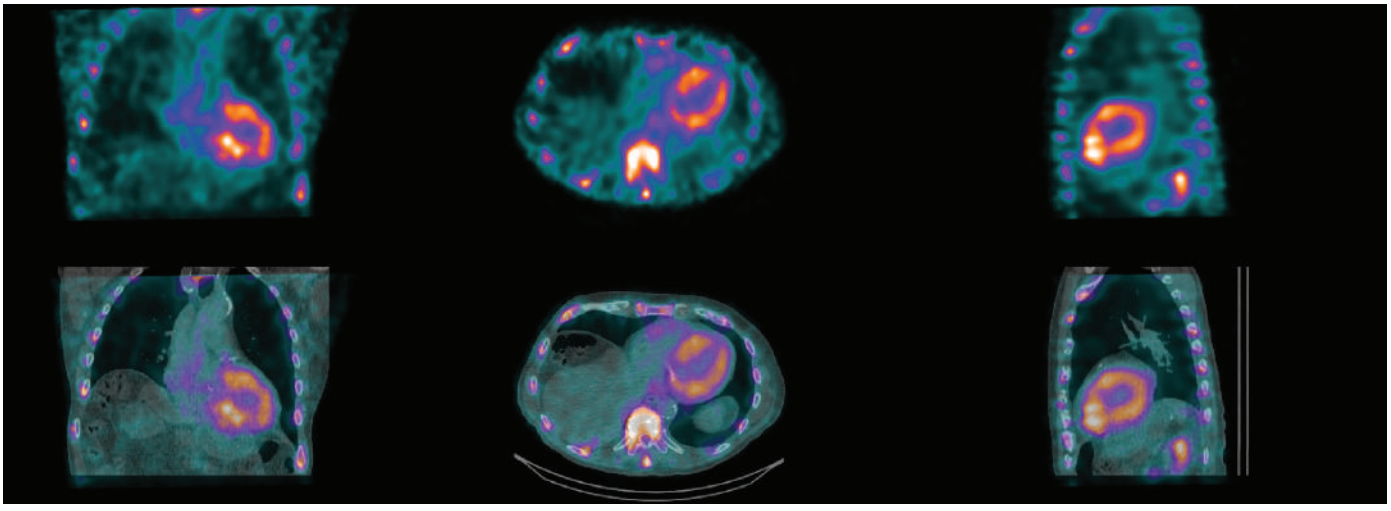
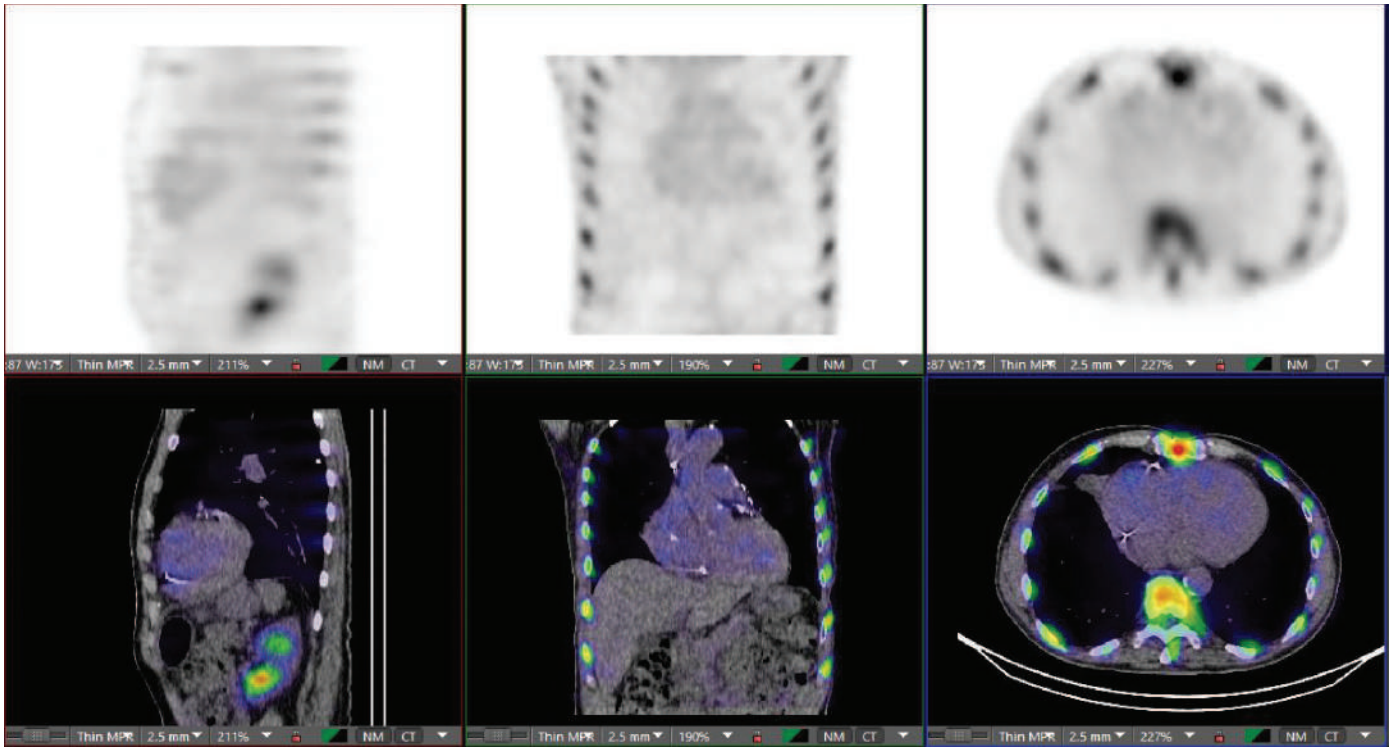
proteinuria is often found, and this may cause hypoalbuminemia. Renal involvement is not a feature of transthyretin amyloidosis. Rarely, in AL amyloidosis with hepatic involvement, the alkaline phosphatase is significantly elevated. Although AL amyloidosis is a plasma cell disorder closely related to multiple myeloma, the sedimentation rate is usually normal or only minimally elevated, unlike the marked elevation that may be seen in myeloma. Hypogammaglobulinemia may be present in AL amyloidosis, but serum and urine protein electrophoresis often do not reveal a monoclonal gammopathy, as the paraprotein level is low. Thus, in suspected AL amyloidosis, serum and urine immunofixation should be performed as these are more sensitive (although nonquantitative) than serum or urine protein electrophoresis. In almost all patients with AL amyloidosis, the level of circulating serum free light chains, either lambda or, less commonly, kappa free light chains, is elevated. It is important to recognize that findings suggestive of a plasma cell dyscrasia in a patient with a cardiomyopathy needs to be interpreted in the context of the clinical picture, as monoclonal gammopathy of unknown significance is common in the older population and may be unrelated to the cardiomyopathy. Unlike TTR cardiomyopathy, there is no definitive noninvasive test to diagnose AL amyloid cardiomyopathy, and thus a tissue biopsy is always needed. A subcutaneous fat pad aspirate or deep-skin needle aspiration biopsy has a high yield of positivity, but needs to be evaluated by a skilled pathologist. A biopsy positive for AL amyloid from a noncardiac site in the presence of imaging consistent with amyloid cardiomyopathy is adequate to conclude that cardiac involvement is present. Immunohistochemistry, performed by many pathology labs, is fraught with diagnostic uncertainty and should be used with great





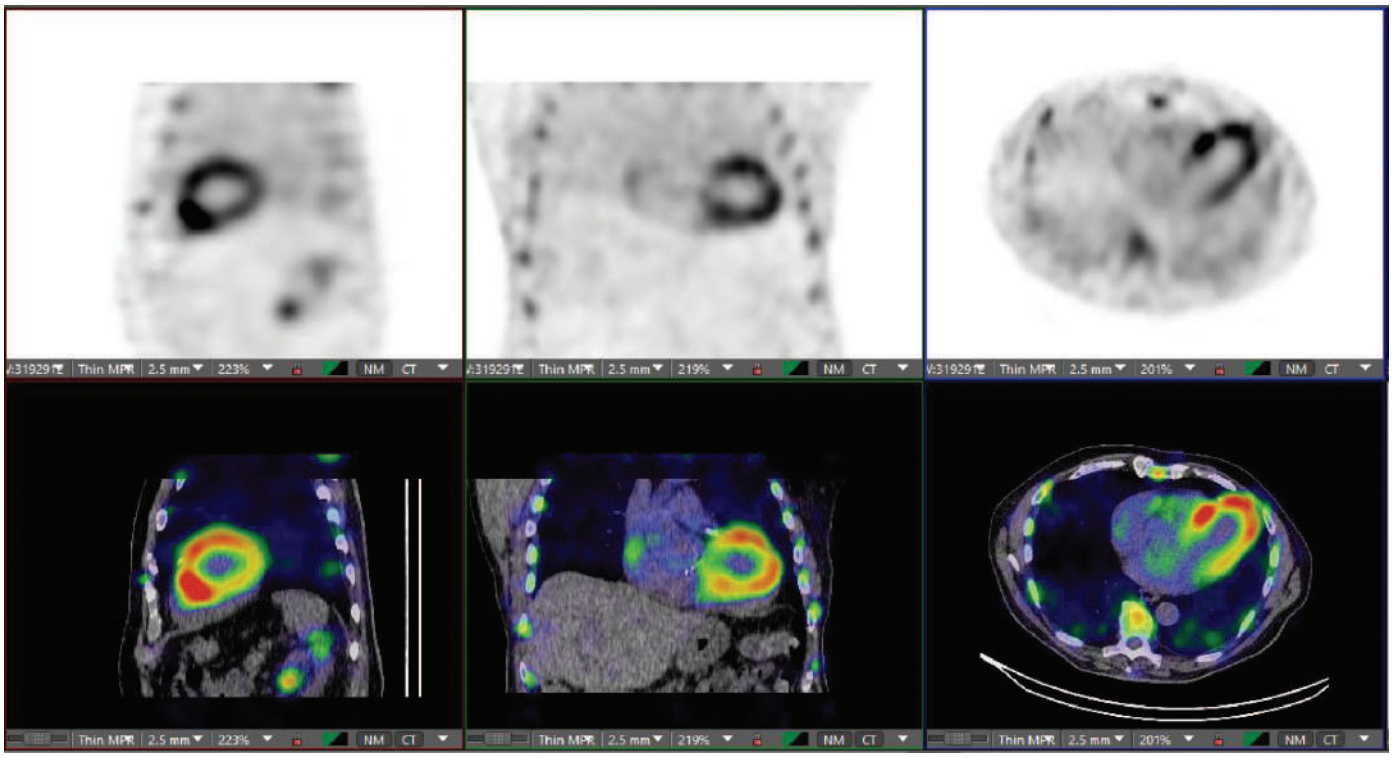


FIGURE 270-6 Technetium pyrophosphate (PYP) scan in a patient with wild-type transthyretin amyloidosis. The top three images are obtained in three separate views with single-photon emission computed tomography (CT) imaging alone, and the bottom three views with added cardiac CT imaging. Both modalities show marked myocardial uptake (*orange*) with absence of blood pool uptake (central clearing) and normal bone uptake. The lower images more precisely localize the uptake to the fused CT images of the heart, which in more equivocal cases helps to localize uptake to the myocardium and prevents misinterpretation as a positive scan due to blood pool uptake without myocardial uptake. PYP uptake is highly sensitive and specific for transthyretin amyloidosis but can occasional be present in AL amyloidosis; thus, exclusion of a plasma cell dyscrasia is mandatory when interpreting this imaging. In the normal heart and almost all other pathologies, there is no myocardial uptake of bone tracers such as PYP.

A

B

FIGURE 270-7 Technetium pyrophosphate (PYP) scan. ***A.*** A normal (negative) PYP scan. The planar images (*top*) show rib and sternal isotope uptake, but there is no uptake in the heart. *Bottom* panel shows single-photon emission computed tomography–computed tomography (SPECT-CT) fusion showing normal appearance of nonamyloid heart after PYP imaging (no isotope uptake). ***B.*** Positive PYP scan in a patient with cardiac transthyretin amyloidosis. caution and always interpreted in the setting of the clinical picture. It is thus strongly recommended that typing of the amyloid ideally be done by mass spectrometry (available as a "send-out test" in the United States). Unless a diagnosis of AL amyloidosis is clear, sequencing of the TTR gene should be done to rule out familial transthyretin amyloidosis as this has obvious ramifications for the family.

TREATMENT

Cardiac Amyloidosis

The treatment of systemic amyloidosis is addressed in detail in Chap. 117. Here, we will concentrate on specific issues related to

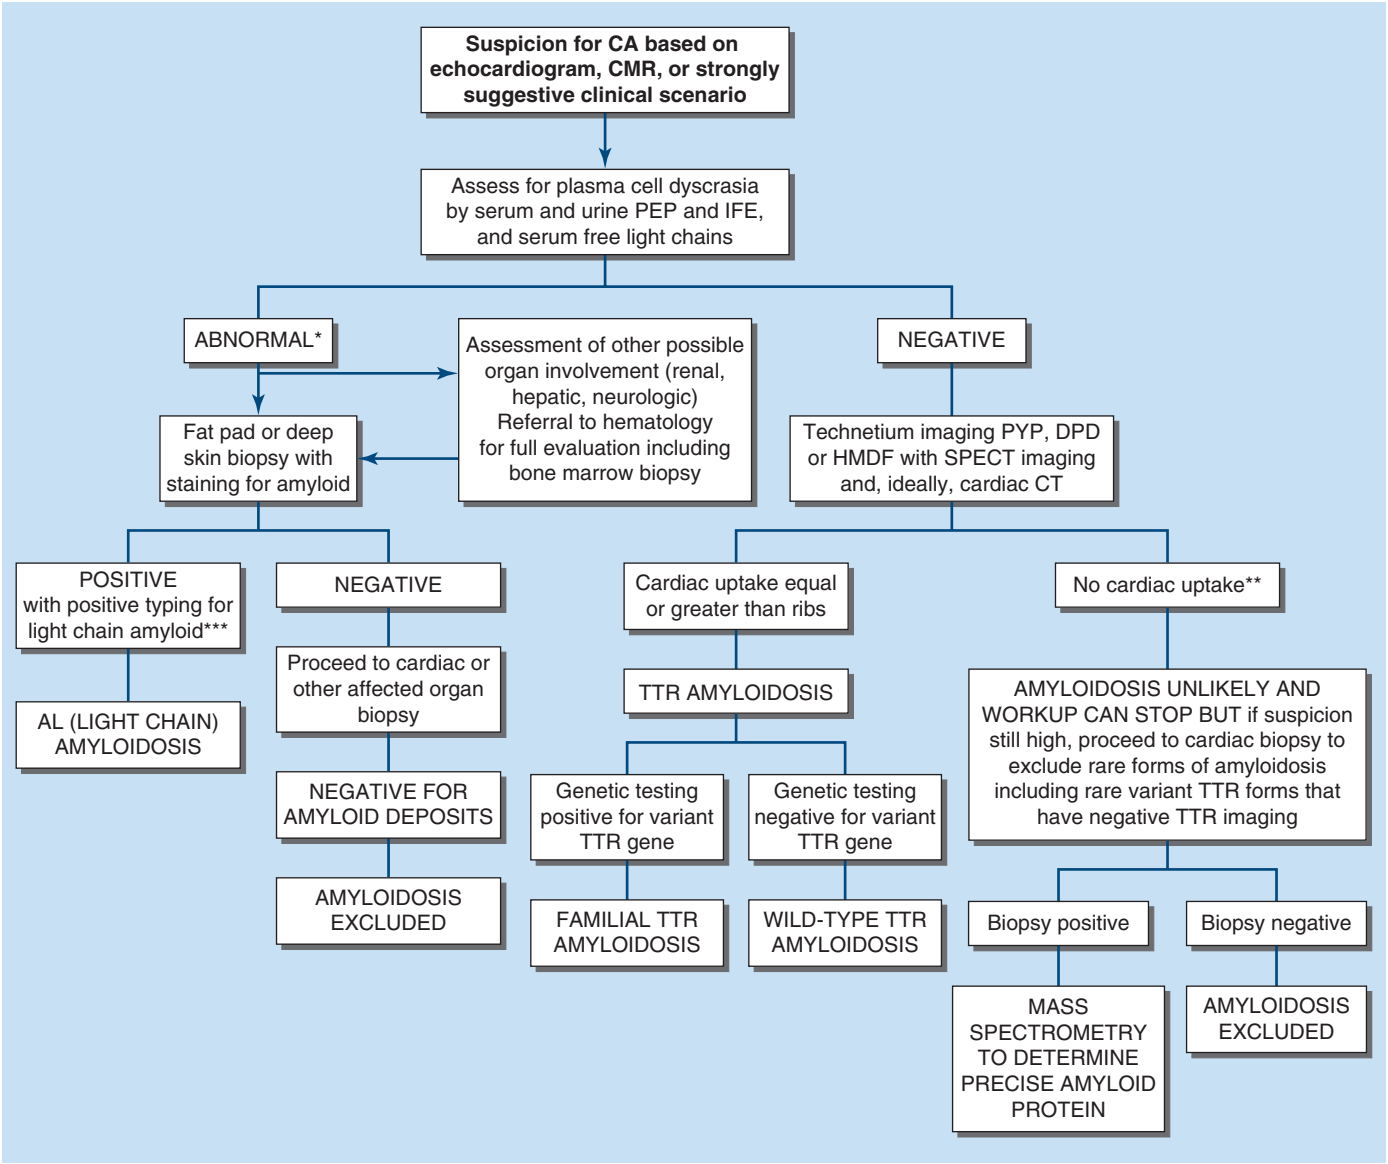

FIGURE 270-8 Diagnostic algorithm. Algorithm for the workup of suspected cardiac amyloidosis (CA). This is a suggested algorithm but, depending on initial degree of suspicion for amyloidosis type, may vary slightly in order. Asterisk footnotes are as follows: *Normal values in workup for a plasma cell dyscrasia are negative serum and urine protein electrophoresis and immunofixation, with normal values for free serum kappa and lambda light chains adjusted for renal function. Abnormalities may not always reflect light chain amyloidosis, as monoclonal gammopathy of unknown significance not uncommonly coexists with TTR amyloidosis and thus expert evaluation of all abnormalities is mandatory. **Patients with bone-imaging uptake present but less than rib uptake should be carefully evaluated to ensure that this is not just blood pool isotope uptake and, if not, should be considered as possible amyloidosis with further evaluation based on expert evaluation of likely cardiac amyloid. ***Typing for amyloidosis should ideally be performed by mass spectrometry, generally only available in specialized centers. Immunohistochemistry, while often used, may be misleading and should be interpreted cautiously within the context of the clinical features of the disease. CMR, cardiac magnetic resonance; CT computed tomography; DPD, technetium-99m 3,3-diphosphono-1,2-propanodicarboxylic acid; HMDP, technetium-99m–hydroxymethylene diphosphonate; IFE, immunofixation electrophoresis; PYP, technetium-99m–pyrophosphate; PEP, protein electrophoresis; SPECT, single-photon emission computed tomography.

the cardiac disease. It is important, when considering treatment of cardiac amyloidosis, not simply to focus on therapies aimed at slowing or stopping the production of the precursor protein but also to address the manifestations of the disease. Sodium restriction is an integral part of management of heart failure in all forms of cardiac amyloidosis with congestive heart failure. The restrictive pathophysiology renders the patient particularly vulnerable to small changes in blood volume, and sodium restriction can significantly improve the response to diuretics. There are no specific clinical trials that evaluate the best way to treat congestive heart failure in cardiac amyloidosis, but it is generally recognized that diuretics are the mainstay of therapy. The combination of a loop diuretics such as furosemide or (preferably) torsemide with spironolactone or eplerenone is usually well tolerated. Renal function should be monitored while adjusting diuretic dose, particularly in patients with ATTRw amyloidosis who tend to be older and to have more baseline renal impairment. The use of other drugs commonly used in congestive heart failure is more controversial. In light chain amyloidosis, autonomic function is often impaired even in the absence of postural hypotension, and the use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers may be associated with profound hypotension. Thus, they are generally avoided. Beta-blockade is also often problematic and associated with decreased exercise tolerance. If a patient is receiving beta blockers when initially seen, we routinely taper and stop their use and reassess the patient's sense of well-being, which, not infrequently, improves. For patients with atrial fibrillation and a rapid ventricular response, beta-blockade may be needed but digoxin can also be used. However, restoration of sinus rhythm is preferable. The use of sodium-glucose cotransporter 2 (SGLT2) inhibitors appears to be clinically well-tolerated. This class of drug has efficacy across the spectrum of patients with heart failure and preserved ejection fraction and those with heart failure and reduced ejection fraction and may be of value in cardiac amyloidosis.

Cardiac arrhythmias in both AL and TTR amyloidosis are common. Most frequently seen is atrial fibrillation or flutter, the onset of which is often associated with clinical deterioration. There is a high risk of thromboembolism in patients with cardiac amyloidosis, and anticoagulation in patients with atrial fibrillation or flutter is mandatory. There does not appear to be increased risk of major bleeding among patients taking anticoagulants in either light chain or transthyretin amyloidosis. Restoration of sinus rhythm should be considered in all patients, particularly since rate-controlling agents are poorly tolerated. Amiodarone appears to be the most effective antiarrhythmic drug for atrial arrhythmias and should ideally be given, starting with a loading dose, prior to elective electrical cardioversion. If a patient is adequately anticoagulated before and during electrical cardioversion, there is no reason to perform transesophageal echocardiography prior to the procedure. If atrial arrhythmias are associated with clinical deterioration and sinus rhythm cannot be maintained despite antiarrhythmic therapy, consideration should be given to an invasive electrophysiologic procedure. Pulmonary venous isolation/atrial fibrillation ablation is often more complex than in nonamyloid patients, with a higher recurrence rate, and we therefore tend to limit ablation procedures to patients with atrial flutter and no evidence of atrial fibrillation. For those with symptomatic atrial fibrillation, atrioventricular nodal ablation with the implantation of a biventricular pacemaker is an effective way of both controlling and regularizing the ventricular rate. Sudden cardiac death may occur in cardiac amyloidosis, being more common in advanced AL amyloidosis, but a prophylactic implantable defibrillator is generally ineffective in preventing this. Thus, consideration of an implantable defibrillator should be highly selective and probably limited to patients with a prior resuscitated cardiac arrest or a history of sustained ventricular tachycardia.

Patients with TTR amyloidosis are at a high risk for the development of high-degree atrioventricular block. This is usually preceded on ECG by bifascicular block or left bundle branch block. Patients should be questioned about unexplained, nonpostural dizzy spells or syncope, and if these occur in the setting of one of these ECG abnormalities, strong consideration should be given to cardiac pacing. If a pacemaker is to be placed, we would generally recommend biventricular pacing, as right ventricular pacing produces abnormalities of septal contraction that, in the presence of a small cavity ventricle, may decrease cardiac output.

SPECIFIC THERAPY OF CARDIAC AMYLOIDOSIS: AL AMYLOIDOSIS

The most common regimen for treating patients with light chain amyloidosis includes daratumumab, bortezomib, cyclophosphamide, and dexamethasone. Dexamethasone may aggravate sodium retention, and it is critical that the cardiologist experienced in amyloidosis co-manages AL amyloidosis patients with cardiac involvement along with the treating hematologist. During therapy, an increased diuretic dose may be needed and/or a reduction in the dexamethasone dose. The other medications are generally well tolerated, but rarely, bortezomib may cause acute, reversible cardiac toxicity. Bortezomib may also cause a neuropathy and aggravate autonomic neuropathy of AL amyloidosis. High-dose melphalan chemotherapy with autologous stem cell transplantation is used in some patients with light chain amyloidosis and may be associated with considerable fluid retention or atrial arrhythmias in patients with cardiac involvement. For patients with AL cardiac amyloidosis, it is mandatory that the patient being considered for this therapy have a pretherapy cardiac evaluation to assess the risk-benefit ratio, along with regular posttransplant follow-up in the acute stage. Following successful chemotherapy (defined as a hematologic remission, with normalization of the serum free light chains), congestive heart failure often improves and is associated with an improvement in left ventricular longitudinal strain. However, some patients remain with very poor cardiac function. Such patients may benefit from cardiac transplantation, but this requires a very careful evaluation at an expert center to determine the extent of extracardiac amyloidosis and its likely effect on posttransplant prognosis.

SPECIFIC THERAPY OF CARDIAC AMYLOIDOSIS: TTR AMYLOIDOSIS

Currently, the aim of treatment of TTR cardiac amyloidosis is focused on reducing or stopping any further amyloid deposition. Tafamidis, a small molecule that stabilizes the tetrameric structure of transthyretin, is effective at slowing disease progression and may halt progression among patients treated early in the clinical presentation of the disease. It is extremely well tolerated. A similar drug, acoramidis, has shown similar efficacy in a pivotal clinical trial. An alternative class of drugs, the TTR silencers, significantly reduce the production of transthyretin by the liver and are approved in the United States for the treatment of familial amyloid polyneuropathy. At the time of writing, two drugs (both of which are only approved for amyloid neuropathy), eplontersen and vutrisiran, both administered subcutaneously, are completing clinical trials for the treatment of transthyretin amyloid cardiomyopathy.

Rarer forms of cardiac amyloidosis are listed in **Table 270-2**. Their rarity relates to the very uncommon nature of the type of amyloid with which they are associated or, as in the example of AA amyloidosis, the uncommon nature of cardiac involvement despite extensive other involvement. The diagnosis of most of these forms of cardiac amyloidosis will be made on mass spectrometry of a tissue biopsy after cardiac amyloidosis is suspected but when there is no evidence of a plasma cell dyscrasia or abnormality on technetium imaging.

TABLE 270-2 Rare Forms of Amyloidosis

AMYLOID TYPE	PRECURSOR PROTEIN	FREQUENCY OF CARDIAC DISEASE	OTHER ORGAN INVOLVEMENT	COMMENT
AA	Serum amyloid A (an inflammatory protein)	<5%	Kidney, liver	Usually associated with longstanding chronic inflammation. Uncommon in developed countries, and cardiac involvement rarely the predominant factor.
AApoA1	Apolipoprotein 1	25–30%	Kidney, liver, spleen, nervous system, larynx	Rare condition, with family history in many cases. Cardiac disease, when present, may be predominantly right-sided with tricuspid valve involvement.
AapoA4	Apolipoprotein 4	65–70%	Kidney	Family history often not present. Renal involvement without proteinuria is common, and cardiac involvement is usually present but often relatively mild.
Afib	Fibrinogen A-alpha (gene mutation)	Not described	Kidney, spleen	Rare. Proteinuria that progresses to renal failure. Typical renal biopsy with glomerular obliteration by amyloid. Typical amyloid cardiomyopathy absent.
ALECT2	Leukocyte cell-derived chemotaxin 2	Not described	Kidney	Liver involvement common. ALECT2 predominantly found in Hispanics.
Gelsolin	Gelsolin	Unknown prevalence. Usually mild, and manifesting as conduction disease	Corneal lattice dystrophy Skin and neurologic features	Predominantly found in Finnish patients.

SUMMARY

Over the past several years, cardiac amyloidosis has come to be recognized as a much more common disease than previously appreciated. In part, this is due to the aging population, in whom TTR amyloidosis is a significant cause of heart failure. The ability to diagnose TTR amyloidosis with noninvasive nuclear scanning rather than needing cardiac biopsy has made the diagnosis much easier, and the availability of effective disease-modifying treatment has added an incentive to diagnose previously untreated disease. AL amyloidosis, although more complex to diagnose, is seen in younger patients, and now effective life-saving treatments and therapies for both types of cardiac amyloidosis are expanding. While a high degree of suspicion is needed to diagnose these diseases, the benefits of diagnosis to the patient are considerable, and the satisfaction of being able to treat a previously untreatable condition is one of the most gratifying aspects of the practice of medicine.

271 Cardiac Transplantation and Prolonged Assisted Circulation

Mandeep R. Mehra

Advanced heart failure, a distinct syndrome, is characterized by refractoriness to conventional therapy and represents a clinical dilemma associated with an increased symptom burden, frequent hospitalization, a poor quality of life, and high risk of death. Such individuals do not tolerate neurohormonal antagonists at recommended doses, exhibit worsening renal function, maintain poor cardiac reserve on cardiopulmonary stress testing, and typically display a low cardiac output state with elevated pulmonary pressures on invasive hemodynamic assessment. In general, therapeutic targets shift away from disease-modifying or neurohormonal therapy to surgical options that attend directly to supporting the dysfunctional heart and address myocardial stress and strain relationships. Most often, prolonged circulatory assistance using mechanical ventricular assist devices or cardiac transplantation is required to reliably improve quality of life and long-term survival.

CARDIAC TRANSPLANTATION

A decade after Norman Shumway had accomplished the technique of a successful heart transplant in canines, Christiaan Barnard successfully performed the first human-to-human transplant on December 3, 1967. Now, >5 decades later, this surgery has become entrenched in the standard armamentarium for treating patients with advanced heart failure who are otherwise healthy enough to receive such a life-altering treatment. Globally, >150,000 patients have undergone cardiac transplantation with a 1-year survival >80% and median survival of 12.5 years and conditional survival of 14.8 years if the recipient survives the first year after transplant. These gains have been ushered in by advances in immunosuppression, identification and management of allograft rejection, and a comprehensive appreciation for late complications including accelerated coronary artery disease, malignancy, and renal failure.

CANDIDATES FOR CARDIAC TRANSPLANTATION

The demand for cardiac transplantation outstrips the availability of organ donors. Hence, attention to the optimal utility, equitable allocation, and patient autonomy must dominate decisions to identify and list candidates for transplantation. Simultaneously, attempts at expanding the donor pool have surfaced. However, vigilance to evaluating candidates most likely to have a successful outcome from transplantation takes pre-eminence. In 2006, the International Society for Heart and Lung Transplantation identified a set of criteria to guide listing of patients. These criteria were updated in 2016 and include additional attention to the growing epidemiology of candidates suffering from congenital heart disease, restrictive and infiltrative cardiomyopathy (such as amyloidosis), and chronic infections in recipients (such as Chagas' disease, tuberculosis, and viral hepatitis). Selected general principles for listing candidates for cardiac transplantation are enumerated in Table 271-1.

PRINCIPLES OF DONOR RECOVERY AND ALLOCATION

Although listing criteria for candidates are typically adjudicated at an individual center level, organ allocation is handled by national regulatory processes in most countries. The allocation of donor hearts is based on (1) the urgency of the recipient clinical situation, (2) the length of time spent on the waiting list, (3) the distance from the recipient center, and (4) blood group. Candidates who are hospitalized in critical status and require extracorporeal membrane oxygenation

TABLE 271-1 Principles for Listing Candidates for Cardiac Transplantation

PRINCIPLE	COMMENT
Advanced disease severity	Refractory heart failure with a VO_2 of <14 mL/kg per min (<12, if on beta blockers) or percent predicted VO_2 <50%; combination of intolerance to disease-modifying therapy, cardiorenal syndrome, use of inotropic therapy to maintain stability, or need for a left ventricular assist system.
Comorbidity	Age is not an absolute contraindication, but frailty should be considered a relative contraindication; a BMI >35 kg/m^2 should require weight loss; cancer should be dealt with on an individual basis (e.g., low-grade prostate cancer may not be a contraindication); poorly controlled diabetes mellitus or end-organ damage may be a contraindication; eGFR <30 mL/min/1.73 m^2 is a relative contraindication (and requires consideration for a combined kidney transplant), if persistent; severe cerebrovascular disease or peripheral vascular disease (which will limit rehabilitation or function) is also a relative contraindication.
Donor-recipient matching	Sensitized individuals with circulating antibodies should have a prospective or virtual cross match; pulmonary vascular resistance with a transpulmonary gradient >15, PVR >3 Wood units, and absolute PA systolic pressure >50 mmHg (provided the systolic blood pressure is >85 mmHg) is a relative contraindication unless reactive to therapy.
Psychosocial issues	Tobacco use in any form limits posttransplant survival and should be stopped for at least 6 months; substance abuse, including marijuana, should be a contraindication if the individual cannot demonstrate control and cessation; patients with severe cognitive-behavioral disabilities or dementia (inability to ever understand and cooperate with medical care) have the potential for self-harm and should not receive a transplant.

Abbreviations: BMI, body mass index; eGFR, estimated glomerular filtration rate; PA, pulmonary artery; PVR, pulmonary vascular resistance; VO_2, peak oxygen consumption.

or temporary mechanical circulatory support devices to support both ventricles are given the highest urgency status, followed by those requiring daily invasive hemodynamic evaluation and intravenous inotropic therapy to maintain stability, or those with complications of a durable left ventricular assist device. Others stable at home while supported by a left ventricular assist device or those able to ambulate and live at home receive a lower urgency status. The geographical regional reach for allocation is based not only on territorial considerations but also on the time that a donor heart would be in transit and therefore in out of body "ischemia time," which is typically limited to 4 h, unless novel techniques for organ transport are employed. A key feature that is included in the allocation offer relates to the ABO blood group as well as the size match of a potential donor with the recipient. Donor organs are offered based on these initial characteristics and then a more detailed donor assessment ensues, resulting in acceptance or decline for any given donor heart. It is important to note that the time constraints imposed on the retrieval process make it difficult to invoke HLA matching of the donor and recipient. In cases where there is a high likelihood of allosensitization in the recipient (preformed circulating antibodies against donor antigens), a prospective or virtual cross match is entertained prior to acceptance. Other clinical criteria that are employed in the decision on accepting an offered donor include the donor-recipient size match (donor body weight no greater than 30% below that of the recipient if it is a same sex transplant, or no greater than 20% for a female to male transplant or assessed using a predicted heart mass calculator), the age of the donor (typically restricted to <55 years, but is often exceeded due to organ shortages), and presence or absence of concomitant pathology such as coronary artery disease, left ventricular hypertrophy, or severe injury to the allograft manifest by excess leak of injury markers (troponins) or poor contractile performance that does not improve in serial testing. In many cases, the prospective cardiac allograft can be reconditioned over time and used for transplantation even if the initial evaluation suggests poor contractile function. In efforts to enhance the donor pool, systems that allow ex situ normothermic perfusion to evaluate and reanimate organs with a prolonged out of body time have being developed that allow use of organs that may otherwise have been discarded. The classical heart donor is derived from a donor with established brain death; however, donors after circulatory death are being increasingly evaluated as candidates for cardiac reanimation using a variety of techniques including ex situ reanimation and subsequent transplantation. Such donor organs obtained after circulatory death are gaining widespread acceptance, and studies suggest that their outcomes after transplantation are no different from those of organs retrieved from brain death donors. However, this donor source is subject to ethical controversy in some geographical regions of the world. To increase the number of viable donors, organs from those infected with hepatitis C virus are increasingly being utilized since preventive or curative antiviral therapy can be used in the recipient shortly after transplantation.

SURGERY FOR CARDIAC TRANSPLANTATION

The most common contemporary operation is referred to as a "bicaval" orthotopic cardiac transplant that mimics the natural anatomic position. In this operation, the donor and recipient superior and inferior venae cavae are connected as are the aortic and pulmonary great vessels. The left atrium of the recipient retains its roof including the draining pulmonary veins, and the donor left atrium is then sutured to the retained atrial tissue. This technique maintains function of the donor right atrium, important for governing early postoperative right heart output, and may prevent atrial arrhythmias. The recipient is left with a surgical denervation, and the allograft is not responsive to any physiologic sympathetic or parasympathetic stimuli. Therefore, early in the adaptive postoperative phase, high-dose catecholamines are required to maintain adequate function. Due to denervation, bradycardia in a cardiac allograft cannot be treated with atropine and the drug of choice is isoproterenol, or temporary electrical pacing is used. Once the cardiac allograft adapts to its host circulation, the function is usually adequate at rest and with exercise, to provide normal physical activity and quality of life.

CARDIAC ALLOGRAFT REJECTION AND IMMUNOSUPPRESSION

The ability to perform endomyocardial biopsies and evaluate rejection pathologically and the introduction of the immunosuppression agent cyclosporine heralded cardiac transplantation as a viable clinical therapy. Triple-drug immunosuppression, which includes a calcineurin inhibitor (cyclosporine or tacrolimus), corticosteroids, and antiproliferative immunosuppression (azathioprine, mycophenolate mofetil, sirolimus, or everolimus), is now the standard combination used. The combination immunosuppression strategy that is most used and that achieves the best standard outcomes includes tacrolimus, mycophenolate mofetil, and prednisone. In those at high risk for rejection (multiparous women, allosensitized individuals, retransplants) or in situations where use of calcineurin inhibitors needs to be delayed (renal dysfunction), induction therapy using monoclonal (basiliximab) or polyclonal antibodies (antithymocyte globulin) to provide augmented immunosuppression is used, although this strategy remains poorly studied. Over several months, as surveillance endomyocardial biopsies are regularly performed and clinical as well as subclinical pathologic quiescence is established, gradual weaning of steroids is undertaken, in some cases to the point of elimination. Table 271-2 describes the immunosuppression drugs in common use.

TABLE 271-2 Immunoprophylaxis Drugs in Cardiac Transplantation

DRUG CLASS	GENERIC DRUG	CELLULAR TARGET	MAJOR SIDE EFFECTS
Calcineurin inhibitors	Cyclosporine	Binds to cyclophilin, which then inhibits calcineurin	Hypertension, dyslipidemia, gum hypertrophy, hypertrichosis
	Tacrolimus	Binds to immunophilin FK506 binding protein, which inhibits calcineurin	Hypertension, dyslipidemia, alopecia, diabetes mellitus
Antithymocyte globulin (ATG)	Rabbit ATG	T-cell depletion in blood and peripheral lymphoid tissues through complement-dependent lysis and T-cell activation and apoptosis	Cytokine release syndrome, leukopenia, thrombocytopenia, serum sickness
	Horse ATG	Same as above	Same as above
Interleukin-2 receptor antagonists	Basiliximab	Inhibition of CD-25 of interleukin 2 receptor	Well tolerated; rare hypersensitivity; increased infection risk if used with calcineurin inhibitors
Antimetabolites	Azathioprine	Imidazolyl derivative and prodrug of 6-mercaptopurine (cell cycle inhibitor)	Bone marrow suppression, pancreatitis, hepatitis
	Mycophenolate Mofetil	Inhibits inosine monophosphate dehydrogenase, which controls guanine monophosphate in the de novo pathway of purine synthesis (inhibits T- and B-cell proliferation)	Leukopenia, gastrointestinal toxicity
Proliferation signal inhibitors	Sirolimus	Binds with FKBP12 and complex inhibits the mechanistic target of rapamycin (mTOR)	Delayed wound healing, nonspecific pneumonia, pericardial effusion, hyperlipidemia (hypertriglyceridemia)
	Everolimus	Binds to FKBP12, which inhibits mTORC1 (and not mTORC2)	Dyslipidemia, stomatitis, pericardial effusions, and pancytopenia

Acute cellular rejection (ACR) and antibody-mediated rejection (AMR) are two separate forms of cardiac allograft rejection that are recognized and can sometimes coexist. ACR occurs early after transplantation and then tends to decline in incidence after 6 months. This occurs due to a T cell–mediated assault on the donor allograft tissue and histologically is characterized by lymphocytic infiltrates in the myocardium. In mild cases, these infiltrates are localized to the perivenular regions, and in severe cases, they progress diffusely into the cardiac interstitium. In late stages of severe ACR, most often associated with hemodynamic compromise, multiclonal cells such as macrophages, neutrophils, and eosinophils are observed with intramyocardial hemorrhage, myocyte injury, and myocyte necrosis. Subclinical ACR is typically treated with high doses of corticosteroid pulses, although some centers choose to simply observe mild forms of infiltration since it is known that many of these patients may recover spontaneously over time. If hemodynamic compromise occurs, rescue polyclonal antibodies are used in tandem with corticosteroids. Conversely, AMR is immunologically described as a noncellular antibody-driven phenomenon associated with a pattern of immunopathologic findings of immunoglobulin deposition and complement fixation on immunofluorescence, along with histopathologic findings of endothelial swelling and interstitial edema and cardiac allograft arteriolar vasculitis. AMR is characterized by the emergence of circulating donor-specific antibodies that are thought to fix complement and bind to the allograft. Commonly, AMR leads to allograft dysfunction, increases the risk for development of cardiac allograft vasculopathy, and is associated with worsened cardiac allograft survival compared with ACR. In this form of rejection, therapy is directed toward suppression and removal of circulating antibodies using plasmapheresis and drugs such as rituximab (chimeric monoclonal antibody directed against the CD20 antigen) or, in refractory cases, bortezomib (a proteasome inhibitor) or eculizumab (a terminal complement inhibitor). Intravenous immunoglobulin is also used as an immune-modulatory agent. The treatment with immunosuppression requires prophylaxis for opportunistic infections and ongoing surveillance and expertise in recognizing the more common clinical presentations of infections caused by cytomegalovirus (CMV), *Aspergillus*, and other opportunistic agents such as *Nocardia* and toxoplasmosis.

LATE COMPLICATIONS AFTER CARDIAC TRANSPLANTATION

The long-term consequences of exposure to chronic immunosuppression result in a variety of nonimmunologic cardiometabolic effects such as hypertension, hyperlipidemia, and hyperglycemia, as well as systemic disorders of bone loss and renal dysfunction. One aggressive complication that limits late survival of cardiac allografts includes the development of an accelerated form of coronary artery disease, referred to as cardiac allograft vasculopathy (CAV). This is characterized by a proliferative thickening of the vascular intima of the vasculature that is initiated as a diffuse endothelialitis in the setting of the confluence of the consequences of brain death, ischemia reperfusion injury during the transplant process, and early immunologic insults. Chronically, the metabolic consequences of hypertension, hyperlipidemia, and disordered glucose regulation result in worsening of vascular lesions that are diffuse and noted throughout the coronary tree. Early diagnosis and preventative therapy are critical since it is commonly silent in its development. Intravascular ultrasound or optical coherence tomography is more sensitive than routine coronary angiography for the diagnosis of CAV. A standardized grading scheme for CAV was proposed by the International Society for Heart and Lung Transplantation in 2010. CAV is graded as absent (CAV0), mild (CAV1), moderate (CAV2), or severe (CAV3) based on extent of angiographic disease and presence of allograft dysfunction by echocardiography or restrictive cardiac physiology. The grade of CAV correlates with patient prognosis. Angiographic CAV is present in ~30% of patients by 5 years after transplant and ~50% of patients by 10 years after transplant. Use of noninvasive testing for coronary flow reserve has been demonstrated to arbitrate prognosis in CAV. Use of statins may help prevent CAV development after heart transplantation, and targeting lipid lowering using nonstatin drugs (e.g., PCSK9 inhibitors) has shown promise. Antihypertensive agents and anti-CMV therapy have demonstrated some benefits in reducing CAV with varying degrees of supportive evidence. Antiproliferative immunosuppressive therapy such as mycophenolate mofetil and sirolimus or everolimus prevents vascular intimal thickening compared with azathioprine-based regimens. Use of the chimeric monoclonal antibody directed against the CD20 antigen, rituximab, may accelerate CAV. Options for medical treatment of established CAV remain limited. Revascularization using percutaneous coronary intervention or coronary artery bypass grafting may be employed in selected cases with focal lesions but does not improve survival in patients with CAV. However, retransplantation is the only definitive form of therapy for advanced CAV **(Fig. 271-1)**.

Another concern in cardiac transplantation is the development of malignancy with a greater frequency than in the normal population, suggesting that immunosuppression plays a sentinel role in its generation. Posttransplant lymphoproliferative disorders, typically driven by Epstein-Barr virus, occur most frequently and require a reduction in immunosuppression, administration of targeted antiviral agents, and traditional chemo- and radiotherapy. Specific antilymphocyte (targeted against CD20) therapy has also shown promise. Solid cancers most often manifest as skin malignancies (both basal cell and squamous cell carcinomas), and regular use of sunscreen is advised. Future research is required to define strategies for immune modulation, immune suppression, and malignancy prevention; however, the impact of decreasing immunosuppression in the treatment of these cancers remains unclear.

PROLONGED ASSISTED CIRCULATION

The quest for a prolonged and durable implantable mechanical circulatory support device has led to the development of continuous flow left ventricular assist systems (LVAS). Initially designed for short-term support as a bridge to recovery or to cardiac transplantation, the most frequent use today entails permanent support for lifetime therapy ("destination therapy"). The decision to implant LVAS dichotomously as either a bridge to transplantation or for destination therapy is not always clear, and in several instances, these devices are used as a "bridge to decision" (in those with potentially reversible underlying relative contraindications such as renal insufficiency or pulmonary hypertension, who may become future candidates for transplantation).

LEFT VENTRICULAR ASSIST SYSTEMS AND CLINICAL TRIALS

A pivotal trial, REMATCH, published in 2001, was the first study to reliably demonstrate that survival of patients with transplant-ineligible, refractory, predominantly inotropic therapy–supported heart failure is improved by implantation of an LVAS. This study used an early-generation pulsatile flow device and demonstrated a 48% reduction in risk of death. However, the LVAS used was of limited durability, and meaningful "out of hospital" survival was prolonged by a median of only 5 months. Furthermore, complications of strokes, multisystem organ failure, and infections reduced enthusiasm for widespread adoption. Over time, continuous flow systems that had small turbo-pumps with minimal moving parts and no valves were introduced, leading to greater durability and more generalized worldwide adoption.

A landmark trial compared the older bulky pulsatile LVAS studied in the REMATCH trial with a newer generation axial continuous flow LVAS, the HeartMate II, and demonstrated a marked improvement in short- and long-term survival, along with an improvement in functional capacity and meaningful quality-of-life enhancement. A centrifugal continuous flow LVAS, the HeartWare HVAD, was also introduced and demonstrated noninferiority to the HeartMate II pump. The HeartMate II is no longer used, and the HVAD has been removed from global distribution. A newer centrifugal device with a fully magnetically levitated system, the HeartMate 3 LVAS, is now the most used pump due to demonstration of reduced adverse events and improved long-term survival. The HeartMate 3 is a centrifugal, continuous flow pump that is placed in the thorax and is engineered to be a more hemocompatible LVAS. This device is constructed with

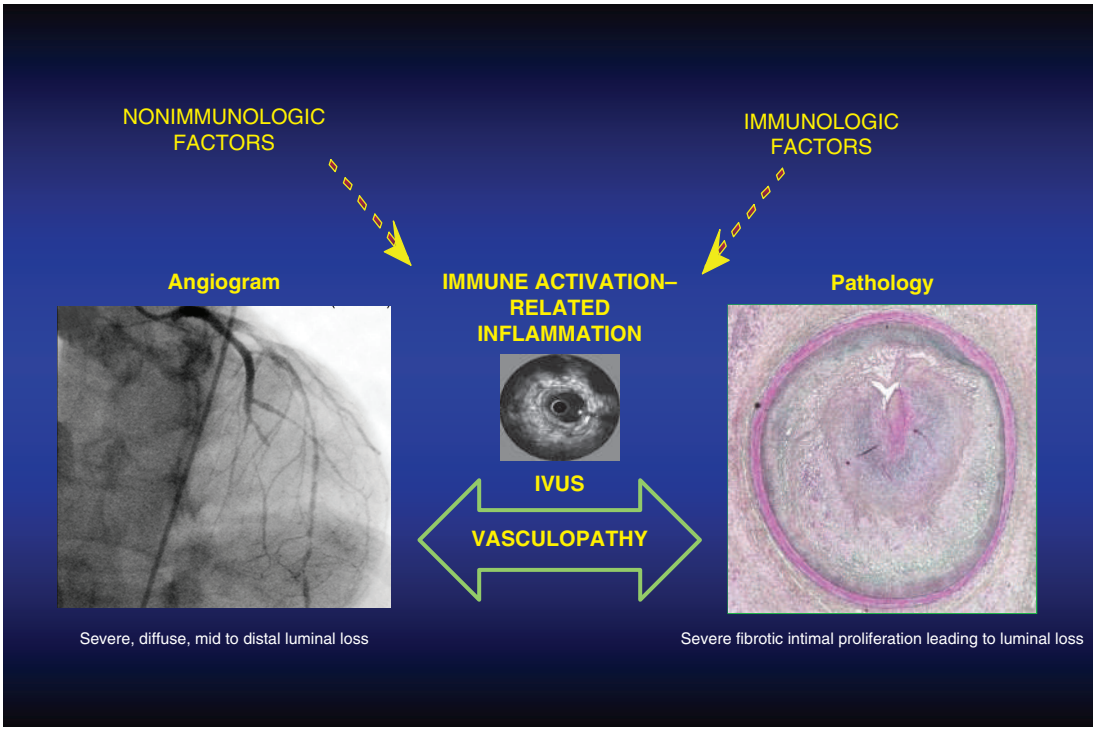

FIGURE 271-1 Cardiac allograft vasculopathy is initiated and propagated by the combined influence of immunologic and nonimmunologic insults on the allograft vasculature. An inflammatory milieu determines the development of diffuse, aggressive luminal blockages that in early forms exhibit intimal thickening and fibrosis. IVUS, intravascular ultrasound (can be used to diagnose early forms of intimal thickening).

a fully magnetically levitated motor, offers wider blood flow paths, and exhibits a fixed intrinsic pulse (by the motor ramping its speed up and down at 2-s intervals). These features have been shown to reduce rates of hemolysis and decrease the shearing of high-molecular-weight multimers of von Willebrand factor. This pump has been tested in the MOMENTUM 3 trial, which reported its final results in 1028 patients randomly allocated to either the HeartMate 3 pump or the HeartMate II LVAS. The fully magnetically levitated HeartMate 3 pump was associated with less frequent need for pump replacement than the HeartMate II device and was superior with respect to survival free of disabling stroke or reoperation to replace or remove a malfunctioning device. The need for pump replacement and occurrence of stroke of any severity, major bleeding, or gastrointestinal hemorrhage were lower in the centrifugal-flow pump group than in the axial-flow pump group. Experience at 5 years with this LVAS has demonstrated an improved long-term survival (Fig. 271-2). This LVAS has been shown to nearly eliminate the complication of pump thrombosis and markedly reduce stroke rates, as well as decrease bleeding complications. Long-term follow-up with this pump has demonstrated a survival of nearly 60% at 5 years, which has been confirmed by real-world experience from registry analyses. In younger patients (<50 years) or those without comorbidity and an uncomplicated surgical course, the 5-year survival rivals that achieved with cardiac transplantation (75%). The patients for whom LVAS should ideally be employed include those with severe persistent systolic heart failure symptoms who have failed to respond to optimal medical management. Commonly, these patients have marked

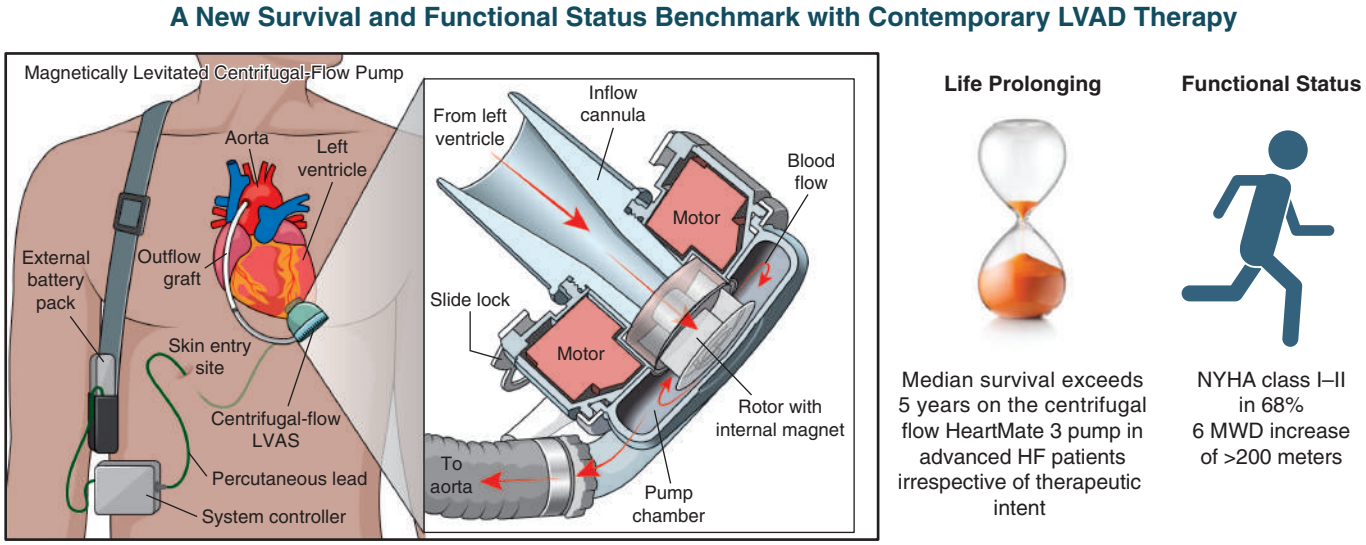

FIGURE 271-2 Due to the technological advances conferred by the HeartMate 3 pump, a new survival and functional status benchmark with contemporary left ventricular assist device (LVAD) therapy has been established. The centrifugal flow HeartMate 3 pump is frictionless and fully magnetically levitated, which does not induce hemolysis or pump thrombosis. This pump is associated with a median survival exceeding 5 years. 6 MWD, 6-min walk distance; HF, heart failure; NYHA, New York Heart Association. *(Left illustration: reproduced with permission from MR Mehra et al: N Engl J Med 376:440, 2017.)*

functional limitation indicated by a peak oxygen consumption of <12 mL/kg per min, or the patient is bound to continuous intravenous inotropic therapy owing to symptomatic hypotension or demonstrates worsening renal function or persistent refractory congestion. In such patients, despite improvements in medical therapy, the median survival is often less than 1 year, and substantial life prolongation can be anticipated with use of the HeartMate 3 LVAS. Currently, the role of LVAS in "less sick" patients (those with moderate symptoms) is less well supported since sufficient equipoise does not exist due to the need to be tethered to an external driveline that connects to a power source.

MANAGEMENT OF LVAS AND THEIR COMPLICATIONS

Continuous flow LVAS rely on pressure gradients between the left ventricular cavity and the aorta. As such, forward flow is critically dependent on management of systemic blood pressure. Due to the low pulsatile nature of the blood flow, blood pressure is measured by using a Doppler ultrasound (which measures mean or opening blood pressure, which is lower than the systolic blood pressure) since a peripheral pulse is usually not detectable. The ideal mean arterial blood pressure should be kept to ≤90 mmHg and antihypertensive drug therapy prescribed using renin-angiotensin-aldosterone system drugs or other vasodilators. The blood flow path through current devices results in increased shear stress, which may manifest in the form of low-grade hemolysis and the development of an acquired von Willebrand disease due to loss of high-molecular-weight multimers of von Willebrand factor. This hematologic aberration has been associated with a risk of gastrointestinal bleeding, particularly resulting from arteriovenous malformations in the intestines. Therefore, a common complication encountered in patients is that of an anemia, often due to iron deficiency.

The unsupported right ventricle often demonstrates worsening function and results in congestion requiring diuretic therapy. While unloading of the left ventricle decreases right-sided afterload, increased device flow results in a greater right heart preload, and effects of the LVAS on the septum reduce right ventricular contractile efficiency, leading to development of right ventricular dilatation and maladaptation between the right ventricle and pulmonary circuit. Cardiac arrhythmias are common in patients supported with LVAS and often require antiarrhythmic therapy or ablation since such events can trigger low flow through the device.

Hemocompatibility-related adverse outcomes include neurologic events (ischemic and hemorrhagic strokes), device-related thrombosis leading to pump malfunction, and nonsurgical bleeding complications **(Fig. 271-3)**. Elimination of aspirin as part of the antithrombotic regimen used (which includes a vitamin K antagonist targeting international normalized ratio to 2–3) has been shown to substantially reduce the risk of nonsurgical bleeding with consequent decrease in bleeding-related hospitalizations and cost of care. This outcome was demonstrated in the ARIES HM3 study with evidence of generalizability among most patients implanted with the HeartMate 3 LVAS. Strokes can occur with the HeartMate 3 LVAS and are generally noted during the surgical implant course with later occurrence in a manner similar to that observed for patients with advanced heart failure who are not supported with LVAS. This complication is an important reason for lack of adoption of device therapy in the less sick population. Another cause of morbidity with legacy devices was pump thrombosis requiring reoperation for device malfunction, which has been largely eliminated with the introduction of the HeartMate 3 LVAS. Lactate dehydrogenase is an excellent (although nonspecific) biomarker of hemolysis and can herald impending or established pump thrombosis, but this is uncommonly encountered except in circumstances where a circulating thrombus is entrained within the pump chamber. Patients who have suspected left ventricular assist device (LVAD) thrombosis and do not undergo LVAD exchange or cardiac transplantation have a high mortality rate, and reoperation (pump exchange) carries a modest perioperative mortality risk and is preferred as the therapy of choice, although this is extremely uncommon.

Infection is common, most often involving the driveline (the conduit connecting the device to the external controller and batteries), and occurs in 20–50% of patients following LVAS implant at 5 years. Such an infection is treated with local internal exploration and requires long-term suppressive antibiotics unless the patient undergoes cardiac transplantation or the device is exchanged. Infection and its inflammatory sequelae predispose to thrombosis and heighten the risk of neurologic complications, leading to a worsening milieu in hemocompatibility.

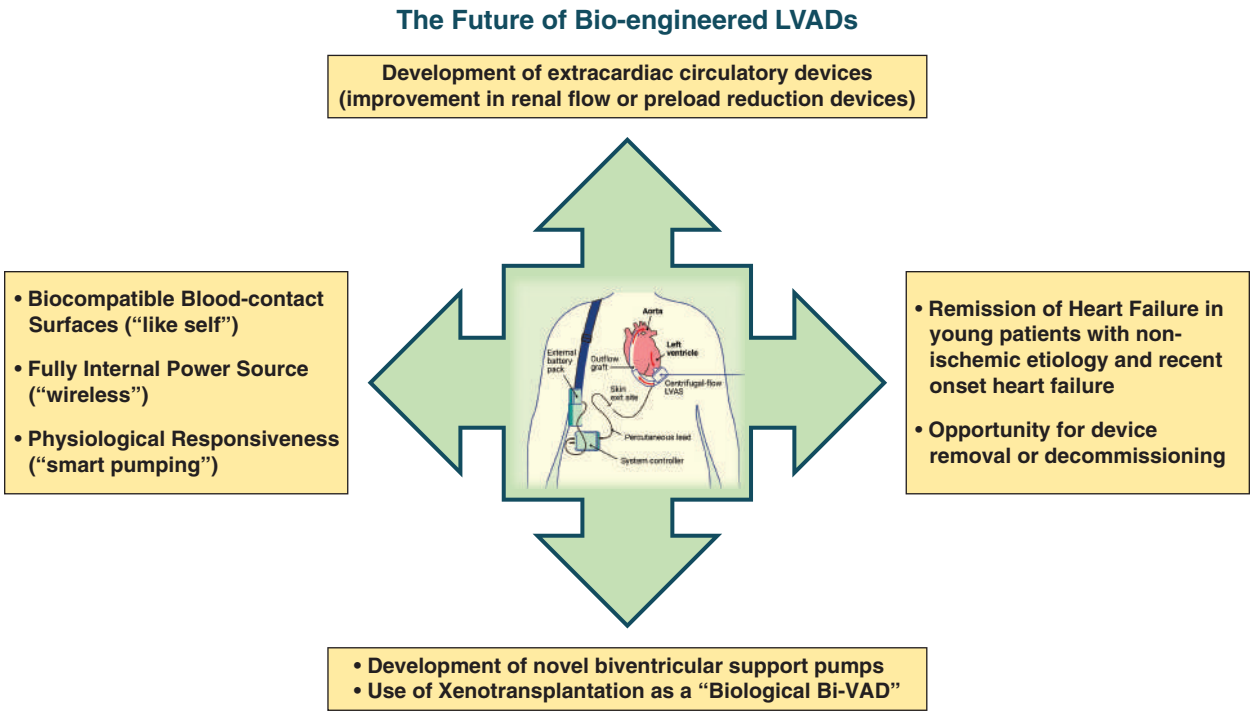

FIGURE 271-3 The future of bioengineered left ventricular assist devices (LVADs). Engineering advances will require development of more biocompatible and fully internally implanted systems with physiologic responsive function. *(Adapted from Boulet J, Wanderley MRB Jr, Mehra MR. Contemporary Left Ventricular Assist Device Therapy as a Bridge or Alternative to Transplantation. Transplantation 108(6):1333-1341: 2024.)*

NOVEL DEVICES

Newer pumps are in development that are designed to overcome challenges inherent in current-generation LVAS. Engineering continues to advance in this field, and we await devices that provide physiologic and synchronized pulsatile flow (rather than the unnatural transapical to aortic flow with current LVADs). The next paradigm shift will likely require a return to natural and pulsatile flow LVAS that are more biocompatible (as opposed to hemocompatible), responsive to physiologic requirements (smart pumps), and forgettable (without an external driveline to power its components).

TOTAL ARTIFICIAL HEART

Not all patients are candidates for an LVAS, particularly those with severe right-sided heart failure or conditions that do not allow placement of an LVAS (restrictive cardiomyopathy, cardiac amyloidosis, massive anterior myocardial infarction, complex congenital heart disease). In such patients, either a biventricular assist device approach or a total artificial heart pump can be considered. The SynCardia total artificial heart is a pulsatile, implantable pump that consists of two polyurethane ventricles with pneumatically driven diaphragms and four tilting disc valves. This requires excision of the native ventricles and thus cannot be employed as a myocardial recovery strategy. There are specific clinical issues that are unique to the total artificial heart management. This device operates on a steep physiologic curve and has little adaptability to tolerate either systemic blood pressure changes or large shifts in blood volume. As the ventricles are excised, most patients exhibit a sharp decline in renal function due to the loss of natriuretic peptide expression by the myocardium. Severe hemolysis is common due to the presence of four mechanical valves, and aberrant erythropoiesis is noted, leading to a severe anemia. Newer artificial hearts using biocompatible surfaces are under study (CARMAT), as well as those that use continuous flow technology (BIVACOR).

XENOTRANSPLANTATION

On January 7, 2022, the first genetically edited pig-to-human heart xenotransplantation was performed. The porcine xenograft was derived from a 10-gene edited animal with four genes that were knocked out (targeting three carbohydrate antigens associated with hyperacute rejection and one anticardiac growth gene) and six genes that were knocked in (targeting human complement regulation, coagulation, and anti-inflammatory pathways). Two transplants have been performed in living human recipients with limited survival of 2 months or less, with death occurring due to delayed graft dysfunction and subsequent loss. There are substantial ongoing concerns with continued immunologic barriers (despite gene modification), costs of donor organ development and recovery, ethical considerations, and considerations of transmission of zoonoses.

GLOBAL CONSIDERATIONS

While LVAS are available worldwide, their use and indications vary from country to country. In the United States, payers used to require discrete discrimination of indication into either a bridge to transplant or destination therapy, whereas in most European countries, this artificial segregation was not used. Cost-effectiveness studies suggest improvement with the newer devices, yet some countries only allow use of this technology as a bridge to transplantation (United Kingdom) while awaiting more definitive long-term studies for lifetime use. The use of LVAS in moderately symptomatic ambulatory patients with chronic systolic heart failure is still discouraged throughout the world, awaiting the availability of devices that can be fully internalized without the need for an external driveline. Globally, the rates of myocardial recovery allowing for decommissioning or removal of devices remain low, although in young patients with nonischemic heart failure of relatively recent onset, this could be an important consideration.

GLOBAL BURDEN OF VALVULAR HEART DISEASE

Valvular heart disease ranks well below ischemic heart disease, stroke, hypertension, obesity, and diabetes as a major threat to the public health. Nevertheless, it can cause significant morbidity and lead to premature death. Rheumatic fever **(Chap. 371)** is the dominant cause of valvular heart disease in low- and middle-income countries. Its prevalence has been estimated to range from as low as 1 per 100,000 school-age children in Costa Rica to as high as 150 per 100,000 in China **(Fig. 272-1)**. Prevalence is higher among females than males, especially for individuals age 20–40 years. Rheumatic heart disease accounts for 12–65% of hospital admissions related to cardiovascular disease and 2–10% of hospital discharges in some endemic countries. Prevalence and mortality rates vary among communities even within the same country as a function of overcrowding, the availability of medical resources, education level, and population-wide programs for detection and treatment of group A streptococcal pharyngitis. In economically deprived areas, tropical and subtropical climates (particularly on the Indian subcontinent and in Southeast Asia), Central America, and the Middle East, rheumatic valvular disease progresses more rapidly than in more developed nations and frequently causes serious symptoms in patients aged <20 years. This accelerated natural history may be due to repeated infections with more virulent strains of rheumatogenic streptococci. Approximately 45–50 million people (575.5 per 100,000) live with rheumatic heart disease worldwide, an estimated prevalence characterized by 300,000 new cases and 233,000 case fatalities (5 per 100,000) per year, with the highest prevalence and age-adjusted mortality rates in sub-Saharan Africa, South Asia, Central Asia, and Oceania. In the United States, rheumatic heart disease accounted for 3876 deaths in 2020. Although globally the age-standardized mortality rate from rheumatic heart disease declined by nearly 50% between 1990 and 2022, the prevalence of heart failure attributable to rheumatic heart disease increased by nearly 90% over the same time interval.

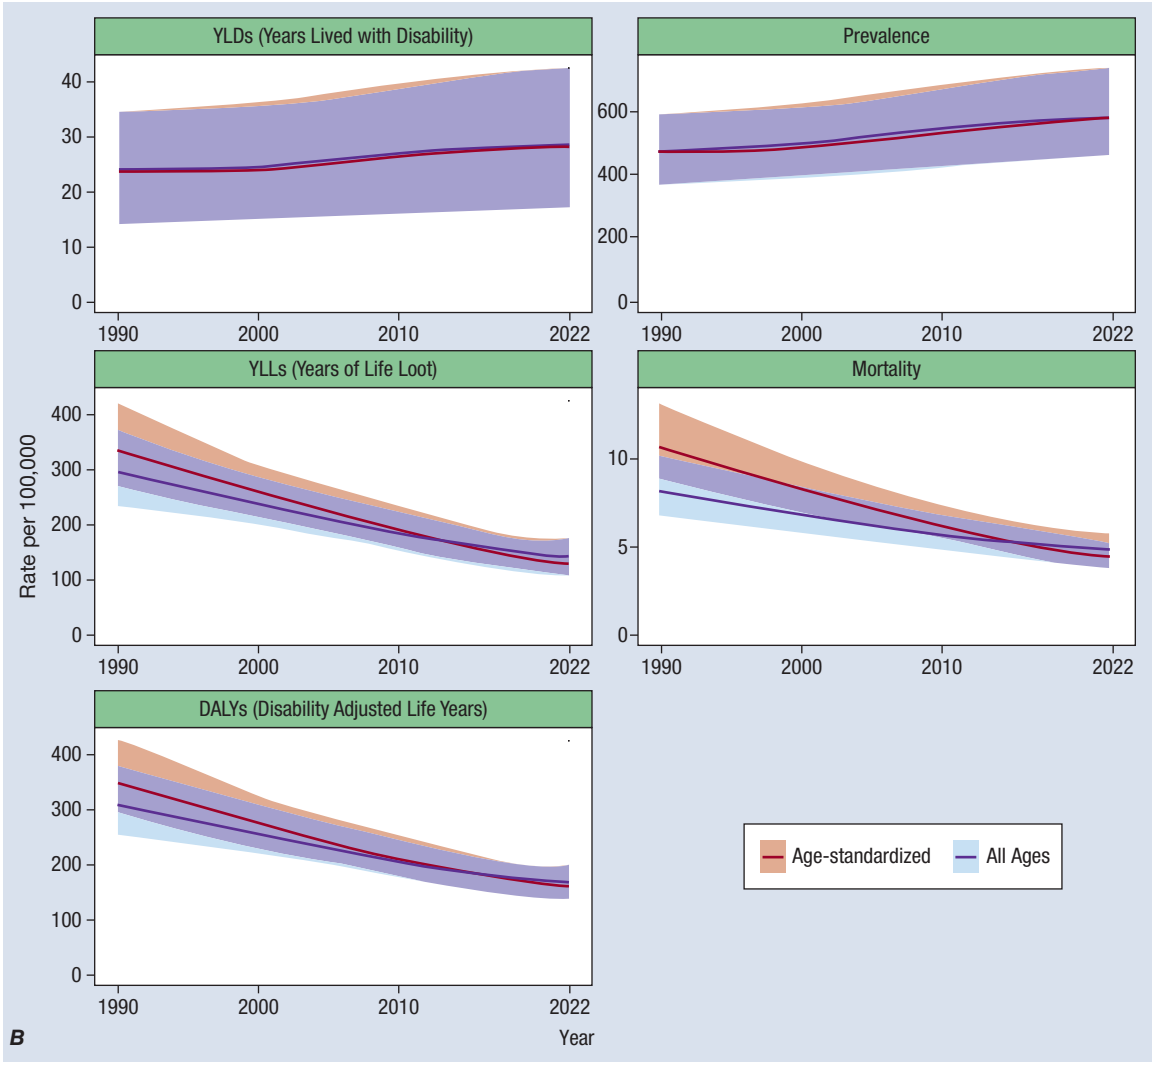

FIGURE 272-1 The global burden of rheumatic heart disease. (***A***) Global map of age-standardized rheumatic heart disease morality rate per 100,000 in 2022. Mortality rates are highest in South Asia and Oceania. (***B***) Global rheumatic heart disease estimates per 100,000 by measure with shaded 95% uncertainty interval, 1990–2022. DALYs, disability-adjusted life-years; YLDs, years lived with disability; YLLs, years of life lost. *(Reproduced with permission from GA Mensah et al: Global burden of cardiovascular diseases and risks, 1990-2022. J Am Coll Cardiol 82:2350, 2023.)*

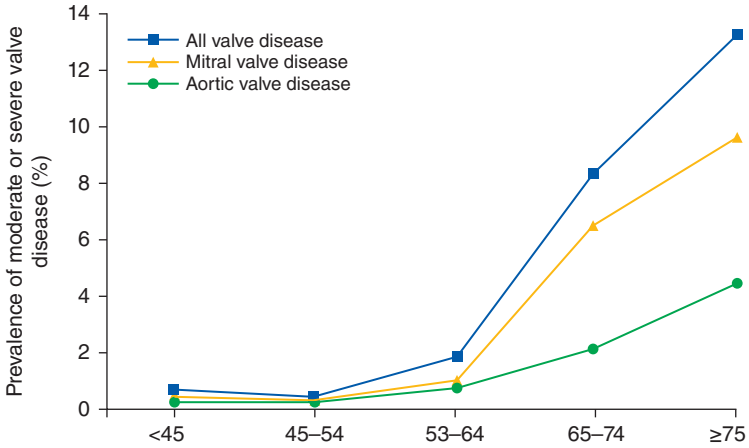

FIGURE 272-2 The burden of moderate or severe mitral and aortic valve disease in the United States. Prevalence estimates are derived from three population-based studies comprising a total of 11,911 individuals: The Coronary Artery Risk Development in Young Adults (CARDIA), the Atherosclerosis Risk in Communities (ARIC), and the Cardiovascular Health Study (CHS). *(Reproduced with permission from VT Nkomo, JM Gardin, TN Skelton, et al: Burden of valvular heart diseases: a population-based study, Lancet 368(9540):1005-1011, 2006.)*

Valve disease in high-income countries is dominated by degenerative or nonrheumatic inflammatory processes that lead to valve thickening, fibrosis, calcification, and dysfunction. The prevalence of valvular heart disease increases significantly with age. Community echocardiographic screening identifies previously undiagnosed, predominantly mild valvular heart disease in ~50% of the population aged >65 years. In this age group, the prevalence of previously undiagnosed moderate or severe valvular heart disease is ~6%. Significant left-sided valve disease may affect as many as 12–13% of adults aged >75 years **(Fig. 272-2)**. Severe aortic stenosis (AS) is estimated to affect 3.5% of the population aged >75 years. A Swedish epidemiologic study estimated the incidence of newly diagnosed valvular heart disease at 64 per 100,000 person-years, with approximately 70% of incident disease observed in individuals 65 years of age or older. AS and mitral regurgitation contributed approximately one-half and one-quarter, respectively, of the valvular heart disease diagnoses in this study.

The incidence of infective endocarditis **(Chap. 133)** has increased with the aging of the population, the more widespread prevalence of vascular grafts and intracardiac devices, the emergence of more virulent multidrug-resistant microorganisms, and the growing epidemic of injection drug use. North American age-standardized incidence rates for endocarditis increased from in 10.1 per 100,000 population in 1990 to 12.54 per 100,000 population in 2019. The more restricted use of antibiotic prophylaxis since 2007 has not been convincingly associated with an increase in incidence rates for infective endocarditis cases attributable to oropharyngeal pathogens. Infective endocarditis has become a relatively more frequent cause of acute valvular regurgitation. Valve surgery during the acute phase of infective endocarditis is performed in ~50–60% of hospitalized patients. Duration of intravenous antibiotic use may be shortened in selected cases.

Bicuspid aortic valve (BAV) disease affects as many as 0.5–1.4% of the general population and is accompanied by an associated aortopathy in ~30–40% of individuals, a disease process expressed as root or ascending aortic aneurysm formation or descending thoracic aortic coarctation. An increasing number of childhood survivors of congenital heart disease present later in life with valvular dysfunction. The global burden of valvular heart disease will continue to progress.

As is true for many other chronic health conditions, disparities in access to and quality of care for patients with valvular heart disease have been well documented, especially for those patients with rheumatic heart disease in low- and middle-income countries. In the Society for Thoracic Surgeons (STS)/American College of Cardiology (ACC) Transcatheter Valve Therapy (TVT) registry, black patients compose <5% of patients in the United States who have received a transcatheter valve for AS. Management decisions and outcome differences based on age, sex, race, geography, and other social determinants of health require intensification of educational efforts and prioritization of resources.

The role of the physical examination in the evaluation of patients with valvular heart disease is also considered in **Chaps. 44 and 246**; of electrocardiography (ECG) in **Chap. 247**; of echocardiography and other noninvasive imaging techniques in **Chap. 248**; and of cardiac catheterization and angiography in **Chap. 249**.

AORTIC STENOSIS

AS is the most common valve lesion among adult patients with chronic valvular heart disease; the majority of adult patients with symptomatic, valvular AS are male.

ETIOLOGY AND PATHOGENESIS

(Table 272-1) AS in adults is due to degenerative calcification of the aortic cusps and occurs most commonly on a substrate of congenital disease (BAV), chronic (trileaflet) deterioration, or previous rheumatic inflammation. A pathologic study of specimens removed at the time of aortic valve replacement (AVR) for AS in adults showed that 53% were bicuspid and 4% were unicuspid. The process of aortic valve deterioration and calcification is not a passive one, but, rather, one that shares many features with vascular atherosclerosis, including endothelial dysfunction, lipid accumulation, inflammatory cell activation, cytokine release, and upregulation of several signaling pathways **(Fig. 272-3)**. Eventually, a fibrocalcific response is established wherein collagen is deposited and valvular myofibroblasts differentiate phenotypically into osteoblasts and actively produce bone matrix proteins that allow for the deposition of calcium hydroxyapatite crystals. Genetic polymorphisms involving the vitamin D receptor, the estrogen receptor in postmenopausal women, interleukin 10, and apolipoprotein E4 have been linked to the development of calcific AS, and a strong familial clustering of cases with trileaflet valves has been reported from western France. Several traditional atherosclerotic risk factors have also been associated with the development and progression of calcific AS, including hypertension, low-density lipoprotein (LDL) cholesterol, lipoprotein(a) (Lp[a]), diabetes mellitus, smoking, chronic kidney disease, and the metabolic syndrome. In a Canadian observational cohort study, the incidence of severe AS was 144 per 100,000 person-years. Hypertension, diabetes mellitus, and dyslipidemia accounted for approximately one-third of the population-attributable risk for severe AS. The presence of aortic valve sclerosis (focal thickening and calcification of the leaflets not severe enough to cause obstruction) is associated with an excess risk of cardiovascular death and myocardial infarction (MI) among persons aged >65. Approximately 30% of persons aged >65 years exhibit some degree of aortic valve sclerosis. Rate and extent of progression to valve obstruction (stenosis) vary among individual patients.

Rheumatic disease of the aortic leaflets produces commissural fusion, sometimes resulting in a bicuspid-appearing valve. This condition, in turn, makes the leaflets more susceptible to trauma and ultimately leads to fibrosis, calcification, and further narrowing. By the time obstruction to left ventricular (LV) outflow causes serious clinical disability, the valve is usually a rigid calcified mass, and careful examination may make it difficult or even impossible to determine

TABLE 272-1 Major Causes of Aortic Stenosis

VALVE LESION	ETIOLOGIES
Aortic stenosis	Congenital (bicuspid, unicuspid)
	Degenerative calcific disease
	Rheumatic fever
	Radiation

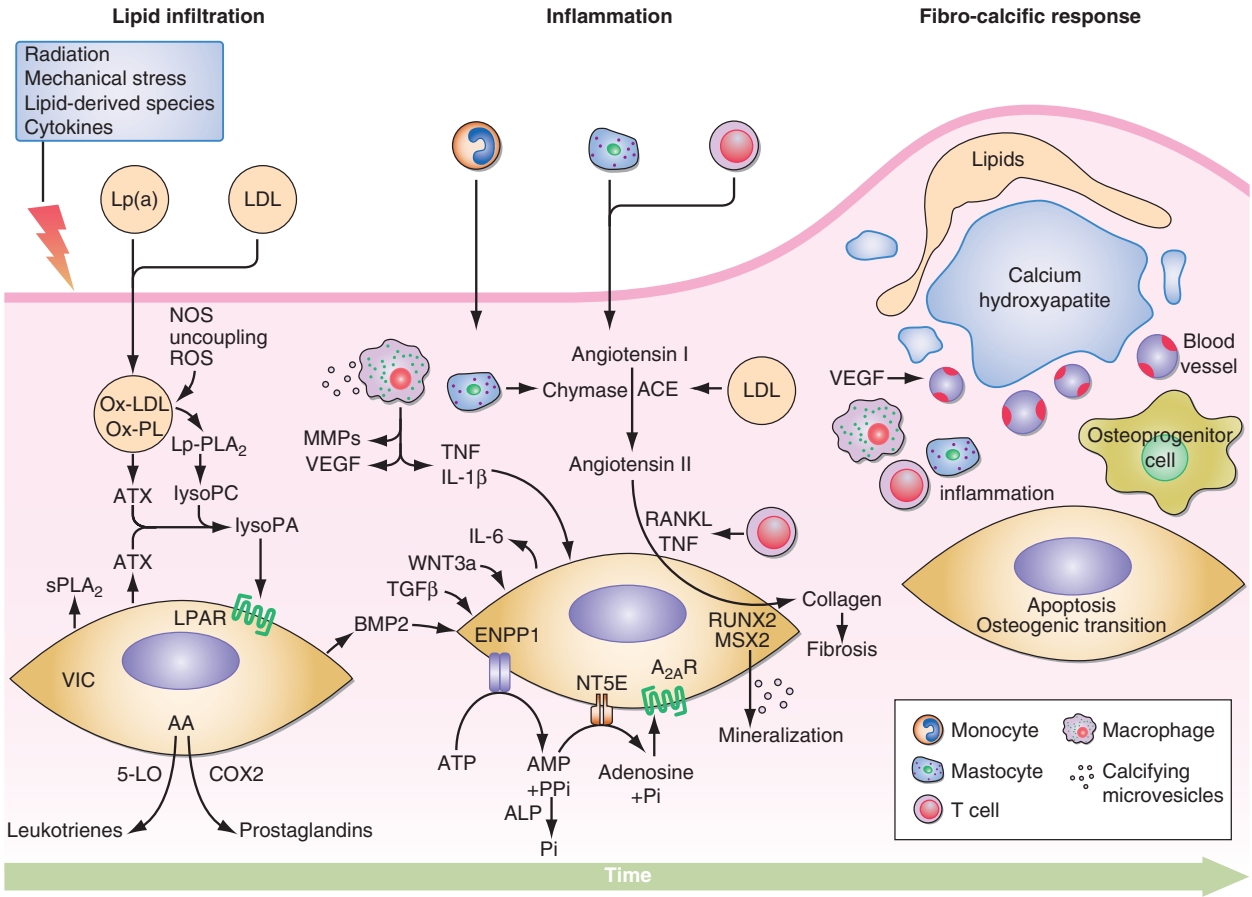

FIGURE 272-3 Pathogenesis of calcific aortic stenosis. Lipid and inflammatory cell infiltration occurs across damaged endothelium. A cascade of events follows that leads eventually to formation of disorganized collagen (fibrosis) and calcium hydroxyapatite (bone) deposition. Valvular interstitial cells (VIC) are critical participants in this active process. AA, arachidonic acid; ACE, angiotensin-converting enzyme; ALP, alkaline phosphatase; ApoB, apolipoprotein B; AMP, adenosine monophosphate; ATP, adenosine triphosphate; ATX, autotaxin; A2AR, adenosine A2A receptor; BMP, bone morphogenetic protein; COX2, cyclooxygenase 2; ENPP, ectonucleotide pyrophosphatase/phosphodiesterase; IL, interleukin; 5-LO, 5-lipoxygenase; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); LPAR, lysophosphatidic acid receptor; Lp-PLA2, lipoprotein-associated phospholipase A2; lysoPA, lysophosphatidic acid; lysoPC, lysophosphatidylcholine; MMP, matrix metalloproteinase; NOS, nitric oxide synthase; Ox-PL, oxidized phospholipid; Ox-LDL, oxidized LDL; RANKL, receptor activator of nuclear factor-κB ligand; ROS, reactive oxygen species; RUNX2, runt-related transcription factor 2; sPLA2, secreted PLA2; TGFβ, transforming growth factor β; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor; VIC, valvular interstitial cell. *(Reproduced with permission from B Lindman et al: Calcific aortic stenosis. Nat Rev Dis Primers 2:16006, 2016.)*

the etiology of the underlying process. Rheumatic AS is almost always associated with involvement of the mitral valve and with aortic regurgitation (AR). Mediastinal radiation can also result in late scarring, fibrosis, and calcification of the aortic leaflets. In this context, the calcification process also affects the mitral annulus.

BICUSPID AORTIC VALVE DISEASE

A bicuspid aortic valve (BAV) is the most common congenital heart valve defect and occurs in 0.5–1.4% of the population with a 2–4:1 male-to-female predominance. The inheritance pattern appears to be autosomal dominant with incomplete penetrance, although some have questioned an X-linked component as suggested by the prevalence of BAV disease among patients with Turner's syndrome. The prevalence of BAV disease among first-degree relatives of an affected individual is ~10%. A single gene defect to explain the majority of cases has not been identified, although mutations in the *NOTCH1*, *GATA5*, and *GATA4* genes have been described in some families. Abnormalities in endothelial nitric oxide synthase and NKX2.5 have been implicated as well. Medial degeneration with ascending aortic aneurysm formation occurs commonly among patients with BAV disease; aortic coarctation is less frequently encountered. Patients with BAV disease have larger aortas than patients with comparable tricuspid aortic valve disease. The aortopathy develops independently of the hemodynamic severity of the valve lesion, but directional shear forces dictated by the anatomic configuration of the valve appear to influence its expression. For example, enlargement of the ascending aorta along its greater curvature is most often associated with right-left cusp fusion (Sievers classification type 1), the most common bicuspid variant. Patients with BAV disease are at risk for aneurysm formation and/or dissection. A BAV can be a component of more complex congenital heart disease with or without other left heart obstructing lesions, as seen in Shone's complex (supravalvar mitral membrane, parachute mitral valve, subvalvar AS, and aortic coarctation).

OTHER FORMS OF OBSTRUCTION TO LEFT VENTRICULAR OUTFLOW

In addition to valvular AS, three other lesions may be responsible for obstruction to LV outflow: *hypertrophic obstructive cardiomyopathy* **(Chaps. 266–270)**, *discrete fibromuscular/membranous subaortic stenosis*, and *supravalvular AS* **(Chap. 280)**. The causes of LV outflow obstruction can usually be differentiated on the basis of the cardiac examination and Doppler echocardiographic findings.

PATHOPHYSIOLOGY

The obstruction to LV outflow produces a systolic pressure gradient between the LV and aorta. When severe obstruction is suddenly produced experimentally, the LV responds by dilation and reduction of stroke volume. However, in some patients, the obstruction may be present at birth and/or increase gradually over the course of many years, and LV contractile performance is maintained by the presence of concentric LV hypertrophy. Initially, this serves as an adaptive

mechanism because it reduces toward normal the systolic stress developed by the myocardium, as predicted by the Laplace relation wall tension normalized to wall thickness ($S = Pr/h$, where S = systolic wall stress, P = pressure, r = radius, and h = wall thickness). A large transaortic valve pressure gradient may exist for many years without a reduction in cardiac output (CO) or the development of LV dilation. Ultimately, however, excessive hypertrophy becomes maladaptive, LV systolic function declines because of afterload mismatch, abnormalities of diastolic function progress, and irreversible myocardial fibrosis develops.

A mean systolic pressure gradient >40 mmHg with a normal CO or an effective aortic orifice area of ~<1 cm^2 (or ~<0.6 cm^2/m^2 body surface area in a normal-sized adult)—i.e., less than approximately one-third of the normal orifice area—is generally considered to represent severe obstruction to LV outflow. The elevated LV end-diastolic pressure observed in many patients with severe AS and preserved ejection fraction (EF) signifies the presence of diminished compliance of the hypertrophied LV. Although the CO at rest is within normal limits in most patients with severe AS, it usually fails to rise normally during exercise. Loss of an appropriately timed, vigorous atrial contraction, as occurs in atrial fibrillation (AF) or atrioventricular dissociation, may cause rapid progression of symptoms. Late in the course, contractile function deteriorates because of afterload excess, the CO and LV–aortic pressure gradient declines, and the mean left atrial (LA), pulmonary artery (PA), and right ventricular (RV) pressures rise. LV performance can be further compromised by superimposed epicardial coronary artery disease (CAD). Stroke volume (and thus CO) can also be reduced in patients with significant hypertrophy and a small LV cavity despite a normal EF. Low-flow (defined as a stroke volume index <35 mL/m^2), low-gradient (defined as a mean pressure gradient <40 mmHg) AS (with either reduced or normal LV systolic function) is both a diagnostic and therapeutic challenge.

The hypertrophied LV causes an increase in myocardial oxygen requirements. In addition, even in the absence of obstructive CAD, coronary blood flow is impaired to the extent that ischemia can be precipitated under conditions of excess demand. Capillary density is reduced relative to wall thickness, compressive forces are increased, and the elevated LV end-diastolic pressure reduces the coronary driving pressure. The subendocardium is especially vulnerable to ischemia by this mechanism.

SYMPTOMS

AS is rarely of clinical importance until the valve orifice has narrowed to ~1 cm^2. Even severe AS may exist for many years without producing any symptoms because of the ability of the hypertrophied LV to generate the elevated intraventricular pressures required to maintain a normal stroke volume. Once symptoms occur, or the LV ejection fraction falls below normal, valve replacement is indicated.

Most patients with pure or predominant AS have gradually increasing obstruction over years but do not become symptomatic until the sixth to eighth decades. Adult patients with BAV disease, however, develop significant valve dysfunction and symptoms one to two decades sooner. Exertional dyspnea, angina pectoris, and syncope are the three cardinal symptoms. Often, there is a history of insidious progression of fatigue and dyspnea associated with gradual curtailment of activities and reduced effort tolerance. *Dyspnea* results primarily from elevation of the pulmonary capillary pressure caused by elevations of LV diastolic pressures secondary to impaired relaxation and reduced LV compliance. *Angina pectoris* usually develops somewhat later and reflects an imbalance between the increased myocardial oxygen requirements and reduced oxygen availability. CAD may or may not be present, although its coexistence is common among AS patients age >65. *Exertional syncope* may result from a decline in arterial pressure caused by vasodilation in exercising muscles and inadequate vasoconstriction in nonexercising muscles in the face of a fixed CO, or from a sudden fall in CO produced by an arrhythmia.

Because the CO at rest is usually well maintained until late in the course, marked fatigability, weakness, peripheral cyanosis, cachexia, and other clinical manifestations of a low CO are usually not prominent until this stage is reached. Orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, i.e., symptoms of LV failure, also occur only in the advanced stages of the disease. Severe pulmonary hypertension leading to RV failure and systemic venous hypertension, hepatomegaly, AF, and tricuspid regurgitation (TR) are usually late findings in patients with isolated severe AS.

When AS and mitral stenosis (MS) coexist, the reduction in flow (CO) caused by MS lowers the pressure gradient across the aortic valve and, thereby, masks many of the clinical findings produced by AS. The transaortic pressure gradient can be increased in patients with concomitant AR due to higher aortic valve flow rates.

PHYSICAL FINDINGS

The heart rhythm is generally regular until late in the course; at other times, AF should suggest the possibility of associated mitral valve disease. Hypertension occurs commonly among older adults with AS. In the late stages, however, when stroke volume declines, the systolic pressure may fall and the pulse pressure narrow. The carotid arterial pulse rises slowly to a delayed peak (*pulsus parvus et tardus*). A thrill or anacrotic "shudder" may be palpable over the carotid arteries, more commonly the left. In the elderly, the stiffening of the arterial wall may mask this important physical sign. In many patients, the *a* wave in the jugular venous pulse is accentuated. This results from the diminished distensibility of the RV cavity caused by the bulging, hypertrophied interventricular septum.

The LV impulse is sometimes displaced laterally in the later stages of the disease. A double apical impulse (with a palpable S_4) may be appreciated, particularly with the patient in the left lateral recumbent position. A systolic thrill may be present at the base of the heart to the right of the sternum when leaning forward or in the suprasternal notch.

Auscultation An early systolic ejection sound is frequently audible in children, adolescents, and young adults with congenital BAV disease. This sound usually disappears when the valve becomes calcified and rigid. As AS increases in severity, LV systole may become prolonged so that the aortic valve closure sound no longer precedes the pulmonic valve closure sound, and the two components may become synchronous, or aortic valve closure may even follow pulmonic valve closure, causing paradoxical splitting of S_2 **(Chap. 246)**. The sound of aortic valve closure can be heard most frequently in patients with AS who have pliable valves; calcification diminishes the intensity of this sound. Frequently, an S_4 is audible at the apex and reflects the presence of LV hypertrophy and an elevated LV end-diastolic pressure; an S_3 generally occurs late in the course when the LV dilates and its systolic function becomes severely compromised.

The murmur of AS is described as an ejection (mid) systolic murmur that commences shortly after the S_1, increases in intensity to reach a peak toward the middle of ejection, and ends just before aortic valve closure. It is characteristically low-pitched, rough, and rasping in character, and loudest at the base of the heart, most commonly in the second right intercostal space. It is transmitted upward along the carotid arteries. Occasionally, it is transmitted downward and to the apex, where it may be confused with the systolic murmur of mitral regurgitation (MR) (Gallavardin effect). In almost all patients with severe obstruction and preserved CO, the murmur is at least grade III/VI. In patients with mild degrees of obstruction or in those with severe stenosis with heart failure and low CO in whom the stroke volume and, therefore, the transvalvular flow rate are reduced, the murmur may be relatively soft and brief.

LABORATORY EXAMINATION

ECG In most patients with severe AS, there is LV hypertrophy. In advanced cases, ST-segment depression and T-wave inversion (LV "strain") in standard leads I and aVL and in the left precordial leads are evident. However, there is no close correlation between the ECG

and the hemodynamic severity of obstruction, and the absence of ECG signs of LV hypertrophy does not exclude severe obstruction. Systemic hypertension can coexist and also contribute to the development of hypertrophy.

Echocardiogram The key findings on transthoracic echocardiogram are thickening, calcification, and reduced systolic opening of the aortic valve leaflets and LV hypertrophy. Eccentric closure of the aortic valve cusps is characteristic of congenitally bicuspid valves. Transesophageal echocardiography imaging can display the obstructed orifice extremely well, but it is not routinely required for accurate characterization of AS. The valve gradient and aortic valve area can be estimated by Doppler measurement of the transaortic velocity. Severe AS is defined by a valve area <1 cm^2, whereas moderate AS is defined by a valve area of 1–1.5 cm^2 and mild AS by a valve area of 1.6–2 cm^2. Aortic valve sclerosis, conversely, is accompanied by a jet velocity of <2.5 m/s (peak gradient <25 mmHg). LV dilation and reduced systolic shortening reflect impairment of LV function. There is a robust experience with the use of longitudinal strain to characterize earlier changes in LV systolic function before a decline in EF can be appreciated. Doppler indices of impaired diastolic function are frequently seen. The frequency with which echocardiography should be repeated during follow-up is dictated by the severity of the stenosis **(Table 272-2)**.

Echocardiography is useful for identifying coexisting valvular abnormalities, differentiating valvular AS from other forms of LV outflow obstruction, and measuring the aortic root and proximal ascending aortic dimensions. These aortic measurements are particularly important for patients with BAV disease. Dobutamine stress echocardiography can be useful for the evaluation of patients with AS and severe LV systolic dysfunction (low-flow, low-gradient, severe AS with reduced EF), in whom the severity of the AS can often be difficult to judge. Patients with severe AS (i.e., valve area <1 cm^2) with a relatively low mean gradient (<40 mmHg) despite a normal EF (low-flow, low-gradient, severe AS with normal EF) are often hypertensive, and efforts to control their systemic blood pressure should be optimized before Doppler echocardiography is repeated. The use of dobutamine stress echocardiography in this setting is not advised. When there is continued uncertainty regarding the severity of AS in patients with reduced CO and reduced or normal LVEF, quantitative analysis of the amount of aortic valve calcium with chest computed tomography (CT) can be helpful. Aortic valve calcium scores that define severe AS differ for men and women, as men tend to have relatively more calcification and women more fibrosis of the valve leaflets. There is increasing use of chest CT angiography to assess aortic valve morphology and function. It has become the imaging method of choice to plan for transcatheter aortic valve implantation (TAVI). Finally, the use of cardiac magnetic resonance (CMR) imaging to screen for the presence of increased extracellular volume (interstitial fibrosis) and late gadolinium enhancement (replacement fibrosis) in patients with severe AS is an area of active investigation. Future management pathways related to the asymptomatic AS patient are likely to include an integrated assessment of the findings from multimodality imaging studies.

Chest X-Ray The chest x-ray may show no or little overall cardiac enlargement for many years. Hypertrophy without dilation may produce some rounding of the cardiac apex in the frontal projection and slight backward displacement in the lateral view. A dilated proximal ascending aorta may be seen along the upper right heart border in the frontal view. Aortic valve calcification may be discernible in the lateral view, but it is usually readily apparent on fluoroscopic examination or by echocardiography; the absence of valvular calcification on fluoroscopy in an adult suggests that severe valvular AS is *not* present. In later stages of the disease, as the LV dilates, there is increasing roentgenographic evidence of LV enlargement, pulmonary congestion, and enlargement of the LA, PA, and right-sided heart chambers.

TABLE 272-2 Frequency of Follow-Up Echocardiography in Aortic Stenosis

STAGE OF DISEASE	FREQUENCY OF ECHOCARDIOGRAPHY
Progressive (stage B)	Every 3–5 years (mild severity, V_{max} 2.0–2.9 m/s) Every 1–2 years (moderate severity, V_{max} 3.0–3.9 m/s)
Severe asymptomatic (stage C1)	Every 6–12 months (V_{max} >4 m/s)

Catheterization Right- and left-sided heart catheterization for invasive assessment of AS is performed infrequently but can be useful when there is a discrepancy between the clinical and noninvasive findings. Concern has been raised that attempts to cross the aortic valve for measurement of LV pressures are associated with a risk of cerebral embolization. Catheterization can also be useful in three distinct categories of patients: (1) *patients with multivalvular disease*, in whom the role played by each valvular deformity should be defined to aid in the planning of operative treatment; (2) *young, asymptomatic patients with noncalcific congenital AS*, to define the severity of obstruction to LV outflow, because operation or percutaneous aortic balloon valvuloplasty (PABV) may be indicated in these patients if severe AS is present, even in the absence of symptoms; and (3) *patients in whom it is suspected that the obstruction to LV outflow may not be at the level of the aortic valve* but rather at the sub- or supravalvular level.

Coronary angiography is indicated to screen for CAD in appropriate patients with severe AS who are being considered for surgical or transcatheter valve intervention. Angiography can be performed invasively at the time of catheterization for hemodynamic assessment or with noninvasive CT techniques. Decision-making regarding the need for coronary artery revascularization at the time of aortic valve intervention is individualized.

NATURAL HISTORY

Death in patients with severe AS occurs most commonly in the seventh and eighth decades. Based on data obtained at postmortem examination in patients before surgical treatment became widely available, the average time to death after the onset of various symptoms was as follows: angina pectoris, 3 years; syncope, 3 years; dyspnea, 2 years; and heart failure, 1.5–2 years. Moreover, in >80% of patients who died with AS, symptoms had existed for <4 years. Among adults dying with valvular AS, sudden death, which presumably resulted from an arrhythmia, occurred in 10–20%; however, most sudden deaths occurred in patients who had previously been symptomatic. Sudden death as the first manifestation of severe AS is very uncommon (~1% per year) in asymptomatic adult patients. Calcific AS is a progressive disease, with an annual reduction in valve area averaging 0.1 cm^2 and annual increases in peak jet velocity and mean valve gradient averaging 0.3 m/s and 7 mmHg, respectively.

TREATMENT

Aortic Stenosis (Fig. 272-4)

MEDICAL TREATMENT

In patients with severe AS (valve area <1 cm^2), strenuous physical activity and competitive sports should be avoided, even in the asymptomatic stage. Care must be taken to avoid dehydration and hypovolemia to protect against a significant reduction in CO. Medications used for the treatment of hypertension or CAD, including beta blockers and angiotensin-converting enzyme (ACE) inhibitors, are generally safe for asymptomatic patients with preserved LV systolic function. Control of blood pressure is important to attenuate the deleterious pathophysiologic effects of two resistance circuits (valve, arterial circulation) in series. Nitroglycerin is helpful in relieving angina pectoris in patients with CAD. Neither HMG-CoA reductase inhibitors ("statins") nor

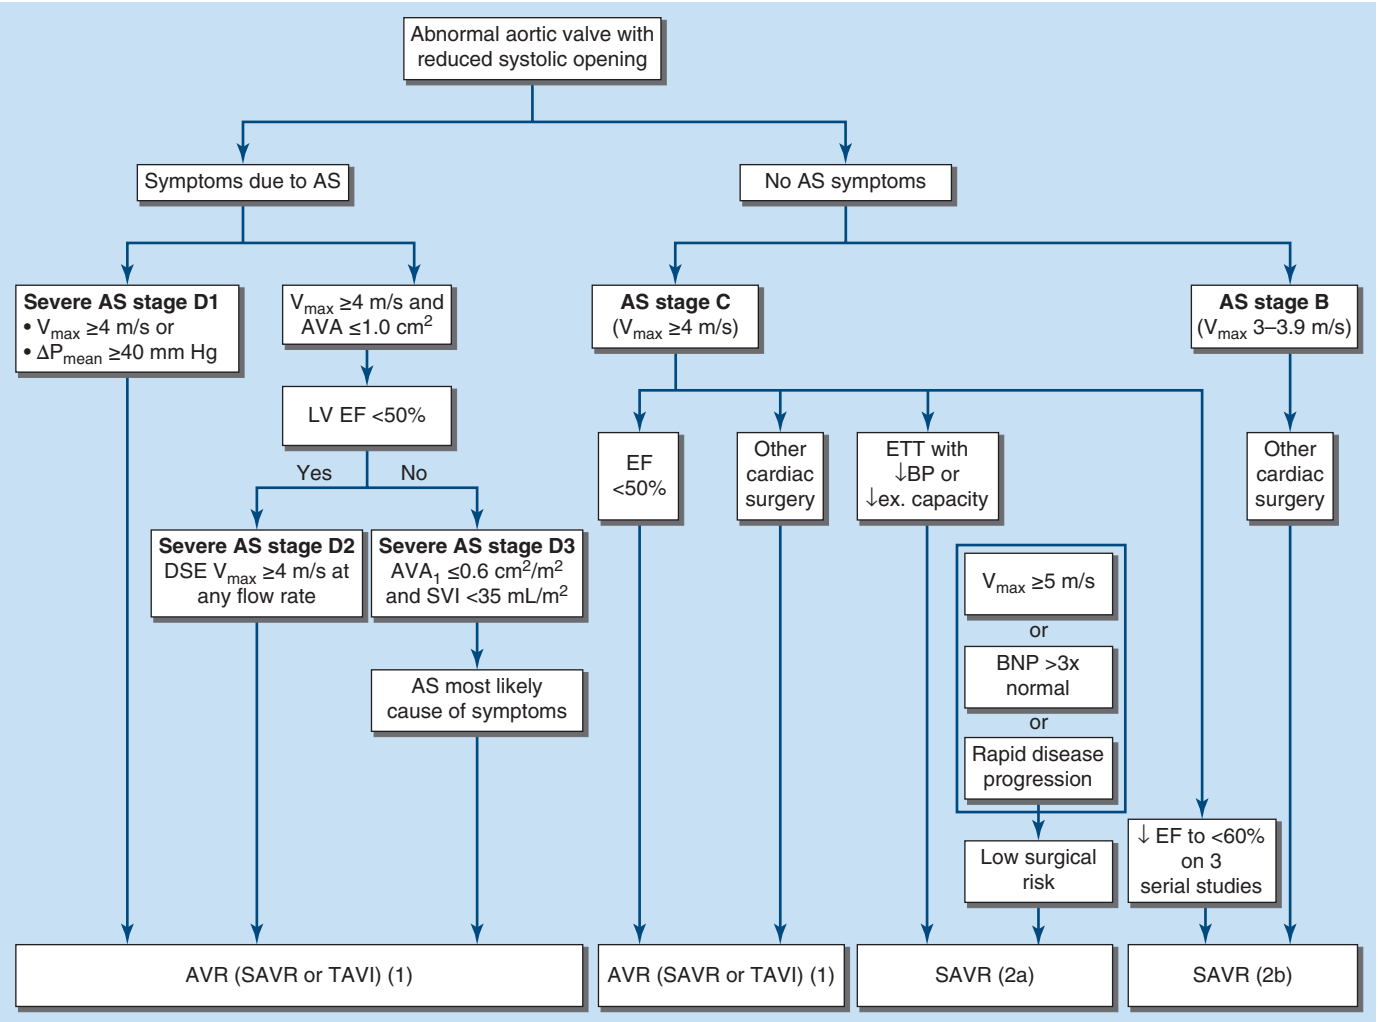

FIGURE 272-4 Management strategy for patients with aortic stenosis. Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. Patients who do not meet criteria for intervention should be monitored with clinical and echocardiographic follow-up. The class designations refer to the American Heart Association/American College of Cardiology methodology for treatment recommendations. Class I recommendations should be performed or are indicated; Class IIa recommendations are considered reasonable to perform; Class IIb recommendations may be considered. The stages refer to the stages of progression of the disease. At disease stage A, risk factors are present for the development of valve dysfunction; stage B refers to progressive, mild-moderate, asymptomatic valve disease; stage C disease is severe in nature but clinically asymptomatic; stage C1 characterizes asymptomatic patients with severe valve disease but compensated ventricular function; stage C2 refers to asymptomatic, severe disease with ventricular decompensation; stage D refers to severe, symptomatic valve disease. With aortic stenosis, stage D1 refers to symptomatic patients with severe aortic stenosis and a high valve gradient (>40 mmHg mean gradient); stage D2 comprises patients with symptomatic, severe, low-flow, low-gradient aortic stenosis and low left ventricular ejection fraction (LVEF); and stage D3 characterizes patients with symptomatic, severe, low-flow, low-gradient aortic stenosis and preserved LVEF (paradoxical, low-flow, low-gradient severe aortic stenosis). Patients with symptomatic severe AS (left side of the diagram, jet velocity ≥4m/s) should be referred for AVR (SAVR or TAVI). Asymptomatic patients with severe AS (jet velocity ≥4m/s) should be referred for AVR (SAVR or TAVI) for LVEF <50% or when other cardiac surgery is needed (e.g., aneurysm repair). There are several findings for which referral for AVR would be reasonable related to results of exercise testing, the presence of a jet velocity >5 m/s, or elevated B-type natriuretic peptide (BNP), provided the patient is considered low risk for complications related to AVR. AS, aortic stenosis; AVA, aortic valve area; AVR, aortic valve replacement; BP, blood pressure; DSE, dobutamine stress echocardiography; EF, ejection fraction; ETT, exercise treadmill test; ΔP_{mean}, mean pressure gradient; SAVR, surgical AVR; TAVI, transcatheter aortic valve implantation; V_{max}, maximum velocity. *(Reproduced with permission from CM Otto et al: 2020 AHA/ACC Guideline for management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 143(5):e72, 2021.)*

inhibitors of the renin-angiotensin-aldosterone system slow the rate of progression of AS. The use of statin medications should be driven by considerations regarding primary and secondary prevention of atherosclerotic cardiovascular disease (ASCVD) events. Studies with agents targeted to Lp(a) are ongoing. The need for endocarditis prophylaxis is restricted to AS patients with a prior history of endocarditis.

SURGICAL TREATMENT

Asymptomatic patients with calcific AS and severe obstruction should be followed carefully for the development of symptoms and for evidence of deteriorating LV function on serial echocardiography. Operation is indicated in patients with severe AS (valve area <1 cm^2 or 0.6 cm^2/m^2 body surface area) who are symptomatic, those who exhibit LV systolic dysfunction (EF <50%), and those with AS due to BAV disease and an aneurysmal root or ascending aorta (maximal dimension >5.5 cm). Operation for aneurysm disease is recommended at smaller aortic diameters (4.5–5.0 cm) for patients with a family history of an aortic catastrophe and for patients who exhibit rapid aneurysm growth (>0.5 cm/year). Patients with asymptomatic moderate or severe AS who are referred for coronary artery bypass grafting surgery should also have AVR. The majority (~80%) of patients with symptomatic severe AS referred for surgery are considered low risk for perioperative death or major complication. Operative risk increases as a function of age, comorbidities, and the need for concomitant aortic or other heart valve surgery or coronary artery bypass grafting. A 2023

analysis from the STS Adult Cardiac Surgery Database reported a 5-year survival rate of 95% following isolated surgical AVR (SAVR) in low-risk AS patients of mean age 74 years. The indications for SAVR in the asymptomatic patient have been the subject of intense debate, as surgical outcomes in selected patients have continued to improve. Relative indications for which surgery is reasonable include an abnormal response to treadmill exercise; rapid progression of AS, especially when urgent access to medical care might be compromised; very severe AS, defined by an aortic valve jet velocity >5 m/s or mean gradient >60 mmHg; excessive LV hypertrophy in the absence of systemic hypertension; and a brain natriuretic peptide level >3 times the upper reference limit, with low surgical risk. Exercise testing can be safely performed in asymptomatic patients, as many as one-third of whom will show signs of functional impairment. In a small randomized controlled trial (RCT) of early surgery versus conservative care for asymptomatic patients with very severe AS (defined by a transaortic valve jet velocity ≥4.5 m/s, mean gradient ≥50 mmHg, or aortic valve area ≤0.75 cm^2), the rate of operative death or death from cardiovascular causes during follow-up was reduced with early surgery. In the conservative care group, the cumulative incidence of sudden death was 4% at 4 years and 14% at 8 years. In another randomized trial of early surgery versus conservative care for asymptomatic patients with lesser degrees of AS (jet velocity ≥4 m/s, mean gradient ≥40 mmHg, aortic valve areas ≤1.0 cm^2) and normal LV systolic function, early surgery resulted in a significant reduction in a composite endpoint of death, MI, stroke, and heart failure hospitalization.

Operation should be carried out promptly (1–3 months) after symptom onset. Clinical decision-making is straightforward for patients with normal-flow (>35 mL/m^2), high-gradient (≥40 mmHg) severe AS. In patients with low-flow, low-gradient severe AS with reduced LVEF, perioperative mortality rates are high (15–20%), and evidence of LV dysfunction usually persists even after a technically successful operation. Long-term postoperative survival correlates with preoperative LV function. Nonetheless, in view of the even worse prognosis of such patients when they are treated medically, there is usually little choice but to advise valve replacement, especially in patients in whom flow reserve can be demonstrated by dobutamine stress echocardiography (defined by a ≥20% increase in stroke volume after dobutamine challenge). Patients in this high surgical risk group are treated with TAVI whenever feasible (see below), but robust data from RCTs in this subpopulation of severe AS patients are lacking. The management of patients with low-flow, low-gradient severe AS with normal LVEF is also challenging. Outcomes are improved with surgery or TAVI compared with conservative care for symptomatic patients with this type of "paradoxical" low-flow AS, but more research is needed to guide therapeutic decision-making for individual patients. In patients in whom severe AS and CAD coexist, relief of the AS and revascularization may sometimes result in striking clinical and hemodynamic improvement.

Because many patients with calcific AS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary function before AVR is recommended. Age alone is not a contraindication to SAVR for AS. The perioperative mortality rate depends to a substantial extent on the patient's preoperative clinical and hemodynamic state. Assessment of frailty is a critical component of preprocedural evaluation. Treatment decisions for AS patients who are not at low operative risk are made by a multidisciplinary heart team with representation from general cardiology, interventional cardiology, multimodality imaging, cardiac surgery, and other subspecialties as needed, including geriatrics. The 8-year survival rate of older adult (mean age 74), low surgical risk patients following isolated SAVR is 85–90%. Recommendations regarding the type of valve prosthesis (biological or mechanical) must weigh the trade-offs between limited bioprosthetic valve durability and the risks of thromboembolism and bleeding with a mechanical valve and are heavily influenced by patient age, expected longevity, and individual preferences. Bioprostheses are generally favored for patients age >65 years. Shared decision-making with younger patients must be individualized, although increasing numbers of patients age <65 now opt for a biological valve replacement. Approximately 10–20% of bioprosthetic valves evidence primary valve failure by 15 years, requiring re-replacement (or valve-in-valve TAVI, see below), and an approximately equal percentage of patients with mechanical prostheses develop hemorrhagic complications as a consequence of treatment with vitamin K antagonists. In a large observational study of patients who underwent SAVR in California between 1996 and 2013, receipt of a biological versus a mechanical prosthesis in patients <55 years old was associated with an excess hazard of death over 15 years of follow-up. Homograft AVR is usually reserved for patients with aortic valve endocarditis.

The Ross procedure involves replacement of the diseased aortic valve with the autologous pulmonic valve and implantation of a homograft in the native pulmonic position. It is a technically complex procedure that may be considered in selected young or middle-aged adult patients when surgical and institutional expertise are available. Late postoperative complications include aortic root dilation, AR, and pulmonary homograft stenosis.

PERCUTANEOUS AORTIC BALLOON VALVULOPLASTY

This procedure is preferable to operation in many children and young adults with congenital, noncalcific AS **(Chap. 280)**. It is not recommended as definitive therapy in adults with severe calcific AS because of a very high restenosis rate (80% within 1 year) and the risk of procedural complications, although on occasion, it has been used successfully as a bridge to operation or TAVI in patients with severe LV dysfunction and shock. It is performed routinely as part of the TAVI procedure (see below).

TRANSCATHETER AORTIC VALVE IMPLANTATION

TAVI surpassed SAVR for treatment of isolated AS in the United States in 2016 and is now available to symptomatic patients across the entire surgical risk spectrum (prohibitive, high, intermediate, and low) on the basis of the favorable results observed in a series of landmark RCTs reported over the past decade. The results of a randomized trial of TAVI versus conventional care in asymptomatic AS patients will be released around 2024–2025. TAVI is most commonly performed using one of two systems, a balloon-expandable valve (BEV) or a self-expanding valve (SEV), both of which incorporate a pericardial bioprosthesis **(Fig. 272-5*A*, *B*)**. TAVI is most frequently undertaken via the transfemoral route, although trans-LV apical, subclavian, carotid, and ascending aortic routes have been used. Nonfemoral access is associated with higher complication rates. Aortic balloon valvuloplasty under rapid RV (or LV) pacing is performed as a first step to create an orifice of sufficient size for the prosthesis. Procedural success rates exceed 95% in appropriately selected patients. Among low surgical risk patients with symptomatic severe AS, randomized trials with follow-up through 4–5 years have demonstrated similar valve performance and clinical outcomes for SAVR versus TAVI using either a BEV or SEV platform **(Fig. 272-6)**. Outcomes achieved with TAVI technology have been very favorable and have allowed the extension of AVR to groups of patients previously considered poor candidates for conventional surgery. Nevertheless, some prohibitive or high surgical risk patients are not candidates for this procedure because their comorbidity profile, frailty, and expected longevity would make its undertaking inappropriate. The heart team is specifically charged with making challenging decisions of this nature. The use of these devices for treatment of patients with structural deterioration of bioprosthetic aortic valves (valve-in-valve TAVI), as an alternative to reoperative valve replacement, has increased sharply over the past 5 years. The technology has also been increasingly applied to selected BAV patients despite the fact that patients with this anatomy were excluded from the landmark RCTs.

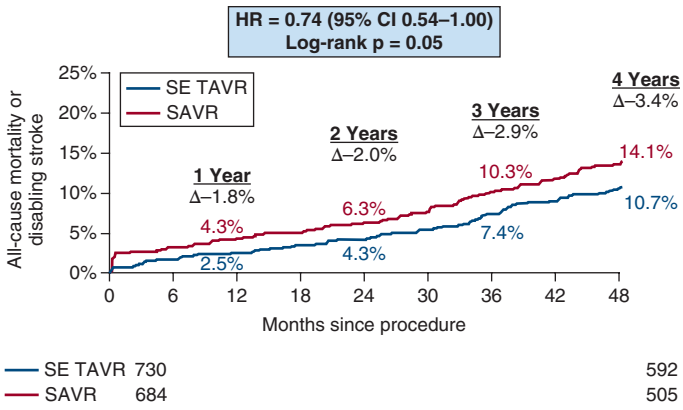

FIGURE 272-6 Four-year cumulative incidence of all-cause mortality or disabling stroke for low surgical risk aortic stenosis patients assigned to self-expanding transcatheter aortic valve implantation (SE-TAVR; n = 730) or surgical aortic valve replacement (SAVR; n = 684). In this study, TAVR was noninferior to SAVR and marginally superior to SAVR for the combined endpoint. *(Reproduced with permission from JK Forrest et al: 4-year outcomes of patients with aortic stenosis in the EVOLUT low risk trial. J Am Coll Cardiol 82:2163, 2023.)*

prefer a biological prosthesis rests on several clinical, imaging, and technical considerations **(Fig. 272-7 and Table 272-3)**. Because there are scant RCT data on TAVI outcomes in patients <65 years, SAVR is recommended in this age group. Aortic valve/root anatomy, as well as the extent, severity, and distribution of calcium, and the distance of the coronary arteries from the plane of the annulus, may dictate a surgical approach, as could the need to perform a concomitant procedure such as ascending aortic replacement. Lastly, inability to achieve transfemoral access is a relative impediment to TAVI given the higher complication rates observed when this procedure is undertaken from other vascular access sites.

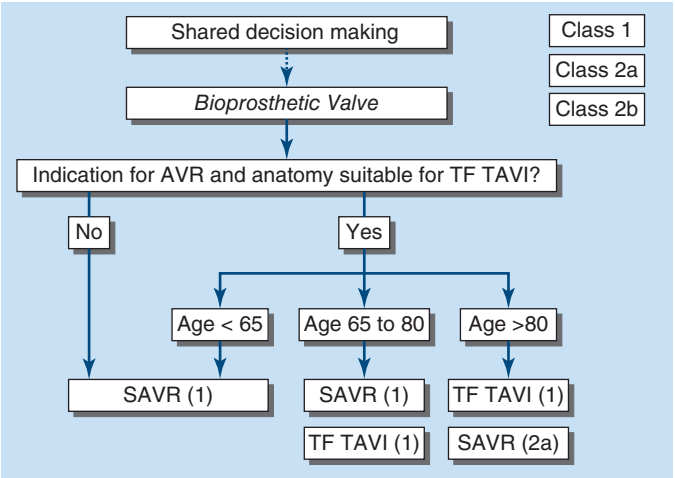

FIGURE 272-7 Suggested decision-making algorithm for the elective choice of transcatheter aortic valve implantation (TAVI) versus surgical aortic valve replacement (SAVR) for aortic stenosis patients with an indication for valve intervention. The pathway emphasizes the premium placed on transfemoral (TF) TAVI access and the age-related differences in recommendations. Patients younger than age 65 are recommended to undergo SAVR given the paucity of prospective randomized data on intermediate- and long-term TAVI outcomes for individuals younger than age 70. AVR, aortic valve replacement. *(Reproduced and abridged with permission from CM Otto et al: 2020 AHA/ACC Guideline for management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 143:e72, 2021.)*

Compared with SAVR, transfemoral TAVI results in fewer periprocedural deaths and confers lower risks of strokes, major bleeding, and AF. Hospital lengths of stay are significantly shorter and return to normal activity more rapid with TAVI. Rates of permanent pacemaker use, perivalvular AR, bioprosthetic leaflet thrombosis, and vascular complications are lower with SAVR. The choice between TAVI versus SAVR for patients with trileaflet AS who

TABLE 272-3 Factors Favoring SAVR, TAVI, or Palliative Care in Patients with Aortic Stenosis

	FAVORS SAVR	FAVORS TAVI	FAVORS PALLIATION
Age/life expectancy[a]	Younger age/longer life expectancy	Older age/fewer expected remaining years of life	Limited life expectancy
Valve anatomy	Bicuspid aortic valve Subaortic (LVOT) calcification Rheumatic valve disease Small or large aortic annulus[b]	Calcific trileaflet AS	
Prosthetic valve preference	Mechanical or surgical bioprosthetic valve preferred Concern for patient-prosthesis mismatch (annular enlargement might be considered)	Bioprosthetic valve preferred Favorable ratio of life expectancy to valve durability TAVI provides larger valve area than same-sized SAVR	
Concurrent cardiac conditions	Aortic dilation[c] Severe primary MR Severe CAD requiring bypass grafting Septal hypertrophy requiring myectomy Atrial fibrillation	Severe calcification of the ascending aorta ("porcelain" aorta)	Irreversible severe LV systolic dysfunction Severe MR due to annular calcification
Noncardiac conditions		Severe lung, liver, or renal disease Mobility issues (high risk for sternotomy)	Symptoms likely due to noncardiac conditions Severe dementia Moderate to severe involvement of 2 or more other organ systems
Frailty	Not frail or few frailty measures	Frailty likely to improve after TAVI	Severe frailty unlikely to improve after TAVI
Estimated risk of SAVR or TAVI	SAVR risk low TAVI risk high	TAVI risk low to medium SAVR risk high to prohibitive	Prohibitive SAVR risk (>15%) or post-TAVI life expectancy <1 year
Procedure-specific impediments	Valve anatomy, annular size, or low coronary ostial height precludes TAVI Vascular access does not allow transfemoral TAVI	Previous cardiac surgery with at-risk coronary grafts Previous chest irradiation	Valve anatomy, annular size, or coronary ostial height precludes TAVI Vascular access does not allow transfemoral TAVI
Goals of care and patient preferences and values	Less uncertainty about valve durability Avoid repeat intervention Lower risk of permanent pacer Life prolongation Symptom relief Improved long-term exercise capacity and QOL Avoid vascular complications Accepts longer hospital stay, pain in recovery period	Accepts uncertainty about valve durability and possible repeat intervention Higher risk of permanent pacer Life prolongation Symptom relief Improved exercise capacity and QOL Prefers shorter hospital stay, less postprocedure pain	Life prolongation not an important goal Avoid futile or unnecessary diagnostic or therapeutic procedures Avoid procedural stroke risk Avoid possibility of cardiac pacer

[a]Data on bioprosthetic valve durability are more robust for SAVR valves than for TAVI valves. Mechanical valves are very durable but require lifelong anticoagulation. Choice of prosthesis is a shared decision-making process accounting for individual patient values and preferences. [b]Surgical root enlargement can be performed at time of SAVR to allow a use of a larger prosthesis and reduce the occurrence of prosthesis-patient mismatch. [c]Aortic root or ascending aortic enlargement may require surgical correction at time of SAVR.

273 Aortic Regurgitation

Patrick T. O'Gara, Joseph Loscalzo

ETIOLOGY

(Table 273-1) Aortic regurgitation (AR) may be caused by primary valve disease, aortic root disease, or their combination.

Primary Valve Disease Rheumatic disease results in thickening, deformity, and shortening of the individual aortic valve cusps, changes that prevent their proper opening during systole and closure during diastole. A rheumatic origin is much less common in patients with isolated AR who do not have associated rheumatic mitral valve disease. Patients with congenital bicuspid aortic valve (BAV) disease may develop predominant AR, and ~20% of these patients will require aortic valve surgery between 10 and 40 years of age. Congenital fenestrations of the aortic valve occasionally produce mild AR. Membranous subaortic stenosis results in a high-velocity systolic jet that often leads to thickening and scarring of the aortic valve leaflets and secondary AR. Prolapse of an aortic cusp, resulting in progressive chronic AR, occurs in ~15% of patients with ventricular septal defect (Chap. 280), but may also occur as an isolated phenomenon or as a consequence of myxomatous degeneration sometimes associated with mitral and/or tricuspid valve involvement.

AR may result from infective endocarditis (IE), which can develop on a valve previously affected by rheumatic disease, a congenitally deformed valve, or on a normal aortic valve, and may lead to perforation or destruction of one or more leaflets. The aortic valve leaflets may become scarred and retracted during the course of syphilis or ankylosing spondylitis and contribute further to the AR that derives primarily from associated root dilation. Although traumatic rupture or avulsion of an aortic cusp is an uncommon cause of acute AR, it represents the most frequent serious lesion in patients surviving nonpenetrating cardiac injuries. The coexistence of hemodynamically significant aortic stenosis (AS) with AR usually excludes all the rarer forms of AR because it occurs almost exclusively in patients with rheumatic or congenital AR. In patients with AR due to primary valvular disease, dilation of the aortic annulus may occur secondarily and lead to worsening regurgitation.

Primary Aortic Root Disease AR also may be due entirely to marked aortic annular dilation, i.e., aortic root disease, without primary involvement of the valve leaflets; widening of the aortic annulus and lack of diastolic coaptation of the aortic leaflets are responsible for the AR (Chap. 291). Medial degeneration of the ascending aorta, which may or may not be associated with other manifestations of Marfan's syndrome; idiopathic dilation of the aorta; annuloaortic ectasia; osteogenesis imperfecta; and severe, chronic hypertension may all widen the aortic annulus and lead to progressive AR. Occasionally AR is caused by retrograde dissection of the aorta involving the aortic annulus. Syphilis and ankylosing spondylitis, both of which may also affect the aortic leaflets, may be associated with cellular infiltration and scarring of the media of the thoracic aorta, leading to aortic dilation, aneurysm formation, and severe regurgitation. In syphilis of the aorta (Chap. 187), now a very rare condition, the involvement of the intima may narrow the coronary ostia, which in turn may be responsible for myocardial ischemia. Takayasu's aortitis and giant cell aortitis can also result in aneurysm formation and secondary AR.

TABLE 273-1 Major Causes of Aortic Regurgitation

VALVE LESION	ETIOLOGIES

	Bicuspid aortic valve
	Nonsyndromic familial aneurysm
	Aortitis
	Hypertension

PATHOPHYSIOLOGY

The total stroke volume ejected by the left ventricle (LV) (i.e., the sum of the effective forward stroke volume and the volume of blood that regurgitates back into the LV) is increased in patients with AR. In patients with severe AR, the volume of regurgitant flow may equal the effective forward stroke volume. In contrast to MR, in which a portion of the LV stroke volume is delivered into the low-pressure left atrium (LA), in AR, the entire LV stroke volume is ejected into a high-pressure zone, the aorta. An increase in the LV end-diastolic volume (increased preload) constitutes the major hemodynamic compensation for AR. The dilation and eccentric hypertrophy of the LV allow this chamber to eject a larger stroke volume without requiring any increase in the relative shortening of each myofibril. Therefore, severe AR may occur with a normal effective forward stroke volume and a normal LV ejection fraction (LVEF, total [forward plus regurgitant] stroke volume/end-diastolic volume), together with an elevated LV end-diastolic pressure and volume. However, through the operation of Laplace's law, LV dilation increases the LV systolic tension required to develop any given level of systolic pressure. Chronic AR is, thus, a state in which LV preload and afterload are both increased. Ultimately, these adaptive measures fail. As LV function deteriorates, the end-diastolic volume rises further and the forward stroke volume and ejection fraction (EF) decline. Deterioration of LV function often precedes the development of symptoms. Considerable thickening of the LV wall also occurs with chronic AR, and at autopsy, the hearts of these patients may be among the largest encountered, sometimes weighing >1000 g.

The reverse diastolic pressure gradient from aorta to LV, which drives the AR flow, decreases progressively during diastole, accounting for the typical decrescendo nature of the diastolic murmur. Equilibration between aortic and LV pressures may occur toward the end of diastole in patients with chronic severe AR, particularly when the heart rate is slow. In patients with acute severe AR, the LV is unprepared for the regurgitant volume load. LV compliance is normal or reduced, and LV diastolic pressures rise rapidly, occasionally to levels >40 mmHg. The LV pressure may exceed the LA pressure toward the end of diastole, and this reversed pressure gradient closes the mitral valve prematurely.

In patients with chronic severe AR, the effective forward cardiac output (CO) usually is normal or only slightly reduced at rest, but often it fails to rise normally during exercise. An early sign of LV dysfunction is a reduction in the EF. In advanced stages, there may be considerable elevation of the LA, pulmonary artery (PA) wedge, PA, and right ventricular (RV) pressures and reduced forward CO at rest.

Myocardial ischemia may occur in patients with AR because myocardial oxygen requirements are elevated by LV dilation, hypertrophy, and elevated LV systolic tension, and coronary blood flow may be compromised. A large fraction (the majority) of coronary blood flow occurs during diastole, when aortic pressure is low, thereby reducing coronary perfusion or driving pressure. This combination of increased oxygen demand and reduced supply may cause myocardial ischemia, particularly of the subendocardium, even in the absence of epicardial coronary artery disease (CAD).

HISTORY

Approximately three-fourths of patients with pure or predominant valvular AR are men; women predominate among patients with primary

valvular AR who have associated rheumatic mitral valve disease. A history compatible with IE may sometimes be elicited from patients with rheumatic or congenital involvement of the aortic valve, and the infection often precipitates or seriously aggravates preexisting symptoms.

In patients with *acute severe AR*, as may occur in IE, aortic dissection, or trauma, the LV cannot dilate sufficiently to maintain stroke volume, and LV diastolic pressure rises rapidly with associated marked elevations of LA and PA wedge pressures. Pulmonary edema and/or cardiogenic shock may develop rapidly.

Chronic severe AR may have a long latent period, and patients may remain relatively asymptomatic for as long as 10–15 years. Uncomfortable awareness of the heartbeat, especially on lying down, may be an early complaint. Sinus tachycardia, during exertion or with emotion, or premature ventricular contractions may produce particularly uncomfortable palpitations as well as head pounding. These complaints may persist for many years before the development of exertional dyspnea, usually the first symptom of diminished cardiac reserve. The dyspnea is followed by orthopnea, paroxysmal nocturnal dyspnea, and excessive diaphoresis. Anginal chest pain even in the absence of CAD may occur in patients with severe AR, even in younger patients. Anginal pain may develop at rest as well as during exertion. Nocturnal angina may be a particularly troublesome symptom, and it may be accompanied by marked diaphoresis. The anginal episodes can be prolonged and often do not respond satisfactorily to sublingual nitroglycerin. Systemic fluid accumulation, including congestive hepatomegaly and ankle edema, may develop late in the course of the disease.

PHYSICAL FINDINGS

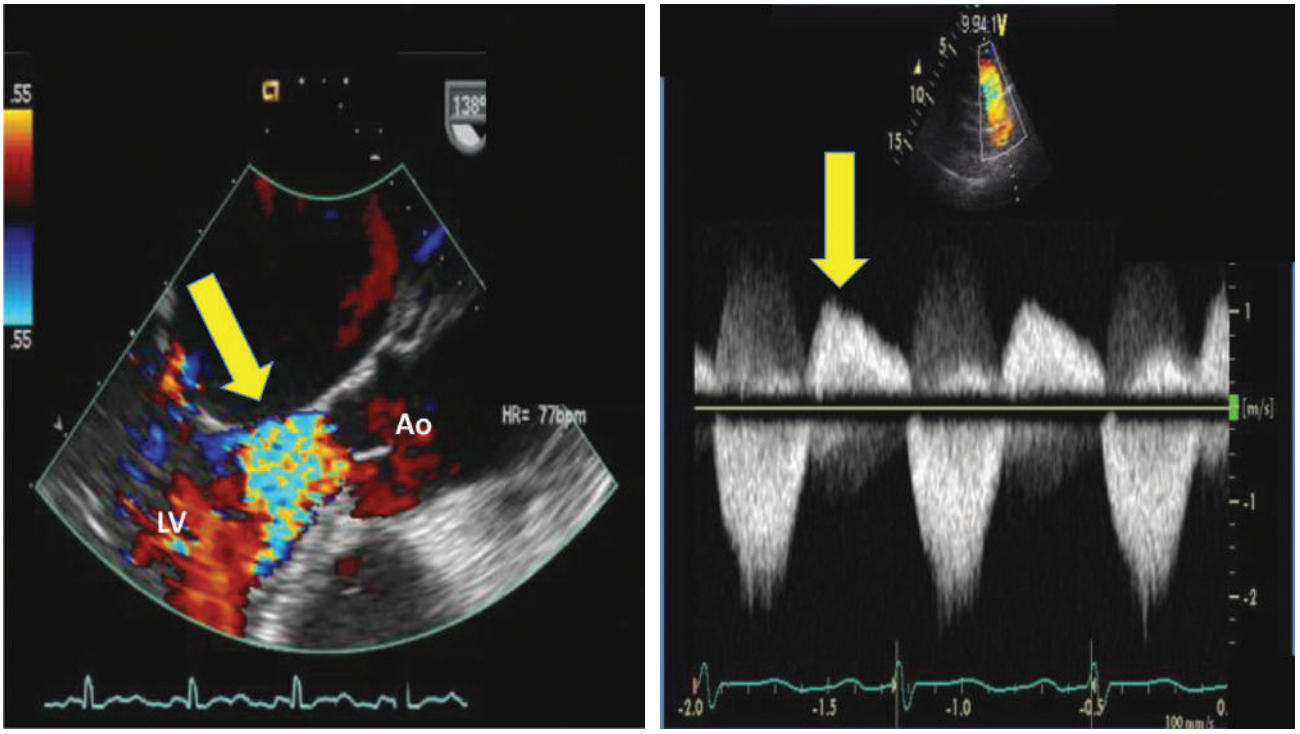
In chronic severe AR, the jarring of the entire body and the bobbing motion of the head with each systole can be appreciated, and the abrupt distention and collapse of the larger arteries are easily visible. The examination should be directed toward the detection of conditions predisposing to AR, such as bicuspid valve, IE, Marfan's syndrome, or ankylosing spondylitis.

Arterial Pulse A rapidly rising "water-hammer" pulse, which collapses suddenly as arterial pressure falls rapidly during late systole and diastole (Corrigan's pulse), and capillary pulsations, an alternate flushing and paling of the skin at the root of the nail while pressure is applied to the tip of the nail (Quincke's pulse), are characteristic of chronic severe AR. A booming "pistol-shot" sound can be heard over the femoral arteries (Traube's sign), and a to-and-fro murmur (Duroziez's sign) is audible if the femoral artery is lightly compressed with a stethoscope.

The arterial pulse pressure is widened as a result of both systolic hypertension and a lowering of the diastolic pressure. The measurement of arterial diastolic pressure with a sphygmomanometer may be complicated by the fact that systolic sounds are frequently heard with the cuff completely deflated. However, the level of cuff pressure at the time of muffling of the Korotkoff sounds (phase IV) generally corresponds fairly closely to the true intra-arterial diastolic pressure. As the disease progresses and the LV end-diastolic pressure rises, the arterial diastolic pressure may actually rise as well, because the aortic diastolic pressure cannot fall below the LV end-diastolic pressure. For the same reason, acute severe AR may also be accompanied by only a slight widening of the pulse pressure. Such patients are invariably tachycardic as the heart rate increases in an attempt to preserve the CO.

Palpation In patients with chronic severe AR, the LV impulse is heaving and displaced laterally and inferiorly. The systolic expansion and diastolic retraction of the apex are prominent. A diastolic thrill may be palpable along the left sternal border in thin-chested individuals, and a prominent systolic thrill may be palpable in the suprasternal notch and transmitted upward along the carotid arteries. This systolic thrill and the accompanying murmur do not necessarily signify the coexistence of AS. In some patients with AR or with combined AS and AR, the carotid arterial pulse may be bisferiens, i.e., with two systolic waves separated by a trough **(see Fig. 246-2*C*)**.

Auscultation In patients with severe AR, the aortic valve closure sound (A_2) is usually absent. A systolic ejection sound is audible in patients with BAV disease, and occasionally an S_4 also may be heard. The murmur of chronic AR is typically a high-pitched, blowing, decrescendo diastolic murmur, heard best in the third intercostal space along the left sternal border **(see Fig. 246-5*B*)**. In patients with mild AR, this murmur is brief, but as the severity increases, it generally becomes louder and longer, indeed holodiastolic. When the murmur is soft, it can be heard best with the diaphragm of the stethoscope and with the patient sitting up, leaning forward, and with the breath held in forced expiration. In patients in whom the AR is caused by primary valvular disease, the diastolic murmur is usually louder along the left than the right sternal border. However, when the murmur is louder along the right sternal border, it suggests that the AR is caused by aneurysmal dilation of the aortic root. "Cooing" or musical diastolic murmurs suggest eversion of an aortic cusp vibrating in the regurgitant stream.



A mid-systolic ejection murmur is frequently audible in isolated AR. It is generally heard best at the base of the heart and is transmitted along the carotid arteries. This murmur may be quite loud without signifying aortic valve obstruction. A third murmur sometimes heard in patients with severe AR is the *Austin Flint murmur*, a soft, low-pitched, rumbling mid-to-late diastolic murmur. It is probably produced by the diastolic displacement of the anterior leaflet of the mitral valve by the AR stream and is not associated with hemodynamically significant mitral valve obstruction. The auscultatory features of AR are intensified by strenuous and sustained handgrip, which augments systemic vascular resistance and increases LV afterload.

In acute severe AR, the elevation of LV end-diastolic pressure may lead to early closure of the mitral valve, a soft S_1, a pulse pressure that is not particularly wide, and a soft, short, early diastolic murmur of AR.

LABORATORY EXAMINATION

ECG In patients with chronic severe AR, ECG signs of LV hypertrophy are common **(Chap. 247)**. In addition, these patients frequently exhibit ST-segment depression and T-wave inversion in leads I, aVL, V_5, and V_6 ("LV strain"). Left axis deviation and/or QRS prolongation may also be present.

Echocardiogram (Fig. 273-1) LV size is increased in chronic AR, and systolic function is normal or even supernormal until myocardial contractility declines, as signaled by a decrease in EF or increase in the end-systolic dimension. A rapid, high-frequency diastolic fluttering of the anterior mitral leaflet produced by the impact of the regurgitant jet is a characteristic finding. The echocardiogram is also useful in determining the cause of AR, by detecting dilation of the aortic annulus and root, aortic dissection or primary leaflet pathology. With severe AR, the central jet width assessed by color flow Doppler imaging exceeds 65% of the width of the LV outflow tract, the regurgitant volume is ≥60 mL/beat, the regurgitant fraction is ≥50%, and there is diastolic flow reversal in the proximal portion of the descending thoracic aorta. The continuous-wave Doppler profile of the AR jet shows a rapid deceleration time in patients with acute severe AR, due to the rapid increase in LV diastolic pressure. Surveillance transthoracic echocardiography (TTE) forms the cornerstone of longitudinal follow-up and allows for the early detection of changes in LV size and/or function. Assessment of LV global longitudinal strain (GLS; a measure of myocardial thickening in systole) with speckle track imaging may demonstrate changes in LV systolic function that precede a fall in EF. There is increasing experience with the use of three-dimensional echocardiography to measure LV volumes. Transesophageal echocardiography (TEE) can provide detailed anatomic assessment of the valve, root, and portions of the aorta. For patients in whom TTE is limited by poor acoustical windows or inadequate characterization of LV function or the cause or severity of the regurgitation, cardiac magnetic resonance (CMR) imaging can be performed. This modality also allows for accurate assessment of LV volumes, as well as aortic size and contour. It can also be utilized to screen for increased LV interstitial (extracellular volume fraction) and replacement fibrosis (late gadolinium enhancement). Both CMR imaging and cardiac computed tomography (CT) can also provide detailed assessment of aortic valve, root, and thoracic aortic anatomy.

A *B*

FIGURE 273-1 Echocardiographic and Doppler depiction of severe aortic regurgitation. (***A***) Color flow transesophageal echocardiographic long axis image in diastole shows a broad jet of severe aortic regurgitation (AR, yellow arrow) directed into the left ventricle. ECG rhythm strip below. Ao, aorta; BPM, beats per minute; HR, heart rate; LV, left ventricle. (***B***) Continuous wave Doppler tracing (middle image) obtained from the suprasternal window (top image) during transthoracic echocardiography shows dense, holodiastolic flow reversal in the descending thoracic aorta (yellow arrow) indicative of severe AR. ECG rhythm strip below.

Chest X-Ray In chronic severe AR, the apex is displaced downward and to the left in the frontal projection. In the left anterior oblique and lateral projections, the LV is displaced posteriorly and encroaches on the spine. When AR is caused by primary disease of the aortic root, aneurysmal dilation of the aorta may be noted, and the aorta may fill the retrosternal space in the lateral view. Echocardiography, CMR imaging, and chest CT angiography are more sensitive than a chest x-ray for the detection of root and ascending aortic enlargement.

Cardiac Catheterization and Angiography When needed, right and left heart catheterization with contrast aortography can provide confirmation of the magnitude of regurgitation and the status of LV function. Coronary angiography is performed routinely in patients at risk of coronary artery disease prior to surgery, although this anatomic information can also be obtained in many patients with coronary CT angiography.

TREATMENT

Aortic Regurgitation

ACUTE AORTIC REGURGITATION (FIG. 273-2)

Patients with acute severe AR may respond to intravenous diuretics and vasodilators (such as sodium nitroprusside), but stabilization is usually short-lived and operation is indicated urgently. Intra-aortic balloon counterpulsation is contraindicated. Beta blockers are best avoided so as not to reduce the CO further or slow the heart rate, thus allowing more time for diastolic filling of the LV. Surgery is the treatment of choice and is usually necessary within 24 h of diagnosis.

CHRONIC AORTIC REGURGITATION

The onset of symptoms, or LV systolic dysfunction, is an indication for surgery. Medical treatment with diuretics and vasodilators (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers [ARBs], dihydropyridine calcium channel blockers, or hydralazine) may be useful as a temporizing measure. Surgery can then be performed in a more controlled setting. The use of vasodilators to extend the compensated phase of chronic severe AR in asymptomatic patients before the onset of symptoms or the development of LV dysfunction is not useful, although these agents should be employed to treat hypertension (systolic blood pressure >140 mmHg). It is often difficult to achieve adequate blood pressure control because of the increased stroke volume and enhanced LV ejection that accompany severe AR. Cardiac arrhythmias and systemic infections are poorly tolerated in patients with severe AR and must be treated promptly and vigorously. Although nitroglycerin and long-acting nitrates are not as helpful in relieving anginal pain as they are in patients with coronary heart disease, they are worth a trial. Patients with syphilitic aortitis should receive a full course of penicillin therapy (Chap. 187). Beta blockers and the ARB losartan may be useful to retard the rate of aortic root enlargement in young patients with Marfan's syndrome and aortic root dilation. A randomized controlled trial showed no difference in efficacy between atenolol and losartan for this indication. Whether beta blockers or ARBs are useful in retarding the rate of growth of aortic aneurysms in other patient subsets (e.g., BAV disease with aortopathy, Takayasu's disease) has not been demonstrated. Beta blockers in patients with valvular AR were previously considered relatively contraindicated due to concern that slowing of the heart rate would allow more time for diastolic regurgitation and LV filling. Observational reports, however, have suggested that beta blockers may provide functional benefit in some patients with chronic AR. Beta blockers can sometimes provide incremental blood pressure lowering in patients with chronic AR and hypertension. They can also lessen the sense of forceful heart action that many patients find uncomfortable. Patients with severe AR, particularly those with an associated aortopathy, should avoid isometric exercises.

SURGICAL TREATMENT

In deciding on the advisability and proper timing of surgical treatment, two points should be kept in mind: (1) patients with chronic severe AR usually do not become symptomatic until *after* the development of myocardial dysfunction; and (2) when delayed too long

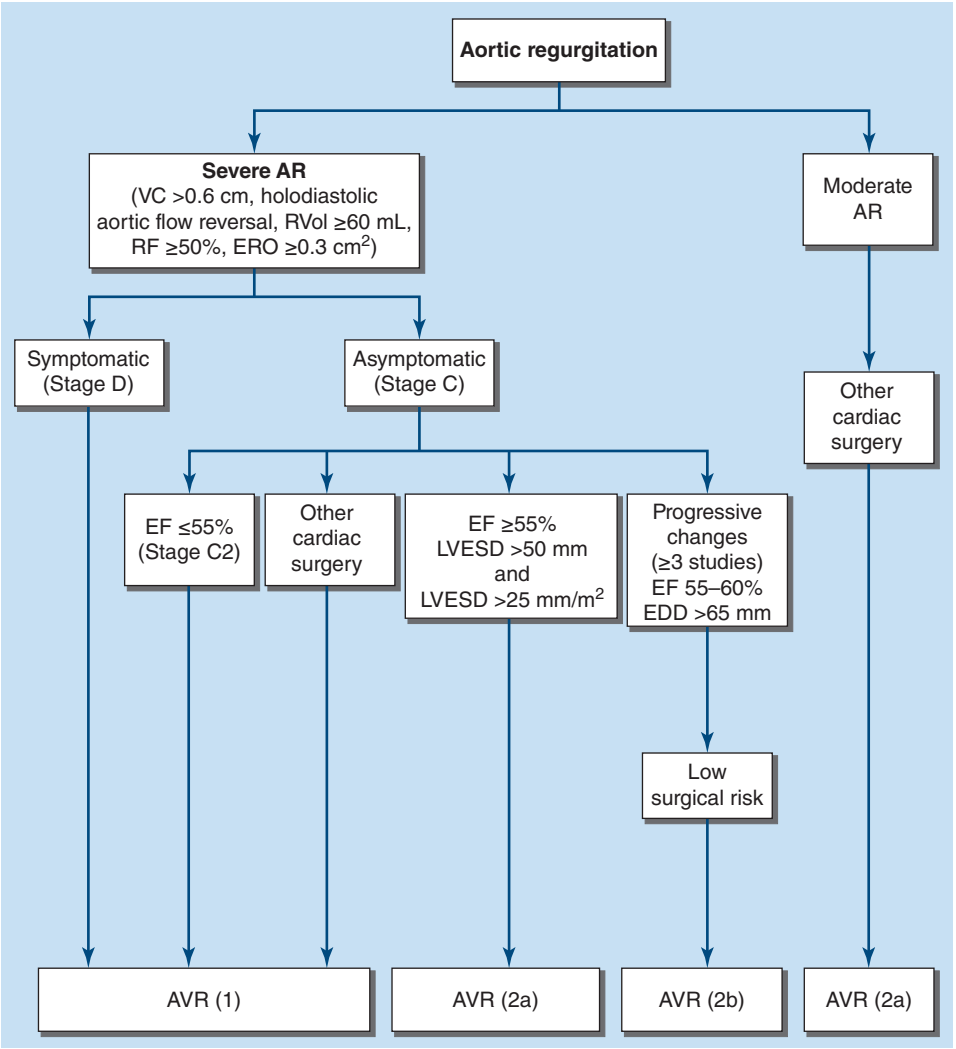


FIGURE 273-2 Management of patients with aortic regurgitation. See legend for Fig. 272-4 for explanation of treatment recommendations (Class I, IIa, and IIb) and disease stages (B, C1, C2, and D). Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. Surgery is indicated for patients with severe AR and symptoms, LV dysfunction, or other indications for operation (e.g., aneurysm disease). Surgery is also reasonable once the LV indexed end-systolic dimension reaches or exceeds 25 mm/m^2. Patients who do not meet criteria for intervention should be monitored periodically with clinical and echocardiographic follow-up. AR, aortic regurgitation; AVR, aortic valve replacement (valve repair may be appropriate in selected patients); EDD, end-diastolic dimension; EF, ejection fraction; ERO, effective regurgitant orifice; LV, left ventricular; LVEDD, left ventricular end-diastolic dimension; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; RF, regurgitant fraction; RVol, regurgitant volume; VC, vena contracta. *(Reproduced with permission from CM Otto et al: 2020 AHA/ACC Guideline for management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation. 2021;143(5):e72.)*

(defined as >1 year from onset of symptoms or LV dysfunction), surgical treatment often does not restore normal LV size and function. Therefore, in patients with chronic severe AR, careful clinical follow-up and noninvasive testing with echocardiography at ~6- to 12-month intervals are necessary if operation is to be undertaken at the optimal time, i.e., *coincident with or after* the onset of LV dysfunction but *prior to* the development of symptoms. Exercise testing may be helpful to assess effort tolerance more objectively and should be employed whenever questions about symptoms arise. Operation can be deferred as long as the patient both remains asymptomatic and retains normal LV function without severe or progressive chamber dilation.

Aortic valve replacement (AVR) is indicated for the treatment of severe AR in symptomatic patients irrespective of LV function. In general, the operation should be carried out in asymptomatic patients with severe AR and progressive LV dysfunction defined by an LVEF <55% on serial studies, an LV end-systolic dimension >50 mm (>25 mm/m^2), or an LV diastolic dimension >65 mm. Smaller dimensions may be appropriate thresholds in individuals of smaller stature or when there is evidence of progressively decreasing LV function or increasing LV size on serial studies and the anticipated risks for surgical morbidity and mortality are low. Two case series from surgical referral centers have suggested that surgery should be performed at an even lower threshold for LV end-systolic dimension index (≥20 mm/m^2), but data from randomized controlled trials are lacking. Abnormal LV GLS (≥ −18%) has been associated with an excess hazard for death in single-center studies. Observational studies using either three-dimensional echocardiography or CMR imaging have also suggested that event-free survival is reduced in asymptomatic patients with an LV end-systolic volume index ≥45 mL/m^2, compared with patients with an LV end-systolic volume index <45 mL/m^2. Patients with severe AR without indications for operation should be followed by clinical and echocardiographic examination every 6–12 months. Transcatheter aortic valve implantation (TAVI) is not recommended for patients with severe AR who are surgical candidates. Technical success with TAVI in patients with chronic AR is limited by the degree of aortic annular dilation and the relative paucity of valvular and annular calcium.

Surgical options for management of aortic valve and root disease have expanded considerably over the past decade. AVR with a suitable mechanical or tissue (biological) prosthesis is generally necessary in patients with rheumatic AR and in many patients with other causes of valvular AR. Rarely, when a leaflet has been perforated during IE

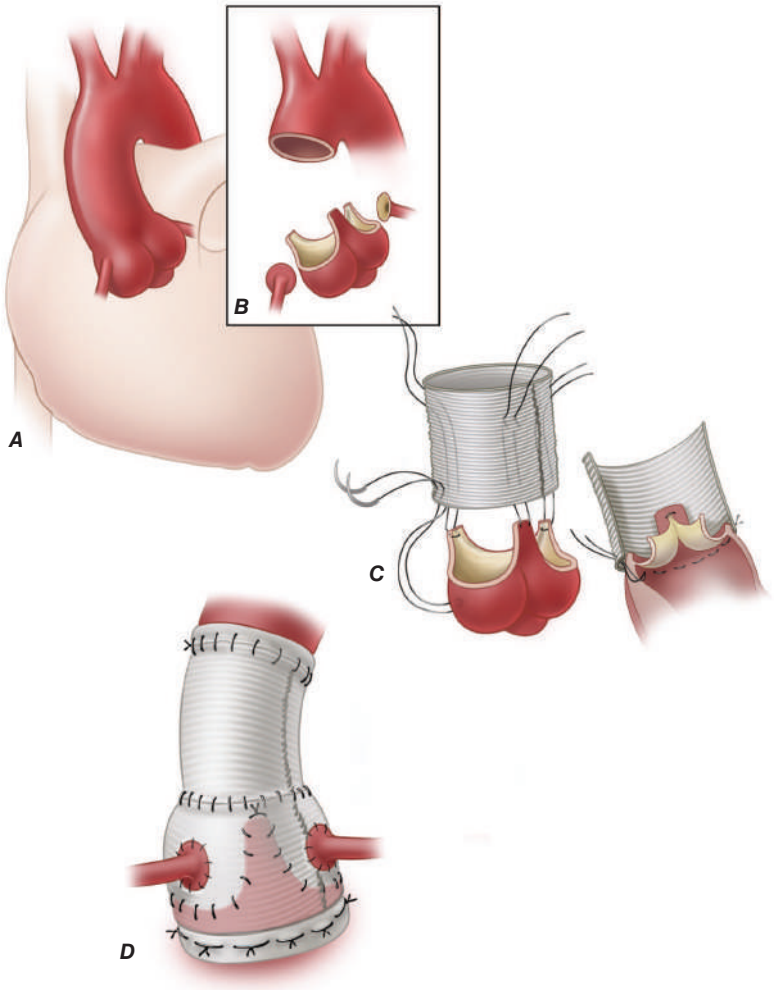

FIGURE 273-3 Valve-sparing aortic root reconstruction (David procedure). Aortic root and proximal ascending aorta (***A***) are resected (***B***) with sinuses of Valsalva and mobilized coronary artery buttons remaining. Subannular sutures (***C***) are placed, commissural posts are drawn up inside the valve, and the annular sutures are passed through the proximal end of the graft. The annular sutures are tied (***D***), the valve is reimplanted inside the graft, aortic continuity is reestablished with another graft of appropriate size, and the coronary buttons are attached to the side of the graft. *(From P Steltzer et al [eds]: Valvular Heart Disease: A Companion to Braunwald's Heart Disease, 3rd ed, Fig. 12-27, p. 200.)*

or torn from its attachments to the aortic annulus by thoracic trauma, primary surgical repair may be possible. When AR is due to aneurysmal dilation of the root or proximal ascending aorta rather than to primary valve involvement, it may be possible to reduce or eliminate the regurgitation by narrowing the annulus or by excising a portion of the aortic root without replacing the valve. Elective, valve-sparing aortic root reconstruction generally involves reimplantation of the valve in a contoured graft with reattachment of the coronary artery buttons into the side of the graft and is best undertaken in specialized surgical centers by experienced operators **(Fig. 273-3)**. Resuspension of the native aortic valve leaflets is possible in ~50% of patients with acute AR in the setting of type A aortic dissection. In other conditions, however, AR can be effectively eliminated only by replacing the aortic valve, as well as the dilated or aneurysmal ascending aorta responsible for the regurgitation, often using a composite prosthetic valve-graft conduit. Pure AR is not by itself a contraindication to the Ross procedure, although the presence of aortic annular dilation and/or an associated aortopathy would eliminate this option.

As is true in patients with other valvular heart disease, both operative and late mortality risks are largely dependent on the stage of the disease and myocardial function at the time of operation. The overall operative mortality rate for isolated AVR performed for pure AR is ~1–2%. The mortality risk doubles when aortic surgery is added to the operation. Patients with AR, marked cardiac enlargement, and established LV dysfunction experience an operative mortality rate of ~5–10% and a late mortality rate of ~3–5% per year due to LV failure despite a technically satisfactory operation. Nonetheless, because of the very poor prognosis with medical management, even patients with advanced LV systolic dysfunction should be considered for operation.

Patients with acute severe AR require prompt (24–48 h) surgical treatment, which may be lifesaving.

274 Mitral Stenosis

Patrick T. O'Gara, Joseph Loscalzo

The role of the physical examination in the evaluation of patients with valvular heart disease is also considered in **Chaps. 44 and 246**; of electrocardiography (ECG) in **Chap. 247**; of echocardiography and other noninvasive imaging techniques in **Chap. 248**; and of cardiac catheterization and angiography in **Chap. 249**.

MITRAL STENOSIS

ETIOLOGY AND PATHOLOGY

Rheumatic fever is the leading cause of mitral stenosis (MS) **(Table 274-1; see also Chap. 371)**. Other less common etiologies of obstruction to left ventricular inflow include congenital mitral valve stenosis, cor triatriatum, mitral annular calcification with extension onto the leaflets, systemic lupus erythematosus, rheumatoid arthritis, left atrial myxoma, and infective endocarditis with large vegetations. Pure or predominant MS occurs in ~40% of all patients with rheumatic heart disease and a history of rheumatic fever **(Chap. 371)**. In other patients with rheumatic heart disease, lesser degrees of MS may accompany mitral regurgitation (MR) and aortic valve disease. With reductions in the incidence of acute rheumatic fever, particularly in temperate climates and middle- to high-income countries, the incidence of MS has declined considerably over the past several decades. However, it remains a major problem in low-income countries, especially in sub-Saharan Africa, India, Southeast Asia, and Oceania **(Chap. 272)**.

In rheumatic MS, chronic inflammation leads to diffuse thickening of the valve leaflets with formation of fibrous tissue often with calcific deposits. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and the pathologic process eventually leads to narrowing at the apex of the funnel-shaped ("fish-mouth") valve. Although the initial insult to the mitral valve is rheumatic, later changes may be exacerbated by inflammation, fibrosis, and trauma due to altered flow patterns. Calcification of the stenotic mitral valve immobilizes the leaflets and narrows the orifice further. Thrombus formation and arterial embolization may arise from the calcific valve itself, but in patients with atrial fibrillation (AF), thrombi arise more frequently from the dilated left atrium (LA), particularly from within the LA appendage.

PATHOPHYSIOLOGY

In normal adults, the area of the mitral valve orifice is 4–6 cm^2. In the presence of significant obstruction, i.e., when the orifice area is reduced to <~2 cm^2, blood can flow from the LA to the left ventricle (LV) only if propelled by an abnormally elevated left atrioventricular pressure gradient, the hemodynamic hallmark of MS. When the mitral valve opening is reduced to <1.5 cm^2, referred to as "severe" MS, an LA pressure of ~25 mmHg is required to maintain a normal cardiac output (CO). The elevated pulmonary venous and pulmonary arterial (PA) wedge pressures reduce pulmonary compliance, contributing to exertional dyspnea. The first bouts of dyspnea are usually precipitated by clinical events that increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure (see below).

To assess the severity of obstruction hemodynamically, both the transvalvular pressure gradient and the flow rate must be measured **(Chap. 249)**. The latter depends not only on the CO but on the heart rate, as well. An increase in heart rate shortens diastole proportionately more than systole and diminishes the time available for flow across the mitral valve. Therefore, at any given level of CO, tachycardia, including that associated with rapid AF, augments the transvalvular pressure gradient and elevates further the LA pressure. Similar considerations apply to the pathophysiology of tricuspid stenosis (TS).

The LV diastolic pressure and ejection fraction (EF) are normal in isolated MS. In MS and sinus rhythm, the elevated LA and PA wedge pressures exhibit a prominent atrial contraction pattern (*a* wave) and a gradual pressure decline after the *v* wave and mitral valve opening (*y* descent). In severe MS and whenever pulmonary vascular resistance is significantly increased, the PA pressure (PAP) is elevated at rest and rises further during exercise, often causing secondary elevations of right ventricular (RV) end-diastolic pressure and volume.

Cardiac Output In patients with severe MS (mitral valve orifice 1–1.5 cm^2), the CO is normal or almost so at rest, but rises subnormally during exertion. In patients with very severe MS (valve area <1 cm^2), particularly those in whom pulmonary vascular resistance is markedly elevated, the CO is subnormal at rest and may fail to rise or may even decline during activity.

Pulmonary Hypertension The clinical and hemodynamic features of MS are influenced importantly by the level of the PAP. Pulmonary hypertension results from (1) passive backward transmission of the elevated LA pressure; (2) pulmonary arteriolar constriction (the so-called "second stenosis"), which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); (3) interstitial edema in the walls of the small pulmonary vessels; and (4) at end stage, organic obliterative changes in the pulmonary vascular bed. Severe pulmonary hypertension results in RV enlargement, secondary tricuspid regurgitation (TR), and pulmonic regurgitation (PR), as well as right-sided heart failure.

SYMPTOMS

In temperate climates, the latent period between the initial attack of rheumatic carditis (in the increasingly rare circumstances in which a history of one can be elicited) and the development of symptoms due to MS is generally about two decades; most patients begin to experience disability in the fourth decade of life. Studies carried out before the development of surgical mitral valvotomy revealed that once a patient with MS became seriously symptomatic, the disease progressed inexorably to death within 2–5 years.

In patients whose mitral orifices are large enough to accommodate a normal blood flow with only mild elevations of LA pressure, marked elevations of this pressure leading to dyspnea and cough may be precipitated by sudden changes in the heart rate, volume status, or CO, as, for example, with severe exertion, excitement, fever, severe anemia, paroxysmal AF and other tachycardias, sexual intercourse, pregnancy, and thyrotoxicosis. As MS progresses, lesser degrees of stress precipitate dyspnea, the patient becomes limited in daily activities, and orthopnea and paroxysmal nocturnal dyspnea develop. The development of persistent AF often marks a turning point in the patient's course and is generally associated with acceleration of the rate at which symptoms progress. *Hemoptysis* **(Chap. 41)** results from rupture of pulmonary-bronchial venous connections secondary to pulmonary venous hypertension. It occurs most frequently in patients who have elevated LA pressures without markedly elevated pulmonary vascular resistances and is rarely fatal. *Recurrent pulmonary emboli* **(Chap. 290)**, sometimes with infarction, are an important cause of morbidity and mortality late in the course of MS and often arise from right atrial mural thrombus. *Pulmonary infections*, i.e., bronchitis, bronchopneumonia, and lobar pneumonia, commonly complicate untreated MS, especially during the winter months. In patients with significant left atrial enlargement,

Myxoma
IE with large vegetations

Abbreviations: IE, infective endocarditis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

cardiovocal syndrome (Ortner's syndrome) may develop with hoarseness secondary to left recurrent laryngeal nerve compression.

Pulmonary Changes In addition to the aforementioned changes in the pulmonary vascular bed, fibrous thickening of the walls of the alveoli and pulmonary capillaries occurs commonly in MS. The vital capacity, total lung capacity, maximal breathing capacity, and oxygen uptake per unit of ventilation are reduced **(Chap. 296)**. Pulmonary compliance falls further as pulmonary capillary pressure rises during exercise.

Thrombi and Emboli *Thrombi* may form in the left atria, particularly within the enlarged atrial appendages of patients with MS. Systemic embolization, the incidence of which is 10–20%, occurs more frequently in patients with AF, in patients >65 years of age, and in those with a reduced CO. However, systemic embolization may be the presenting feature in otherwise asymptomatic patients with only mild MS.

PHYSICAL FINDINGS

(See also Chaps. 44 and 246).

Inspection and Palpation In patients with severe MS, there may be a malar flush with pinched and blue facies. In patients with sinus rhythm and severe pulmonary hypertension or associated TS, the jugular venous pulse reveals prominent *a* waves due to vigorous right atrial systole. The systemic arterial pressure is usually normal or slightly low. A parasternal lift signifies an enlarged RV. A diastolic thrill may very rarely be present at the cardiac apex, with the patient in the left lateral recumbent position.

Auscultation The first heart sound (S_1) is usually accentuated in the early stages of the disease and slightly delayed. The pulmonic component of the second heart sound (P_2) also is often accentuated with elevated PAPs, and the two components of the second heart sound (S_2) are closely split. The opening snap (OS) of the mitral valve is most readily audible in expiration at, or just medial to, the cardiac apex. This sound generally follows the sound of aortic valve closure (A_2) by 0.05–0.12 s. The time interval between A_2 and OS varies inversely with the severity of the MS. The OS is followed by a low-pitched, rumbling, diastolic murmur, heard best at the apex with the patient in the left lateral recumbent position **(see Fig. 246-5)**; it is accentuated by mild exercise (e.g., a few rapid sit-ups) carried out just before auscultation. In general, the duration of this murmur correlates with the severity of the stenosis in patients with preserved CO. In patients with sinus rhythm, the murmur often reappears or becomes louder during atrial systole (presystolic accentuation). Soft, grade I or II/VI systolic murmurs may be heard at or medial to the apex and may signify mixed mitral valve disease with regurgitation. Hepatomegaly, ankle edema, ascites, and pleural effusion, particularly in the right pleural cavity, may occur in patients with MS and RV failure.

Associated Lesions With severe pulmonary hypertension, a pansystolic murmur produced by functional TR may be audible along the left sternal border. This murmur is usually louder during inspiration and diminishes during forced expiration (Carvallo's sign). When the CO is markedly reduced in MS, the typical auscultatory findings, including the diastolic rumbling murmur, may not be detectable (silent MS), but they may reappear as compensation is restored. The *Graham Steell murmur* of PR, a high-pitched, diastolic, decrescendo blowing murmur along the left sternal border, results from dilation of the pulmonary valve ring and occurs in patients with mitral valve disease and severe pulmonary hypertension. This murmur may be indistinguishable from the more common murmur produced by aortic regurgitation (AR), although it may increase in intensity with inspiration and is accompanied by a loud and often palpable P_2.

LABORATORY EXAMINATION

ECG In MS and sinus rhythm, the P wave usually suggests LA enlargement **(see Fig. 247-8)**. It may become tall and peaked in lead II and upright in lead V_1 when severe pulmonary hypertension or TS complicates MS and right atrial (RA) enlargement develops. The QRS complex is usually normal. However, with severe pulmonary hypertension, right axis deviation and RV hypertrophy are often present.

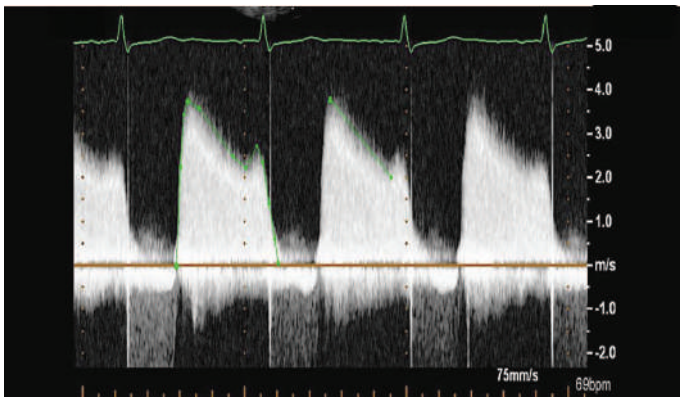

FIGURE 274-1 Continuous wave Doppler interrogation of transmitral valve velocities in a patient with severe rheumatic mitral stenosis. Electrocardiogram on top. Vertical scale in meters/second. Horizontal scale in seconds at sweep speed of 75 mm/se. Velocity is converted to pressure using the Bernoulli equation. In this example, the mean mitral valve gradient (area under the green tracing) is calculated to 38 mmHg and mitral valve area to 0.7 cm^2.

Echocardiogram (See also Chap. 248) Transthoracic echocardiography (TTE) with color flow and spectral Doppler imaging provides critical information, including measurements of mitral inflow velocity during early (E wave) and late (A wave in patients in sinus rhythm) diastolic filling, estimates of the transvalvular peak and mean gradients and mitral orifice area **(Fig. 274-1)**, the presence and severity of any associated MR, the extent of leaflet calcification and restriction, the degree of distortion of the subvalvular apparatus, and the anatomic suitability for percutaneous mitral balloon commissurotomy (PMBC; see below). In addition, TTE provides an assessment of LV and RV function, chamber sizes, an estimation of the PA systolic pressure based on the tricuspid regurgitant jet velocity, and an indication of the presence and severity of any associated valvular lesions, such as aortic stenosis (AS) and/or regurgitation. Transesophageal echocardiography (TEE) provides superior images and should be used when TTE is inadequate for guiding management decisions. TEE is especially indicated to exclude the presence of LA thrombus prior to PMBC. The performance of TTE with exercise to evaluate the mean mitral diastolic gradient, PAPs, and RV function can be very helpful in the evaluation of patients with MS when there is a discrepancy between the clinical findings and the resting hemodynamics.

Chest X-Ray The earliest changes are straightening of the upper left border of the cardiac silhouette, prominence of the main PAs, dilation of the upper lobe pulmonary veins, and posterior displacement of the esophagus by an enlarged LA. Kerley B lines are fine, dense, opaque, horizontal lines that are most prominent in the lower and mid-lung fields that result from distention of interlobular septae and lymphatics with edema when the resting mean LA pressure exceeds ~20 mmHg.

DIFFERENTIAL DIAGNOSIS

Like MS, significant MR may also be associated with a prominent diastolic murmur at the apex due to increased antegrade transmitral flow, but in patients with isolated MR, this diastolic murmur commences slightly later than in patients with MS, and there is often clear-cut evidence of LV enlargement. An OS and increased P_2 are absent, and S_1 is soft or absent. An apical pansystolic murmur of at least grade III/VI intensity as well as an S_3 suggests significant MR. Similarly, the apical mid-diastolic murmur associated with severe AR (*Austin Flint murmur*) may be mistaken for MS but can be differentiated from it because it is not intensified in pre-systole and becomes softer with administration of amyl nitrite or other arterial vasodilators. TS, which occurs rarely in the absence of MS, may mask many of the clinical features of MS or be clinically silent; when present, the diastolic murmur of

TS increases with inspiration and the *y* descent in the jugular venous pulse is delayed.

Atrial septal defect **(Chap. 280)** may be mistaken for MS; in both conditions, there is often clinical, ECG, and chest x-ray evidence of RV enlargement and accentuation of pulmonary vascularity. However, the absence of LA enlargement and of Kerley B lines and the demonstration of fixed splitting of S_2 with a grade II or III mid-systolic murmur at the mid to upper left sternal border all favor atrial septal defect over MS. Atrial septal defects with large left-to-right shunts may result in functional TS because of the enhanced diastolic flow. An incomplete right bundle branch block pattern on ECG is often present.

Left atrial myxoma **(Chap. 282)** may obstruct LA emptying, causing dyspnea, a diastolic murmur, and hemodynamic changes resembling those of MS. However, patients with an LA myxoma often have features suggestive of a systemic disease, such as weight loss, fever, anemia, systemic emboli, and elevated serum IgG and interleukin 6 (IL-6) concentrations. The auscultatory findings may change markedly with body position. The diagnosis can be established by the demonstration of a characteristic echo-producing mass in the LA with TTE.

CARDIAC CATHETERIZATION

Left and right heart catheterization can be useful when there is a discrepancy between the clinical and noninvasive findings, including those from TEE and exercise echocardiographic testing when appropriate. Catheterization can also be helpful in assessing associated lesions, such as AS and AR, and in patients with recurring or worsening symptoms late after mitral valve intervention. Computed tomographic coronary angiography is increasingly used to screen preoperatively for the presence of coronary artery disease in appropriate patients prior to heart valve surgery or transcatheter treatment.

TREATMENT

Mitral Stenosis (Fig. 274-2)

Penicillin prophylaxis of group A β-hemolytic streptococcal infections **(Chap. 371)** for secondary prevention of rheumatic fever is important for at-risk patients with rheumatic MS. Recommendations for infective endocarditis prophylaxis are similar to those for other valve lesions and are restricted to patients at high risk for complications from infection, including patients with a history of endocarditis. In symptomatic patients, some improvement usually occurs with restriction of sodium intake and small doses of oral diuretics. Beta blockers, nondihydropyridine calcium channel blockers (e.g., verapamil or diltiazem), and digitalis glycosides are useful in slowing the ventricular rate of patients with AF. Vitamin K antagonist therapy (such as warfarin) targeted to an international normalized ratio (INR) of 2–3 should be administered indefinitely to patients with MS who have AF, a history of thromboembolism, or demonstrated LA thrombus. The routine use of a vitamin K antagonist in patients in sinus rhythm with LA enlargement (maximal dimension >5.5 cm) with or without spontaneous echo contrast is more controversial. In a randomized trial of patients with rheumatic MS and AF, there was a significantly higher incidence of death among patients treated with rivaroxaban than with vitamin K antagonist therapy. A vitamin K antagonist is

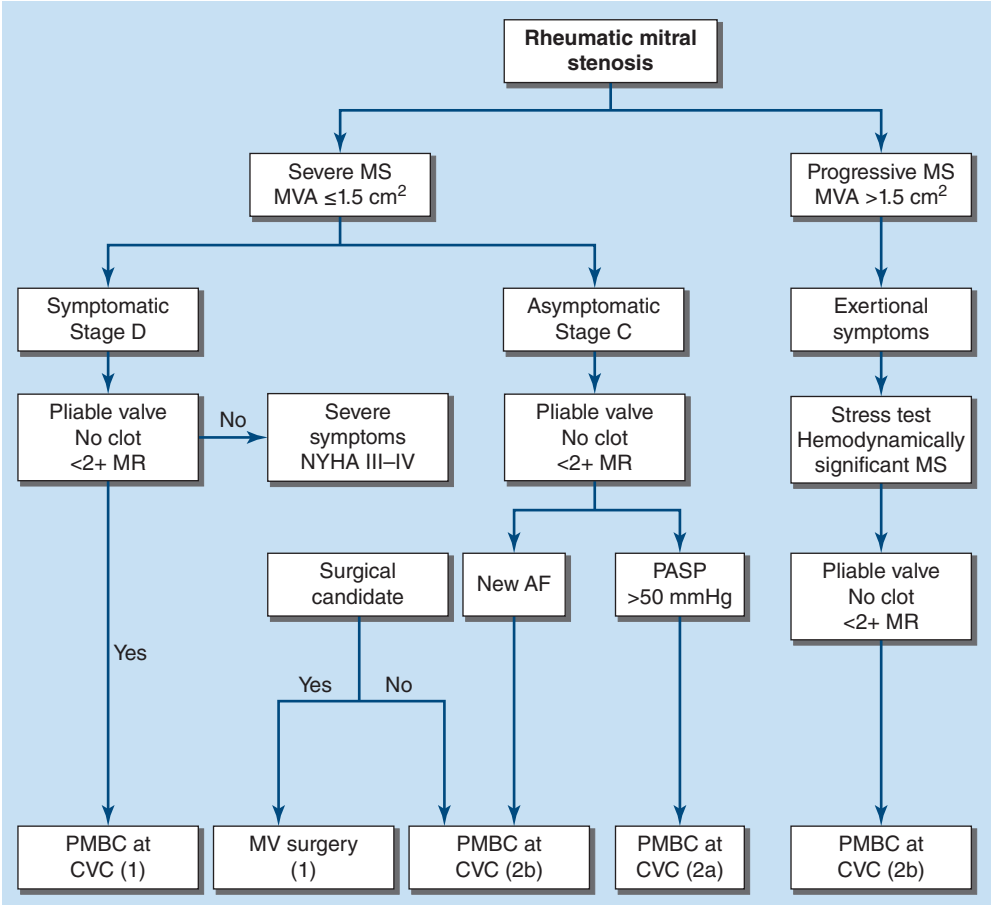

FIGURE 274-2 Management of rheumatic mitral stenosis. See legend for **Fig. 272-4** for explanation of treatment recommendations (Class I, IIa, IIb) and disease stages (C, D). Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. AF, atrial fibrillation; CVC, comprehensive valve center; MR, mitral regurgitation; MS, mitral stenosis; MV, mitral valve; MVA, mitral valve area; MVR, mitral valve surgery (repair or replacement); NYHA, New York Heart Association; PASP, pulmonary arterial systolic pressure; PMBC, percutaneous mitral balloon commissurotomy. *(Reproduced with permission from CM Otto et al: ACC/AHA guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. Circulation 143:e72, 2021.)*

recommended to reduce the risk for stroke or systemic embolism in at-risk patients with rheumatic MS.

If AF is of relatively recent onset in a patient whose MS is not severe enough to warrant PMBC or surgical intervention, reversion to sinus rhythm pharmacologically or by means of electrical countershock is indicated. Usually, cardioversion should be undertaken after the patient has had at least 3 consecutive weeks of anticoagulant treatment to a therapeutic INR. If cardioversion is indicated more urgently, then intravenous heparin should be provided and TEE performed to exclude the presence of LA thrombus before the procedure. Conversion to sinus rhythm is rarely successful or sustained in patients with severe MS, particularly those in whom the LA is significantly enlarged or in whom AF has been present for >1 year, conditions that favor the development of an LA myopathy.

MITRAL COMMISSUROTOMY

Unless there is a contraindication, mitral commissurotomy is indicated in symptomatic (New York Heart Association [NYHA] functional class II–IV) patients with isolated severe MS, whose effective orifice (valve area) is <~1 cm^2/m^2 body surface area or <1.5 cm^2 in normal-sized adults. Mitral commissurotomy can be carried out either percutaneously or surgically. In PMBC **(Figs. 274-3 and 274-4)**, a catheter is directed into the LA after transseptal puncture, and a single balloon is directed across the valve and inflated in the valvular orifice. Ideal patients have relatively pliable leaflets with little or no commissural calcium. In addition, the subvalvular structures should not be significantly scarred or thickened, and there should be no LA thrombus. Any associated MR should be of ≤2+/4+ severity. The short- and long-term results of this procedure in appropriate patients are similar to those of surgical commissurotomy, but with less morbidity and a lower periprocedural mortality rate. Event-free survival in younger (<45 years) patients with pliable valves is excellent, with rates as high as 80–90% over 3–7 years. Therefore, PMBC is the procedure of choice for such patients when it can be performed by a skilled operator in a high-volume center.

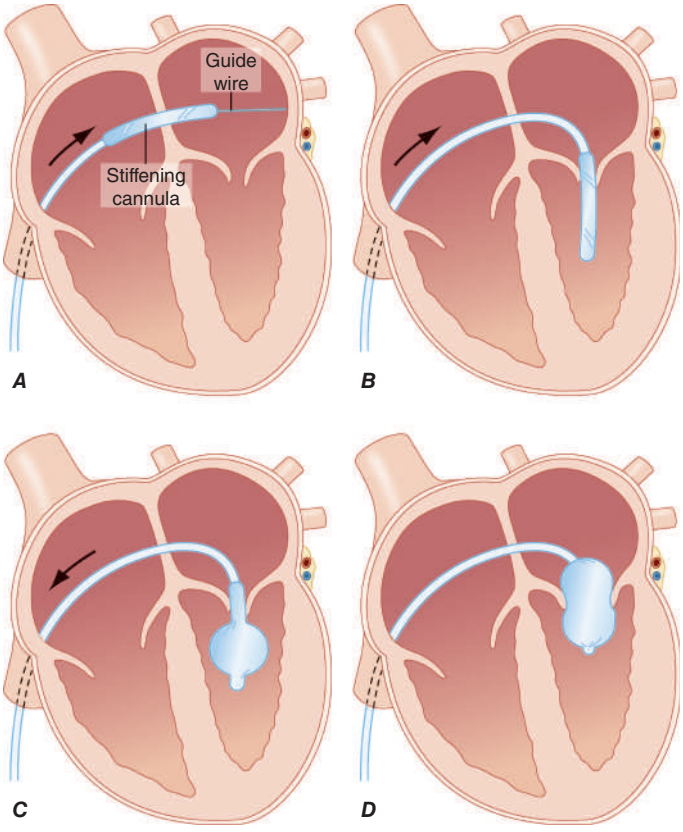

FIGURE 274-3 Inoue balloon technique for percutaneous mitral balloon commissurotomy. *A.* After transseptal puncture, the deflated balloon catheter is advanced across the interatrial septum, then across the mitral valve and into the left ventricle. ***B–D.*** The balloon is inflated stepwise within the mitral orifice.

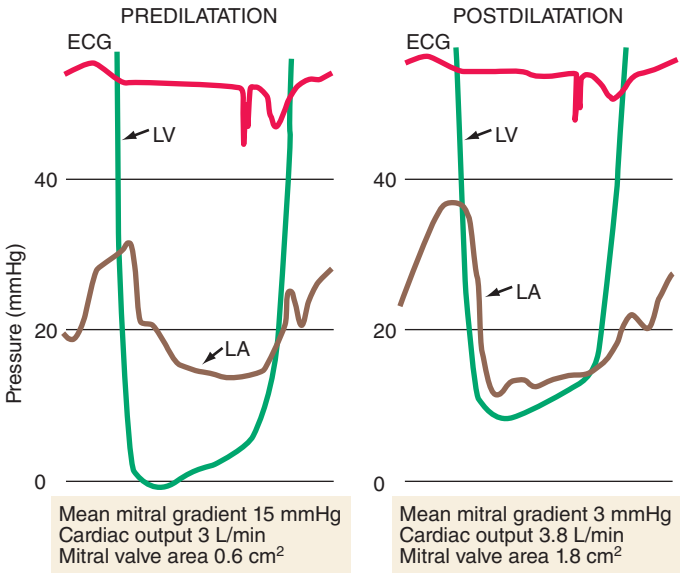

FIGURE 274-4 Simultaneous left atrial (LA) and left ventricular (LV) pressure before and after percutaneous mitral balloon commissurotomy (PMBC) in a patient with severe mitral stenosis. ECG, electrocardiogram. *(Courtesy of Raymond G. McKay, MD.)*

TTE is helpful in identifying patients for the percutaneous procedure; TEE is performed routinely to exclude LA thrombus and to assess the degree of MR at the time of the scheduled procedure. An "echo score" has been developed to help guide decision-making. The score accounts for the degree of leaflet thickening, calcification, and mobility, and for the extent of subvalvular thickening. A lower score predicts a higher likelihood of successful PMBC.

In patients in whom PMBC is not possible or unsuccessful, or in many patients with restenosis after previous surgery, an "open" surgical commissurotomy using cardiopulmonary bypass is necessary. In addition to opening the valve commissures, it is important to loosen any subvalvular fusion of papillary muscles and chordae tendineae; to remove large deposits of calcium, thereby improving valvular function; and to remove atrial thrombi. The perioperative mortality rate for this type of mitral valve repair procedure is ~2%.

Successful commissurotomy is defined by a 50% reduction in the mean mitral valve gradient and a doubling of the mitral valve area. Successful commissurotomy, whether balloon or surgical, usually results in striking symptomatic and hemodynamic improvement and prolongs survival. However, there is no evidence that the procedure improves the prognosis of patients with slight or no functional impairment. Therefore, unless recurrent systemic embolization or severe pulmonary hypertension has occurred (PA systolic pressures >50 mmHg at rest or >60 mmHg with exercise), commissurotomy is *not* recommended for patients who are asymptomatic and/or who have mild or moderate stenosis (mitral valve area >1.5 cm^2). When there is little symptomatic improvement after commissurotomy, it is likely that the procedure was ineffective, that it induced MR, or that associated valvular or myocardial disease was present. About half of all patients undergoing surgical mitral commissurotomy require reoperation by 10 years. In the pregnant patient with MS, commissurotomy should be carried out if pulmonary congestion occurs despite intensive medical treatment. PMBC is the preferred strategy in this setting and is performed with TEE and no or minimal x-ray exposure.

Mitral valve replacement (MVR) is necessary in patients with MS and significant associated MR, those in whom the valve has been severely distorted by previous transcatheter or operative manipulation, or those in whom the surgeon does not find it possible to improve valve function significantly with commissurotomy. MVR is now routinely performed with preservation of the chordal attachments to optimize LV functional recovery. Perioperative mortality rates with MVR vary with age, LV function, the presence of CAD, and associated comorbidities. They average 2–5% overall but

are lower in young patients and may be twice as high in patients >65 years of age with significant comorbidities. Because there are also long-term complications of valve replacement, patients in whom preoperative evaluation suggests the possibility that MVR may be required should be operated on only if they have severe MS—i.e., an orifice area ≤1.5 cm^2—and are in NYHA class III, i.e., symptomatic with ordinary activity despite optimal medical therapy. The overall 10-year survival of surgical survivors is ~70%. Long-term prognosis is worse in patients >65 years of age and those with marked disability and marked depression of the CO preoperatively. Pulmonary hypertension and RV dysfunction are additional risk factors for poor outcome.

TABLE 275-1 Major Causes of Mitral Regurgitation (MR)

Etiologies
Acute
IE
Papillary muscle rupture (post-MI)
Chordal rupture/leaflet flail (MVP, IE)
Blunt trauma
Chronic
Primary (affecting leaflets, chordae)
Myxomatous (MVP, Barlow's, *forme fruste*)
Rheumatic fever
IE (healed)
Congenital (cleft, AV canal)
Radiation
Secondary (leaflets, chordae are "innocent bystanders")
Ischemic cardiomyopathy
Dilated cardiomyopathy
HOCM (with SAM)
AF with LA enlargement and annular dilation (atrial functional MR)
Mitral annular calcification[a]

[a]Mitral annular calcification may include elements of both primary and secondary MR (mixed) as the disease process may encroach on the leaflets, impair the normal sphincteric function of the annulus, or both. There are additional examples of "mixed" secondary MR such as the coexistence of MVP with an ischemic cardiomyopathy.

Abbreviations: AF, atrial fibrillation; AV, atrioventricular; HOCM, hypertrophic obstructive cardiomyopathy; IE, infective endocarditis; LA, left atrial; LV, left ventricular; MI, myocardial infarction; MVP, mitral valve prolapse; SAM, systolic anterior motion.

275 Mitral Regurgitation

Patrick T. O'Gara, Joseph Loscalzo

The role of the physical examination in the evaluation of patients with valvular heart disease is also considered in **Chaps. 44 and 246**; of electrocardiography (ECG) in **Chap. 247**; of echocardiography and other noninvasive imaging techniques in **Chap. 248**; and of cardiac catheterization and angiography in **Chap. 249**.

ETIOLOGY

Mitral regurgitation (MR) may result from an abnormality or disease process that affects any one or more of the five functional components of the mitral valve apparatus (leaflets, annulus, chordae tendineae, papillary muscles, and subjacent myocardium) **(Table 275-1)**. Acute MR can occur in the setting of acute myocardial infarction (MI) with papillary muscle rupture **(Chap. 286)**, following blunt chest wall trauma, or during the course of infective endocarditis (IE) owing to leaflet perforation or destruction. With acute MI, the posteromedial papillary muscle is involved much more frequently than the anterolateral papillary muscle because of its singular blood supply. Transient, acute MR can occur during periods of active ischemia and bouts of angina pectoris. Rupture of chordae tendineae can result in "acute-on-chronic MR" in patients with myxomatous degeneration of the valve apparatus.

Chronic MR can result from several disease processes (Table 275-1). Distinction should be drawn between primary (degenerative) MR, in which the leaflets and/or chordae tendineae are primarily responsible for abnormal valve function, and secondary (functional) MR, in which the leaflets and chordae tendineae are usually normal but the regurgitation is caused by left ventricular (LV) and/or left atrial remodeling, annular dilation, papillary muscle displacement, dyssynchrony, leaflet tethering, or their combination. Patient assessment, treatment approach, and long-term prognosis differ significantly between primary and secondary MR. Mitral valve prolapse (MVP) is discussed more extensively in **Chap. 276**. The rheumatic process produces rigidity, deformity, and retraction of the valve cusps and commissural fusion, as well as shortening, contraction, and fusion of the chordae tendineae. MR can persist after resolution of the acute phase of infection and inflammation. MR may occur as a congenital anomaly **(Chap. 280)**, most commonly as a defect of the endocardial cushions (atrioventricular cushion defects). A cleft anterior mitral valve leaflet accompanies ostium primum atrial septal defect. Radiation can result in leaflet thickening, retraction, and calcification, often in association with annular and chordal involvement and some degree of mitral stenosis. Chronic MR occurs frequently after prior MI(s) associated with changes in LV size, shape, and function. Similar mechanisms of annular dilation and ventricular remodeling contribute to the MR that occurs among patients with nonischemic forms of dilated cardiomyopathy once the LV end-diastolic dimension reaches 6 cm. The MR associated with hypertrophic obstructive cardiomyopathy (HOCM) is usually dynamic in nature and dependent on systolic anterior motion of the anterior mitral valve leaflet into a narrowed LV outflow tract. Patients with chronic persistent atrial fibrillation (AF) may develop atrial remodeling and annular dilation with inadequate leaflet lengthening and MR (atrial functional MR). Secondary MR due to LV remodeling is more frequently encountered in the community than secondary MR that occurs in association with AF and annular dilation. Annular calcification can result in MR when it encroaches on the leaflets or results in decreased sphincteric function, is especially prevalent among patients with advanced renal disease, and is commonly observed in women >65 years of age with hypertension and diabetes mellitus. Irrespective of cause, chronic severe MR is often progressive because enlargement of the left atrium (LA) places tension on the posterior mitral leaflet, pulling it further away from the mitral orifice and thereby aggravating the valvular dysfunction. Similarly, LV dilation increases the regurgitation, which, in turn, enlarges the LA and LV further, resulting in a vicious cycle; hence the aphorism, "MR begets MR."

PATHOPHYSIOLOGY

The resistance to LV emptying (LV afterload) is reduced in patients with MR. As a consequence, the LV is decompressed into the LA during ejection, and with the reduction in LV size during systole, there is a rapid decline in LV tension. The initial compensation to MR is more complete LV emptying. However, LV volume increases progressively with time as the severity of the regurgitation increases and as LV contractile function deteriorates. This increase in LV volume is often accompanied

by a reduced forward cardiac output (CO). LV compliance is often increased, and thus, LV diastolic pressure does not increase until late in the course. The regurgitant volume varies directly with the LV systolic pressure and the size of the regurgitant orifice; the latter, in turn, is influenced by the extent of LV and mitral annular dilation, as well as by leaflet morphology. Because ejection fraction (EF) rises in severe MR in the presence of normal LV function, even a modest reduction in this parameter (<60%) reflects significant contractile dysfunction.

During early diastole, as the distended LA empties, there is a particularly rapid *y* descent in the absence of accompanying MS. A brief, early diastolic LA-LV pressure gradient (often generating a rapid filling sound [S_3] and mid-diastolic murmur masquerading as MS) may occur in patients with pure, severe MR as a result of the very rapid flow of blood across a normal-sized mitral orifice.

Measurements of LV ejection fraction (LVEF), CO, pulmonary arterial (PA) systolic pressure, regurgitant volume, regurgitant fraction (RF), and the effective regurgitant orifice area can be obtained during a careful Doppler echocardiographic examination. These measurements can also be obtained accurately with cardiac magnetic resonance (CMR) imaging, although this technology is not widely available. Left and right heart catheterization with contrast ventriculography is used less frequently. Chronic, severe MR is defined by a regurgitant volume ≥60 mL/beat, RF ≥50%, and effective regurgitant orifice area ≥0.40 cm^2. In patients with secondary MR, in whom the severity of MR can be underappreciated using echocardiographic/Doppler techniques, lesser degrees of regurgitation may carry relatively greater prognostic weight. The adverse prognosis in secondary MR related to adverse LV remodeling is intimately related to the degree of myocardial dysfunction.

LA Compliance In acute severe MR, the regurgitant volume is delivered into a normal-sized LA having normal or reduced compliance. As a result, LA pressures rise markedly for any increase in LA volume. The *v* wave in the LA pressure pulse is usually prominent, LA and pulmonary venous pressures are markedly elevated, and pulmonary edema is common. Because of the rapid rise in LA pressures during ventricular systole, the murmur of acute MR is early in timing and decrescendo in configuration ending well before S_2, as a reflection of the progressive diminution in the LV-LA pressure gradient. LV systolic function in acute MR may be normal, hyperdynamic, or reduced, depending on the clinical context.

Patients with chronic severe MR, on the other hand, develop marked LA enlargement and *increased* LA compliance with little if any increase in LA and pulmonary venous pressures for any increase in LA volume. The LA *v* wave is relatively less prominent. The murmur of chronic MR is classically holosystolic in timing and plateau in configuration, as a reflection of the near-constant LV-LA pressure gradient. These patients usually complain of severe fatigue and exhaustion secondary to a low forward CO, whereas symptoms resulting from pulmonary congestion are less prominent initially; AF is almost invariably present once the LA dilates significantly.

SYMPTOMS

Patients with chronic mild-to-moderate, isolated MR are usually asymptomatic. This form of LV volume overload is well tolerated. Fatigue, exertional dyspnea, and orthopnea are the most prominent complaints in patients with chronic severe MR. Palpitations are common and may signify the onset of AF. Late-onset right-sided heart failure, with painful hepatic congestion, ankle edema, distended neck veins, ascites, and secondary tricuspid regurgitation (TR), occurs in patients with MR who have associated pulmonary vascular disease and pulmonary hypertension. Acute pulmonary edema is common in patients with acute severe MR.

PHYSICAL FINDINGS

In patients with chronic severe MR, the arterial pressure is usually normal, although the carotid arterial pulse may show a sharp, low-volume upstroke owing to the reduced forward CO. A systolic thrill is often palpable at the cardiac apex, the LV is hyperdynamic with a brisk systolic impulse and a palpable rapid-filling wave (S_3), and the apex beat is often displaced laterally.

In patients with acute severe MR, the arterial pressure may be reduced with a narrow pulse pressure, the jugular venous pressure and waveforms may be normal or increased and exaggerated, the apical impulse is not displaced, and signs of pulmonary congestion are prominent.

Auscultation S_1 is generally absent, soft, or buried in the holosystolic murmur of chronic, severe MR. In patients with severe MR, the aortic valve may close prematurely (due to the reduced forward cardiac output), resulting in wide but physiologic splitting of S_2. A low-pitched S_3 occurring 0.12–0.17 s after the aortic valve closure sound, i.e., at the completion of the rapid-filling phase of the LV, is believed to be caused by the sudden tensing of the papillary muscles, chordae tendineae, and valve leaflets. It may be followed by a short, rumbling, mid-diastolic murmur, even in the absence of structural MS. In patients with ischemic or dilated cardiomyopathy, however, a third sound (S_3) may also signify ventricular dysfunction. A fourth heart sound is often audible in patients with *acute* severe MR who are in sinus rhythm. A presystolic murmur is not ordinarily heard with isolated MR.

A systolic murmur of at least grade III/VI intensity is the most characteristic auscultatory finding in chronic severe MR. It is usually holosystolic **(see Fig. 246-5*A*)**, but as previously noted, it is decrescendo and ceases in mid-to-late systole in patients with acute severe MR. The systolic murmur of chronic MR is usually most prominent at the apex and radiates to the axilla. However, in patients with ruptured chordae tendineae or primary involvement of the posterior mitral leaflet with prolapse or flail, the regurgitant jet is eccentric, directed anteriorly, and strikes the LA wall adjacent to the aortic root. In this situation, the systolic murmur is transmitted to the base of the heart and, therefore, may be confused with the murmur of AS. The murmur associated with anterior leaflet prolapse or flail is directed to the axilla. In patients with ruptured chordae tendineae, the systolic murmur may have a cooing or "seagull" quality, whereas a flail leaflet may produce a murmur with a musical quality. The systolic murmur of chronic MR not due to MVP is intensified by isometric exercise (handgrip) but is reduced during the strain phase of the Valsalva maneuver because of the associated decrease in LV preload.

LABORATORY EXAMINATION

ECG In patients with sinus rhythm, there is evidence of LA enlargement, but right atrial (RA) enlargement also may be present when pulmonary hypertension is significant and affects right ventricular function and size. Chronic severe MR is frequently associated with AF. In many patients, there is no clear-cut ECG evidence of enlargement of either ventricle. In others, the signs of eccentric LV hypertrophy are present.

Echocardiogram (Fig. 275-1) Transthoracic echocardiography (TTE) is indicated to assess the mechanism of the MR and its hemodynamic severity. LV function can be assessed from LV end-diastolic and end-systolic volumes and EF. Observations can be made regarding leaflet structure and function, chordal integrity, LA and LV size, annular calcification, and regional and global LV systolic function. Doppler imaging should demonstrate the width or area of the color flow MR jet within the LA, the duration and intensity of the continuous wave Doppler signal, the pulmonary venous flow contour, the early peak mitral inflow velocity, and quantitative measures of regurgitant volume, RF, and effective regurgitant orifice area. In addition, the PA pressures (PAPs) can be estimated from the TR jet velocity. TTE is also indicated to follow the course of patients with chronic MR and to provide rapid assessment for any clinical change. Transesophageal echocardiography (TEE) provides greater anatomic detail than TTE **(see Fig. 248-5)**. Exercise testing with TTE can be useful to assess exercise capacity as well as any dynamic change in MR severity, PA systolic pressures, and biventricular function, for patients in whom there is a discrepancy between clinical findings and the results of other noninvasive testing.

Chest X-Ray The LA and LV are the dominant chambers in chronic MR. Late in the course of the disease, the LA may be massively enlarged and forms the right border of the cardiac silhouette. Pulmonary venous congestion, interstitial edema, and Kerley B lines

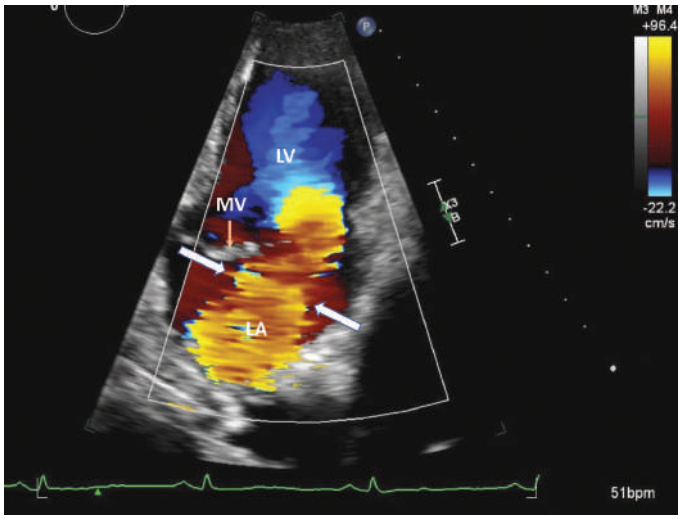

FIGURE 275-1 Mitral regurgitation. Apical two-chamber transthoracic color flow Doppler echocardiographic display of a broad systolic jet of severe mitral regurgitation (yellow stream between the two white arrows) from the left ventricle directed posteriorly into the left atrium. LA, left atrium; LV, left ventricle; MV, anterior leaflet of the mitral valve.

are sometimes noted. Marked calcification of the mitral leaflets occurs commonly in patients with long-standing, combined rheumatic MR and MS, as well as in patients with radiation-induced mitral valve disease. Calcification of the mitral annulus may be visualized, particularly on the lateral view of the chest. Patients with acute severe MR may have asymmetric pulmonary edema if the regurgitant jet is directed predominantly to the orifice of an upper lobe pulmonary vein.

TREATMENT (FIGS. 275-2 AND 275-3)

Mitral Regurgitation

MEDICAL TREATMENT

The management of chronic severe MR depends to some degree on its cause. Anticoagulation with either warfarin or a direct oral agent (e.g., apixaban, rivaroxaban) should be provided if AF intervenes, as guided by the CHA_2DS_2-VASc risk score. The direct oral anticoagulants should not be used if moderate or severe rheumatic mitral stenosis is also present **(Ch. 274)**; they are also not approved for use in patients with mechanical prosthetic heart valves. Cardioversion should be considered depending on the clinical context, AF chronicity, and LA size. In contrast to the acute setting, there are no large, long-term prospective studies to substantiate the use of vasodilators for the treatment of chronic, isolated severe primary MR with preserved LV systolic function *in the absence of systemic hypertension.* However, the severity of secondary MR in the setting of an ischemic or dilated cardiomyopathy may diminish with aggressive guideline-directed medical therapy (GDMT) of heart failure including the use of diuretics for decongestion, beta blockers, angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers, angiotensin-neprilysin inhibitors, mineralocorticoid receptor antagonists, sodium-glucose cotransporter

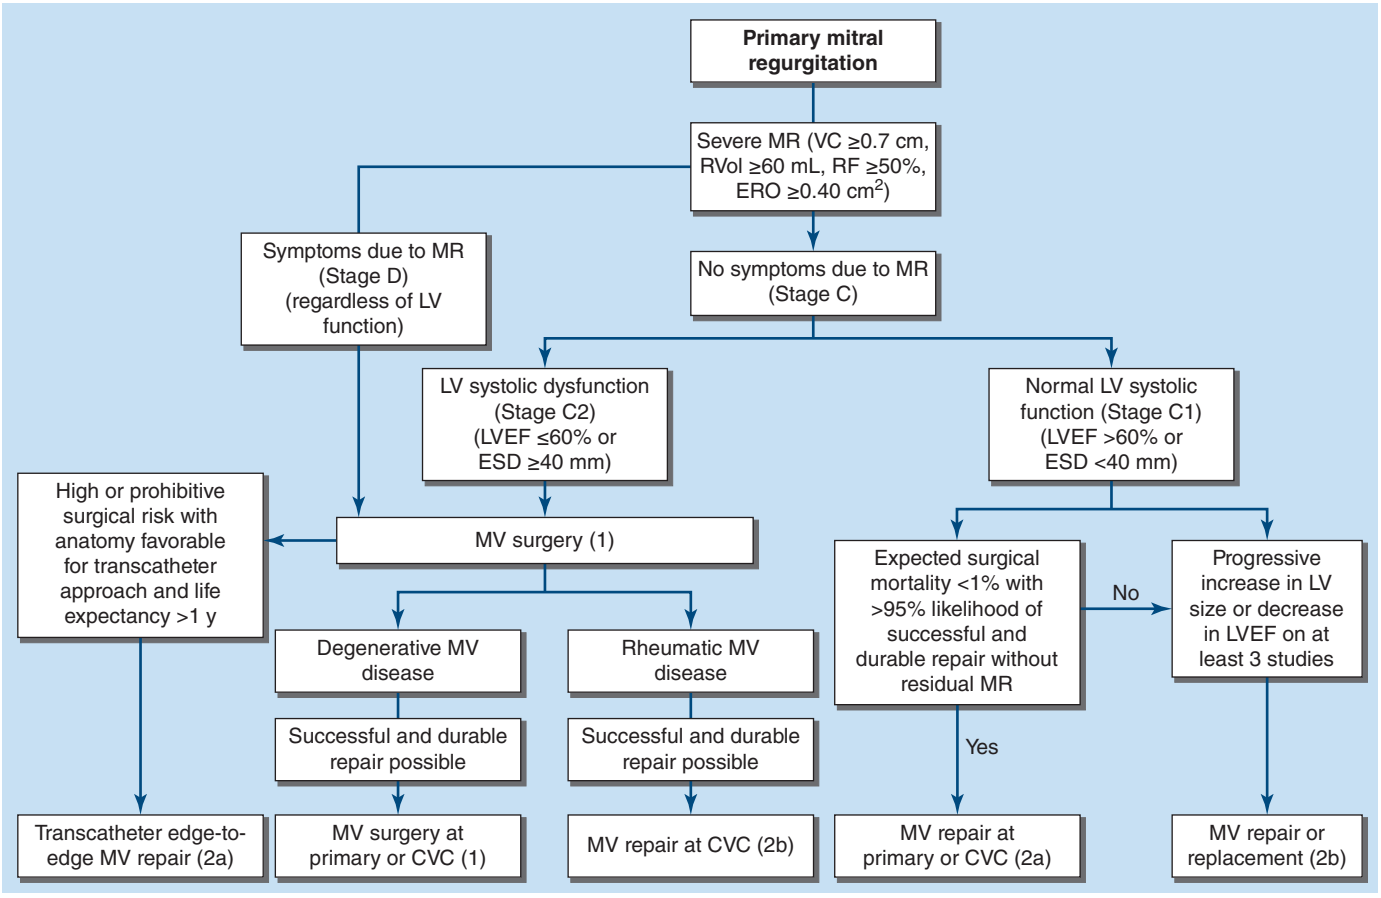

FIGURE 275-2 Management of primary mitral regurgitation (MR). See legend for **Fig. 272-4** for explanation of treatment recommendations (Class I, IIa, IIb) and disease stages (B, C1, C2, D). Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. Mitral valve repair is strongly preferred over valve replacement whenever feasible for surgical treatment of primary MR. Transcatheter edge-to-edge repair (TEER) is reserved for high or prohibitive surgical risk patients with appropriate anatomy on transesophageal imaging. CVC, comprehensive valve center; EF, ejection fraction; ERO, effective regurgitant orifice; ESD, end-systolic dimension; LV, left ventricular; MV, mitral valve; RF, regurgitant fraction; RVol, regurgitant volume; VC, vena contracta. *(Reproduced with permission from CM Otto et al: ACC/AHA guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. Circulation. 2021; 143(5):e72.)*

2 inhibitors, and biventricular pacing (cardiac resynchronization therapy [CRT]) when indicated. Antibiotic prophylaxis for prevention of IE is indicated for MR patients with a prior history of IE. Asymptomatic patients with severe MR in sinus rhythm with normal LV size and systolic function should avoid isometric forms of exercise.

Patients with acute severe MR require urgent stabilization and preparation for surgery. Diuretics, intravenous vasodilators (particularly sodium nitroprusside), and even mechanical circulatory support may be needed for patients with post-MI papillary muscle rupture or other forms of acute severe MR.

SURGICAL TREATMENT

In the selection of patients with chronic, severe, primary MR for surgical treatment, the often slowly progressive nature of the condition must be balanced against the immediate and long-term risks associated with operation. These risks are significantly lower for primary valve repair than for valve replacement (Table 275-2). In a 2023 analysis of outcomes reported to the Society of Thoracic Surgeons Adult Cardiac Surgical Database, investigators reported a mean perioperative mortality risk of 1.16% (<0.5% for patients <65 years of age) for repair of primary MR. Repair usually consists of valve reconstruction using a variety of valvuloplasty techniques and insertion of an annuloplasty ring. Repair spares the patient the long-term adverse consequences of valve replacement, including thromboembolic and hemorrhagic complications in the case of mechanical prostheses and late valve failure necessitating repeat valve replacement in the case of bioprostheses. In addition, by preserving the integrity of the papillary muscles, subvalvular apparatus, and chordae tendineae, mitral repair and valvuloplasty maintain LV function to a relatively greater degree than does valve replacement.

Surgery for chronic severe primary MR is indicated once symptoms occur, especially if valve repair is feasible (Fig. 275-2). Surgery should also be recommended for asymptomatic patients with LV dysfunction characterized by an EF ≤60% or an LV end-systolic dimension (LV ESD) ≥40 mm. Other indications for early consideration of mitral valve repair in asymptomatic patients include a progressive decrease in LVEF or increase in LV ESD on serial imaging as well as mitral valve anatomy that would predict a >95% of a successful and durable repair in a low surgical risk patient.

TABLE 275-2 Mortality Rates After Mitral Valve Surgery[a]

OPERATION	NUMBER	UNADJUSTED OPERATIVE MORTALITY (%)
MVR (isolated)	10,699	4.5
MVR + CAB	3509	9.6
MVRp	12,424	1.2
MVRp + CAB	4093	5.4

[a]Data are for calendar year 2018 during which 1088 participant groups reported a total of 287,872 procedures. Surgical mitral valve commissurotomy cases are included in the mitral valve repair procedures.

Abbreviations: CAB, coronary artery bypass; MVR, mitral valve replacement; MVRp, mitral valve repair.

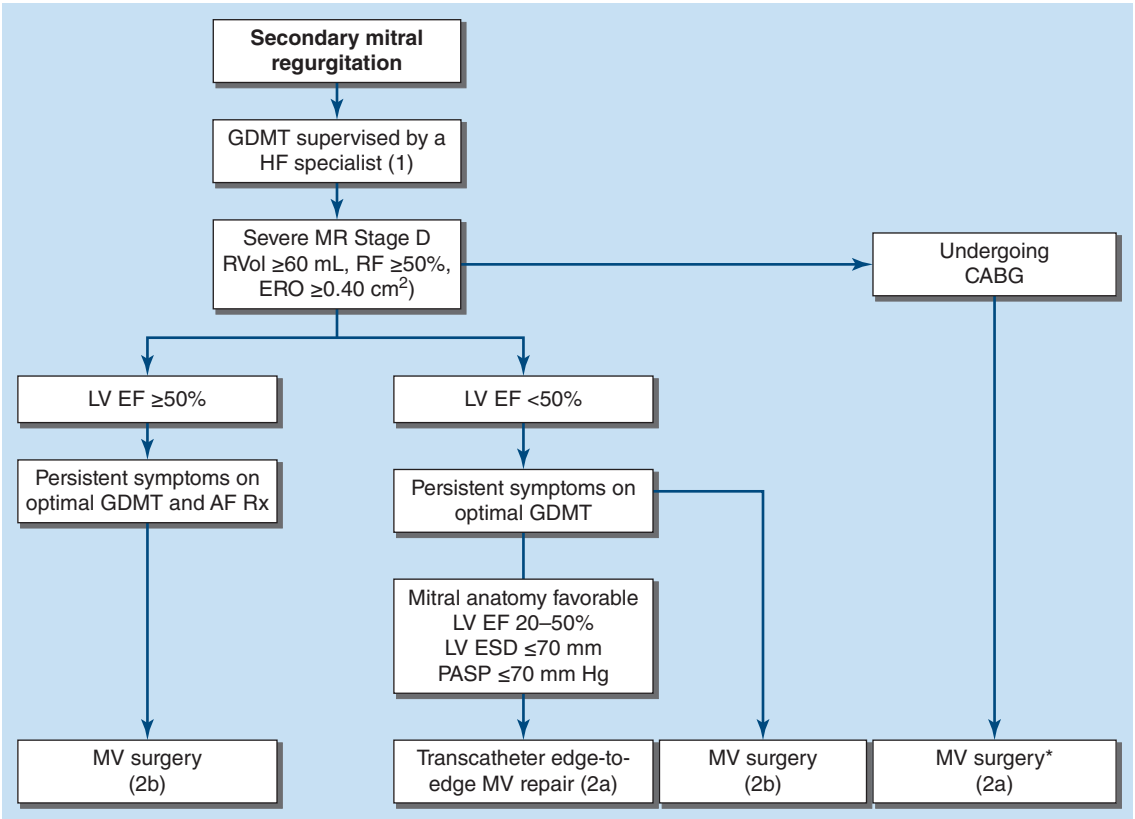

FIGURE 275-3 Management of secondary mitral regurgitation. See legend for Fig. 272-4 for explanation of treatment recommendations (Class I, IIa, IIb) and disease stages (B, C1, C2, D). Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. Surgery is recommended for patients with left ventricular ejection fraction (LVEF) >50%. Transcatheter edge-to-edge repair (TEER) is reasonable in selected patients after guideline-directed management and therapy (GDMT) has been optimized. *MV replacement may be preferred over MV repair for ischemic MR; AF, atrial fibrillation; CABG, coronary artery bypass grafting; EF, ejection fraction; ERO, effective regurgitant orifice; ESD, end-systolic dimension; HF, heart failure; LV, left ventricular; MR, mitral regurgitation, MV, mitral valve; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume; Rx, treatment. *(Reproduced with permission from CM Otto et al: ACC/AHA guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. Circulation. 2021; 143(5):e72.)*

These aggressive recommendations for surgery are predicated on the adverse long-term consequences of waiting for LV function to decline further as well as the outstanding results achievable with mitral valve repair by reference surgeons at high-volume centers. Indeed, the majority of patients <75 years of age with degenerative MR, normal LV systolic function, and no coronary artery disease (CAD) can now undergo successful and durable repair of degenerative MR (e.g., prolapse, flail) by an experienced surgeon at very low risk for perioperative death or major complication. Repair is feasible in up to 95% of patients with degenerative disease operated on by a high-volume surgeon in a referral center of excellence. Repair techniques include chordal transfer, creation of neochords, limited leaflet resection, and insertion of an annuloplasty band. Long-term durability is excellent; the incidence of reoperative surgery for failed primary repair is ~1% per year for the first 10 years after surgery. For patients with paroxysmal or persistent AF, left or biatrial maze surgery, or radiofrequency or cryoablative isolation of the pulmonary veins, along with left atrial appendage amputation, is performed to reduce the risk of recurrent postoperative AF and associated thrombus formation.

The surgical management of patients with secondary MR is more complicated. Surgery for patients with ischemic MR most often involves simultaneous coronary artery revascularization. Current surgical practice includes either annuloplasty repair with an undersized, rigid ring or chord-sparing valve replacement for patients with moderate or greater degrees of MR. Valve repair for ischemic MR is associated with lower perioperative mortality rates than valve replacement but significantly higher rates of recurrent MR over time. Thus, replacement may be preferred over repair in this context. In patients with ischemic MR and significantly impaired LV systolic function (EF <30%), the risk of surgery is higher, recovery of LV performance is incomplete, and long-term survival is reduced. Referral for surgery must be individualized and made only after aggressive attempts to improve symptoms with GDMT and CRT, when indicated. The routine performance of surgical valve repair in patients with significant secondary MR due to a dilated cardiomyopathy has not been shown to improve long-term survival compared with optimal GDMT, especially in the era of quadruple medical therapy for heart failure with reduced EF. Patients with acute severe MR can often be stabilized temporarily with appropriate medical therapy, but surgical correction will be necessary emergently in the case of papillary muscle rupture and within days in most other settings.

When surgical treatment is contemplated, left and right heart catheterization and left ventriculography *may* be helpful in confirming the presence of severe MR in patients in whom there is a discrepancy between the clinical and TTE findings that cannot be resolved with TEE or CMR. Coronary angiography identifies patients who require concomitant coronary revascularization.

TRANSCATHETER MITRAL VALVE REPAIR AND REPLACEMENT

A transcatheter approach to the treatment of either primary or secondary MR may be feasible in selected patients with appropriate mitral valve anatomy. One approach involves the deployment of a clip delivered via transseptal puncture that grasps the leading edges of the mitral leaflets in their mid-portion (anterior scallop to posterior scallop). The length and width of the gap between the leading edges of the leaflets, as well as other considerations such as leaflet thickening and calcification, dictate patient eligibility. There are two commercially available transcatheter systems employing clip technology for the treatment of degenerative MR in symptomatic patients considered to be at high or prohibitive surgical risk **(Fig. 275-4)**. Randomized trials of transcatheter

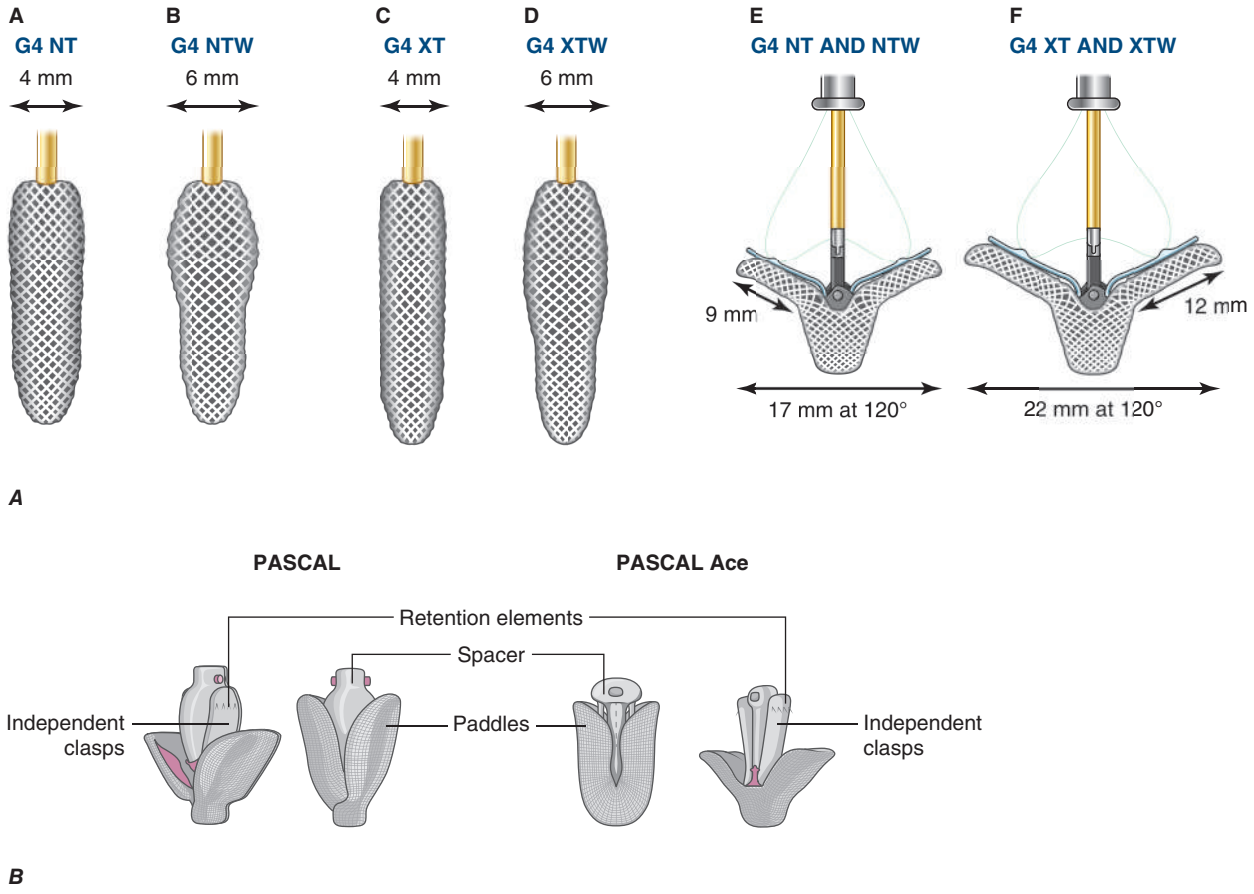

FIGURE 275-4 Clip devices used to grasp the free edges of the anterior and posterior leaflets in their midsections during transcatheter mitral valve repair of selected patients with mitral regurgitation. ***A.*** Fourth-generation of the first approved edge-to-edge repair device. ***B.*** System approved in 2022 includes a central spacer device and two paddles. The spacer is designed to reduce stress on the leaflets and preserve mitral valve area. *(MitraClip is a trademark of Abbott or its related companies. PASCAL is an Edwards Lifesciences tradename.)*

edge-to-edge repair (TEER) versus surgical repair are ongoing to determine if the extension of clip technology to low- and intermediate-risk surgical patients with significant degenerative MR is appropriate. The TEER system is also approved for the treatment of heart failure patients with secondary MR. The results of transthoracic and transesophageal echocardiographic imaging are critical to patient selection, along with an assessment of the adequacy of GDMT for heart failure. The use of TEER with a clip device in addition to medical therapy was shown to be superior to medical therapy alone in a trial involving symptomatic heart failure patients with reduced EF and at least moderately severe secondary MR followed through 5 years. Patients treated with the clip device had significantly lower rates of heart failure hospitalizations and all-cause mortality than those treated medically. This was the first randomized trial to show a survival benefit in patients with heart failure and secondary MR. There has been a rapid expansion over the past 5 years in both the number of sites offering mitral valve TEER and the number of cases reported to the Society of Thoracic Surgeons/American College of Cardiology Transcatheter Valve Therapy Registry.

Other transcatheter approaches to mitral valve repair have included the deployment of a device within the coronary sinus that can be adjusted to reduce mitral annular circumference and the effective orifice area of the valve much like a surgically implanted ring. Variations in the anatomic relationship of the coronary sinus to the mitral annulus and circumflex coronary artery have limited the applicability of this technique. Attempts to reduce the septal-lateral dimension of a dilated annulus using adjustable cords placed across the LV in a subvalvular location have been investigated. Construction of neochords to the mitral leaflets under TEE guidance using a system delivered via the cardiac apex has also been studied. Investigational experience with transcatheter mitral valve replacement systems remains in early clinical stages, although the field is evolving rapidly. Many high surgical risk patients are not candidates for transcatheter mitral valve repair, and thus, there is keen interest in refining this technology. Challenges with transseptal delivery and LV outflow tract obstruction from the devices used have prompted iterative changes in the systems utilized in early feasibility studies.

276 Mitral Valve Prolapse

Patrick T. O'Gara, Joseph Loscalzo

The role of the physical examination in the evaluation of patients with valvular heart disease is also considered in **Chaps. 44 and 246**; of electrocardiography (ECG) in **Chap. 247**; of echocardiography and other noninvasive imaging techniques in **Chap. 241**; and of cardiac catheterization and angiography in **Chap. 249**.

MITRAL VALVE PROLAPSE

Mitral valve prolapse (MVP), also variously termed the *systolic click-murmur syndrome, Barlow's syndrome* **(Fig. 276-1)**, *floppy-valve syndrome,* and *billowing mitral leaflet syndrome*, is a relatively common but highly variable clinical syndrome resulting from diverse pathologic mechanisms affecting the mitral valve apparatus. Among these are excessive or redundant mitral leaflet tissue, which is commonly associated with myxomatous degeneration and greatly increased concentrations of certain glycosaminoglycans. MVP is the most common abnormality leading to primary mitral regurgitation (MR) and mitral valve repair surgery **(see Chap. 275)**.

In most patients with MVP, the cause is unknown, but in some, it appears to be genetically determined. A reduction in the production of type III collagen has been implicated, and electron microscopy has revealed fragmentation of collagen fibrils. A meta-analysis of six

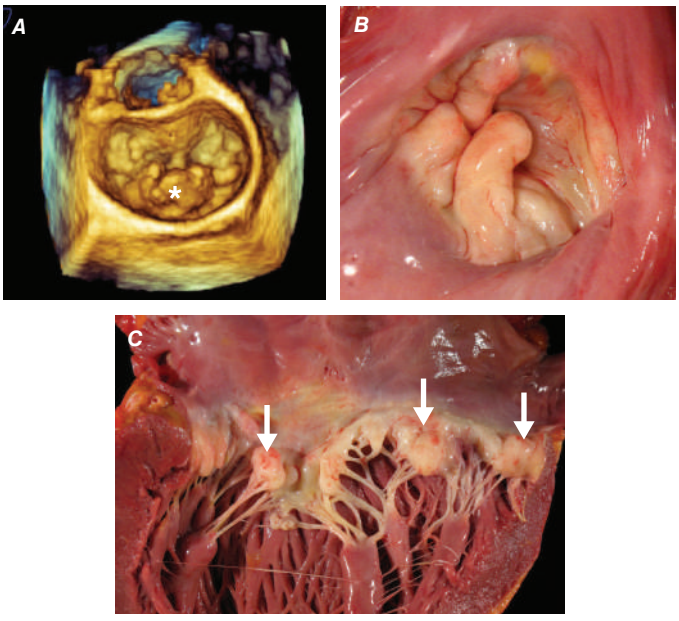

FIGURE 276-1 Mitral valve prolapse. Myxomatous thickening and prolapse of the mitral valve can occur in isolation in 2–3% of the general population or may be associated with heritable connective tissue disorders, such as Marfan syndrome. Myxomatous degeneration of the valve predisposes to severe regurgitation and chordal rupture and is a frequent indication for mitral valve repair or replacement. Prolapse can affect one or both leaflets, to varying degrees. ***A.*** Three-dimensional transesophageal echocardiogram showing a myxomatous mitral valve from the left atrial *en face* aspect. There is billowing and prolapse of the entire middle scallop of the posterior leaflet (*asterisk*). *(Figure courtesy of Douglas C. Shook, MD, Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital.)* ***B.*** The posterior leaflet of the mitral valve demonstrates marked prolapse and hooding in all segments and severe redundancy in this postmortem photograph taken from the vantage point of the left atrium. ***C.*** Opening the left heart reveals prominent mitral leaflet hooding (*arrows*). The chordae are focally thickened but are not fused as would be the case in rheumatic valve disease. *(Used with permission from JC Wu, RF Padera: Clinicopathologic correlates, in Atlas of Echocardiography, 2nd ed, SD Solomon [ed], E Braunwald [series ed]. Philadelphia, Current Medicine Group LLC, 2008. p 363.)*

genome-wide association studies and 4884 MVP cases identified 14 genetic loci associated with MVP. Candidate genes included *LMCD1, SPTBN1, LTBP2, TGFB2, NMB,* and *ALPK3*. A polygenic risk score improved the performance of a clinical risk prediction model for the development of MVP, although overall performance was modest. Other work has identified genetic associations with *LMNA, FLNC,* and *FLNA*, which are often expressed as cardiomyopathies.

MVP is a frequent finding in patients with heritable disorders of connective tissue, including Marfan syndrome **(Chap. 425)**, osteogenesis imperfecta, and Ehlers-Danlos syndrome. MVP may be associated with thoracic skeletal deformities similar to but not as severe as those in Marfan syndrome, such as a high-arched palate and alterations of the chest and thoracic spine, including kyphosis and the so-called straight back syndrome. Other associated features can include a history of inguinal hernias, joint dislocations, meniscal tears, and easy bruisability.

In most patients with MVP, myxomatous degeneration is confined to the mitral valve, although the tricuspid and aortic valves may also be affected. Prolapse can affect one or both leaflets. The posterior mitral leaflet is usually more affected than the anterior, and the mitral valve annulus is often dilated. In many patients, elongated, redundant, or ruptured chordae tendineae cause or contribute to the regurgitation.

MVP also may occur rarely as a sequel to acute rheumatic fever, in ischemic heart disease, and in various cardiomyopathies (see above), as well as in 20% of patients with ostium secundum atrial septal defect.

MVP may lead to excessive stress on the papillary muscles, leading to localized ischemia, infarction, and replacement fibrosis. The latter, which may be a nidus for ventricular arrhythmias, may be visible on cardiac magnetic resonance imaging as late gadolinium enhancement and occurs in the absence of coronary artery disease. Rupture of chordae tendineae and progressive annular dilation and calcification contribute to valvular regurgitation, which then places more stress on the diseased mitral valve apparatus, thereby creating a vicious cycle.

CLINICAL FEATURES

MVP is more common in women than men and occurs most frequently between the ages of 15 and 30 years; the clinical course is most often benign. MVP may also be observed in older (>50 years) patients, often men, in whom MR is often more severe because of chordal rupture and requires surgical treatment. There is an increased familial incidence for some patients, suggesting an autosomal dominant form of inheritance with incomplete penetrance. MVP varies in its clinical expression, ranging from only a systolic click and murmur with mild prolapse of the posterior leaflet to severe MR due to chordal rupture and leaflet flail. The degree of myxomatous change of the leaflets can also vary widely. In many patients, the condition progresses over years or decades; in others, it worsens rapidly as a result of chordal rupture or endocarditis.

Most patients are asymptomatic and remain so for their entire lives. However, in North America, MVP is now the most common cause of isolated severe MR requiring surgical treatment. Arrhythmias, most commonly ventricular premature contractions and paroxysmal supraventricular and ventricular tachycardia, as well as atrial fibrillation (AF), have been reported and may cause palpitations, light-headedness, and syncope. Sudden death is a very rare complication and occurs most often in patients with severe MR and depressed left ventricle (LV) systolic function, although it can occur in individuals with normal LV size and function. A small subset of MVP patients with high-grade ventricular ectopy has been identified with phenotypic features including electrocardiographic inferior-apical T-wave abnormalities, high-density premature ventricular complexes at rest, mitral annular disjunction (defined as abnormal atrial displacement of the mitral valve leaflet hinge point), and papillary muscle fibrosis on cardiac magnetic resonance imaging (see above). In addition, there may be an excess risk of sudden death among patients with a flail leaflet. Most of these patients have severe MR. Many patients with MVP have chest pain that can be difficult to evaluate; it is often substernal, prolonged, and not related to exertion, but may rarely resemble angina pectoris. Transient cerebral ischemic attacks secondary to emboli from the mitral valve due to endothelial disruption have been reported. Infective endocarditis may occur in patients with MR and/or leaflet thickening.

Auscultation A frequent finding is the mid- or late (nonejection) systolic click, which occurs 0.14 s or more after S_1 and is thought to be generated by the sudden tensing of slack, elongated chordae tendineae or by the prolapsing mitral leaflet when it reaches its maximal excursion. Systolic clicks may be multiple and may be followed by a high-pitched, mid-late systolic crescendo–decrescendo murmur, which occasionally is "whooping" or "honking" and is heard best at the apex. Radiation of the murmur will depend on the involved leaflet. With posterior leaflet prolapse, the jet of MR is directed anteriorly and the murmur will radiate to the base of the heart. With anterior leaflet involvement, the jet of MR is directed posteriorly and the murmur will radiate to the axilla and back. The click and murmur occur earlier with standing, during the strain phase of the Valsalva maneuver and with any intervention that decreases LV volume (preload), exaggerating the propensity of the leaflet to prolapse. Conversely, squatting and isometric exercises, which increase LV volume, diminish MVP; the click-murmur complex is delayed, moves away from S_1, and may even disappear. Some patients have a mid-systolic click without a murmur; others have a murmur without a click. Still others have both sounds at different times.

LABORATORY EXAMINATION

The ECG most commonly is normal but may show biphasic or inverted T waves in leads II, III, and aVF and, occasionally, supraventricular or ventricular premature beats. Transthoracic echocardiography (TTE) is particularly effective in identifying the abnormal position and prolapse of the mitral valve leaflets. A useful echocardiographic definition of MVP is systolic displacement (in the parasternal long axis view) of the belly of the mitral valve leaflets by at least 2 mm into the left atrium (LA) superior to the plane of the mitral annulus. There can be prolapse of one or both leaflets **(Fig. 276-2)**. Color flow and continuous wave Doppler imaging is helpful to evaluate the associated MR and provide estimates of severity. The jet lesion of MR due to MVP is most often eccentric, and assessment of the effective regurgitant orifice area and regurgitant volume can be difficult with standard techniques. Both three-dimensional echocardiography and cardiac magnetic resonance imaging can provide more precise determinations of LV volumes. Transesophageal echocardiography (TEE) is indicated when more accurate anatomic information is required and is performed routinely for intraoperative guidance during surgical or transcatheter valve repair. Exercise testing can be performed when there is uncertainty regarding functional capacity. It is often combined with rest and immediate poststress TTE to assess LV and right ventricular (RV) function and the dynamic nature of MR and pulmonary artery pressures. Left ventriculography done at the time

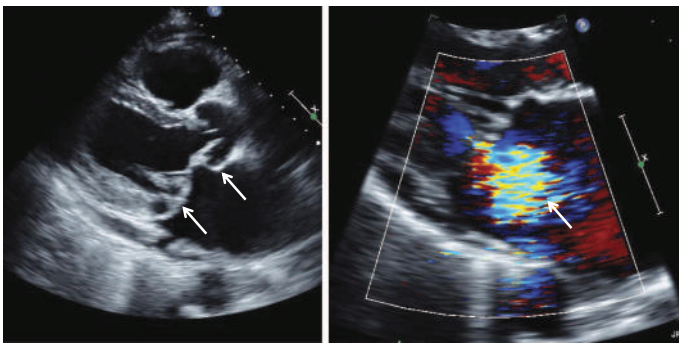

FIGURE 276-2 Barlow's valve with classic mitral valve prolapse, as seen on transthoracic echocardiogram in parasternal long-axis windows. Left: parasternal long-axis window, showing both myxomatous leaflets (*arrows*) billowing into the left atrium in late systole. Right: same window with color Doppler showing significant mitral regurgitation (*arrow*) in systole. *(Courtesy of Justina Wu, MD, PhD.)*

of right and left heart catheterization is rarely necessary but can also show prolapse of the posterior and sometimes of both mitral valve leaflets.

TREATMENT

Mitral Valve Prolapse

Infective endocarditis prophylaxis is indicated for patients with a prior history of endocarditis. Beta blockers sometimes relieve chest pain and control palpitations. Decisions regarding anticoagulation for stroke prevention in AF should be based on the CHA_2DS_2-VASc score and an assessment of bleeding risk. If the patient is symptomatic from severe MR, mitral valve repair is indicated **(see Fig. 275-2)**. Other indications for surgery for MVP with severe primary MR include findings of established or progressive LV systolic dysfunction. Surgery can also be considered for low-risk asymptomatic patients in whom a successful and durable repair can be achieved with at least 95% likelihood by an expert surgeon. Mitral valve repair is preferred over replacement in patients with MVP or flail mitral leaflet **(see Table 275-2)**; technical success is dependent not only on the anatomic findings but also on the skill and experience of the surgeon. Repair of isolated posterior leaflet prolapse is usually straightforward, but increasingly more complex pathologies (e.g., anterior leaflet prolapse, bileaflet prolapse, Barlow's deformity) require advanced skills. Careful pre- and intraoperative TEE imaging is an important component of patient evaluation and surgical planning. Transcatheter edge-to-edge repair (TEER) using one of two commercially available systems to grasp the anterior and posterior leaflets together can be considered for treatment of symptomatic patients at prohibitive or high surgical risk with severe primary MR due to MVP **(see Chap. 275 and Fig. 275-4)**. Most often, the MR will be reduced in severity but not eliminated. Nevertheless, symptom status and indices of LV size and function can be improved with this approach, which is now offered at >540 specialized sites in the United States. Reported hospital mortality rates following the procedure are <2%. Transcatheter replacement devices remain under active investigation but are not yet approved for use in the United States **(see Chap. 275)**.

277 Tricuspid Valve Disease

Patrick T. O'Gara, Joseph Loscalzo

TRICUSPID STENOSIS

Tricuspid stenosis (TS), which is much less prevalent than mitral stenosis (MS) in North America and Western Europe, is generally rheumatic in origin and is more common in women than men **(Table 277-1)**. It does not occur as an isolated lesion and is usually associated with MS.

TABLE 277-1 Causes of Tricuspid Valve Diseases

VALVE LESION	ETIOLOGIES
Tricuspid stenosis	Rheumatic
	Congenital
Tricuspid regurgitation	**Primary (organic, leaflet, or chordal related)**
	Rheumatic
	Endocarditis
	Myxomatous (TVP)
	Carcinoid
	Radiation
	Congenital (Ebstein's)
	Trauma (including that due to RV endomyocardial biopsy)
	Secondary (functional, atrial, and/or ventricular)
	RV and/or tricuspid annular dilation due to multiple causes (e.g., long-standing pulmonary HTN, remodeling post-RV MI, left-sided heart disease, cardiomyopathy, AF (atrial functional tricuspid regurgitation)
	CIED related
	Leaflet impingement, adherence, laceration, perforation, avulsion; chordal entrapment

Abbreviations: AF, atrial fibrillation; CIED, cardiac implanted electronic device; HTN, hypertension; MI, myocardial infarction; RV, right ventricular; TVP, tricuspid valve prolapse.

Hemodynamically significant TS occurs in 5–10% of patients with severe MS; rheumatic TS is commonly associated with some degree of tricuspid regurgitation (TR). Nonrheumatic causes of TS are rare.

PATHOPHYSIOLOGY

A diastolic pressure gradient between the right atrium (RA) and right ventricle (RV) defines TS. It is augmented when the transvalvular blood flow increases during inspiration and declines during expiration. A mean diastolic pressure gradient of 4 mmHg is usually sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion. Unless sodium intake has been restricted and diuretics administered, this venous congestion is associated with hepatomegaly, ascites, and edema, sometimes severe. In patients with sinus rhythm, the RA *a* wave may be extremely tall and may even approach the level of the RV systolic pressure. The *y* descent is prolonged. The cardiac output (CO) at rest is usually depressed, and it fails to rise during exercise. The low CO is responsible for the normal or only slightly elevated left atrial (LA), pulmonary artery (PA), and RV systolic pressures despite the presence of MS. Thus, the presence of TS can mask the hemodynamic and clinical features of any associated MS.

SYMPTOMS

Because the development of MS generally precedes that of TS, many patients initially have symptoms of pulmonary congestion and fatigue. Characteristically, patients with severe TS complain of relatively little dyspnea for the degree of hepatomegaly, ascites, and edema that they have. However, fatigue secondary to a low CO and discomfort due to signs of right-sided congestion such as hepatomegaly and ascites are common in patients with advanced TS and/or TR. In some patients, TS may be suspected for the first time when symptoms of right-sided failure persist after an adequate mitral commissurotomy.

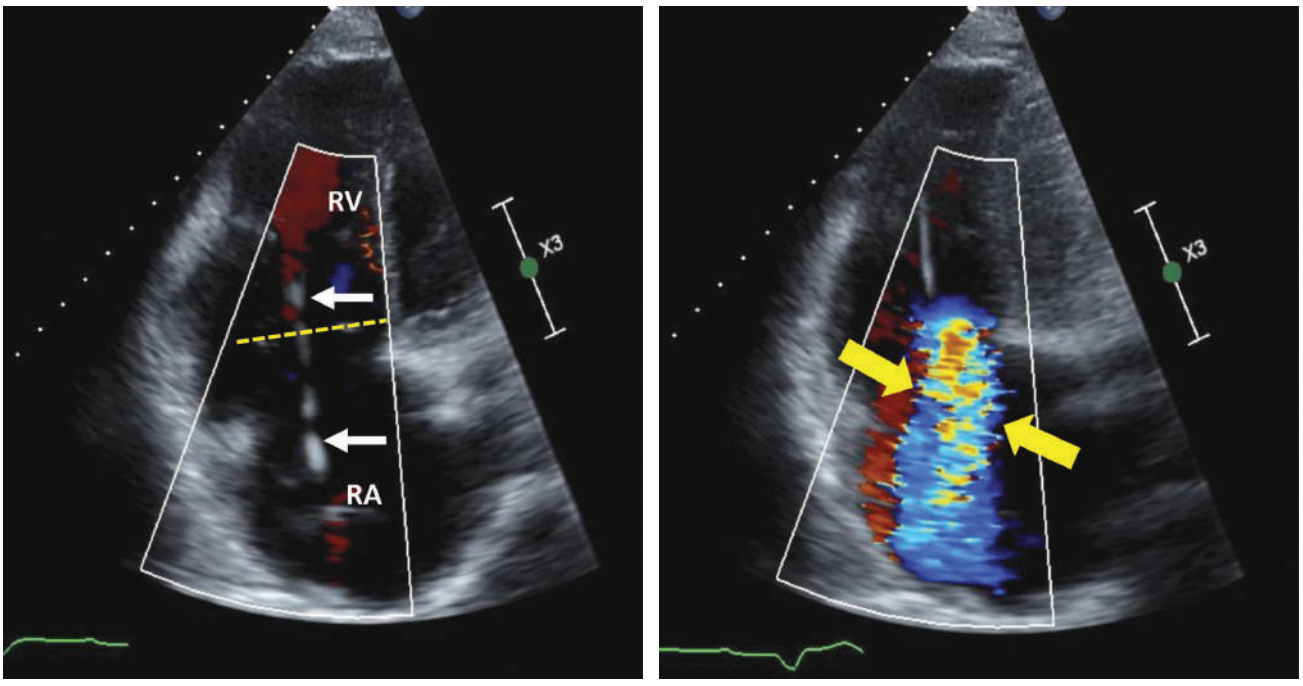
PHYSICAL FINDINGS

Because TS usually occurs in the presence of other obvious valvular disease, the diagnosis may be missed unless it is considered. Severe TS is associated with marked hepatic congestion, often resulting in cirrhosis, jaundice, serious malnutrition, anasarca, and ascites. Congestive hepatomegaly and, in cases of severe tricuspid valve disease, splenomegaly are present. The jugular veins are distended, and in patients with sinus rhythm, there may be giant *a* waves. The *v* waves are less conspicuous, and because tricuspid obstruction impedes RA emptying during diastole, there is a slow *y* descent. In patients with sinus rhythm, there may be prominent presystolic pulsations of the enlarged liver as well.

On auscultation, an opening snap (OS) of the tricuspid valve may rarely be heard ~0.06 s after pulmonic valve closure. The diastolic murmur of TS has many of the qualities of the diastolic murmur of MS, and because TS almost always occurs in the presence of MS, it may be missed. However, the tricuspid murmur is generally heard best along the left lower sternal border and over the xiphoid process and is most prominent during presystole in patients with sinus rhythm. The murmur of TS is augmented during inspiration, and it is reduced during expiration and particularly during the strain phase of the Valsalva maneuver, when tricuspid transvalvular flow is reduced.

LABORATORY EXAMINATION

The electrocardiogram (ECG) features of RA enlargement **(see Fig. 247-8)** include tall, peaked P waves in lead II, as well as prominent, upright P waves in lead V_1. The *absence* of ECG evidence of RV hypertrophy (RVH) in a patient with right-sided heart failure who is believed to have MS should suggest associated tricuspid valve disease. The chest x-ray in patients with combined TS and MS shows particular prominence of the RA and superior vena cava without much enlargement of the PA and with less evidence of pulmonary vascular congestion than occurs in patients with isolated MS; engorgement of the azygos vein can often be appreciated. On transthoracic echocardiographic (TTE) examination, the tricuspid valve is usually thickened and domes in diastole; the transvalvular gradient can be estimated by continuous wave Doppler echocardiography. Severe TS is characterized by a valve area ≤1 cm^2 or pressure half-time of ≥190 ms. The RA and inferior vena cava (IVC) are enlarged. TTE provides additional information regarding the severity of any associated TR, mitral valve structure and function, left ventricular (LV) and RV size and function, and PA pressure. Cardiac catheterization is not routinely necessary for assessment of TS.



TREATMENT

Tricuspid Stenosis

Patients with TS generally exhibit marked systemic venous congestion; salt restriction, bed rest, and diuretic therapy are required during the preoperative period. Such a preparatory period may diminish hepatic congestion and thereby improve hepatic function sufficiently so that the risks of operation, particularly bleeding, are diminished. Surgical relief of the TS should be carried out, preferably at the time of surgical mitral commissurotomy or mitral valve replacement (MVR) for mitral valve disease, in patients with moderate or severe TS who have mean diastolic pressure gradients exceeding ~4 mmHg and tricuspid orifice areas <1.5–2 cm^2. TS is almost always accompanied by significant TR. Operative repair may permit substantial improvement of tricuspid valve function. If repair cannot be accomplished, the tricuspid valve may have to be replaced. Meta-analysis has shown no difference in overall survival between mechanical and tissue valve replacement. Mechanical valves in the tricuspid position are more prone to thromboembolic complications than in other positions. Percutaneous tricuspid balloon commissurotomy for isolated severe TS without significant TR is very rarely performed.

TRICUSPID REGURGITATION

More than 85% of TR cases encountered in clinical practice are secondary (functional) in nature and related to tricuspid annular dilation and leaflet tethering in the setting of RV remodeling caused by pressure or volume overload (or both), myocardial infarction (MI), or trauma (Table 277-1). Secondary TR is commonly seen in the late stages of heart failure due to rheumatic or congenital heart disease with severe PA hypertension (PA systolic pressure >55 mmHg), as well as in other types of left-sided valvular (e.g., mitral regurgitation) or myocardial diseases (e.g., ischemic and idiopathic dilated cardiomyopathies). TR can often emerge in the setting of new-onset atrial fibrillation (AF), particularly in older patients (atrial functional TR). Rheumatic fever may produce primary TR, often associated with TS. Tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, radiation, infective endocarditis, and leaflet trauma can also produce primary TR. Less commonly, primary TR results from congenitally deformed tricuspid valves and can occur with defects of the atrioventricular canal, as well as with Ebstein's malformation of the tricuspid valve **(Chap. 280)**. A third category of TR is that associated with cardiac implantable electronic device (CIED) leads from pacemakers or defibrillators. When placed across the tricuspid valve, the leads can result

A *B*

FIGURE 277-1 Tricuspid regurgitation. ***A.*** Transthoracic apical two-chamber view showing right atrium on bottom and right ventricle on top. There is a pacemaker lead (*white arrows*) traversing the tricuspid valve. The plane of tricuspid valve closure is shown by the *dotted yellow line*. ***B.*** Corresponding color flow Doppler image in systole shows a broad jet of severe tricuspid regurgitation (*between the yellow arrows*) refluxing into the right atrium. RA, right atrium; RV right ventricle.

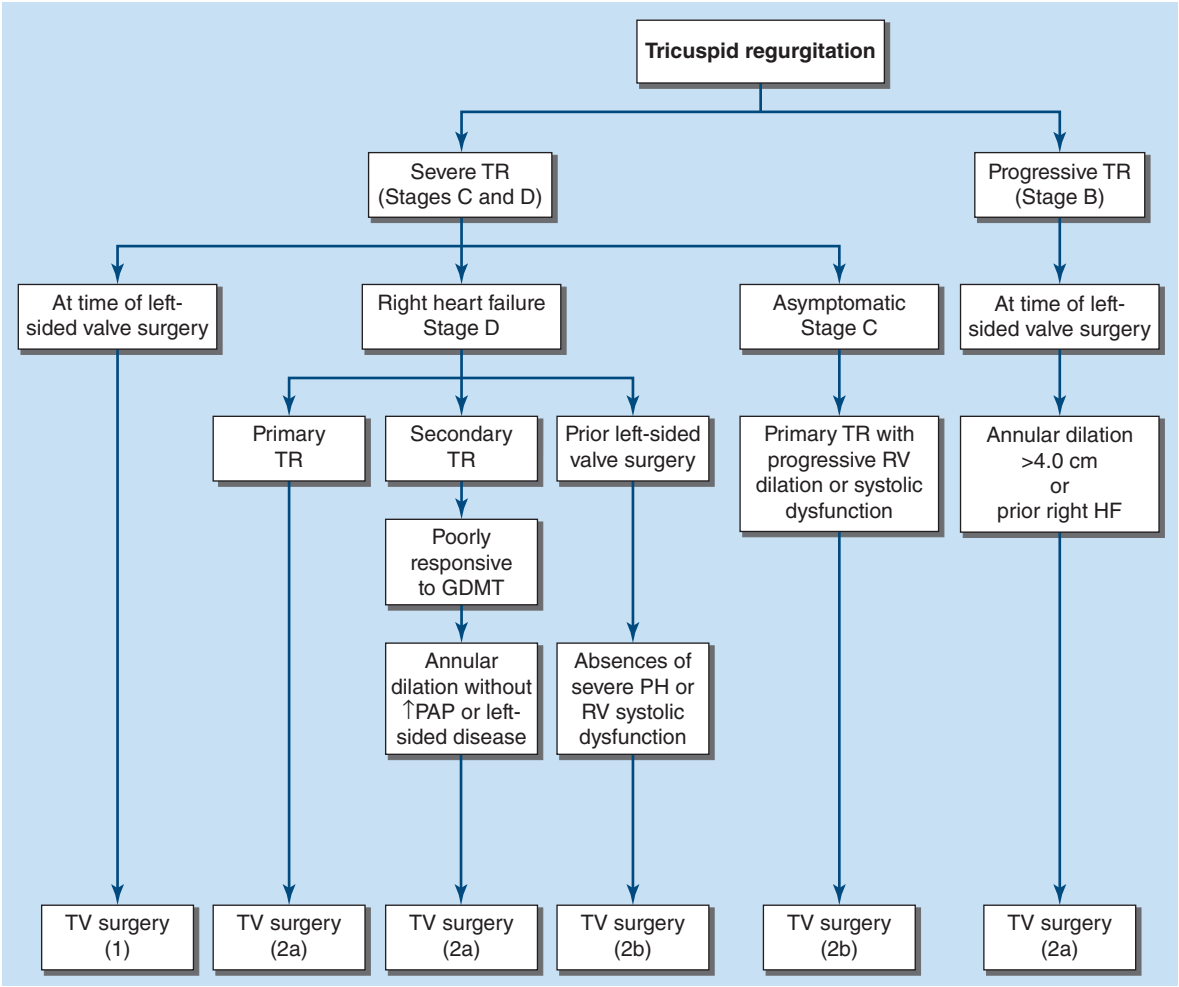


FIGURE 277-2 Management of tricuspid regurgitation. See legend for Fig. 272-4 for explanation of treatment recommendations (Class I, IIa, IIb) and disease stages (B, C, D). Preoperative coronary angiography should be performed routinely as determined by age, symptoms, and coronary risk factors. Cardiac catheterization and angiography may also be helpful when there is a discrepancy between clinical and noninvasive findings. GDMT, guideline-directed management and therapy; HF, heart failure; PAP, pulmonary artery pressure; PH, pulmonary hypertension; RV, right ventricular; TR, tricuspid regurgitation; TV, tricuspid valve. Annular dilation is defined by >40 mm on transthoracic echocardiography (>21 mm/m^2) or >70 mm on direct intraoperative measurement. *(Reproduced with permission from CM Otto et al: 2020 AHA/ACC Guideline for management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 143:e72, 2021.)*

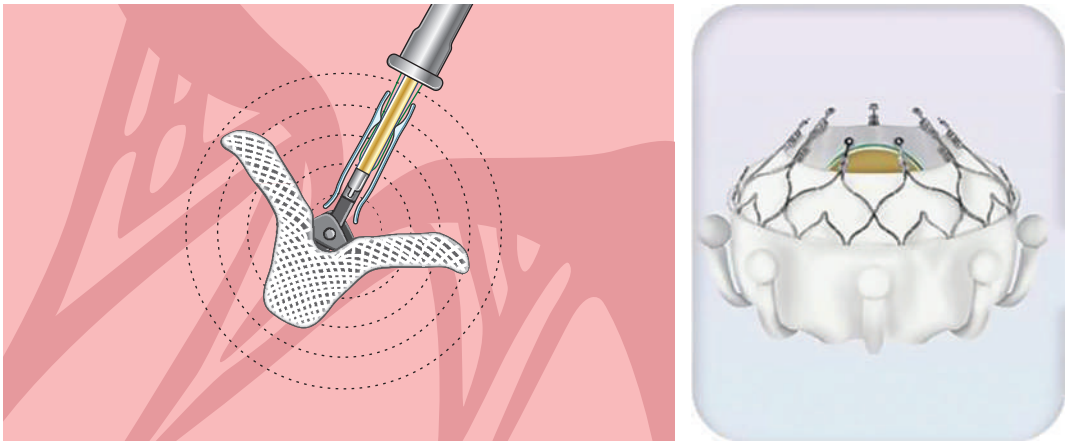
in leaflet entrapment or perforation. In addition, pacing from the right ventricular apex can result in dyssynchronous ventricular contraction and functional TR.

PATHOPHYSIOLOGY



The incompetent tricuspid valve allows blood to flow backward from the RV into the RA, the volume of which is dependent on the driving pressure (i.e., RV systolic pressure) and the size of the regurgitant orifice. The severity and physical signs of TR can vary as a function of PA systolic pressure (in the absence of RV outflow tract stenosis), the dimensions of the tricuspid valve annulus, the respiratory cycle-dependent changes in RV preload, and RA compliance. RV filling is increased during inspiration. With TR, forward CO is reduced and does not augment with exercise. Significant degrees of TR will lead to RA enlargement and elevation of the RA and jugular venous pressures with prominent *c-v* waves in the pulse tracings. Progressively severe TR can lead to "ventricularization" of the RA wave form **(see Fig. 246-1*B*)**. Severe TR is also characterized by RV dilation (RV volume overload) and eventual systolic dysfunction, the progression of which can be accelerated by a concomitant pressure load from PA hypertension or by myocardial fibrosis from previous injury.

SYMPTOMS

Mild or moderate degrees of TR are usually well tolerated in the absence of other hemodynamic disturbances. Because TR often coexists with left-sided valve lesions, LV dysfunction, and/or PA hypertension, symptoms related to these lesions may dominate the clinical picture. Atrial functional TR due to atrial fibrillation is usually accompanied by palpitations. Fatigue and exertional dyspnea owing to reduced forward CO are early symptoms of isolated, severe TR. As the disease progresses and RV function declines, patients may report cervical pulsations, abdominal fullness/bloating, diminished appetite, and muscle wasting, although with progressive weight gain and painful swelling of the lower extremities.

PHYSICAL FINDINGS

The neck veins in patients with severe TR are distended with prominent *c-v* waves and rapid *y* descents (in the absence of TS). TR is more often diagnosed by examination of the neck veins than by auscultation of the heart sounds. Other findings may include marked hepatomegaly with systolic pulsations, ascites, pleural effusions, edema, and a positive hepatojugular reflux sign. A prominent RV pulsation in the left parasternal region and a blowing holosystolic murmur along the lower left sternal margin, which may be intensified during inspiration (Carvallo's sign) and reduced during expiration or the strain phase of the Valsalva maneuver, are characteristic findings. The murmur of TR may sometimes be confused with that of mitral regurgitation (MR) unless attention is paid to its variation during the respiratory cycle and the extent of RV enlargement is appreciated. AF may be the driver of TR or may emerge later in the disease with ventricular and atrial remodeling.

A B

FIGURE 277-3 Transcatheter tricuspid valve (TV) repair and replacement. *A.* Shown is a clip device that can be used to grasp the leading edges of the TV leaflets to reduce the severity of tricuspid regurgitation (TR) by decreasing the effective orifice area of the valve. *(TriClip is a trademark of Abbott or its related companies.)* ***B.*** Bioprosthetic heart valve replacement approved for percutaneous treatment of severe TR is selected for high or prohibitive surgical risk patients. *(EVOQUE is a trademark of Edwards Lifesciences.)*

LABORATORY EXAMINATION

The ECG may show changes characteristic of the lesion responsible for the TR, e.g., an inferior Q-wave MI suggestive of a prior RV MI, RVH, or a bizarre right bundle branch block–type pattern with preexcitation in patients with Ebstein's anomaly. ECG signs of RA enlargement may be present in patients with sinus rhythm; AF is frequently noted. The chest x-ray may show RA and RV enlargement, depending on the chronicity and severity of TR. TTE is usually definitive with demonstration of RA dilation and RV volume overload and prolapsing, flail, scarred, or displaced/tethered tricuspid leaflets with annular dilatation; the diagnosis and assessment of TR can be made by color flow Doppler imaging **(see Figs. 248-8 and 277-1)**. Severe TR is accompanied by hepatic vein systolic flow reversal. Continuous wave Doppler of the TR velocity profile is useful in estimating PA systolic pressure, except when the TR is very severe and the jet velocity is blunted by rapidly increasing RA pressure. Accurate assessment of TR severity, PA pressures, and RV size and systolic function with TTE can be quite challenging in many patients. Real-time three-dimensional echocardiography and cardiac magnetic resonance (CMR) imaging provide alternative imaging modalities to aid in the assessment of TR severity, although they are not widely available. In patients with severe TR, the CO is usually markedly reduced, and the RA pressure pulse may not exhibit an *x* descent during early systole but rather show a prominent *c-v* wave with a rapid *y* descent. The mean RA and RV end-diastolic pressures are often elevated. Exercise testing can be used to assess functional capacity in patients with asymptomatic severe TR. The prognostic significance of exercise-induced changes in TR severity and RV function has not been well studied. (See Fig. 277-1.)

TREATMENT

Tricuspid Regurgitation (Fig. 277-2)

Diuretics can be useful for patients with severe TR and signs of right heart failure. An aldosterone antagonist may be particularly helpful because many patients have secondary hyperaldosteronism from marked hepatic congestion. Therapies to reduce elevated PA pressures and/or pulmonary vascular resistance, including those targeted at left-sided heart disease, can also be considered for patients with PA hypertension and severe secondary TR. Tricuspid valve surgery is recommended for patients with *severe TR* who are undergoing left-sided valve surgery and is also undertaken frequently for treatment of even moderate TR in patients undergoing left-sided valve surgery especially those with tricuspid annular dilation (>40 mm), a history of right heart failure, or PA hypertension. Operation most often comprises repair rather than replacement in these settings and has become more routine in many surgical centers. In a randomized trial of tricuspid valve annuloplasty surgery at the time of mitral valve surgery for degenerative MR in patients with *moderate TR* or *mild TR with annular dilation*, there was a significant reduction in the 2-year incidence of a composite endpoint of reoperation, progression of TR, or all-cause death among those who underwent tricuspid surgery versus those who had mitral valve surgery alone. The composite endpoint was driven by a reduction in the progression of TR. Surgery may also infrequently be required for treatment of severe, primary TR with right heart failure not responsive to standard medical therapy or because of progressively declining RV systolic function. Reported perioperative mortality rates for isolated tricuspid valve surgery (repair and replacement) are high (~8–9%) and likely are influenced by the hazards encountered during reoperation on patients who have undergone previous left-sided valve surgery and have reduced RV function.

There have been several recent advances in the application of transcatheter tricuspid valve repair and replacement techniques in patients with severe TR and high or prohibitive surgical risk. In a randomized trial of percutaneous transcatheter edge-to-edge repair versus medical therapy, clip repair resulted in a significant reduction in TR severity and improvement in quality-of-life scores, but no differences in all-cause mortality or hospitalization for heart failure over 1-year follow-up. The U.S. Food and Drug Administration approved the use of a transcatheter tricuspid valve replacement system in early 2024 based on favorable hemodynamic, echocardiographic, clinical, and quality-of-life results from prospective single-arm studies. **(See Figure 277-3.)**

278 Pulmonic Valve Disease

Patrick T. O'Gara, Joseph Loscalzo

PULMONIC STENOSIS

Pulmonic valve stenosis (PS) is essentially a congenital disorder (Table 278-1). With isolated PS, the valve is typically domed. Dysplastic pulmonic valves are seen as part of the Noonan syndrome (Chap. 292), which maps to chromosome 12. Mutations in the *PTPN1* gene are associated with about half of all cases of Noonan syndrome. Much less common etiologies include carcinoid and obstructing tumors or bulky vegetations. The pulmonic valve is only very rarely affected by the rheumatic process.

PATHOPHYSIOLOGY

PS is defined hemodynamically by a systolic pressure gradient between the right ventricle (RV) and the main pulmonary artery (PA). RV hypertrophy (RVH) develops as a consequence of sustained obstruction to RV outflow, and systolic ejection is prolonged. Compared with the ability of the LV to compensate for the pressure overload imposed by aortic stenosis (AS), RV dysfunction from afterload mismatch occurs earlier in the course of PS and at lower peak systolic pressures, because the RV adapts less well to this type of hemodynamic burden. With normal systolic function and cardiac output (CO), severe PS is defined by a peak systolic gradient across the pulmonic valve of >64 mmHg (mean gradient >35 mmHg, Doppler jet velocity >4 m/s); moderate PS correlates with a peak gradient of 36–64 mmHg (Doppler jet velocity 3–4 m/s). Mild PS is characterized by a jet velocity <3 m/s (peak gradient <36 mmHg). PS rarely progresses in patients with mild PS but may worsen with age in those with moderate disease due to valve thickening and calcification. The right atrial (RA) *a* wave elevates in relation to the higher pressures needed to fill a noncompliant, hypertrophied RV. A prominent RA *v* wave signifies functional tricuspid regurgitation (TR) from RV and annular dilation. The CO is maintained until late in the course of the disease.

SYMPTOMS

Patients with mild or even moderate PS are usually asymptomatic and first come to medical attention because of a heart murmur (or early systolic click) that leads to echocardiography. With severe PS, patients may report exertional dyspnea or early-onset fatigue. Anginal chest pain from RV oxygen supply-demand mismatch and syncope may occur with very severe forms of obstruction, particularly in the presence of a destabilizing trigger such as atrial fibrillation, fever, infection, anemia, or pregnancy.

PHYSICAL FINDINGS

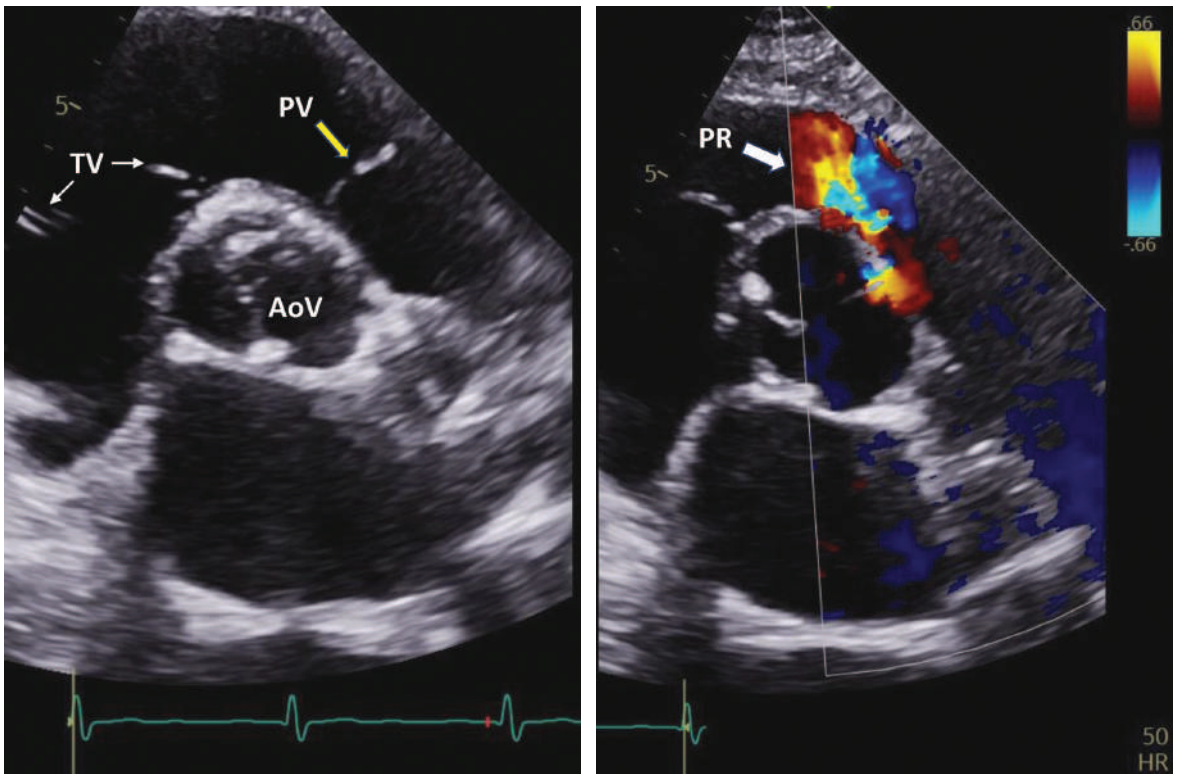
The murmur of mild or moderate PS is mid-systolic in timing, crescendo–decrescendo in configuration, heard best in the left second interspace, and usually introduced by an ejection sound (click) in younger adults whose valves are still pliable. The ejection sound is the only right-sided acoustic event that decreases in intensity with inspiration. This phenomenon reflects premature opening of the pulmonic valve by the elevated RV end-diastolic (post-atrial *a* wave) pressure. The systolic murmur increases in intensity during inspiration. With progressively severe PS, the ejection sound moves closer to the first heart sound and eventually becomes inaudible. A right-sided fourth heart sound may emerge. The systolic murmur peaks later and may persist through the aortic component of the second heart sound (A_2). Pulmonic valve closure is delayed, and the pulmonic component of the second heart sound (P_2) is reduced or absent. A prominent *a* wave, indicative of the higher atrial pressure necessary to fill the noncompliant RV, may be seen in the jugular venous pulse. A parasternal or RV lift can be felt with significant pressure overload. Signs of right heart failure due to RV systolic dysfunction, such as hepatomegaly, ascites, and edema, are uncommon but may appear very late in the disease.

TABLE 278-1 Causes of Pulmonic Valve Disease

VALVE LESION	ETIOLOGIES
Pulmonic stenosis	Congenital Carcinoid Tumor Endocarditis
Pulmonic regurgitation	Primary valve disease Congenital Post-valvotomy Endocarditis Carcinoid Annular enlargement Pulmonary hypertension Idiopathic dilation Marfan syndrome

LABORATORY EXAMINATION

The electrocardiogram (ECG) will show right axis deviation, RVH, and RA enlargement in adult patients with severe PS. Chest x-ray findings include poststenotic dilation of the main PA in the frontal plane projection and filling of the retrosternal airspace due to RV enlargement on the lateral film. In some patients with RVH, the cardiac apex appears to be lifted off the left hemidiaphragm. The RA may also be enlarged. Transthoracic echocardiography (TTE) allows definitive diagnosis and characterization in most cases, with depiction of the valve and assessment of the jet velocity, gradient, RV function, PA pressures (which should be low), and any associated cardiac lesions. Transesophageal echocardiography (TEE) may be useful in some patients for improved delineation of the RV outflow tract (RVOT) and assessment of infundibular hypertrophy. Cardiac catheterization is not usually necessary for diagnostic purposes, but if performed, pressures should be obtained from just below and above the pulmonic valve with attention to the possibility that a dynamic component to the gradient may exist. The correlation between Doppler assessment of peak instantaneous gradient and catheterization-measured peak-to-peak gradient is weak. The latter may correlate better with the Doppler mean gradient.



TREATMENT

Pulmonic Stenosis

Diuretics can be used to treat symptoms and signs of right heart failure. Provided there is less than moderate pulmonic regurgitation (PR), percutaneous pulmonic balloon valvuloplasty is recommended for symptomatic patients with moderate or severe PS and for asymptomatic patients with a peak gradient >64 mmHg (or mean gradient >35 mmHg). Surgery may be required when the valve is dysplastic (as seen in patients with Noonan's syndrome and other disorders). A multidisciplinary heart team is best positioned to make treatment decisions of this nature.

PULMONIC REGURGITATION

PR may develop as a consequence of primary valve pathology, annular enlargement, or their combination; after surgical treatment of RVOT obstruction in children with such disorders as tetralogy of Fallot; or after percutaneous pulmonic balloon valvotomy (Table 278-1). Carcinoid usually causes mixed pulmonic valve disease with PR and PS. Long-standing severe PA hypertension from any cause can result in dilation of the pulmonic valve ring and PR. Trace or mild PR of no hemodynamic or clinical consequence is frequently observed on TTE in the absence of structural pulmonic valve disease (Fig. 278-1).

A *B*

FIGURE 278-1 Pulmonic regurgitation. ***A.*** Transthoracic short axis window at the level of the aortic valve (AoV). The pulmonic valve (PV) is shown with the *yellow arrow*. Tricuspid valve (TV) leaflets are partially visualized (*white arrows*). ***B.*** Color flow Doppler image shows moderate pulmonic regurgitation (PR, *white arrow*).

PATHOPHYSIOLOGY

Severe PR results in RV chamber enlargement and eccentric hypertrophy. As is the case for aortic regurgitation (AR), PR is a state of increased preload and afterload. The diastolic pressure gradient between the PA to the RV, which drives the PR, progressively decreases throughout diastole and accounts for the decrescendo nature of the murmur. As RV diastolic pressure increases, the murmur becomes shorter in duration. The forward CO is preserved during the early stages of the disease but may not increase normally with exercise and declines over time. A reduction in RV ejection fraction may be an early indicator of hemodynamic compromise. In advanced stages, there is significant enlargement of the RV and RA with marked elevation of the jugular venous pressure.

SYMPTOMS

Mild or moderate degrees of PR do not, by themselves, result in symptoms. Other issues, such as PA hypertension, may dominate the clinical picture. With progressively severe PR and RV dysfunction, fatigue, exertional dyspnea, abdominal fullness/bloating, and lower extremity swelling may be reported.

PHYSICAL FINDINGS

The physical examination hallmark of PR is a high-pitched, decrescendo diastolic murmur (Graham Steell murmur) heard along the left sternal border that can be difficult to distinguish from the more frequently appreciated murmur of AR. The Graham Steell murmur may become louder with inspiration and is usually associated with a loud and sometimes palpable P_2 and an RV lift, as would be expected in patients with significant PA hypertension of any cause. Survivors of childhood surgery for tetralogy of Fallot or PS/pulmonary atresia may have an RV-PA conduit that is freely regurgitant because it does not contain a valve. PA pressures in these individuals are not elevated, and the diastolic murmur can be misleadingly low pitched and of short duration despite significant degrees of PR and RV volume overload.

LABORATORY EXAMINATION

Depending on both the etiology and severity of PR, the ECG may show findings of RVH and RA enlargement. On chest x-ray, the RV and RA may be enlarged. Pulmonic valve morphology and function can be assessed with transthoracic Doppler echocardiography. RV systolic pressure can be estimated from the tricuspid valve systolic jet velocity. Cardiac magnetic resonance (CMR) imaging can provide greater anatomic detail, particularly in patients with repaired congenital heart disease, and more precise assessment of RV volumes and function. Cardiac catheterization is not routinely necessary but would be performed as part of a planned transcatheter PV procedure.

TREATMENT

Pulmonic Regurgitation

In patients with significant functional PR due to PA hypertension and annular dilation, efforts to reduce pulmonary vascular resistance and pressure should be pursued. Such efforts may include pharmacologic/vasodilator and/or surgical/interventional strategies, depending on the cause of the PA hypertension (e.g., idiopathic PA hypertension, left-sided heart valve disease). Diuretics can be used to treat the manifestations of right heart failure. Surgical valve replacement for primary, severe, pulmonic valve disease, such as carcinoid or endocarditis, is rarely undertaken. Transcatheter pulmonic valve replacement has been successfully performed in many patients with severe PR after childhood repair of tetralogy of Fallot or pulmonic valve stenosis or atresia. This procedure was introduced clinically prior to transcatheter aortic valve replacement. Earlier concerns regarding an excess hazard of infective endocarditis with first-generation valves have led to procedural modifications.

279 Multiple and Mixed Valvular Heart Disease

Patrick T. O'Gara, Joseph Loscalzo

Many acquired and congenital cardiac lesions may result in stenosis and/or regurgitation of one or more heart valves. For example, rheumatic heart disease can involve the mitral (mitral stenosis [MS], mitral regurgitation [MR], or MS and MR), aortic (aortic stenosis [AS], aortic regurgitation [AR], or AS and AR), and tricuspid (tricuspid stenosis [TS], tricuspid regurgitation [TR], or TS and TR) valve, alone or in combination. The common association of functional TR with significant mitral valve disease is discussed in **Chap. 277**. Severe mitral annular calcification can result in regurgitation (due to decreased annular shortening during systole) and mild or moderate stenosis (caused by extension of the calcification onto the leaflets resulting in restricted valve opening). Patients with severe AS and left ventricular (LV) remodeling may develop functional MR that may not improve after isolated aortic valve replacement (AVR). Primary MR due to mitral valve prolapse or chordal rupture has been noted in patients with severe AS. Aortic valve infective endocarditis (IE) may secondarily involve the mitral apparatus either by abscess formation and contiguous spread via the intervalvular fibrosa or by "drop metastases" from the aortic leaflets onto the anterior leaflet of the mitral valve. Mediastinal radiation may result in aortic, mitral, and even tricuspid valve disease, most often with mixed stenosis and regurgitation. Carcinoid heart disease may cause mixed lesions of either or both the tricuspid and pulmonic valves. Ergotamines, and the previously used combination of fenfluramine and phentermine, can rarely result in mixed lesions of the aortic and/or mitral valve. Patients with Marfan syndrome may have both AR from aortic root dilation and MR due to mitral valve prolapse (MVP). Myxomatous degeneration causing prolapse of multiple valves (mitral, aortic, tricuspid) can also occur in the absence of an identifiable connective tissue disorder. Bicuspid aortic or pulmonic valve disease can result in mixed stenosis and regurgitation. The former is also associated with aortic aneurysm disease and a predisposition to aortic dissection.

PATHOPHYSIOLOGY

In patients with multivalvular heart disease, the pathophysiologic derangements associated with the more proximal valve disease can mask the full expression of the attributes of the more distal valve lesion. For example, in patients with rheumatic mitral and aortic valve disease, the reduction in cardiac output (CO) imposed by the mitral valve disease will decrease the magnitude of the hemodynamic derangements related to the severity of the aortic valve lesion (stenotic, regurgitant, or both). Alternatively, the development of atrial fibrillation (AF) during the course of MS can lead to sudden worsening in a patient whose aortic valve disease was not previously felt to be significant. The development of reactive pulmonary vascular disease, sometimes referred to as a "secondary obstructive lesion in series," can impose an additional challenge in these settings. As CO falls with progressive tricuspid valve disease, the severity of any associated mitral or aortic disease can be underestimated.

One of the most common examples of multivalve disease is that of functional TR in the setting of significant mitral valve disease. Functional TR occurs as a consequence of right ventricular and annular dilation; pulmonary artery (PA) hypertension may be present. The tricuspid leaflets are morphologically normal. Progressive degrees of TR lead to right ventricular volume overload and continued chamber and annular dilation. The TR is usually central in origin; reflux into the right atrium (RA) is expressed as large, systolic *c-v* waves in the RA pressure pulse. The height of the *c-v* wave is dependent on RA compliance and the volume of regurgitant flow. The RA waveform may become "ventricularized" in advanced stages of chronic, severe TR. CO falls and the severity of the associated mitral valve disease may become more difficult to appreciate. Findings related to advanced right heart failure (e.g., ascites, edema) predominate. Primary rheumatic tricuspid valve disease may occur with rheumatic mitral disease and cause hemodynamic changes reflective of TR, TS, or their combination. With TS, the *y* descent in the RA pressure pulse is prolonged. Typically, however, findings related to the mitral valve disease predominate over those related to the tricuspid valve disease.

Another example of rheumatic, multivalve disease involves the combination of mitral and aortic valve pathology, frequently characterized by MS and AR. In isolated MS, LV preload and diastolic pressure are reduced as a function of the severity of inflow obstruction. With concomitant AR, however, LV filling is enhanced and diastolic pressure may rise depending on the compliance characteristics of the chamber. Because the CO falls with progressive degrees of MS, transaortic valve flows will decline, masking the potential severity of the aortic valve lesion (AR, AS, or its combination). As noted above, onset of AF in such patients can be especially deleterious. The loss of atrial systole with AF may result in a critical reduction in CO, a rise in left atrial (LA) and LV diastolic pressures, and a further deleterious increase in heart rate.

Secondary (functional) MR may complicate the course of some patients with severe AS. The mitral valve leaflets and chordae tendineae are usually normal. Incompetence is related to changes in LV geometry (remodeling) and abnormal systolic tethering of the leaflets in the context of markedly elevated LV systolic pressures. Relief of the excess afterload with surgical or transcatheter AVR may result in reduction of the secondary MR. Persistence of significant, secondary MR following AVR is associated with impaired functional outcomes and reduced survival. Identification of patients who would benefit from concomitant treatment of their secondary MR at time of AVR is quite challenging. Most surgeons perform mitral valve repair of moderate-to-severe or severe secondary MR at time of surgical AVR. Significant primary MR may also coexist with AS and is routinely managed with repair (or replacement) at the time of AVR. There is increasing experience with the combination of transcatheter aortic valve implantation (TAVI) and transcatheter edge-to-edge mitral valve repair (TEER) in high surgical risk patients with severe AS and moderate-severe primary or secondary MR. Decision-making regarding the need for mitral valve intervention can be challenging.

In patients with mixed AS and AR, assessment of valve stenosis can be influenced by the magnitude of the regurgitant valve flow. Because transvalvular systolic flow velocities are augmented in patients with AR and preserved LV systolic function, the LV-aortic Doppler-derived pressure gradient and the intensity of the systolic murmur will be elevated to values higher than expected for the true systolic valve orifice size as measured by planimetry. Uncorrected, the Gorlin formula, which relies on forward CO (systolic transvalvular flow) and the mean pressure gradient for calculation of valve area, is not accurate in the setting of mixed aortic valve disease. Similar considerations apply to patients with mixed mitral valve disease. The peak mitral valve Doppler E wave velocity (v_0) is increased in the setting of severe MR because of enhanced early diastolic flow and may not accurately reflect the contribution to LA hypertension from any associated MS. When either AR or MR is the dominant lesion in patients with mixed aortic or mitral valve disease, respectively, the LV is dilated. When AS or MS predominates, LV chamber size will be normal or small. It can sometimes be difficult to ascertain whether stenosis or regurgitation is the dominant lesion in patients with mixed valve disease, although an integrated clinical and noninvasive assessment can usually provide clarification for purposes of patient management. For patients with moderate, mixed AS and AR in whom stenosis is the dominant lesion, the natural history tends to parallel what might be expected for isolated severe AS, and the treatment approach should be accordingly aligned.

Patients with significant AS, a nondilated LV chamber, and concentric hypertrophy will poorly tolerate the abrupt development of aortic regurgitation, as may occur, for example, with IE or after surgical AVR or TAVI complicated by paravalvular leakage. The noncompliant LV is not prepared to accommodate the sudden volume load, and as a result, LV diastolic pressure rises rapidly and severe heart failure develops.

Indeed, significant paravalvular regurgitation is a significant risk factor for short- to intermediate-term death following transcatheter AVR. Conditions in which the LV may not be able to dilate in response to chronic AR (or MR) include radiation heart disease, cardiac amyloid, and, in some patients, the cardiomyopathy associated with obesity and diabetes. Noncompliant ventricles of small chamber size predispose to earlier onset diastolic dysfunction and heart failure in response to any further perturbation in valve function.

SYMPTOMS

Compared with patients with isolated, single-lesion valve disease, patients with multiple or mixed valve disease may develop symptoms at a relatively earlier stage in the natural history of their disease. Symptoms such as exertional dyspnea and fatigue are usually related to elevated filling pressures, reduced CO, or their combination. Palpitations may signify AF and identify mitral valve disease as an important component of the clinical presentation, even when not previously suspected. Chest pain compatible with angina could reflect left or right ventricular oxygen supply/demand mismatch on a substrate of hypertrophy and pressure/volume overload with or without superimposed coronary artery disease. Symptoms related to right heart failure (abdominal fullness/bloating, edema) are late manifestations of advanced disease.

PHYSICAL FINDINGS

Mixed disease of a single valve is most often manifested by systolic and diastolic murmurs, each with the attributes expected for the valve in question. Thus, patients with AS and AR will have characteristic mid-systolic, crescendo-decrescendo and blowing, decrescendo diastolic murmurs at the base of the heart in the second right interspace and along the left sternal edge, respectively. Many patients with significant AR have mid-systolic outflow murmurs even in the absence of valve sclerosis/stenosis, and other findings of AS must be sought. The separate murmurs of AS and AR can occasionally be difficult to distinguish from the continuous murmurs associated with either a patent ductus arteriosus (PDA) or ruptured sinus of Valsalva aneurysm. With mixed aortic valve disease, the systolic murmur should end before, and not envelope or extend through, the second heart sound (S_2). The murmur associated with a PDA is heard best to the left of the upper sternum. The continuous murmur heard with a ruptured sinus of Valsalva aneurysm is often first appreciated after an episode of acute chest pain. An early ejection click, which usually defines bicuspid aortic valve disease in young adults, is often not present in patients with congenital mixed AS and AR. As noted above, both the intensity and duration of these separate murmurs can be influenced by a reduction in CO and transvalvular flow due to coexistent mitral valve disease or AF. In patients with isolated MS and MR, expected findings would include a blowing, holosystolic murmur and a mid-diastolic rumble (with or without an opening snap) best heard at the cardiac apex. An irregularly irregular heart rhythm in such patients would likely signify AF. Findings with TS and TR would mimic those of left-sided MS and MR, save for the expected changes in the murmurs with respiration. The murmurs of pulmonic stenosis and regurgitation behave in a fashion directionally similar to AS and AR; dynamic changes during respiration should be noted. Specific attributes of these cardiac murmurs are reviewed in **Chaps. 44 and 277.**

LABORATORY EXAMINATION

The electrocardiogram (ECG) may show evidence of ventricular hypertrophy and/or atrial enlargement. ECG signs indicative of right-sided cardiac abnormalities in patients with left-sided valve lesions should prompt additional assessment for PA hypertension and/or right-sided valve disease. The presence of AF in patients with aortic valve disease may be a clue to the presence of previously unsuspected mitral valve disease in the appropriate context. The chest x-ray can be reviewed for evidence of cardiac chamber enlargement, valve and/or annular calcification, and any abnormalities in the appearance of the pulmonary vasculature. The latter could include enlargement of the main and proximal pulmonary arteries with PA hypertension and pulmonary venous redistribution/engorgement or Kerley B lines with increasing degrees of LA and pulmonary venous hypertension. An enlarged azygos vein in the frontal projection indicates RA hypertension. Roentgenographic findings not expected based on a single or mixed valve lesion may reflect other valve disease.

Transthoracic echocardiography (TTE) is the most commonly used imaging modality for the diagnosis and characterization of multiple and/or mixed valvular heart disease and may often demonstrate findings not clinically suspected. Transesophageal echocardiography (TEE) may sometimes be required for more accurate assessment of valve anatomy (specifically, the mitral valve) and when IE is considered responsible for the clinical presentation. TTE findings of particular interest include those related to valve morphology and function, calcification, chamber size, ventricular wall thickness, biventricular function, estimated PA systolic pressure, and the dimensions of the great vessels, including the root and ascending aorta, PA, and inferior vena cava. Exercise testing (with or without echocardiography) can be useful when the degree of functional limitation reported by the patient is not adequately explained by the findings on TTE performed at rest. An integrated assessment of the clinical and TTE findings is needed to help determine the dominant valve lesion(s) and establish an appropriate plan for treatment and follow-up. Natural history is usually influenced to a relatively greater degree by the dominant lesion.

Cardiac magnetic resonance (CMR) imaging can be used to provide additional anatomic and physiologic information when echocardiography proves suboptimal but is less well suited to the evaluation of valve morphology. Cardiac computed tomography (CT) has been used to assess intracardiac structures in patients with complicated IE. It is invaluable in planning for transcatheter valve implantation. Coronary CT angiography provides a noninvasive alternative for the assessment of coronary artery anatomy prior to surgery or transcatheter intervention.

Invasive hemodynamic evaluation with right and left heart catheterization may be required to characterize more completely the individual contributions of each lesion in patients with either multiple or mixed valvular heart disease. It is strongly recommended when there is a discrepancy between the clinical and noninvasive findings in a symptomatic patient. Measurement of PA pressures and calculation of pulmonary vascular resistance (PVR) can help inform clinical decision-making in certain patient subsets, such as those with advanced mitral and tricuspid valve disease. It is important to identify any potential contribution to the clinical picture from pulmonary vascular disease. Attention to the accurate assessment of CO is essential. Coronary angiography (if indicated) can be performed as part of the procedure. Contrast ventriculography and great vessel angiography are performed infrequently.

TREATMENT

Multiple and Mixed Valve Disease

Management of patients with multiple or mixed valve disease can be challenging. As noted above, it is helpful to determine the dominant valve lesion and proceed according to the treatment and follow-up recommendations for it **(Chaps. 272–278)**, being mindful of deviations from the expected course due to the contributions of more than one valve lesion. For example, AF that emerges in the course of moderate mitral valve disease may precipitate heart failure in patients with concomitant, severe aortic valve disease that was previously asymptomatic.

Medical therapies are limited and include diuretics when indicated for relief of congestion and anticoagulation to prevent stroke and thromboembolism in patients with AF. Blood pressure–lowering medications may be needed to treat systemic hypertension, which may aggravate left-sided regurgitant valve lesions, but should be initiated and titrated carefully. Pulmonary vasodilators to lower PVR are not generally effective in this context.

There is a paucity of evidence to inform practice guidelines for surgical and/or transcatheter valve intervention in patients with multiple or mixed valve disease. When there is a clear, dominant lesion, as for example in a patient with severe AS and mild AR, indications for intervention are straightforward and follow those recommended for patients with AS **(Chap. 272)**. In other patients, however, there is less clarity, and decisions regarding intervention should be based on several considerations, including those related to lesion severity, ventricular remodeling, functional capacity, and PA pressures. In this regard, it is important to realize that patients with multiple and/or mixed valve disease may develop limiting symptoms or signs of physiologic impairment even with moderate valve lesions.

Concomitant aortic and mitral valve replacement surgery is associated with a significantly higher perioperative mortality risk than replacement of either valve alone; therefore, operation should be carefully considered. Double valve replacement surgery is usually performed for treatment of severe (unrepairable) valve disease at both locations and for the combination of severe disease at one location with moderate disease at the other to avoid the hazards of reoperation in the intermediate to late term for progressive disease of the unoperated valve. In addition, the presence of a prosthesis in the aortic position significantly restricts surgical exposure of the native mitral valve. The need for double valve replacement may also impact the decision regarding the type of prosthesis (i.e., mechanical vs tissue). In selected patients, TAVI for severe AS followed by edge-to-edge clip repair for severe MR can be accomplished during the same procedure.

Tricuspid valve repair for moderate or severe secondary (functional) TR at the time of left-sided valve surgery is now commonplace, particularly if there is dilation of the tricuspid annulus (>40 mm). The addition of tricuspid valve repair, consisting usually of insertion of an annuloplasty ring, adds little time or complexity to the procedure and is well tolerated, but may be associated with an excess risk of heart block and the need for a permanent pacemaker. Reoperation for repair (or replacement) of progressive TR years after initial surgery for left-sided valve disease, on the other hand, is associated with a relatively high perioperative mortality risk. Mitral valve repair or replacement for moderate or severe secondary MR at time of AVR for AS can usually be undertaken with acceptable risk for perioperative death or major complication.

The presence of moderate or severe MR in patients with rheumatic MS is a contraindication to percutaneous mitral balloon commissurotomy (PMBC). TAVI can be performed for mixed AS and AR when the anatomic findings related to annulus size, coronary height, and the distribution of calcium are favorable. Transcatheter management of both severe AS and severe primary or secondary MR (with deployment of an edge-to-edge clip) has been undertaken with increasing frequency in appropriately selected patients with prohibitive or high surgical risk. Further advances in transcatheter treatments for multiple and mixed valve disease are anticipated.

280 Congenital Heart Disease in the Adult

Anne Marie Valente, Michael J. Landzberg

PREVALENCE

The number of adults with congenital heart disease (CHD) living in the United States is estimated to be at least 1.4 million. It is now projected that >10% of adults living with CHD in Europe will be over 60 years old by 2030. The majority of adults with CHD were diagnosed in childhood, although a substantial percentage may have CHD first recognized as adults. Lifelong follow-up in coordination with, or directly by, clinicians with expertise in adult congenital heart disease (ACHD) is recommended. In this chapter, we will review the current field of ACHD, with an introduction to CHD nomenclature and cardiac development. This is followed by a summary of the more common CHD lesions that may be diagnosed in adulthood. Lastly, some of the common repaired CHD lesions that are encountered in adults are discussed. Throughout the chapter, to aid in the understanding of congenital cardiac anatomy and physiology, we include figures displaying the passage of blood flow between blood vessels and cardiac chambers in various disorders **(Fig. 280-1)**.

THE CHANGING LANDSCAPE OF ADULT CHD

A Relatively New Subspecialty in Cardiovascular Disease

Over the past two decades, the field of caring for adults with CHD has blossomed, and several nationwide initiatives have been initiated to standardize care. The American College of Cardiology and American Heart Association developed guidelines for the care of adults with CHD, first published in 2008 and revised in 2018, which emphasize the need for collaboration among primary care practitioners, cardiologists, and ACHD subspecialty cardiologists. The body of medical knowledge and competencies attendant with ACHD combined with skill acquisition in coordination of complex care over a patient's medical lifetime led in 2015 to ACHD board certification examinations by the American Board of Medical Subspecialties, as well as the establishment of requirements for advanced fellowship training in ACHD care by the Accreditation Council for Graduate Medical Education. In temporal association, the Adult Congenital Heart Association (ACHA) developed a process for ACHD care program accreditation based on standardization of infrastructural components felt requisite to achieve quality outcomes for ACHD.

SPECIAL CONSIDERATIONS FOR THE ACHD PATIENT

Due to the need for lifelong care, it is essential that pediatric cardiology programs partner with ACHD programs to provide successful transition of patients. However, gaps in care are common during transition, much of which may be due to disparities in social determinants of health, such as race, ethnicity, socioeconomic status, access to insurance, and residence in geographically remote locations. Additionally, adults with CHD may not recognize subtle changes in their exercise capacity, some of which are associated with worse survival; by the time symptoms are recognized, irreversible physiologic changes may have occurred. ACHD patients are, therefore, advised to undergo regular evaluations for surveillance of anatomic, hemodynamic, and electrophysiologic sequelae that may be present. In addition, specific situations may arise in which it is prudent to review care in consultation with an ACHD specialist, several of which are outlined below.

Noncardiac Surgery Nearly all adults with CHD can be classified with stage A (harboring risk) or greater degrees of heart failure. As such, adults with CHD may demonstrate limited hemodynamic reserve to altered myocardial perfusion or loading conditions and may have subclinical organ dysfunction that is not recognized by standard laboratory assessment. Comprehensive, multispecialty assessment and care strategy review are recommended in advance of invasive or

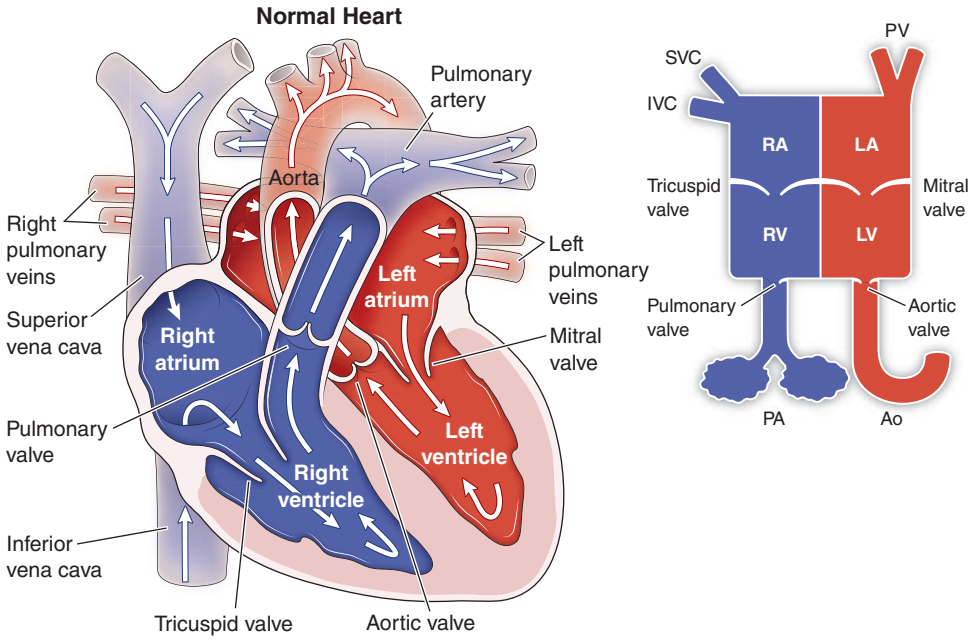

FIGURE 280-1 Normal heart. Understanding of congenital cardiac anatomy and physiology is facilitated by use of box diagrams, displaying passage of blood flow between blood vessels and cardiac chambers. Labeling (e.g., structure names, arrows to denote direction of flow, coloring to represent oxygen saturation, connections or obstructions, chamber or vascular pressures, oxygen saturations) can aid in representation. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

operative procedures for adults with CHD. Figure 280-2 illustrates the multiorgan considerations that should be considered in adults with CHD during perioperative resuscitation and convalescence. Anesthetic management requires knowledge of anatomy, physiologic consequence of underlying defects, myocardial and vascular performance, presence and nature of previous palliative procedures and residual shunts, alteration of venous or arterial pathways within the circulation, and status of noncardiovascular organ physiology.

Pregnancy Women with CHD should receive counseling regarding both maternal and fetal risks prior to conceiving a pregnancy and should be cared for in institutions with experience in treating CHD during pregnancy. Preconception evaluation includes detailed medical history, with particular attention to the women's functional capacity, which is closely linked to maternal and fetal outcomes. Table 280-1 lists the World Health Organization classification of risk during pregnancy in women with heart disease; women at risk should be strongly counseled about the significant risks of morbidity and mortality during pregnancy and the postpartum period. Normal physiologic hemodynamic changes of pregnancy are significant, occur over a relatively condensed period of time, and may be compounded in adults with CHD. Silversides and colleagues have developed a weighted-risk score for pregnant women with heart disease, based on a large registry known as CARPREG 2. The highest-weighted risk factors (weight of 3 points) include a prior history of cardiac events or arrhythmias, decreased functional status (New York Heart Association class ≥III), and presence of a mechanical heart valve. Risk factors that account for 2 points include ventricular dysfunction, high-risk left-sided valve disease/left ventricular outflow tract obstruction, pulmonary hypertension, coronary artery disease, and high-risk aortopathy. One point is assigned for late pregnancy assessment or no prior cardiac intervention. In this cohort, 16% of women experienced an adverse cardiac outcome, primarily heart failure and arrhythmia related. The predicted risks for cardiac events stratified according to point score were as follows: ≤1 point, 5%; 2 points, 10%; 3 points, 15%; 4 points, 22%; and >4 points, 41%.

Prepregnancy medications should be reviewed to ensure their safety in pregnancy. Alternatives to angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, direct oral anticoagulants, and endothelin receptor blockers should be considered, as these agents are teratogenic and contraindicated during pregnancy and should be discontinued. Women requiring anticoagulation must be advised of the challenges of managing anticoagulation during pregnancy, and individualized strategies should be developed. A fetal echocardiogram between 18 and 22 weeks of gestation is advised for patients with CHD. Additionally, both men and women with CHD should be counseled regarding the risk of CHD in their offspring.

CONGENITAL TERMINOLOGY, DEVELOPMENT, AND GENETICS

Congenital Nomenclature One of the challenges in caring for adults with CHD is the inconsistent terminology used to describe the congenital heart lesions. Several classification systems have been proposed, from the initial descriptions by Maude Abbott, Maurice Lev, and Jesse Edwards, to the extensive characterizations by Stella and Richard Van Praagh and Robert Anderson. In this chapter, we follow a segmental approach. The heart is composed of several segments that are

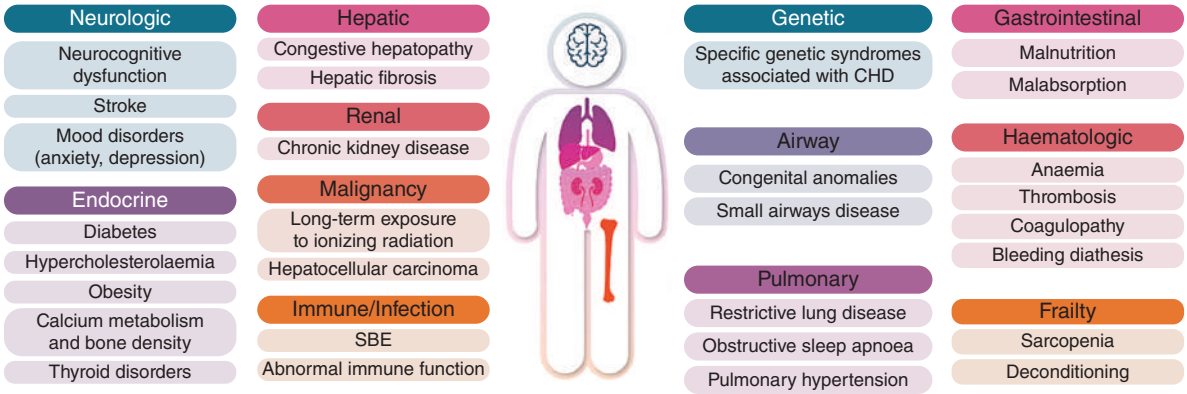

FIGURE 280-2 Noncardiac considerations in adults with congenital heart disease (CHD). SBE, subacute bacterial endocarditis. *(Modified from J Buber et al: Common congenital heart problems in acute and intensive care. Eur Heart J Acute Cardiovasc Care 12:267, 2023.)*

TABLE 280-1 Modified World Health Organization (mWHO) Classification of Heart Disease in Pregnancy

	mWHO I	mWHO II	mWHO II–III	mWHO III	mWHO IV
Diagnosis (if otherwise well and uncomplicated)	Small or mild Pulmonary stenosis Patent ductus arteriosus Mitral valve prolapse Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage) Atrial or ventricular ectopic beats, isolated	Unoperated atrial or ventricular septal defect Repaired tetralogy of Fallot Most arrythmias (supraventricular arrhythmias) Turner syndrome without aortic dilatation	Mild left ventricular impairment (EF >45%) Hypertrophic cardiomyopathy Native or tissue valve disease not considered WHO I or IV (mild mitral stenosis, moderate aortic stenosis) Marfan or other HTAD syndrome without aortic dilatation Aorta <45 mm in bicuspid aortic valve pathology Repaired coarctation Atrioventricular septal defect	Moderate left ventricular impairment (EF 30–45%) Previous peripartum cardiomyopathy without any residual left ventricular impairment Mechanical valve Systemic right ventricle with good or mildly decreased ventricular function Fontan circulation Fontan circulation with good clinical course and without associated comorbidities Unrepaired cyanotic heart disease Other complex heart disease Moderate mitral stenosis Severe asymptomatic aortic stenosis Moderate aortic dilatation (40–45 mm in Marfan syndrome or other HTAD; 45–50 mm in bicuspid aortic valve, Turner syndrome ASI 20–25 mm/m^2, tetralogy of Fallot <50 mm) Ventricular tachycardia	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (EF <30% or NYHA class III–IV) Previous peripartum cardiomyopathy with any residual left ventricular impairment Severe mitral stenosis Severe symptomatic aortic stenosis Systemic right ventricle with moderate or severely decreased ventricular function Severe aortic dilatation (>45 mm in Marfan syndrome or other HTAD, >50 mm in bicuspid aortic valve, Turner syndrome ASI >25 mm/m^2, tetralogy of Fallot >50 mm) Vascular Ehlers-Danlos Severe (re)coarctation Fontan with any complication
Risk	No detectable increased risk of maternal mortality and no/mild increased risk in morbidity	Small increased risk of maternal mortality or moderate increase in morbidity	Intermediate increased risk of maternal mortality or moderate to severe increase in morbidity	Significantly increased risk of maternal mortality or severe morbidity	Extremely high risk of maternal mortality or severe morbidity

Abbreviations: ASI, aortic size index; EF, ejection fraction; HTAD, heritable thoracic aortic disease.

analyzed separately before formulating a comprehensive diagnosis. The principal segments are the atria, the ventricles, and the great arteries, which are joined together by the atrioventricular canal and the conus (infundibulum). In the normal heart, the right ventricle (RV) is right-sided and organized inflow-to-outflow from right to left, while the left ventricle (LV) is left-sided and organized inflow-to-outflow from left to right. It is important to determine the segmental alignments, that is, what drains into what. For example, in the normal heart, the right atrium (RA) is aligned with the RV and the LV with the aorta. Finally, the segmental connections, the way in which adjacent segments are physically linked to each other, are described. For example, in the normal heart, the pulmonary artery (PA) is connected to the RV by a complete muscular conus (infundibulum), while the aorta is connected to the LV by aortic-mitral fibrous continuity (without a complete conus). Alignment and connection are different concepts, and both are important, especially in complex defects.

Cardiac Development The heart starts to form in the third week of gestation and is nearly fully formed by 8 weeks' gestation. Mesodermal precardiac cells migrate to form the cardiac crescents (primary heart fields) in anterior lateral plate mesoderm, which are then brought together to form a primary linear heart tube by ventral closure of the embryo. Cells of the second heart field continue to proliferate outside the heart and are added to the heart tube over the course of embryogenesis, contributing to the atria, the RV, and outflow tract. Additionally, cardiac neural crest cells migrate into the developing heart in the 5th–6th weeks and are essential for septation of the outflow, formation of the semilunar valves, and patterning of the aortic arches. Once formed, the heart tube grows and elongates by addition of cells from the second heart field. The ends of the heart tube are relatively fixed by the pericardial sac so that as it elongates it must loop (bend), and in the vast majority of hearts, the loop falls to the right (D-loop). Further elongation pushes the mid-portion of the tube (future ventricles) inferior or caudal to the inflow, resulting in the normal relationship between the atria and ventricles. Further growth pushes the outflow medially and is associated with outflow rotation, both processes essential for normal alignment of the outflow. Finally, the proximal part of the outflow is incorporated in the RV, shortening the outflow in association with further rotation. While this remodeling is occurring, the outflow is undergoing septation under the influence of cardiac neural crest cells. Septation proceeds from distal to proximal, culminating in formation and muscularization of the infundibular, or muscular, outflow septum, which inserts onto the superior endocardial cushion at the rightward rim of the outflow foramen, walling the aorta into the LV via the outflow foramen and the PA directly into the RV.

Genetic Considerations CHD is the most commonly occurring birth defect; etiologic contributors are increasingly recognized, although often speculated to be multifactorial. Children born with trisomy 21 have a 50% chance of having CHD, most commonly defects in the atrioventricular canal. Conotruncal defects are associated with several chromosomal abnormalities, most notably a deletion at chromosome 22q11 (DiGeorge syndrome). Echocardiographic clues to this association in patients with a conotruncal defect include an associated right aortic arch or aberrant subclavian artery. Many adults currently living with conotruncal defects may not have undergone testing for DiGeorge syndrome. This condition is important to recognize because a variety of psychiatric disorders and disabilities in cognitive function may be present and go untreated. Patients with Noonan syndrome commonly have a dysplastic pulmonary valve and have facial and lymphatic abnormalities. Several defects in specific genes have been associated with Noonan syndrome, most notably *PTPN11*. Adults with Williams syndrome (7q11.23 deletion) commonly have supravalvar aortic stenosis and diffuse arteriopathy, with a "cocktail-like" personality and hypercalcemia. There is a growing importance of genome-wide analyses in subjects with CHD.

TABLE 280-2 Congenital Etiologies of Right Heart Dilation

Congenital tricuspid valve disease
Tricuspid valve dysplasia with regurgitation
Ebstein anomaly
Congenital pulmonary valve regurgitation
Pulmonary arterial hypertension
Myocardial abnormalities
Arrhythmogenic RV cardiomyopathy
Uhl's anomaly
Shunt lesions
Partial anomalous pulmonary venous return
Primum ASD
Secundum ASD
Sinus venosus defect
Coronary sinus septal defect
Gerbode defect (LV-RA shunt)
Coronary artery fistula to the RA, CS
Postoperative residual shunts

Abbreviations: ASD, atrial septal defect; CS, coronary sinum; LV, left ventricle; RA, right atrium; RV, right ventricle.

SPECIFIC CHD LESIONS

Dilated Right Heart There are many congenital etiologies for right heart dilation (Table 280-2). These include congenital valvular anomalies (such as Ebstein anomaly or pulmonary regurgitation), intrinsic RV myocardial anomalies (arrhythmogenic RV dysplasia, Uhl's anomaly), or shunt lesions occurring proximal to the tricuspid valve (atrial septal defects or partial anomalous pulmonary veins). Cardiac imaging is critical in determining the etiology of right heart dilation, and knowledge of the anatomy and physiology of various shunt lesions is essential.

Atrial Septal Defect One of the most common etiologies of right heart dilation is presence of an atrial septal defect (ASD; Fig. 280-3*A*). Intracardiac communications allow blood transmission between chambers or spaces based on relative resistance, propulsion, and flow patterns. Patients with large ASDs often present in childhood; however, many ASDs are not discovered until adult life. The physiology of an ASD is predominantly that of a "left-to-right" shunt (flow of pulmonary venous, or oxygenated, blood toward systemic venous, or deoxygenated, chambers or vessels). The degree of left-to-right shunting determines the amount of right heart volume loading and is dictated by the size of the defect as well as the diastolic properties of the heart. As patients age, several factors, such as diabetes mellitus, systemic hypertension, and atherosclerosis, may contribute to decreased compliance of the left-sided cardiac chambers and contribute to increased left-to-right shunting and symptomatology. The classic physical examination finding is a wide, fixed splitting of the second heart sound, which is due to prolonged RV ejection and increased PA capacitance, which, in turn, delay pulmonary valve closure. The surface electrocardiogram (ECG) commonly displays an incomplete right bundle branch block. Symptoms, when they occur, most commonly include exercise intolerance, arrhythmia, and dyspnea with exertion. It is not uncommon for adults to have incidentally noted asymptomatic ASD during evaluation of other comorbid issues. Right heart dilation, without additional etiology for such, in the setting of unrepaired ASD is considered a risk for progression toward symptomatic right heart failure, atrial arrhythmias, and potential development of pulmonary arterial hypertension (if such is not already present). Therefore, a patient with an ASD and right heart dilation, particularly with symptoms attributable to such, should be offered ASD closure. Pulmonary vascular disease leading to pulmonary hypertension develops in up to 10% of patients with unrepaired ASD, and Eisenmenger syndrome (ES) is a rare complication (see below). Management of patients with concomitant ASD and pulmonary hypertension should be coordinated with both ACHD and pulmonary hypertension experts.

Figure 280-3*B* illustrates the locations of various ASDs. The most common type of an ASD is a secundum ASD, which is a defect, or true deficiency in the atrial septum, in the region of the fossa ovalis. This should be differentiated from a patent foramen ovale (PFO), which is persistence of patency of the flap valve of the fossa ovalis (not associated with right-sided cardiac dilation) and persists in up to 25% of adults. Secundum ASDs can often be closed with occluder devices placed percutaneously. However, certain anatomic determinants make percutaneous closure less favorable, including large defects, inadequate tissue rims surrounding the defect, and concomitance of anomalous draining pulmonary veins. A primum ASD is a deficiency of the atrioventricular (AV) canal portion of the atrial septum; primum ASD is always associated with abnormal development of the AV valves,

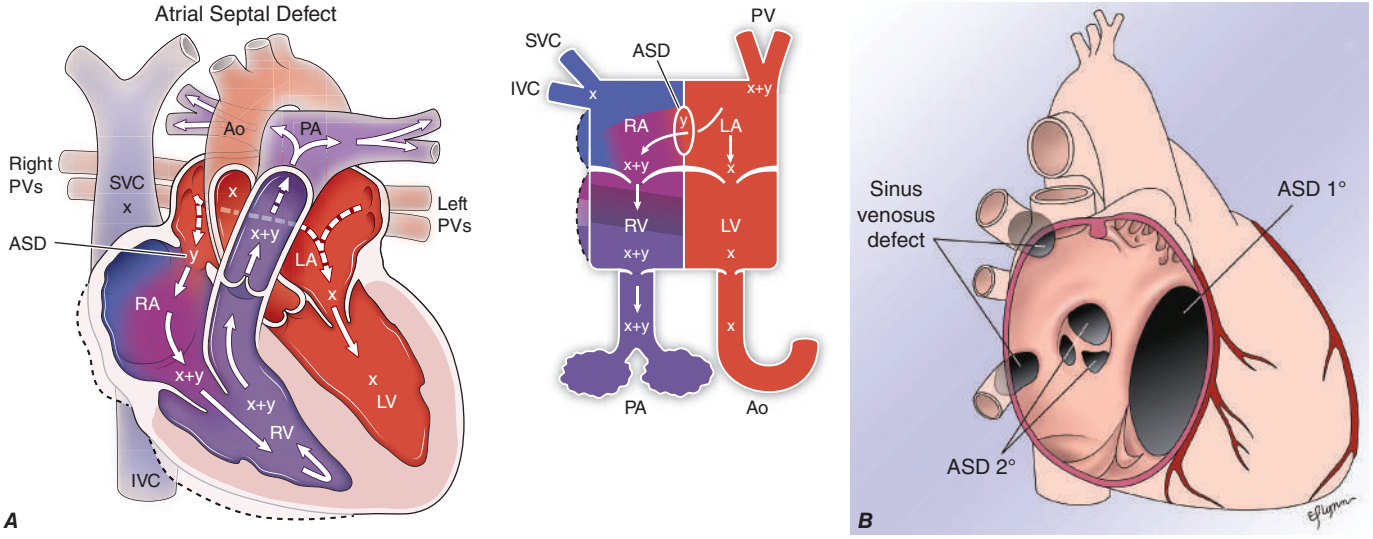

FIGURE 280-3 ***A.*** Atrial septal defect. In the presence of an atrial septal defect, the difference in compliance between the (RA + RV) as compared to the (LA + LV), combined with the size of the defect itself, allows for a "shunt" of flow ("y") of "red" (oxygenated) blood from the left side of the heart to the right side (deoxygenated). Systemic venous return of pure deoxygenated blood ("x") is increased by the oxygenated shunted blood ("y") to increase volume of blood ("x + y") in the RA, RV, and total blood flow to the lungs. If the volume or the sequelae of the shunted blood are sufficient, RA and RV can dilate (*hashed lines*), and arrhythmias or shortness of breath (and occasionally pulmonary hypertension) can ensue. Ao, aorta; ASD, atrial septal defect; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava. ***B.*** Diagrammatic representation of the location of various atrial septal defects. ASD 1, primum atrial septal defect; ASD 2, secundum atrial septal defect. *(Part B used with permission from Emily Flynn McIntosh, illustrator.)*

most commonly resulting in a cleft in the mitral valve. A coronary sinus defect is rare and involves an opening between the coronary sinus and the left atrium. A sinus venosus defect is not a defect in the atrial septum but, rather, a defect between either the right superior vena caval–atrial junction and the right upper pulmonary vein(s) or, less commonly, the inferior vena caval–atrial junction and the right lower pulmonary veins. Surgical closure is required for primum ASDs, sinus venosus defects, and coronary sinus septal defects.

Partial Anomalous Pulmonary Venous Return Partial anomalous pulmonary venous return (PAPVR) is occasionally discovered in adults with right heart dilation or incidentally on cross-sectional imaging **(Fig. 280-4)**. There are several possible anomalous connections, with the most common being a left upper pulmonary vein to an ascending vertical vein into the innominate vein or the right upper pulmonary vein draining to the superior vena cava. In the latter case, careful attention should be paid to ensure that there is not an associated sinus venosus defect. Concomitant pulmonary hypertension can occur but is uncommon. Symptomatology may be absent, and a decision to repair isolated PAPVR should include variance in anatomy, lung ventilation and perfusion, hemodynamic response to shunt, symptoms, and surgical experience.

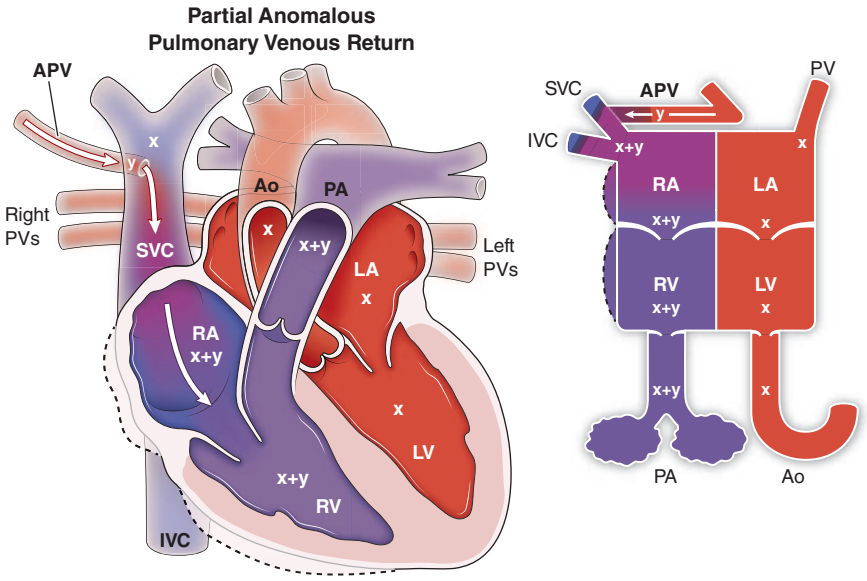

FIGURE 280-4 Partial anomalous pulmonary venous return. In the presence of an anomalously draining pulmonary vein (typically to a systemic vein such as the left innominate vein, SVC, or rarely IVC), an obligate "shunt" of flow ("y") of "red" (oxygenated) blood from the affected pulmonary vein to the right heart (deoxygenated) ensues. Systemic venous return of pure deoxygenated blood ("x") is increased by the oxygenated shunted blood ("y") to increase volume of blood ("x + y") in the SVC, RA, RV, and total blood flow to the lungs. If the volume or the sequelae of the shunted blood are sufficient, RA and RV can dilate (*hashed lines*), or shortness of breath can ensue. Ao, aorta; APV, anomalous pulmonary vein; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Ebstein Anomaly Ebstein anomaly **(Fig. 280-5)** is the result of embryologic failure of delamination, or "peeling away," of the tricuspid valve leaflets from the ventricular myocardium, resulting in adherence of the valve leaflets to the underlying myocardium. This results in a wide variety of abnormalities, including apical and posterior displacement of the dilated tricuspid valve annulus, dilation of the "atrialized" portion of the RV, and fenestrations, redundancy, and tethering typically of the anterior leaflet of the tricuspid valve. The malformed tricuspid valve is usually regurgitant but may occasionally be stenotic. The clinical presentation of Ebstein anomaly in the adult depends on several factors, including the extent of tricuspid valve leaflet distortion, degree of tricuspid regurgitation (TR), right atrial pressure, and presence of an atrial level shunt. The physical examination of a patient with Ebstein anomaly may vary depending on the severity of disease. In more severe cases, the first heart sound may be split and the second component of the first heart sound may have a distinctive snapping quality (known as the sail sign, due to the redundancy of the anterior tricuspid valve leaflet). Patients with significant TR may have prominent "v" waves of the jugular venous pulsations; however, this finding is often absent due to abnormal right atrial compliance. The ECG is often abnormal, with right atrial and ventricular enlargement. Up to 20% of patients have evidence of ventricular preexcitation (Wolff-Parkinson-White pattern). Surgical treatment includes a tricuspid valve repair or replacement, closure of any atrial level defects, and arrhythmia ablative procedures.

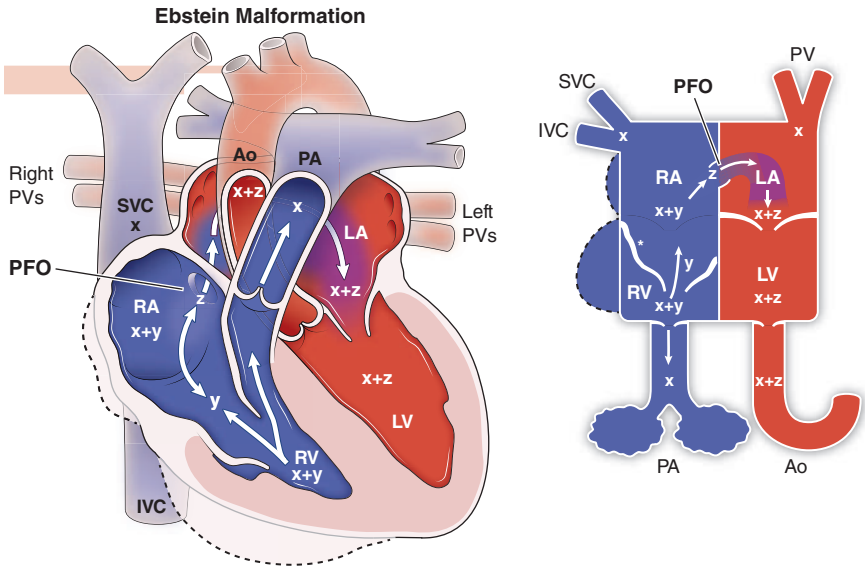

FIGURE 280-5 Ebstein malformation. In the presence of Ebstein anomaly, the tricuspid valve leaflets can be redundant, fenestrated, and sail-like (typically seen in the anterior leaflet*) or adherent to the underlying myocardium with apical displacement of the nonadherent components (typically the septal and posterior leaflets). Location and degree of leaflet coaptation are variable and account for varying degrees of tricuspid regurgitation, shift of the functional tricuspid valve anterior from the anatomic annulus into the right ventricle, "atrialization" of the right ventricle, and most commonly angulation of the tricuspid valve into the RV outflow tract. RA and RV dilation (*hashed lines*) can occur due to the effects of combined volume from systemic venous return ("x") and tricuspid regurgitant flow ("y"). PFO is frequent; worsening compliance and elevation of pressure in the RA as compared to the LA can lead to increasing "right-to-left" (deoxygenated to oxygenated) shunt and cyanosis. RV myocardial function may be abnormal. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PFO, patent foramen ovale; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava; *, anterior tricuspid valve leaflet.

Shunt Lesions Causing Left Heart Dilation Intracardiac shunts or intravascular passages that occur below the level of the tricuspid valve result in left heart dilation. The two major types of congenital shunts that result in left heart dilation are a ventricular septal defect (VSD; **Fig. 280-6A**) and patent ductus arteriosus (PDA; **Fig. 280-7**).

Ventricular Septal Defects VSDs are the most common congenital anomaly recognized at

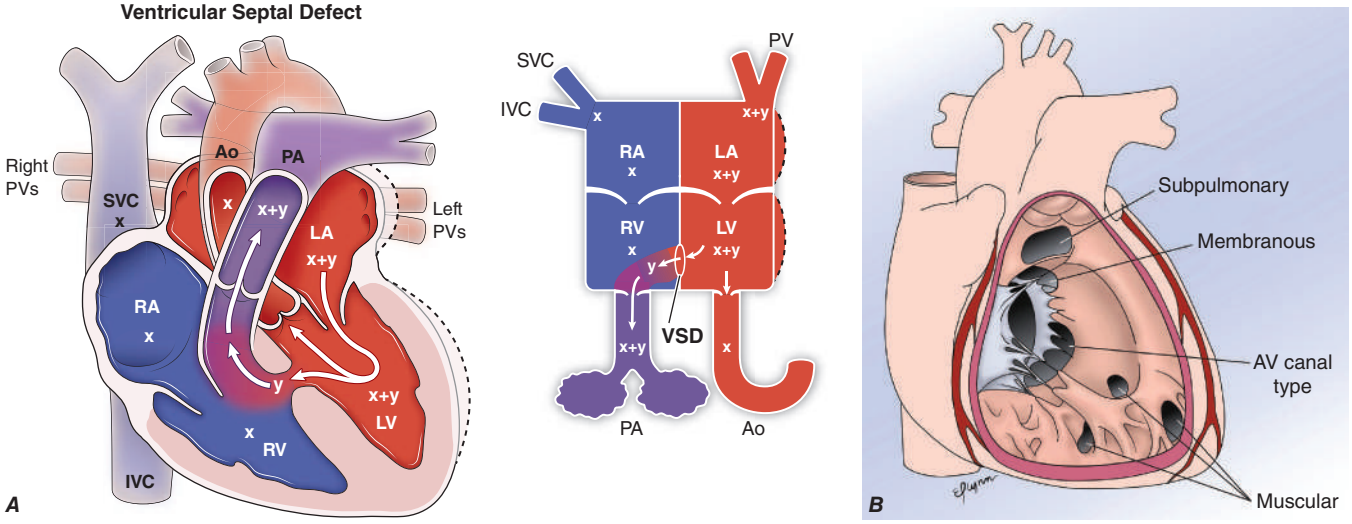

FIGURE 280-6 ***A.*** Ventricular septal defect. In the presence of a ventricular septal defect, the difference in pressure and outflow resistance in systole (and the difference in compliance in diastole) between the RV and LV, combined with the size of the defect itself, allow for a "shunt" of flow ("y") of "red" (oxygenated) blood from the left side of the heart to the right side (deoxygenated). Systemic venous return of pure deoxygenated blood ("x") is increased by the oxygenated shunted blood ("y") to increase volume of blood ("x + y") through the outflow of the RV into the lungs, and in the left atrium and left ventricle. If the volume or the sequelae of the shunted blood are sufficient, LA and LV can dilate (*hashed lines*), and arrhythmias or shortness of breath (and occasionally pulmonary hypertension) can ensue. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava; VSD, ventricular septal defect. ***B.*** Diagrammatic representation of the location of various ventricular septal defects. AV, atrioventricular. *(Part B used with permission from Emily Flynn McIntosh, illustrator.)*

birth; however, they account for only ~10% of CHD in the adult, due to the high rate of spontaneous closure of small VSDs during the early years of life. Large VSDs usually cause symptoms of heart failure and poor somatic growth and are most often surgically closed before adulthood. Several classification systems for VSDs exist. **Figure 280-6*B*** illustrates various locations of VSDs; the most common location is in the membranous septum (also referred to as perimembranous or outlet defects). Muscular defects that persist into adult life are often pressure and flow restricted, resulting in no significant hemodynamic consequence. AV canal defects, also referred to as inlet defects, are located in the crux of the heart and are associated with abnormalities of the AV valve leaflets. Subpulmonary defects, also known as *conal septal defects*, are commonly associated with prolapse of the right coronary cusp and aortic insufficiency. The outcome for adults with small VSDs without evidence of ventricular dilation or pulmonary hypertension is generally excellent.

Patent Ductus Arteriosus A PDA courses between the aortic isthmus and the origin of one of the branch PAs. Small PDAs are often silent to auscultation and do not cause hemodynamic changes. The classic murmur is heard best just below the left clavicle and typically extends from systole past the second heart sound into diastole, reflecting flow turbulence and gradient between the aorta and the PAs (resulting in left-to-right shunting). Large PDAs will lead to left heart dilation and may lead to chronically elevated pulmonary vascular resistance, including the potential for ES.

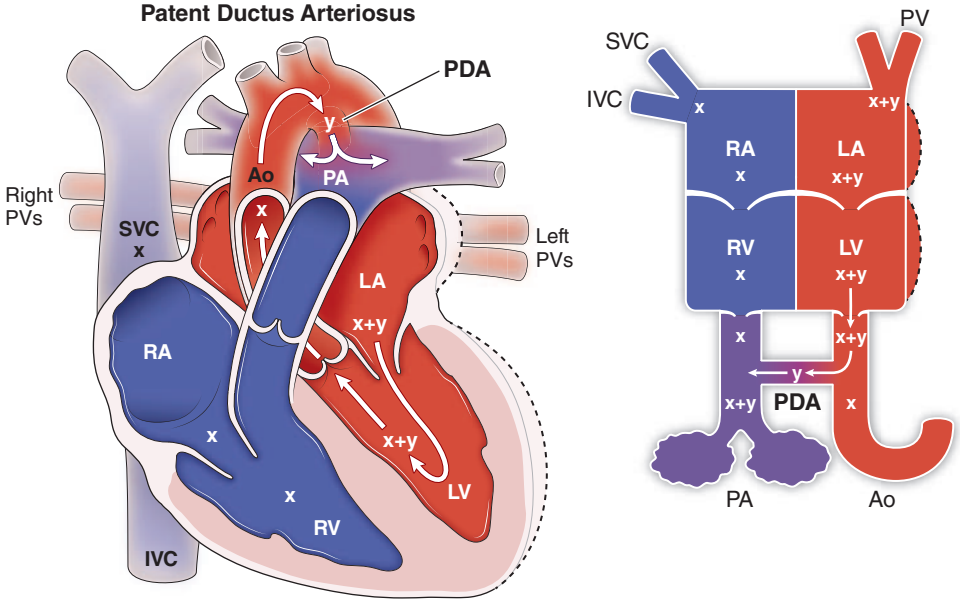

FIGURE 280-7 Patent ductus arteriosus. In the presence of a patent ductus arteriosus, the difference in pressure and resistance in both systole and diastole between the pulmonary arteries and the aorta, combined with the size of the ductus itself, allow for a "shunt" of flow ("y") of "red" (oxygenated) blood from the aorta to the pulmonary arteries (deoxygenated). Systemic venous return of pure deoxygenated blood ("x") is increased by the oxygenated shunted blood ("y") to increase volume of blood ("x + y") in the lungs, the left atrium, the left ventricle, and out the aortic valve. If the volume or the sequelae of the shunted blood are sufficient, LA and LV can dilate (*hashed lines*), and arrhythmias or shortness of breath (and occasionally pulmonary hypertension) can ensue. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PDA, patent ductus arteriosus; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

MODERATE AND COMPLEX CHD

Tetralogy of Fallot Tetralogy of Fallot (TOF) is the most common form of cyanotic CHD, occurring in 0.5 per 1000 live births. It involves anterior deviation of the conal septum, resulting in RV outflow tract (RVOT) obstruction, a VSD, RV hypertrophy, and an overriding aorta (Fig. 280-8*A, B*). There is a large spectrum of severity of disease in TOF, from patients who have only mild pulmonary stenosis to those with complete pulmonary atresia (TOF/PA). Current surgical strategies involve primary repair in infancy (Fig. 280-8*C*); however, many adults may have first undergone palliative procedures (Blalock-Taussig, Potts, Waterston shunts) prior to a complete repair. The goal of surgical repair is to alleviate the pulmonary stenosis and close the VSD. Up to 10% of patients with TOF have an anomalous coronary artery, most commonly, an anomalous left anterior descending coronary artery from the right coronary cusp. Patients with an anomalous coronary as well as those with TOF/PA may require an RV-to-PA conduit.

Adults with repaired TOF often have hemodynamic sequelae that may require reintervention in adulthood (Table 280-3). Pulmonary

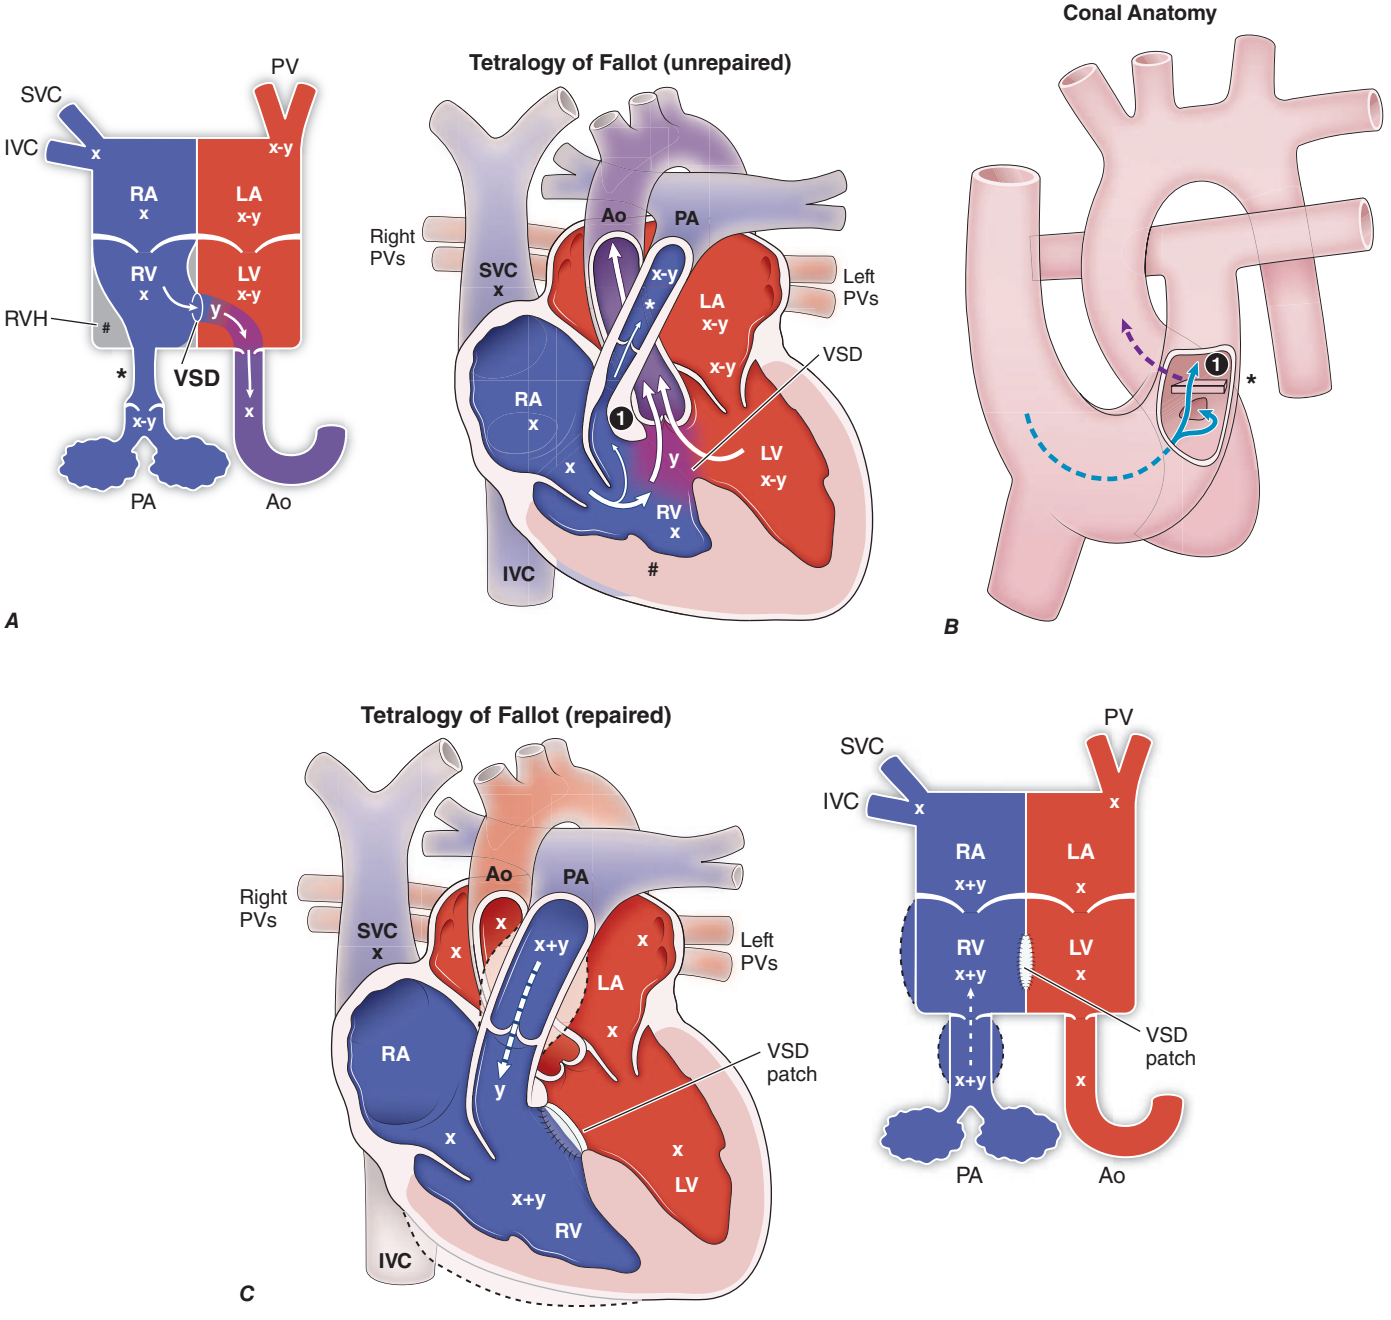

FIGURE 280-8 ***A.*** Tetralogy of Fallot involves anterior and superior malalignment of a bar of tissue (conal septum) (see *in part ***B***, which presents a cut-away view through the anterior surface of the RV, into the RV outflow), partially obstructing the right ventricular outflow (under the pulmonary valve, i.e., "subpulmonary stenosis"; labeled as 1), and leaving a gap in the interventricular septum (VSD). The pulmonary valve annulus is typically hypoplastic. Outflow obstruction prevents regression of right ventricular hypertrophy (#), which was present in utero. The difference in pressure and outflow resistance in systole (and the difference in compliance in diastole) between the obstructed RV and the LV allows for a "shunt" of flow ("y") of "blue" (deoxygenated) blood from the right side of the heart to the left side (oxygenated). Systemic venous return of pure deoxygenated blood ("x") is decreased by the shunted blood ("y"), leading to a total decrease in the volume of blood ("x – y") passing beyond into the lungs. The deoxygenated shunted blood ("y") mixes with fully oxygenated blood in the LV, contributing to systemic arterial cyanosis. ***C.*** Tetralogy of Fallot—repaired. After modern repair of tetralogy of Fallot, VSD has been patched closed, and outflow tract obstruction has been surgically removed, frequently at the expense of a patch enlarging the pulmonary valve annulus at the expense of sacrificing the integrity of the pulmonary valve (causing pulmonary regurgitation). The pulmonary regurgitant volume ("y") is added to systemic venous return ("x"), contributing to RV chamber enlargement (*hashed lines*) and may be associated with tricuspid annular dilation and valve regurgitation, resulting in RA enlargement. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; RVH, right ventricular hypertrophy; SVC, superior vena cava; VSD, ventricular septal defect.

TABLE 280-3 Potential Sequelae of Repaired Tetralogy of Fallot

Right ventricular dilation
Right ventricular dysfunction
Right ventricular outflow tract obstruction
Pulmonary regurgitation
Branch pulmonary artery stenosis
Tricuspid regurgitation
Residual ventricular septal defect
Left ventricular dysfunction
Aortic root dilation
Atrial arrhythmias
Ventricular arrhythmias
Sudden cardiac death

regurgitation is common following TOF repair and is usually associated with RV dilation. Accurate quantification of RV size, function, and mass is particularly important in adults after repair of TOF, as RV dilation, dysfunction, and hypertrophy are associated with adverse outcomes in these patients. Patients may also have residual RVOT obstruction, which may occur beneath the pulmonary valve, at the valve level, above the valve, or in the branch PAs. Cardiac magnetic resonance imaging is routinely used in the surveillance of these patients. Left ventricular dysfunction is present in at least 20% of adults with repaired TOF, particularly those who were repaired later in life, had prior palliative shunts, or have concomitant RV dysfunction.

As patients age with repaired TOF, both atrial and ventricular arrhythmias occur with increasing frequency. A QRS duration on a resting ECG of 180 ms or more has been associated with increased risk of ventricular tachycardia and sudden death in this patient population. In one prospective follow-up study of 144 adults with repaired TOF, there was a 72% survival at 40 years, but only a 25% cumulative event-free survival. These events include need for reintervention (most commonly pulmonary valve replacement [PVR]), symptomatic arrhythmias, and heart failure.

The most common reintervention in a repaired TOF patient is a PVR. However, optimal timing of PVR in asymptomatic patients with repaired TOF remains unclear. Traditionally, PVR has been accomplished with a surgical procedure; however, percutaneous implantation of pulmonary valves is becoming increasingly utilized in clinical practice.

Patients with repaired TOF may also undergo interventions including closure of residual VSDs, dilation and/or stenting of the RVOT or branch PAs, and tricuspid valve repair. Patients with clinically significant arrhythmias may benefit from catheter ablation.

Transposition of the Great Arteries Transposition of the great arteries (TGA) is defined by the great arteries arising from the opposite side of the ventricular septum than normal; as such, the aorta arises from the RV and the PA from the LV. The more common form of TGA, known as *D-loop TGA*, involves AV concordance and ventricular-arterial discordance, resulting in a physiology that allows two circuits to be in parallel rather than in series **(Fig. 280-9*A*)** and intense cyanosis shortly after birth. This physiology is not compatible with long-term survival without surgical intervention. Patients with TGA may be born with additional congenital defects (most commonly a VSD).

The surgical repairs for D-loop TGA have evolved over time. In the late 1950s through the 1970s, the atrial switch procedure (Mustard, Senning procedures) was performed **(Fig. 280-9*B*)**. These atrial switch

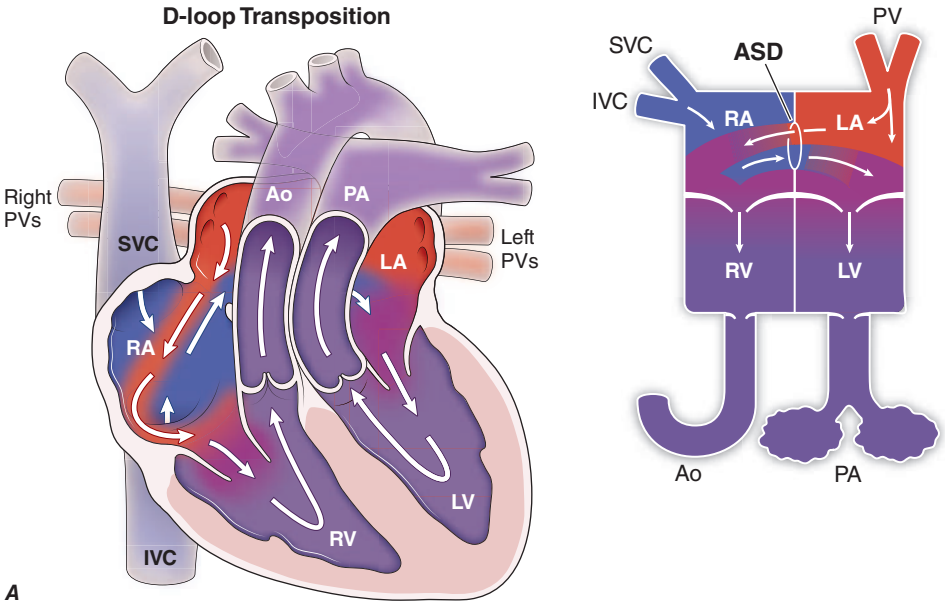

FIGURE 280-9 ***A.*** Transposition of the great arteries. When the great arteries are transposed, the aorta arises from the RV, and the pulmonary artery arises from the LV, leaving deoxygenated blood circulating from systemic veins to systemic arteries in separated fashion from oxygenated blood, which circulates from pulmonary veins to pulmonary arteries. Without interchamber or intravascular communications, this circulation is incompatible with life. Presence of an atrial septal defect (ASD), depicted here, ventricular septal defect (VSD), or patent ductus arteriosus (PDA) allows for some interchamber or intravascular mixing and, at best, partial relief of cyanosis and sustenance of life, at the expense of increased pulmonary blood flow. ***B.*** Atrial switch. Atrial level switch procedures (Mustard and Senning) were the first standardized surgeries to alter the natural course of complex congenital heart disease, utilizing intracardiac rerouting via a "baffle" to redirect blood flow. The atrial switch simulates inverted trousers, with each "pants leg" (*) attaching to either the SVC or the IVC, transporting deoxygenated blood through the interior of the trousers to the "waist of the trousers" and directing blood through the mitral valve to the LV and out the PA. Surgical removal of the atrial septum allows pulmonary venous return to traverse from posterior left atrium through the space between the pants legs of the baffle, through the tricuspid valve to the RV (serving as the "systemic ventricle," i.e., that pumps to the systemic arterial circulation), through the aorta. Non-infrequent sequelae include sinus node dysfunction, atrial arrhythmias, systolic dysfunction of the RV, tricuspid regurgitation (from RV to LA), leaks in the baffle material allowing shunting of blood, and obstruction of the systemic or pulmonary venous baffles. ***C.*** Arterial switch. The arterial switch operation allowed both anatomic and physiologic correction for D-loop transposition of the great arteries. Successful surgical switching of the PA and the Ao above the level of the native roots (*hashed lines*) necessitated ability to transfer coronary artery origins contained within a button of tissue (*) back to the neo-aorta (now supported by the LV). Deoxygenated blood flow from SVC and IVC passes from RA to RV to PA, and oxygenated blood passes from PV to LA to LV to Ao. Uncommon sequelae include obstruction at any of the surgical sites (supravalvar PA or Ao stenosis, coronary orifice obstruction) or more distal obstructions due to tension placed on the PA, Ao, or coronary arteries. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

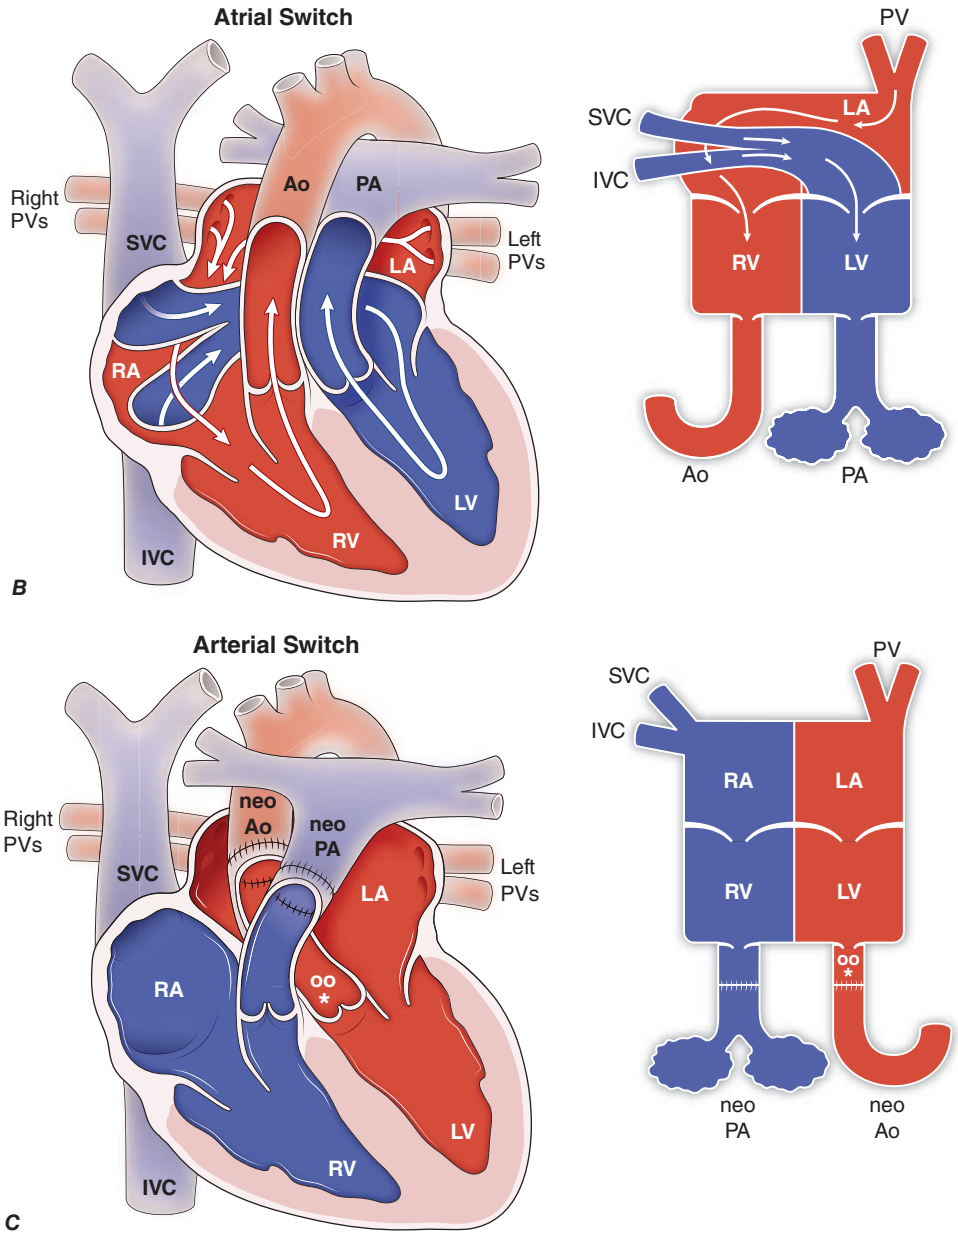

FIGURE 280-9 (Continued)

procedures relieved the cyanosis but left the patient with a systemic RV. Despite moderate-term survival over decades, there are multiple long-term sequelae that may present following the atrial switch procedure. The most worrisome complication is that of systemic RV dysfunction. The prevalence of RV dysfunction in this population is not well defined. Limited study has failed to reveal medical therapies effective for systemic RV dysfunction.

A subset of patients with D-loop TGA, VSD, and PS may have undergone a Rastelli procedure. This intervention involves placing an RV-to-PA conduit and routing the LV to the aorta through the VSD, which results in relief of cyanosis and the benefit of a systemic LV.

In the 1980s, the arterial switch operation (ASO; **Fig. 280-9*C***) became the surgical procedure of choice for D-loop TGA. This procedure involves transecting the great arteries above the sinuses and placing the PAs anteriorly to come into alignment with the RV, resulting in draping of the branch PAs over the ascending aorta. A coronary artery translocation is performed. The ASO has resulted in substantial long-term survival.

The potential long-term sequelae of the various surgical procedures for D-loop TGA are listed in **Table 280-4**.

The less common form of TGA, known as *L-loop TGA* (physiologically corrected or "congenitally corrected" TGA; **Fig. 280-10**), may not require surgical intervention but is presented here in relation to other forms of TGA. L-loop TGA involves both AV discordance (RA allowing passage of deoxygenated systemic venous return to the LV, and

TABLE 280-4 Long-Term Sequelae of D-Loop TGA Surgery

ATRIAL SWITCH	ARTERIAL SWITCH	RASTELLI PROCEDURE
Systemic venous baffle	Arterial anastomosis stenosis	Subaortic stenosis
Pulmonary venous baffle	Branch PA stenosis	RV-PA conduit obstruction
RV (systemic) dysfunction	Neo-aortic root dilation	Pulmonary regurgitation
Tricuspid regurgitation	Neo-aortic regurgitation	Ventricular dysfunction
Baffle leaks	Coronary artery stenosis	
LVOT obstruction (PS)	LV dysfunction	

Abbreviations: LV, left ventricle; LVOT, left ventricular outflow tract; PA, pulmonary artery; PS, pulmonary stenosis; RV, right ventricle; TGA, transposition of the great arteries.

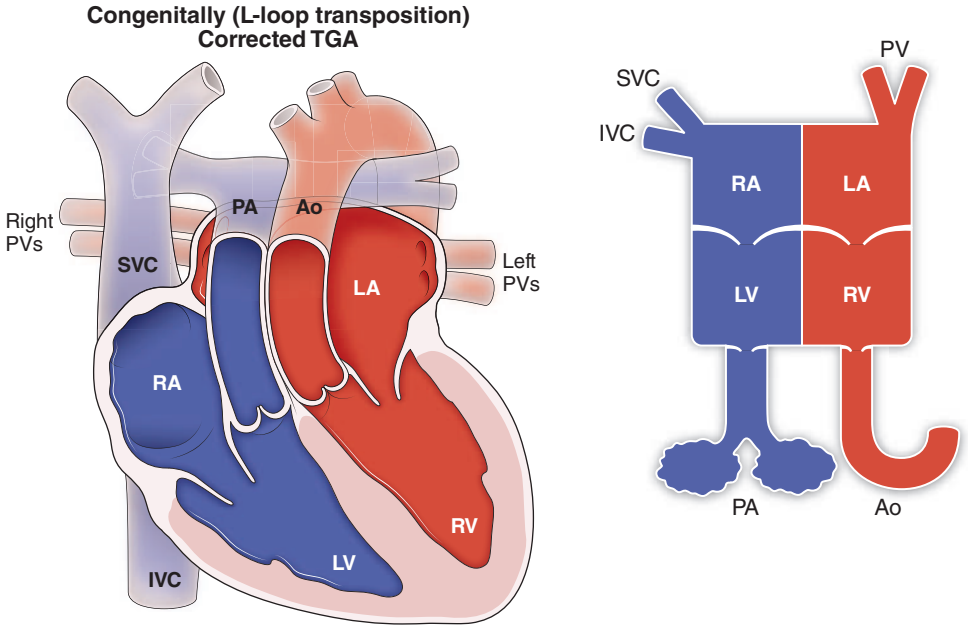

FIGURE 280-10 Congenitally corrected transposition of the great arteries. Physiologically corrected transposition of the great arteries (also known as *congenitally corrected transposition of the great arteries*) is characterized by atrioventricular discordance and ventriculoarterial discordance. Systemic venous blood passes from the right atrium (RA) through the mitral valve into the morphologic left ventricle (LV) to the pulmonary artery (PA). Oxygenated blood then returns to the lungs to the left atrium (LA) through the tricuspid valve into the morphologic right ventricle (RV) and then out the aorta (Ao). IVC, inferior vena cava; PV, pulmonary veins; SVC, superior vena cava.

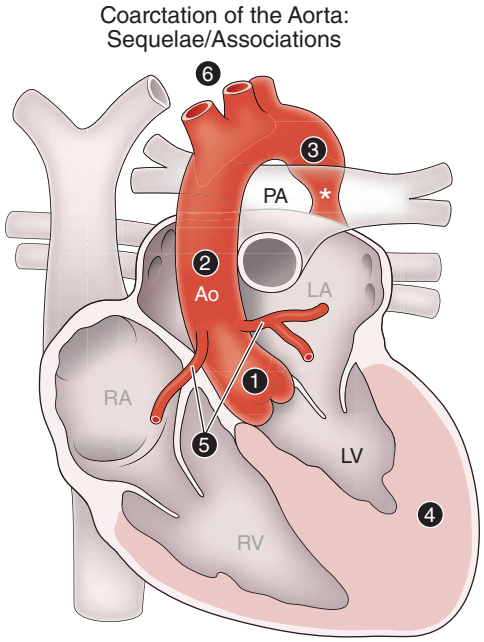
conversely, the left atrium conducting oxygenated pulmonary venous blood to the RV) as well as ventriculoarterial discordance (connections of LV to PA, RV to aorta). This results in normal arterial oxygen saturation, yet an RV associated with the aorta. Patients with L-loop TGA commonly have associated congenital anomalies, including dextrocardia, ASDs, a dysplastic tricuspid valve, and pulmonary stenosis. Conduction disturbances are common, and complete heart block occurs in up to 30% of patients. Those patients without associated defects may not present until later in life, most commonly with heart failure, TR, or newly recognized conduction disease.

Coarctation of the Aorta Adults with coarctation of the aorta **(Fig. 280-11)** typically have a shelf-like obstruction at the level of the descending aorta that passes just posterior to the junction of the main and left PA; obstruction less commonly involves the transverse aortic arch. On physical examination, the lower extremity blood pressure and pulses are lower than (and delayed in timing, in contrast to) the upper extremity values, unless significant aortic collaterals have developed. A continuous murmur over the scapula may be present due to the collateral blood flow. Significant coarctation increases afterload to all proximal structures in the path of oxygenated blood, from LV and coronary arteries to ascending and transverse aorta, to cerebral and arm vessels and proximal descending aorta. Bicuspid aortic valve (typically with right-left commissural fusion) is a common association. In women with short stature, webbed neck, lymphedema, and primary amenorrhea, a concomitant diagnosis of Turner syndrome should be considered, the presence of which indicates greater degree of, and risks from, sequelae from seemingly similar anatomy and physiology. Patients who have undergone surgical repair in general have a good prognosis; however, they remain at risk for systemic hypertension, premature atherosclerosis, LV failure, and aortic aneurysm, dissection, and recurrent coarctation.

Single Ventricle The term *single ventricle heart disease* is imprecise but useful in some settings, as it refers to congenital heart conditions in which one ventricle or its valves preclude surgical creation of a biventricular circulation. Common congenital diagnoses in this category include tricuspid atresia, double inlet LV, and hypoplastic left heart syndrome. Most patients with single ventricle physiology undergo a series of surgeries culminating in a Fontan procedure **(Fig. 280-12*A*, *B*)**. Since its initial use for tricuspid valve atresia in 1971, multiple modifications of this procedure have occurred, with common features of near complete separation of the pulmonary and systemic circulations. The Fontan procedure utilizes the single ventricle to pump pulmonary venous (oxygenated) blood through the aorta to the body and allows for "passive" flow of systemic venous return of deoxygenated blood through surgically created connections to the lungs. Patients who have undergone a Fontan procedure are at risk for multiple comorbidities in adulthood, including atrial arrhythmias, heart failure, renal and hepatic dysfunction, and both venous and arterial thrombosis and embolism.



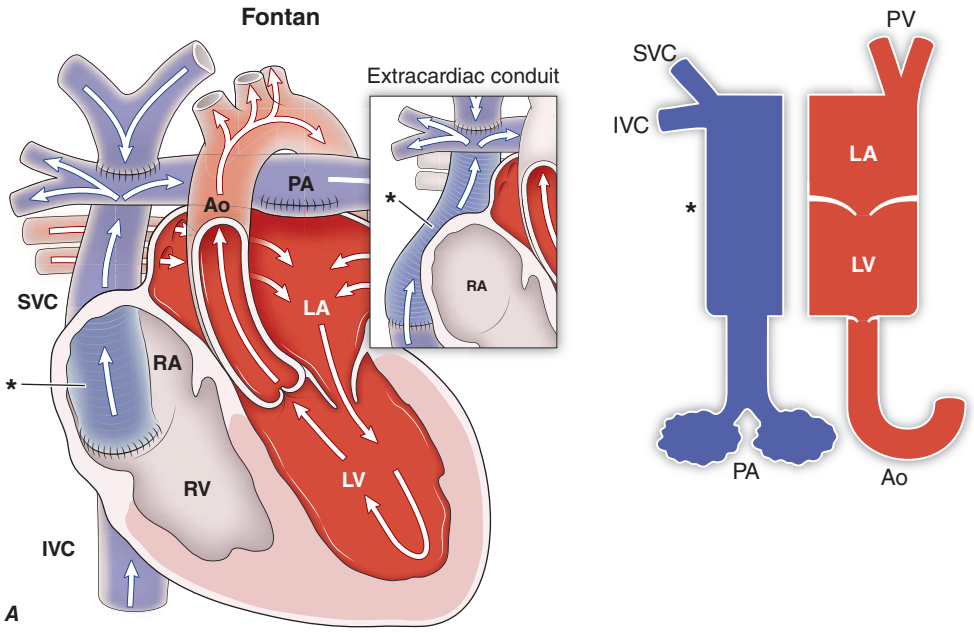


FIGURE 280-11 Aortic coarctation (*). Bicuspid aortic valve (1) is most common concomitant lesion. Sequelae from aortic coarctation (unrepaired or repaired) include systemic arterial hypertension, ascending (2) or descending (3) aortic enlargement or aneurysm formation, left ventricular (LV) hypertrophy (4), LV diastolic and systolic heart failure, accelerated coronary (5) or cerebral (6) atherosclerosis, cerebral aneurysm formation, and recurrence of coarctation after repair. Ao, aorta; PA, pulmonary arteries.

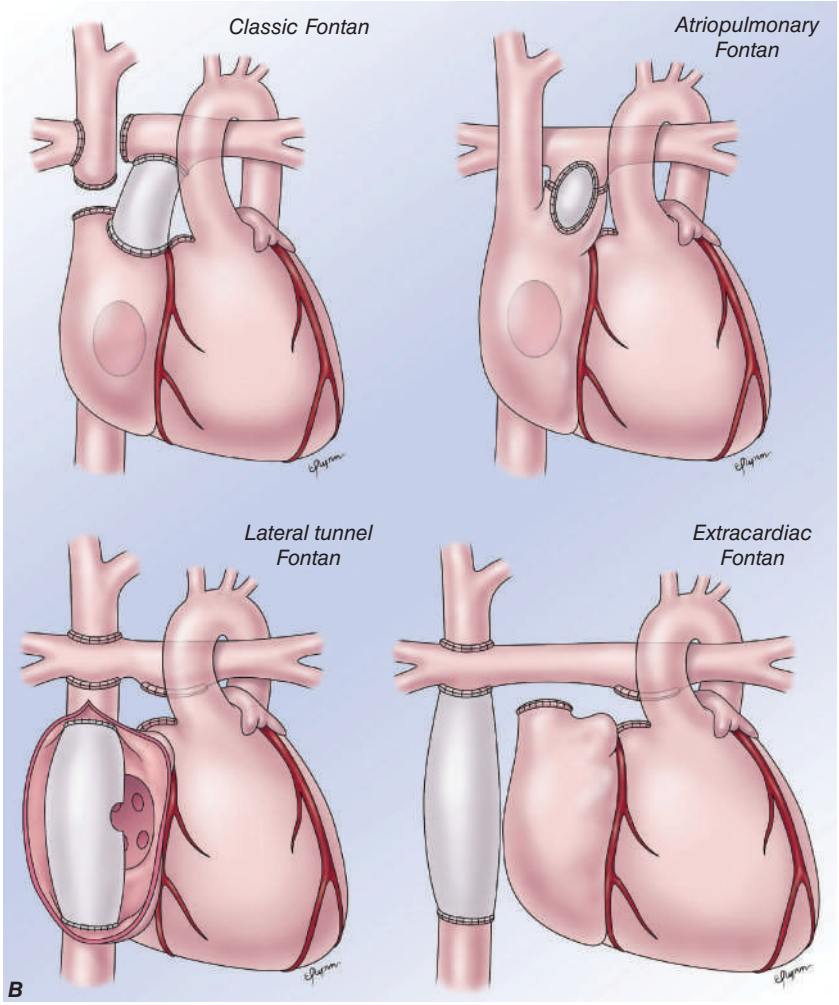

FIGURE 280-12 ***A.*** Fontan surgery creates a unique circulation in which deoxygenated blood is directed to the PAs from the SVC and IVC in a fashion that bypasses any pumping chamber. The SVC and IVC are connected (*) via either an internal "tunnel" or an extracardiac conduit that guides flow to the PA. Pulmonary venous (oxygenated) return courses from PV to LA to LV to aorta. In contrast to physiology in normal adults (where pressure is generated by an RV to propel blood flow from a lower pressure RA to a higher pressure LA), in Fontan circulation, by definition, due to the absence of a pumping chamber to the PA, RA pressure is greater than LA pressure, permitting flow through the lungs. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PV, pulmonary veins; SVC, superior vena cava; *, Fontan baffle. ***B.*** Diagrammatic representation of the location of various types of Fontan operations. *(Part B used with permission from Emily Flynn McIntosh, illustrator.)*

Eisenmenger Syndrome ES is felt to be the consequence of a long-standing high-volume or pressurized left-to-right shunt in which excessive blood flow to the pulmonary vasculature leads to severely increased pulmonary vascular resistance that eventually results in reversal of the shunt, creating bidirectional or right-to-left flow. ES is a multiple-organ condition and may occur with any CHD with an initial left-to-right shunt. The natural history of ES is variable, and although there is significant morbidity, in general, adults with ES appear to survive longer than those with other forms of pulmonary arterial hypertension. Medical care recommendations have included sustaining adequate hydration, avoiding, and treating anemia including iron supplementation when appropriate, and anticoagulation (although this remains controversial due to predisposition to bleeding and occurrence of clinical hemoptysis, which has frequently been associated with pulmonary vascular thrombosis). Elevation of hematocrit above that considered appropriate for the degree of cyanosis can be managed in symptomatic patients by hydration alone or, on occasion, by performing phlebotomy with isovolumic replenishment. Routine phlebotomy in the asymptomatic adult with ES is contraindicated. Appropriate optimization of iron stores has been demonstrated to improve quality of life and functional performance in iron-deficient adults with ES. Contraception for women with ES who are of childbearing age is strongly recommended, avoiding use of estrogen, which may be thrombogenic. Pregnancy is contraindicated in these women due to the high risk of maternal mortality.

Selective pulmonary vasodilators, such as bosentan or sildenafil, are efficacious in ES. Select patients may be candidates for combined heart–lung transplantation or preferably lung transplantation with concomitant repair of the intracardiac defect, if feasible.

The Role of Palliative Care in ACHD In aggregate, adults with CHD demonstrate both quality-of-life–limiting comorbidities and premature mortality far in excess of age-matched controls. The reported prevalence of pain, anxiety, depression, dyspnea, and fatigue appears similar to that reported for adults who are decades older and engaged in palliative care for acquired cardiovascular disease at end of life (EOL). Similarly, at EOL with ACHD, frequencies of hospitalization, intensive care admission, 30-day readmission, and increased length of hospital stay appear greater (despite younger age) than for adults with cancer. In a retrospective study of ACHD patients who died during a hospital admission, only a minority had engaged in EOL discussions with their providers. Surveys of both adults with CHD and their providers suggest that the overwhelming majority of patients wish to participate in advanced care planning and discussion of palliative care; this contrasts with statements from ACHD care providers noting their uncertainties regarding EOL prognostication and concerns over discussion about EOL. Palliative care specialists who are embedded within or aligned with ACHD care teams can play an important and iterative role in defining and addressing alignment of patient and clinician goals within the boundaries of frequently complex care decisions over the adult life span.

Global Considerations As survival patterns improve for all medically complex patients, the internist and general practitioner are faced with particular challenges and dilemmas; foremost is accrual of sufficient knowledge and competency so as to be able both to engage in patient care provision as well as to seek greater expertise, guidance, and support, when such is appropriate. Across the globe, lifelong care for adults with CHD typifies this growing demand. Care for adults with CHD within medical care centers that contain an ACHD specialty care program has been associated with improved overall survival. However, current analyses suggest that the majority of adults with CHD seek and receive their medical care outside of such ACHD specialty care centers and within the hands of the general practitioner, internist, and cardiologist. Under a surface of adaptability and determination, adults with CHD present a wide spectrum of cognitive and functional performance, multiple organ system comorbidities, abnormalities of systemic and pulmonary vasculature, and a near universal presence of heart failure of one stage or another, all over a lifetime. It appears incumbent on the ACHD specialist and ACHD specialty care centers to serve as a hub for partnering practitioners, encouraging engagement to the level of highest competencies, and providing education, oversight, and support, so as to achieve optimal outcomes.

281 Pericardial Disease

Joseph Loscalzo

NORMAL FUNCTIONS OF THE PERICARDIUM

The normal pericardium is a double-layered sac of the visceral pericardium and parietal pericardium. The visceral pericardium is a serous membrane that is separated from the fibrous parietal pericardium by a small quantity (15–50 mL) of fluid, an ultrafiltrate of plasma. The normal pericardium, by exerting a restraining force, prevents sudden dilation of the cardiac chambers, especially the right atrium and ventricle, e.g., during exercise. It also restricts the anatomic position of the heart and likely retards the spread of infections from the lungs and pleural cavities to the heart. Nevertheless, *total* absence of the pericardium, either congenital or after surgery, does not produce obvious clinical disease. In *partial* left pericardial defects, the main pulmonary artery and left atrium may bulge through the defect; very rarely, herniation and subsequent strangulation of the left atrium may cause sudden death.

ACUTE PERICARDITIS

Acute pericarditis, by far the most common pathologic process involving the pericardium **(Table 281-1)**, has four principal diagnostic features:

1. *Chest pain* is usually present in acute infectious pericarditis and in many of the forms presumed to be related to hypersensitivity,

TABLE 281-1 Classification of Pericarditis

Clinical Classification

I. Acute pericarditis (<6 weeks)
  A. Fibrinous
  B. Effusive (serous or sanguineous)
II. Subacute pericarditis (6 weeks to 6 months)
  A. Effusive-constrictive
  B. Constrictive
III. Chronic pericarditis (>6 months)
  A. Constrictive
  B. Adhesive (nonconstrictive)

Etiologic Classification

I. Infectious pericarditis
  A. Viral (coxsackievirus A and B, echovirus, herpesviruses, mumps, adenovirus, hepatitis, HIV, post-acute COVID, mpox)
  B. Pyogenic (pneumococcus, *Streptococcus, Staphylococcus, Neisseria, Legionella, Chlamydia*)
  C. Tuberculous
  D. Fungal (histoplasmosis, coccidioidomycosis, *Candida*, blastomycosis)
  E. Other infections (syphilitic, protozoal, parasitic)
II. Noninfectious pericarditis
  A. Acute idiopathic
  B. Renal failure
  C. Neoplasia
    1. Primary tumors (benign or malignant, mesothelioma)
    2. Tumors metastatic to pericardium (lung and breast cancer, lymphoma, leukemia)
  D. Trauma (penetrating chest wall, nonpenetrating)
  E. Aortic dissection (with leakage into pericardial sac)
  F. Acute myocardial infarction
  G. Postirradiation
  H. Familial Mediterranean fever and other autoinflammatory syndromes
  I. Familial pericarditis
    1. Mulibrey nanism[a]
  J. Metabolic (myxedema, cholesterol)
III. Pericarditis presumably related to autoimmunity
  A. Rheumatic fever
  B. Collagen vascular disease (systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, scleroderma, acute rheumatic fever, granulomatosis with polyangiitis, IgG4 disease)
  C. Drug-induced (e.g., procainamide, hydralazine, phenytoin, isoniazid, minoxidil, anticoagulants, methysergide)
  D. Postcardiac injury
    1. Postpericardiotomy
    2. Posttraumatic
    3. Postmyocardial infarction (Dressler's syndrome)

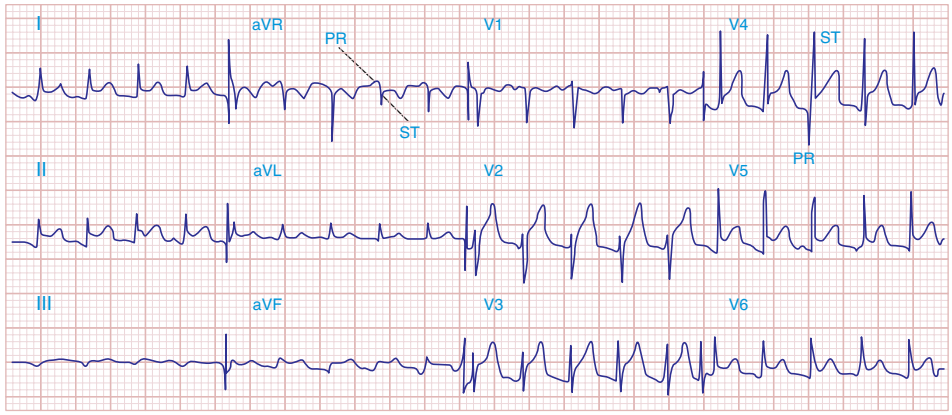
[a]An autosomal recessive syndrome characterized by growth failure, muscle hypotonia, hepatomegaly, ocular changes, enlarged cerebral ventricles, intellectual disability, ventricular hypertrophy, and chronic constrictive pericarditis.

Abbreviation: COVID, coronavirus disease.

autoimmunity, or of unknown cause (idiopathic). The pain of acute pericarditis is often severe, retrosternal and/or left precordial, and referred to the neck, arms, or left shoulder. Frequently the pain is pleuritic, consequent to accompanying pleural inflammation (i.e., sharp and aggravated by inspiration and coughing); however, at times, it is steady, radiates to the trapezius ridge or into either arm, and resembles that of myocardial ischemia. For this reason, confusion with acute myocardial infarction (AMI) is common. Characteristically, pericardial pain may be intensified by lying supine and relieved by sitting up and leaning forward **(Chap. 15)**. Pain is often absent in slowly developing tuberculous, postirradiation, neoplastic, and uremic pericarditis.

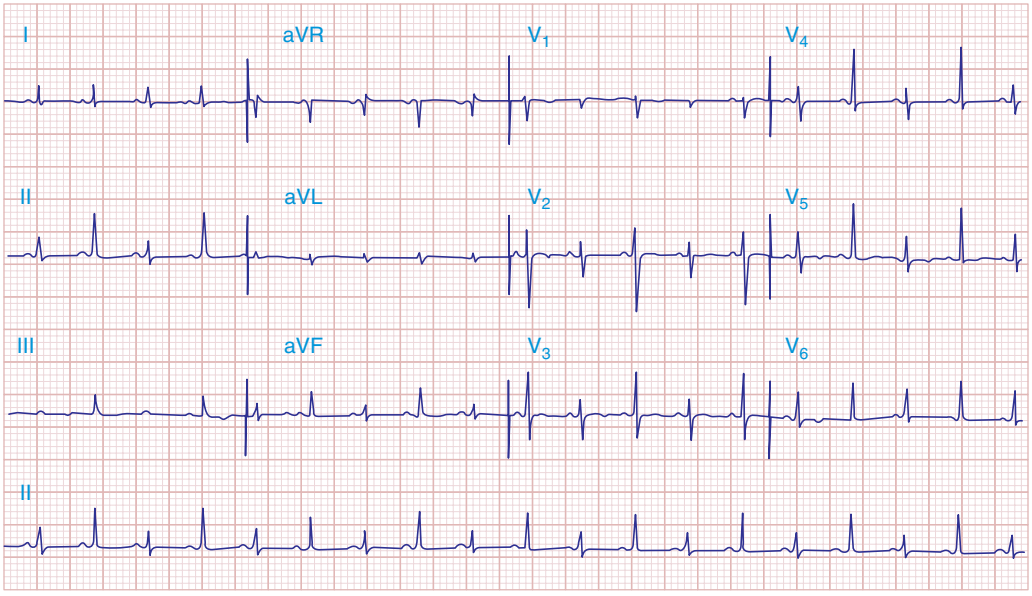
The differentiation of AMI from acute pericarditis may be challenging when, with the latter, serum biomarkers of myocardial damage rise, presumably because of concomitant involvement of the epicardium in the inflammatory process (an epi-myocarditis) with resulting myocyte necrosis. If they occur, however, these elevations are quite modest compared to those in AMI, given the superficial (sub-)epicardial injury despite often extensive electrocardiographic ST-segment elevation in pericarditis. This dissociation is useful in differentiating between these conditions.

2. A *pericardial friction rub* is audible at some point in the illness in approximately 85% of patients with acute pericarditis. The rub may have up to three components per cardiac cycle and is described as rasping, scratching, or grating **(Chap. 246)**; it is heard most frequently at end expiration with the patient upright and leaning forward.
3. The *electrocardiogram* (ECG) in acute pericarditis without massive effusion usually displays changes secondary to acute subepicardial inflammation **(Fig. 281-1*A*)**, and typically evolves through four stages. In stage 1, there is widespread elevation of the ST segments, often with upward concavity, involving two or three standard limb leads and V_2–V_6, with reciprocal depressions only in aVR and occasionally V_1. In addition, there is depression of the PR segment below the TP segment, reflecting atrial involvement, an early change that may occur prior to ST segment elevation. Usually there are no significant changes in QRS complexes unless a large pericardial effusion develops (see below). After several days, the ST segments return to normal (stage 2), and only then, or even later, do the T waves become inverted (stage 3). Weeks or months after the onset of acute pericarditis, the ECG returns to normal (stage 4). In contrast, in AMI, ST elevations are upwardly convex, and reciprocal depression is usually more prominent; these changes may return to normal within a day or two **(Chaps. 285 and 286)**.
4. *Pericardial effusion* is usually associated with pain and/or the ECG changes mentioned above and, if the effusion is large, with electrical alternans **(Fig. 281-1*B*)**. Pericardial effusion is especially important clinically when it develops within a relatively short time because it may lead to cardiac tamponade (see below). Differentiation from cardiac enlargement on physical examination may be difficult, but heart sounds may be fainter with large pericardial effusion. The friction rub and the apex impulse may disappear. The base of the left lung may be compressed by pericardial fluid, producing *Ewart's sign*, a patch of dullness, increased fremitus, and egophony beneath the angle of the left scapula. The chest x-ray may show enlargement of the cardiac silhouette, with a "water bottle" configuration, but may be normal in patients with small effusions.



Diagnosis *Echocardiography* **(Chap. 248)** is the most widely used imaging technique. It is sensitive, specific, simple, and noninvasive; may be performed at the bedside; and allows localization and estimation of the quantity of pericardial fluid. The presence of pericardial fluid is recorded by two-dimensional transthoracic echocardiography as a relatively echo-free space between the posterior pericardium and left ventricular epicardium and/or as a space between the anterior right ventricle and the parietal pericardium just beneath the anterior chest wall **(Fig. 281-2)**.

The diagnosis of pericardial fluid or thickening may be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI). These techniques may be superior to echocardiography in detecting loculated pericardial effusions and pericardial thickening, and in the identification of pericardial masses. MRI is also helpful in detecting pericardial inflammation **(Fig. 281-3)**.



TREATMENT

Acute Pericarditis

There is no specific therapy for acute idiopathic pericarditis, but bed rest may be recommended, and anti-inflammatory treatment with aspirin (2–4 g/d) or nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (600–800 mg tid) or indomethacin (25–50 mg tid), should be administered along with gastric protection (e.g., omeprazole 20 mg/d). In responsive

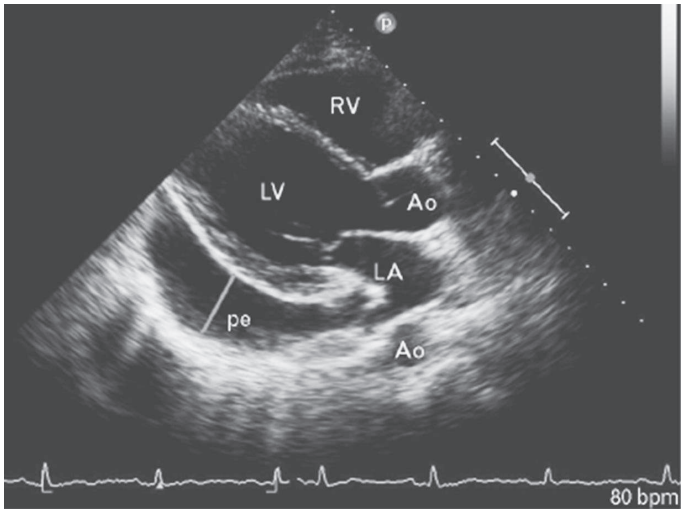
patients, these doses should be continued for 1–2 weeks and then tapered over several weeks. In addition, colchicine (0.5 to 0.6 mg qd [<70 kg] or 0.5 to 0.6 mg bid [>70 kg]) should be administered for 3 months. Colchicine enhances the response to NSAIDs and also aids in reducing the risk of recurrent pericarditis. This drug is concentrated in and interferes with the migration of neutrophils, may cause diarrhea and other gastrointestinal side effects, and is contraindicated in patients with hepatic or renal dysfunction. Glucocorticoids (e.g., prednisone 1 mg/kg per day) usually suppress the clinical manifestations of acute pericarditis in patients who have failed therapy with or do not tolerate NSAIDs and colchicine. However, since they increase the risk of subsequent recurrence, full-dose corticosteroids should be given for only 2–4 days and then tapered. Anticoagulants should be avoided because their use could cause bleeding into the pericardial cavity and tamponade.



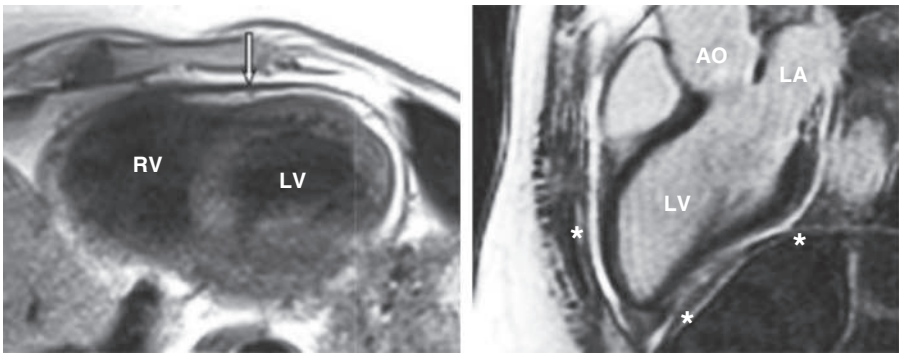


FIGURE 281-2 Two-dimensional echocardiogram in lateral view in a patient with a large pericardial effusion. Ao, aorta; LA, left atrium; LV, left ventricle; pe, pericardial effusion; RV, right ventricle. *(Reproduced with permission from Imazio M: Contemporary management of pericardial diseases. In patients with multiple, frequent, and disabling recurrences that continue for >2 years, are not prevented by continuing colchicine and other NSAIDs, and are not controlled by glucocorticoids, treatment with azathioprine or anakinra (an interleukin 1β receptor antagonist) has been reported to be of benefit. Rarely, pericardial stripping may be necessary; however, this procedure may not always terminate the recurrences.

The majority of patients with acute pericarditis can be managed as outpatients with careful follow-up. However, when specific causes (tuberculosis, neoplastic disease, bacterial infection) are suspected, or if any of the predictors of poor prognosis (fever >38°C, subacute onset, large pericardial effusion, immunosuppression, or evidence of pericardial tamponade) are present, hospitalization is advisable.

CARDIAC TAMPONADE

The accumulation of fluid in the pericardial space in a quantity sufficient to cause serious obstruction of the inflow of blood into the ventricles results in cardiac tamponade. This complication may be fatal if it is not recognized and treated promptly. The most common causes of tamponade are idiopathic pericarditis and pericarditis secondary to neoplastic disease, tuberculosis, or bleeding into the pericardial space after leakage from an aortic dissection, cardiac operation, trauma, or treatment with anticoagulants.

The three principal features of tamponade (*Beck's triad*) are hypotension, soft or absent heart sounds, and jugular venous distention with a prominent *x* (early systolic) descent but an absent *y* (early diastolic) descent. The limitations to ventricular filling are responsible for reductions of cardiac output and arterial pressure. The quantity of fluid necessary to produce cardiac tamponade may be as small as 200 mL when the fluid develops rapidly or be as much as >2000 mL in slowly developing effusions when the pericardium has had the opportunity to stretch and adapt to an increasing volume.

A high index of suspicion for cardiac tamponade is required because in many instances no obvious cause for pericardial disease is apparent. This diagnosis should be considered in any patient with otherwise unexplained sudden enlargement of the cardiac silhouette, hypotension, and elevation of jugular venous pressure. Reductions in amplitude of the QRS complexes and *electrical alternans* of the P, QRS, or T waves should also raise the suspicion of cardiac tamponade (Fig. 281-1).

Table 281-2 lists the features that distinguish acute cardiac tamponade from constrictive pericarditis.

Paradoxical Pulse This important clue to the presence of cardiac tamponade consists of a greater than normal (10 mmHg) inspiratory decline in systolic arterial pressure. When severe, it may be detected by palpating weakness or even disappearance of the arterial pulse during inspiration, but usually sphygmomanometric measurement of systolic pressure during slow respiration is required.

Because both ventricles share a tight incompressible covering, i.e., the pericardial sac, the inspiratory enlargement of the right ventricle

TABLE 281-2 Features That Distinguish Cardiac Tamponade from Constrictive Pericarditis and Similar Clinical Disorders

causes leftward bulging of the interventricular septum, reducing left ventricular volume, stroke volume, and arterial systolic pressure. Paradoxical pulse also occurs in approximately one-third of patients with constrictive pericarditis (see below), and in some cases of hypovolemic shock, acute and chronic obstructive airway disease, and pulmonary embolism. Right ventricular infarction **(Chap. 286)** may resemble cardiac tamponade with hypotension, elevated jugular venous pressure, a slow *y* descent in the jugular venous pulse, and, occasionally, a paradoxical pulse (Table 281-2).

Diagnosis Because immediate treatment of cardiac tamponade may be lifesaving, prompt establishment of the diagnosis, usually by echocardiography, should be undertaken. When pericardial effusion causes tamponade, Doppler ultrasound shows that tricuspid and pulmonic valve flow velocities increase markedly during inspiration, whereas pulmonic vein, mitral, and aortic flow velocities decrease (as in constrictive pericarditis, see below) **(Fig. 281-4)**. In tamponade, there is late diastolic inward motion (collapse) of the right ventricular free wall and the right atrium. Transesophageal echocardiography, CT, or cardiac MRI may be necessary to diagnose a loculated effusion responsible for cardiac tamponade.

TREATMENT

Cardiac Tamponade

Patients with acute pericarditis should be observed frequently for the development of an effusion. If a large effusion is present, pericardiocentesis should be performed or the patient watched closely for signs of tamponade with serial echocardiography and monitoring of arterial and venous pressures.

PERICARDIOCENTESIS

If manifestations of tamponade appear, pericardiocentesis using an apical, parasternal, or, most commonly, subxiphoid approach must be carried out at once because if left untreated, tamponade may be rapidly fatal. Whenever possible, this procedure should be carried out under echocardiographic guidance. Intravenous saline may be administered as the patient is being readied for the procedure, but the pericardiocentesis must not be delayed. If possible, intrapericardial pressure should be measured before fluid is withdrawn, and the pericardial cavity should be drained as completely as possible. A small, multiholed catheter may be advanced over the needle inserted into the pericardial cavity and left in place to allow draining of the pericardial space if fluid reaccumulates. Surgical drainage through a limited (subxiphoid) thoracotomy may be required in recurrent tamponade to remove loculated effusions and/or when it is necessary to obtain tissue for diagnosis.

Pericardial fluid obtained from an effusion may have the physical characteristics of an exudate. In developed nations, bloody fluid is most commonly due to neoplasm, renal failure, or cardiac trauma. In developing nations, tuberculosis may also cause exudative and/or bloody effusion.

The pericardial fluid should be analyzed for red and white blood cells and cytology for neoplastic cells. Cultures should be obtained. The presence of DNA of *Mycobacterium tuberculosis* determined by the polymerase chain reaction and/or of an elevated adenosine deaminase strongly supports the diagnosis of tuberculous pericarditis; however, it is often necessary to obtain pericardial tissue to make this diagnosis **(Chap. 183)**.

VIRAL OR IDIOPATHIC ACUTE PERICARDITIS

In many instances, acute pericarditis occurs in association with or following illnesses of known or presumed viral origin and probably is caused by the same agent. There may be an antecedent infection of the respiratory tract, but viral isolation and serologic studies are usually negative. In some cases, coxsackievirus A or B or the virus of influenza, echovirus, mumps, herpes simplex, varicella-zoster, adenovirus, or cytomegalovirus has been isolated from pericardial fluid, and/or appropriate elevations in viral antibody titers have been observed. Frequently, a viral cause cannot be established, and the term *idiopathic acute pericarditis* is appropriate.

Viral or idiopathic acute pericarditis occurs at all ages but is most common in young adult males and is often associated with pleural effusion and pneumonitis. The almost simultaneous development of fever and precordial pain, often 10–12 days after a presumed viral illness, constitutes an important feature in the differentiation of acute pericarditis from AMI, in which chest pain precedes fever. The constitutional symptoms are usually mild to moderate, and a pericardial friction rub is often audible. The disease ordinarily runs its course in a few days to 4 weeks. Elevations of C-reactive protein and of the white blood cell count are common. The ST-segment alterations in the ECG usually disappear after 1 or more weeks, but the abnormal T waves may persist for as long as several years and be a source of confusion in persons without a clear history of pericarditis. Accumulation of some pericardial fluid is common, and both tamponade and constrictive pericarditis are possible, but infrequent, complications.

The most frequent complication is recurrent (relapsing) pericarditis, which occurs in approximately one-fourth of patients with acute idiopathic pericarditis. A smaller number of individuals have multiple recurrences.

Postcardiac Injury Syndrome Acute pericarditis may appear in a variety of circumstances that have one common feature—previous injury to the myocardium with blood in the pericardial cavity. The syndrome may develop after a cardiac operation (postpericardiotomy syndrome), after blunt or penetrating cardiac trauma **(Chap. 283)**, or after perforation of the heart with a catheter; rarely, it follows AMI.

The clinical picture mimics acute viral or idiopathic pericarditis. The principal symptom is the pain of acute pericarditis, which usually develops 1–4 weeks after the cardiac injury. Recurrences are common and may occur up to 2 years or more following the injury. Fever, pleuritis, and pneumonitis are accompanying features, and the illness usually subsides in 1 or 2 weeks. The pericarditis may be of the fibrinous variety, or it may be a pericardial effusion, which is often serosanguinous and rarely causes tamponade. ECG changes typical of acute pericarditis may also occur. This syndrome is probably the result of a hypersensitivity (or autoimmune) reaction to antigen(s) that originate from injured myocardial tissue and/or pericardium.

Often no treatment is necessary aside from aspirin and analgesics. When the illness is severe or followed by a series of disabling recurrences, therapy with another NSAID, colchicine, or a glucocorticoid, such as described for treatment of acute pericarditis, is usually effective.

DIFFERENTIAL DIAGNOSIS

Because there is no specific test for *acute idiopathic pericarditis*, the diagnosis is one of exclusion. Consequently, all other disorders that

may be associated with acute fibrinous pericarditis must be considered. A common diagnostic error is mistaking acute viral or idiopathic pericarditis for AMI and vice versa.

Pericarditis secondary to postcardiac injury is differentiated from acute idiopathic pericarditis chiefly by timing. If it occurs within a few days or weeks of a chest blow, a cardiac perforation, a cardiac operation, or an AMI, the two are probably related.

It is important to distinguish *pericarditis due to collagen vascular disease* from acute idiopathic pericarditis. Most important in the differential diagnosis is the pericarditis due to systemic lupus erythematosus (SLE; **Chap. 368**) or drug-induced (hydralazine or procainamide) lupus. When pericarditis occurs in the absence of any obvious underlying disorder, the diagnosis of SLE may be suggested by a rise in the titer of antinuclear antibodies. Acute pericarditis is an occasional complication of *rheumatoid arthritis*, *scleroderma*, and *polyarteritis nodosa*, and other evidence of these diseases is usually obvious at the time of presentation with acute pericarditis.

Pyogenic (purulent) pericarditis is usually secondary to cardiothoracic operations, by extension of infection from the lungs or pleural cavities, from rupture of the esophagus into the pericardial sac, or from rupture of a valvular ring abscess in a patient with infective endocarditis. It may also complicate the viral, bacterial, mycobacterial, and fungal infections that occur with HIV infection. It is generally accompanied by fever, chills, septicemia, and evidence of infection elsewhere, and generally has a poor prognosis. The diagnosis is made by examination of the pericardial fluid. It requires immediate drainage as well as vigorous antibiotic treatment.

Pericarditis of renal failure (*uremic pericarditis*) occurs in up to one-third of patients with severe renal dysfunction and is also seen in patients undergoing chronic dialysis who have normal levels of blood urea nitrogen (*dialysis-associated pericarditis*). These two forms of pericarditis may be fibrinous and are generally associated with serosanguinous effusions; frank hemorrhagic effusions may be seen in some cases of uremic pericarditis prior to the onset of dialysis. A pericardial friction rub is common, but pain is usually absent or mild. Treatment with an NSAID and intensification of dialysis are usually adequate. Occasionally, tamponade occurs and pericardiocentesis is required. When the pericarditis of renal failure is recurrent or persistent, a pericardial window should be created or pericardiectomy may be necessary.

Pericarditis due to *neoplastic diseases* results from extension or invasion of metastatic tumors (most commonly carcinoma of the lung and breast, malignant melanoma, lymphoma, and leukemia) to the pericardium. The pain of pericarditis, tamponade, and atrial arrhythmias are complications that occur occasionally. Diagnosis is made by pericardial fluid cytology or pericardial biopsy. *Mediastinal irradiation* for neoplasm may cause acute pericarditis and/or chronic constrictive pericarditis. Unusual causes of acute pericarditis include syphilis, fungal infection (histoplasmosis, blastomycosis, aspergillosis, and candidiasis), and parasitic infestation (amebiasis, toxoplasmosis, echinococcosis, and trichinosis) (Table 281-1).

CHRONIC PERICARDIAL EFFUSIONS

Chronic pericardial effusions are sometimes encountered in patients without an antecedent history of acute pericarditis. They may cause few symptoms per se, and their presence may be detected by finding an enlarged cardiac silhouette on a chest roentgenogram. *Tuberculosis* and myxedema may be causal. Neoplasms, SLE, rheumatoid arthritis, mycotic infections, radiation therapy to the chest, and chylopericardium may also cause chronic pericardial effusion and should be considered and specifically sought in such patients. Aspiration and analysis of the pericardial fluid are often helpful in diagnosis. Pericardial fluid should be analyzed as described under pericardiocentesis. Grossly sanguineous pericardial fluid results most commonly from a neoplasm, tuberculosis, renal failure, or slow leakage from an aortic dissection. Pericardiocentesis may resolve large effusions, but pericardiectomy may be required in patients with recurrence. Intrapericardial instillation of sclerosing agents may be used to prevent reaccumulation of fluid, most commonly in recurrent neoplastic effusions.

CHRONIC CONSTRICTIVE PERICARDITIS

This disorder results when the healing of an acute fibrinous or serofibrinous pericarditis or the resorption of a chronic pericardial effusion is followed by obliteration of the pericardial cavity with the formation of granulation tissue. The latter gradually contracts and forms a firm scar encasing the heart, which may become calcified. In developing nations, a high percentage of cases are of tuberculous origin, but this is now an uncommon cause in North America or Western Europe. Chronic constrictive pericarditis may follow acute or relapsing viral or idiopathic pericarditis, trauma with organized blood clot, or cardiac surgery of any type, or results from mediastinal irradiation, purulent infection, histoplasmosis, neoplastic disease (especially breast cancer, lung cancer, and lymphoma), rheumatoid arthritis, SLE, or chronic renal failure treated by chronic dialysis. In many patients, the cause of the pericardial disease is undetermined, and in these patients, an asymptomatic or forgotten bout of viral pericarditis, idiopathic or acute, may have been the inciting event.

The basic physiologic abnormality in patients with chronic constrictive pericarditis is the inability of the ventricles to fill owing to the limitations imposed by the rigid, thickened pericardium. Ventricular filling is unimpeded during early diastole but is reduced abruptly when the elastic limit of the pericardium is reached, whereas in cardiac tamponade, ventricular filling is impeded throughout diastole. In both conditions, ventricular end-diastolic and stroke volumes are reduced and the end-diastolic pressures in both ventricles and the mean pressures in the atria, pulmonary veins, and systemic veins are all elevated to similar levels (i.e., within 5 mmHg of one another). Despite these hemodynamic changes, systolic function may be normal or only slightly impaired at rest. However, in advanced cases, the fibrotic process may extend into the myocardium and cause myocardial scarring and atrophy, and venous congestion may then be due to the combined effects of the pericardial and myocardial lesions.

In constrictive pericarditis, the right and left atrial pressure pulses display an M-shaped contour, with prominent *x* and *y* descents. The *y* descent, which is absent or diminished in cardiac tamponade, is the most prominent deflection in constrictive pericarditis; it reflects rapid early filling of the ventricles. The *y* descent is interrupted by a rapid rise in atrial pressure during early diastole, when ventricular filling is impeded by the constricting pericardium. These characteristic changes are transmitted to the jugular veins where they may be recognized by inspection. In constrictive pericarditis, the ventricular pressure pulses in both ventricles exhibit the characteristic "square root" sign during diastole. These hemodynamic changes, although characteristic, are not pathognomonic of constrictive pericarditis and may also be observed in restrictive cardiomyopathies **(Chaps. 266–270, Table 266-1)**.

CLINICAL AND LABORATORY FINDINGS

Weakness, fatigue, weight gain, increased abdominal girth, abdominal discomfort, and edema are common. The patient often appears chronically ill, and in advanced cases, anasarca, skeletal muscle wasting, and cachexia may be present. Exertional dyspnea is common, and orthopnea may occur, although it is usually not severe. The neck veins are distended and may remain so even after intensive diuretic treatment, and venous pressure may fail to decline during inspiration (*Kussmaul's sign*). The latter is common in chronic pericarditis but may also occur in tricuspid stenosis, right ventricular infarction, and restrictive cardiomyopathy.

The pulse pressure is normal or reduced. A paradoxical pulse can be detected in about one-third of cases. Congestive hepatomegaly is pronounced, may impair hepatic function, and may cause jaundice; ascites is common and is usually more prominent than dependent edema. Pleural effusions and splenomegaly may also be present. The apical pulse is reduced and may retract in systole (*Broadbent's sign*). The heart sounds may be distant; an early third heart sound (i.e., a pericardial knock) occurring at the cardiac apex with the abrupt cessation of ventricular filling is often conspicuous.

The ECG frequently displays low voltage of the QRS complexes and diffuse flattening or inversion of the T waves. Atrial fibrillation is present in about one-third of patients. The *chest roentgenogram* shows

a normal or slightly enlarged heart. Pericardial calcification is most common in tuberculous pericarditis. Pericardial calcification may, however, occur in the absence of constriction, and constriction may occur without calcification.

Inasmuch as the common physical signs of cardiac disease (murmurs, cardiac enlargement) may be inconspicuous or absent in chronic constrictive pericarditis, hepatic enlargement and dysfunction associated with jaundice and intractable ascites may lead to a mistaken diagnosis of hepatic cirrhosis. This error can be avoided if the neck veins are inspected and found to be distended with the characteristic waveform features.

The transthoracic *echocardiogram* often shows pericardial thickening, dilation of the inferior vena cava and hepatic veins, and a sharp halt to rapid left ventricular filling in early diastole, with normal ventricular systolic function and flattening of the left ventricular posterior wall. There is a distinctive pattern of transvalvular flow velocity on Doppler echocardiography (Fig. 281-4). During inspiration, there is an exaggerated reduction in blood flow velocity in the pulmonary veins and across the mitral valve, and a leftward shift of the ventricular septum; the opposite occurs during expiration. Diastolic flow velocity in the inferior vena cava into the right atrium and across the tricuspid valve increases in an exaggerated manner during inspiration and declines during expiration. However, echocardiography cannot definitively establish or exclude the diagnosis of constrictive pericarditis; CT and MRI are more accurate, with the latter useful in evaluating myocardial involvement.

DIFFERENTIAL DIAGNOSIS

As with chronic constrictive pericarditis, cor pulmonale **(Chap. 264)** may be associated with marked systemic venous hypertension, little pulmonary congestion, a (left) heart that is not enlarged, and a paradoxical pulse. However, in cor pulmonale, advanced parenchymal pulmonary disease is usually apparent and venous pressure *falls* during inspiration (i.e., Kussmaul's sign is negative). *Tricuspid stenosis* **(Chap. 277)** may also simulate chronic constrictive pericarditis with congestive hepatomegaly, splenomegaly, ascites, and venous distention. However, the characteristic murmur and that of accompanying mitral stenosis are usually present.

Because it can be corrected surgically, it is important to distinguish chronic constrictive pericarditis from restrictive cardiomyopathy **(Chap. 266)**, which has a similar pathophysiologic underpinning (i.e., restriction of ventricular filling). The differentiating features are summarized in Table 281-2. When a patient has progressive, disabling, and unresponsive congestive heart failure and displays any of the features of constrictive heart disease, Doppler echocardiography to record respiratory effects on transvalvular flow (Fig. 281-4) should be performed and an MRI or CT scan should be obtained to detect or exclude constrictive pericarditis because the latter is usually correctable.

TREATMENT

Constrictive Pericarditis

Pericardial resection is the only definitive treatment of constrictive pericarditis and should be as complete as possible. Coronary arteriography should be carried out preoperatively in patients aged >50 years to exclude accompanying coronary artery disease. The benefits derived from cardiac decortication are usually progressive over a period of months. The risk of this operation depends on the extent of penetration of the myocardium by the fibrotic and calcific process, the severity of myocardial atrophy, the extent of secondary impairment of hepatic and/or renal function, and the patient's general condition. Operative mortality is in the range of 5–10% even in experienced centers; the patients with the most severe disease, especially secondary to radiation therapy, are at highest risk. Therefore, surgical treatment should, if possible, be carried out as early as possible.

Subacute Effusive-Constrictive Pericarditis This form of pericardial disease is characterized by the combination of a tense effusion in the pericardial space and constriction of the heart by thickened pericardium. As such, it shares a number of features with both chronic pericardial effusion producing cardiac compression and with pericardial constriction. It may be caused by tuberculosis (see below), multiple attacks of acute idiopathic pericarditis, radiation, traumatic pericarditis, renal failure, scleroderma, and neoplasms. The heart is generally enlarged, and a paradoxical pulse is usually present. After pericardiocentesis, the physiologic findings may change from those of cardiac tamponade to those of pericardial constriction. Furthermore, the intrapericardial pressure and the central venous pressure may decline, but not to normal. The diagnosis can be established by pericardiocentesis followed by pericardial biopsy. Wide excision of both the visceral and parietal pericardium is usually effective therapy.

Tuberculous Pericardial Disease This chronic infection is a common cause of chronic pericardial effusion, especially in the developing world where active tuberculosis and HIV are endemic. Tuberculous pericarditis may present as pericardial effusion, chronic constrictive pericarditis, or subacute effusive-constrictive pericarditis (see above). The clinical picture is that of a chronic, systemic illness in a patient with pericardial effusion. It is important to consider this diagnosis in a patient with known tuberculosis, with HIV, and with fever, chest pain, weight loss, and enlargement of the cardiac silhouette of undetermined origin. If the etiology of chronic pericardial effusion remains obscure despite detailed analysis including culture of the pericardial fluid, a pericardial biopsy, preferably by a limited thoracotomy, should be performed. If definitive evidence is still lacking but the specimen shows granulomas with caseation, antituberculous chemotherapy **(Chap. 183)** is indicated.

If the biopsy specimen shows a thickened pericardium after 2–4 weeks of antituberculous therapy, pericardiectomy should be performed to prevent the development of constriction. Tubercular cardiac constriction should be treated surgically while the patient is receiving antituberculous chemotherapy.

282 Atrial Myxoma and Other Cardiac Tumors

Stephen Tsaur, Eric H. Awtry

Cardiac tumors can be broadly classified into those that arise primarily in the heart and those that reflect metastatic disease from a distant primary source. Primary cardiac tumors can be further divided into those that are pathologically benign and those that are malignant.

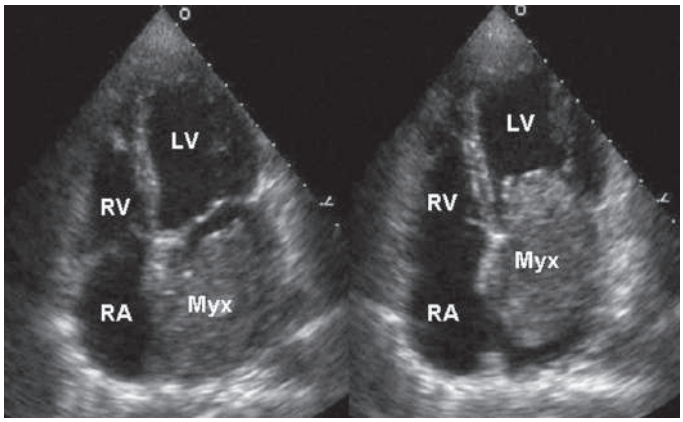
TABLE 282-1 Imaging Modalities and Their Utility in the Evaluation of Cardiac Tumors

MODALITY	UTILITY IN CARDIAC TUMOR EVALUATION
Transthoracic echocardiography (TTE) (including two-dimensional, three-dimensional, and contrast)	Assessment of tumor location and size and its impact on adjacent structures (e.g., valves, pericardium).
Transesophageal echocardiography (TEE)	Improved tumor characterization and spatial resolution compared with TTE. May aid in determining surgical approach.
Cardiac magnetic resonance imaging (MRI) with gadolinium contrast	Improved tissue characterization, definition of tumor size, and identification of local invasion when compared with TTE or TEE. May differentiate tumor from thrombus.
Gated cardiac computed tomography (CT)	Provides anatomic assessment and tissue characterization of the tumor. Useful when patients cannot tolerate MRI or when MRI is not feasible (e.g., patients with implantable cardiac devices). Allows for better assessment of calcified lesions and evaluation of extracardiac tumor involvement.
Nuclear imaging (including ^{18}F-fluorodeoxyglucose positron emission tomography [FDG-PET])	Definition of extracardiac disease. May be useful in diagnosis of certain cardiac tumors (e.g., neuroendocrine tumors), but assessment of smaller tumors may be limited by surrounding myocardial FDG uptake.

Overall, primary cardiac tumors are relatively uncommon, whereas secondary involvement of the heart or pericardium occurs in as many as 20% of patients with end-stage metastatic cancer. While patients with cardiac tumors may present with a variety of symptoms, many patients are asymptomatic at the time of diagnosis, with the tumor being identified incidentally on imaging studies performed for other reasons. Cardiac tumors need to be differentiated from other cardiac masses such as vegetation, thrombus, inflammatory myofibroblastic tumors, or myocardial hypertrophy. Echocardiography is usually the initial imaging modality used to evaluate cardiac tumors; however, a variety of imaging modalities are now available, and a multimodality approach is often necessary for accurate diagnosis and clarification of treatment options (Table 282-1). When diagnosis is uncertain after echocardiography, cardiac magnetic resonance imaging (MRI) is often useful to help further differentiate lesions. Imaging characteristics, including size, location, presence of myocardial infiltration, and first pass perfusion of gadolinium contrast agents, can help differentiate benign from malignant tumors. However, tissue histology remains the gold standard for diagnosis of cardiac tumors.

PRIMARY TUMORS

Primary tumors of the heart are rare, occurring in ~1 in 2000 patients in autopsy series. Approximately three-quarters are histologically benign, the majority of which are myxomas. Malignant tumors, almost all of which are sarcomas, account for 25% of primary cardiac tumors. All cardiac tumors, regardless of pathologic type, have the potential to cause life-threatening complications. Many tumors are now surgically curable; thus, early diagnosis is imperative.



Clinical Presentation Cardiac tumors may present with a wide array of cardiac and noncardiac manifestations. These manifestations, which depend in large part on the location and size of the tumor as well as its impact on surrounding cardiac structures, are often nonspecific features of more common forms of heart disease, and include chest pain, syncope, congestive heart failure (CHF), murmurs, arrhythmias, conduction disturbances, pericardial effusion, and pericardial tamponade. Additionally, embolic phenomena and constitutional symptoms may occur.

Myxoma Myxomas are the most common type of primary cardiac tumor in adults, accounting for one-third to one-half of all cases at postmortem examination, and approximately three-quarters of the tumors treated surgically. They occur at all ages most commonly in the third through sixth decades, with a female predilection. Approximately 90% of myxomas are sporadic; the remainder are familial with autosomal dominant transmission. The familial variety often occurs as part of a syndrome complex (Carney complex) that includes (1) myxomas (cardiac, skin, and/or breast), (2) lentigines and/or pigmented nevi, and (3) endocrine overactivity (primary nodular adrenal cortical disease with or without Cushing's syndrome, testicular tumors, and/or pituitary adenomas with gigantism or acromegaly). The genetic basis of this complex has not been elucidated completely; however, inactivating mutations in the tumor-suppressor gene *PRKAR1A*, which encodes the protein kinase A type I-α regulatory subunit, have been identified in ~70% of patients with Carney complex.

Pathologically, myxomas are gelatinous structures that consist of myxoma cells embedded in a stroma rich in glycosaminoglycans. Most sporadic tumors are solitary, arise from the interatrial septum in the vicinity of the fossa ovalis (particularly in the left atrium), and are often pedunculated on a fibrovascular stalk. In contrast, familial or syndromic tumors tend to occur in younger individuals, are often multiple, may be ventricular in location, and are more likely to recur after initial resection.

Myxomas commonly present with obstructive signs and symptoms. The most common clinical presentation mimics that of mitral valve disease: either stenosis owing to tumor prolapse into the mitral orifice or regurgitation resulting from tumor-induced valvular trauma or distortion. Ventricular myxomas may cause outflow tract obstruction similar to that caused by subaortic or subpulmonic stenosis. The symptoms and signs of myxoma may be sudden in onset or positional in nature, owing to the effects of gravity on tumor position. A characteristic low-pitched sound, a "tumor plop," may be appreciated on auscultation during early or mid-diastole and is thought to result from the impact of the tumor against the mitral valve or ventricular wall. Myxomas also may present with peripheral or pulmonary embolic phenomenon (resulting from embolization of tumor fragments or tumor-associated thrombus) or with constitutional signs and symptoms, including fever, weight loss, cachexia, malaise, arthralgias, rash, digital clubbing, and Raynaud's phenomenon. These constitutional symptoms are likely the result of cytokines (e.g., interleukin 6) secreted by the myxoma. Laboratory abnormalities, such as hypergammaglobulinemia, anemia, polycythemia, leukocytosis, thrombocytopenia or thrombocytosis, elevated erythrocyte sedimentation rate, and elevated C-reactive protein level are often present. These features account for the frequent misdiagnosis of patients with myxomas as having endocarditis, collagen vascular disease, or a paraneoplastic syndrome.

Two-dimensional and three-dimensional transthoracic and/or transesophageal echocardiography are useful in the diagnosis of cardiac myxoma and allow for assessment of tumor size and determination of the site of tumor attachment, both of which are important considerations in the planning of surgical excision (Fig. 282-1).

A *B*

FIGURE 282-1 Transthoracic echocardiogram demonstrating a large atrial myxoma. The myxoma (Myx) fills the entire left atrium in systole (***A***) and prolapses across the mitral valve and into the left ventricle (LV) during diastole (***B***). RA, right atrium; RV, right ventricle. *(Courtesy of Dr. Michael Tsang; with permission.)*

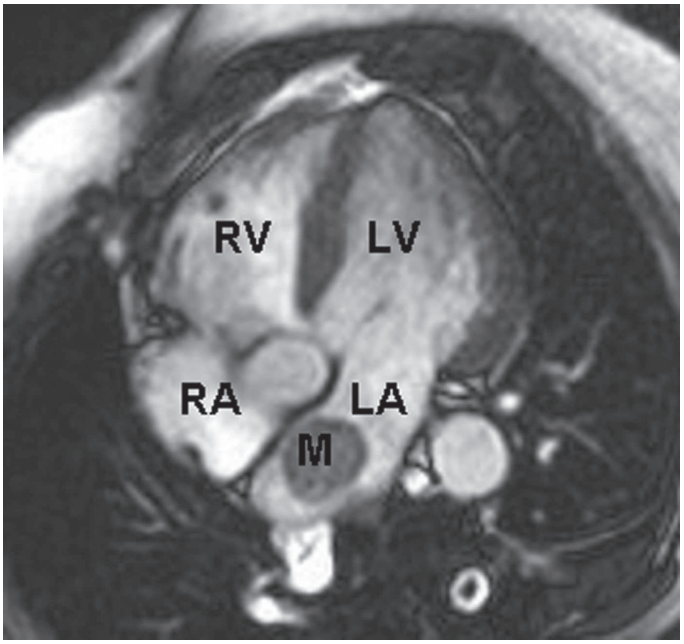


FIGURE 282-2 Cardiac magnetic resonance imaging demonstrating a rounded mass (M) within the left atrium (LA). Pathologic evaluation at the time of surgery revealed it to be an atrial myxoma. LV, left ventricle; RA, right atrium; RV, right ventricle.

Computed tomography (CT) and MRI may provide important additional information regarding size, shape, composition, and surface characteristics of the tumor **(Fig. 282-2)**.

Although cardiac catheterization and angiography were previously performed routinely before tumor resection, they no longer are considered mandatory when adequate noninvasive information is available and other cardiac disorders (e.g., coronary artery disease) are not considered likely. Additionally, catheterization of the chamber from which the tumor arises carries the risk of tumor embolization. Because myxomas may be familial, echocardiographic screening of first-degree relatives is appropriate, particularly if the patient is young and has multiple tumors or features of a myxoma syndrome.

TREATMENT

Myxoma

Surgical excision using cardiopulmonary bypass is indicated regardless of tumor size and is generally curative. Myxomas recur in 12–22% of familial cases but in only 1–2% of sporadic cases. Tumor recurrence most likely results from multifocal lesions in the former setting and incomplete tumor resection in the latter.

Other Benign Tumors Cardiac *lipomas*, although relatively common, are usually incidental findings at postmortem examination; however, they may grow as large as 15 cm, may present as an abnormality of the cardiac silhouette on chest x-ray, and should be resected if they produce symptoms owing to mechanical interference with cardiac function, arrhythmias, or conduction disturbances. *Papillary fibroelastomas* are friable tumors with frond-like projections that are usually solitary and are the most common tumors of the cardiac valves. Although usually clinically silent, they can cause valve dysfunction and may embolize distally, resulting in transient ischemic attacks, stroke, or myocardial infarction. In general, these tumors should be resected even when asymptomatic, although a more conservative approach may be considered for small, right-sided lesions. *Rhabdomyomas* and *fibromas* are the most common cardiac tumors in infants and children and usually occur in the ventricles, where they may produce mechanical obstruction to blood flow, thereby mimicking valvular stenosis, CHF, restrictive or hypertrophic cardiomyopathy, or pericardial constriction. Rhabdomyomas are probably hamartomatous growths, are multiple in

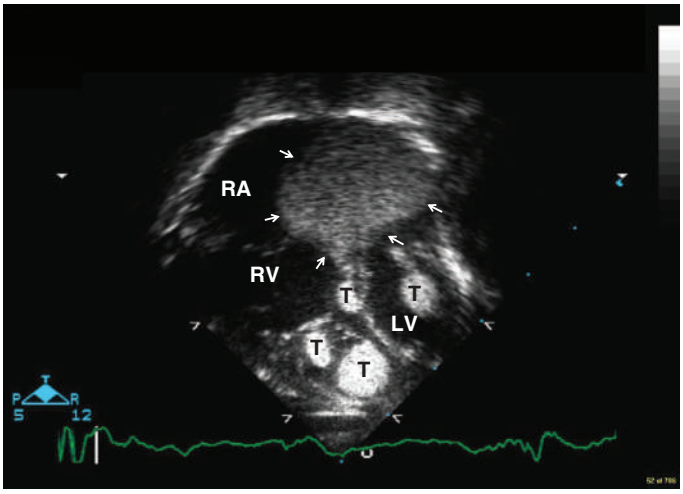

FIGURE 282-3 Transthoracic echocardiogram revealing multiple tumors (T) consistent with rhabdomyomas in a 1-day-old infant. The largest tumor (*arrows*) was located in the left antrioventricular groove and measured 2 cm × 2 cm. LV, left ventricle; RA, right atrium; RV, right ventricle.

90% of cases, occur in ~50% of children with tuberous sclerosis, and are associated with mutations in the tumor-suppressor genes *TSC1* and *TSC2* **(Fig. 282-3)**. These tumors have a tendency to regress completely or partially; only tumors that cause obstruction require surgical resection. Fibromas are usually single, universally ventricular in location, often calcified, and may be associated with mutations in the tumor-suppressor gene *PTCH1*. Fibromas tend to grow and cause arrhythmias and obstructive symptoms and should be completely resected when possible. *Paragangliomas* are rare chromaffin cell tumors that represent extra-adrenal pheochromocytomas. Most are located in the roof of the left atrium and can be identified on cardiac CT or MRI or with nuclear scanning using ^{131}I-metaiodobenzylguanidine. They are highly vascular and may be hormonally active, resulting in uncontrolled hypertension. Extensive surgical resection is usually required. *Hemangiomas* and *mesotheliomas* are generally small tumors, most often intramyocardial in location, and may cause atrioventricular (AV) conduction disturbances and even sudden death as a result of their propensity to develop in the region of the AV node. Other benign tumors arising from the heart include *teratoma*, *chemodectoma*, *neurilemoma*, and *granular cell myoblastoma*.

Malignant Tumors Almost all malignant primary cardiac tumors are sarcomas, which may be of several histologic types; angiosarcomas are the most common type in adults, whereas rhabdomyosarcomas are the most common type in children. In general, sarcomas are characterized by rapid progression that culminates in the patient's death within weeks to months from the time of presentation as a result of hemodynamic compromise, local invasion, or distant metastases. Almost one-third are metastatic at the time of initial diagnosis, usually involving the lungs. Sarcomas commonly involve the right side of the heart, are rapidly growing, frequently invade the pericardial space, and may obstruct the cardiac chambers or venae cavae. Sarcomas also may occur on the left side of the heart and may be mistaken for myxomas. Isolated cardiac lymphomas have been rarely described but more commonly occur in the context of systemic disease. They are more common in men and in the elderly; usually involve the right heart; may present with arrhythmias, syncope, CHF, or constitutional symptoms; and are usually of the large B-cell type.

TREATMENT

Malignant Tumors

The optimal therapy for cardiac sarcoma is complete resection, often with neoadjuvant and postoperative chemotherapy; however, at the time of presentation, many of these tumors have spread too extensively to allow for surgical excision. Although there are

scattered reports of palliation with radiotherapy and/or chemotherapy, the response of cardiac sarcomas to these therapies is generally poor. The one exception appears to be cardiac lymphosarcomas, which may respond to a combination of chemo- and radiotherapy. Primary cardiac lymphoma is the most chemotherapy-sensitive primary cardiac malignancy, with long-term survival achieved in ~40% of treated individuals.

TUMORS METASTATIC TO THE HEART

Metastatic cardiac tumors are much more common than primary cardiac tumors, and their incidence is likely to increase as the life expectancy of patients with various forms of malignant neoplasms is extended by more effective therapy and improved imaging modalities allow earlier identification of metastatic disease. Although cardiac metastases may occur with any tumor type, the relative incidence is especially high in malignant melanoma and, to a somewhat lesser extent, leukemia and lymphoma **(Fig. 282-4)**. In absolute terms, the most common primary sites from which cardiac metastases originate are carcinoma of the breast and lung, reflecting the high incidence of these malignancies. Cardiac metastases almost always occur in the setting of widespread primary disease; most often, there is either primary or metastatic disease elsewhere in the thoracic cavity.

Cardiac metastases may occur via hematogenous or lymphangitic spread or by direct tumor invasion. While they generally manifest as small, firm nodules, diffuse infiltration also may occur, especially with sarcomas or hematologic neoplasms. The pericardium is most often involved, followed by myocardial involvement of any chamber and, rarely, by involvement of the endocardium or cardiac valves.

Cardiac metastases are clinically apparent only ~10% of the time, are usually not the cause of the patient's presentation, and rarely are the cause of death. The vast majority occur in the setting of a previously recognized malignant neoplasm. As with primary cardiac tumors, the clinical presentation reflects more the location and size of the tumor than its histologic type. When symptomatic, cardiac metastases may result in a variety of clinical features, including dyspnea, acute pericarditis, cardiac tamponade, ectopic tachyarrhythmias, heart block, and CHF. Importantly, many of these signs and symptoms may also result from myocarditis, pericarditis, or cardiomyopathy induced by radiotherapy or chemotherapy, and a high index of suspicion for cardiac involvement should be maintained for patients with malignant disease who develop these symptoms.

Electrocardiographic (ECG) findings are nonspecific but may reveal features consistent with pericarditis or may demonstrate low QRS voltage and electrical alternans in the setting of a large pericardial effusion. On chest x-ray, the cardiac silhouette is most often normal but may be enlarged or exhibit a bizarre contour. Echocardiography is useful for identifying and assessing the significance of pericardial effusions and visualizing larger metastases, although CT and radionuclide imaging may define the tumor burden more clearly. Cardiac MRI offers superb image quality and plays a central role in the diagnostic evaluation of cardiac metastases and cardiac tumors in general. Pericardiocentesis may allow for a specific cytologic diagnosis in patients with malignant pericardial effusions with a reported sensitivity of 67–92%. Angiography is rarely necessary but may help to delineate discrete myocardial lesions.

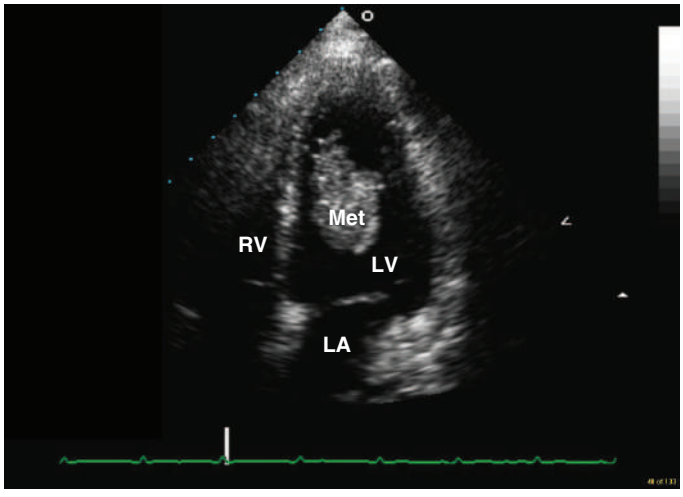

FIGURE 282-4 Large metastatic lesion (Met) in the left ventricle (LV) of a patient with diffusely metastatic bladder cancer. The mass arose from the interventricular septum and prolapsed into the aortic outflow tract during systole.

TREATMENT

Tumors Metastatic to the Heart

Most patients with cardiac metastases have advanced malignant disease; thus, therapy is generally palliative and consists of controlling symptoms and treatment of the primary tumor. Symptomatic malignant pericardial effusions should be drained by pericardiocentesis. For patients with refractory or recurrent malignant pericardial effusion, the surgical creation of a pericardial window allowing for drainage of the effusion to the adjacent pleural or peritoneal space may prevent recurrent pericardial tamponade. Prolonged drainage (3–5 days) and concomitant instillation of a sclerosing agent (e.g., bleomycin) can be considered as a palliative measure in terminally ill patients. Given the overall poor prognosis of these patients, discussions regarding goals of care and involvement of palliative care services are often appropriate.

283 Cardiac Trauma

Alexandra R. Pipilas, Eric H. Awtry

CARDIAC TRAUMA

Traumatic cardiac injury may be caused by either penetrating or nonpenetrating trauma; the latter is often referred to as blunt cardiac injury (BCI). *Penetrating injuries* most often result from gunshot or knife wounds, and the site of entry is usually obvious. *Blunt cardiac injuries* most often occur during motor vehicle accidents, either from rapid deceleration or from impact of the chest, but can also result from falls from heights, crush injuries, blast injuries, violent assault, or significant physical contact during sporting events. Importantly, rapid deceleration following motor vehicle accidents may be associated with significant cardiac injury even in the absence of external signs of thoracic trauma.

BLUNT CARDIAC INJURY

Myocardial contusion is a nonspecific term that has been used to describe a broad spectrum of nonpenetrating cardiac injuries that

TABLE 283-1 Spectrum of Cardiac Abnormalities Following Blunt Cardiac Injury

ABNORMALITY	COMMENTS
ECG abnormalities	Sinus tachycardia, RBBB, heart block, ST-T wave abnormalities, atrial and ventricular arrhythmias
Elevated cardiac biomarkers	Troponin I or T are most specific
Focal wall motion abnormality or hematoma	Most commonly involving RV free wall, LV apex, and interventricular septum
Valvular insufficiency	Most commonly involving mitral and tricuspid valves and occasionally the aortic valve
Myocardial rupture	Ventricular septal defect or free wall rupture
Coronary artery injury	Most commonly involving the LAD; usually presents as STEMI
Pericardial effusion and tamponade	Resulting from free wall rupture or coronary artery laceration

Abbreviations: ECG, electrocardiogram; LAD, left anterior descending coronary artery; LV, left ventricle; RBBB, right bundle branch block; RV, right ventricle; STEMI, ST-segment elevation myocardial infarction.

result in abnormalities on electrocardiogram (ECG), elevation in cardiac biomarkers, and acute structural cardiac abnormalities **(Table 283-1)**. Importantly, the cardiac injury may initially be overlooked in trauma patients as the clinical focus is directed toward other, more obvious injuries. Unfortunately, there is no one sign or symptom that confirms the diagnosis of BCI, and clinical, laboratory, and radiographic findings may be nonspecific in the setting of significant trauma. The physical examination may be challenging in the setting of chest wall injury; however, patients should be carefully examined to detect pericardial rubs, cardiac murmurs, and evidence of pericardial tamponade **(Chap. 281)**. The mechanism of injury and the presence of other chest trauma should be considered when determining the index of suspicion for BCI; however, there is no proven association between sternal or rib fractures and the presence of BCI, and significant cardiac injury may be present in the absence of chest wall abnormalities.

Chest pain is common following thoracic trauma, and while it can indicate cardiac ischemia or pericardial injury, it often reflects musculoskeletal trauma. Nonetheless, myocardial necrosis may occur as a direct result of the blunt injury or as a result of traumatic coronary laceration, dissection, or thrombosis. The injured myocardium is pathologically similar to infarcted myocardium and may be associated with atrial or ventricular arrhythmias, conduction disturbances including bundle branch and atrioventricular (AV) nodal block, or abnormalities on ECG resembling those of infarction or pericarditis. Thus, it is important to obtain an ECG in all patients presenting with chest trauma.

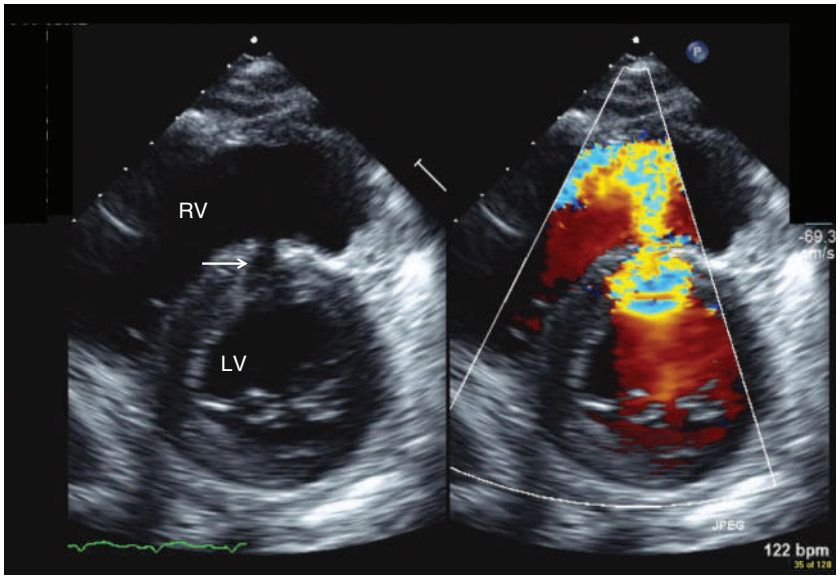
Serum creatine kinase, myocardial band (CK-MB) isoenzyme levels are increased in ~20% of patients who experience blunt chest trauma but may be falsely elevated in the presence of massive skeletal muscle injury and should not be relied upon to confirm the diagnosis of BCI in the setting of trauma. Cardiac troponin levels are more specific for identifying cardiac damage; patients with normal serial troponin levels after chest trauma are very unlikely to have sustained cardiac injury. When combined with a normal ECG, a normal troponin level at 6–8 h after chest trauma essentially excludes BCI. Echocardiography is the most useful modality for the detection of structural and functional sequelae of BCI, including regional wall motion abnormalities (most commonly involving the right ventricle, interventricular septum, or left ventricular apex), pericardial effusion, valvular dysfunction, and ventricular or ventricular septal rupture. A transthoracic echocardiogram (TTE) should be performed in all patients with suspected BCI, especially in those with an abnormal ECG, elevated troponin, or hemodynamic instability; transesophageal echocardiography should be considered for patients in whom adequate TTE images cannot be obtained.

Traumatic rupture of the cardiac valves or their supporting structures, most commonly of the tricuspid or aortic valves, leads to acute valvular incompetence. This complication is usually heralded by the development of a loud murmur, may be associated with rapidly progressive heart failure, and can be diagnosed by either TTE or transesophageal echocardiography. BCI may also result in dissection, occlusion, or laceration of the coronary arteries. ST elevation may be seen on the ECG, and prompt intervention is often required.

The most serious consequence of nonpenetrating cardiac injury is myocardial rupture. Free wall rupture may result in hemopericardium and tamponade while a ventricular septal rupture can result in significant intracardiac shunting. Although generally fatal, up to 40% of patients with cardiac rupture have been reported to survive long enough to reach a specialized trauma center. Hemopericardium also may result from traumatic rupture of a pericardial vessel or a coronary artery. Additionally, pericarditis and/or pericardial effusion may develop weeks or even months after blunt chest trauma as a manifestation of the post–cardiac injury syndrome, an inflammatory condition that resembles the postpericardiotomy syndrome **(Chap. 281)**.

Blunt, nonpenetrating, often innocent-appearing injuries to the chest may trigger ventricular fibrillation even in the absence of structural myocardial damage. This syndrome, referred to as *commotio cordis*, occurs most often in adolescents during sporting events (e.g., baseball, hockey, football, and lacrosse) and is an electrical phenomenon that probably results from an impact to the chest wall overlying the heart during the susceptible phase of repolarization (just before the peak of the T wave). Survival depends on prompt defibrillation. Sudden emotional or physical trauma, even in the absence of direct cardiac trauma, may precipitate a transient catecholamine-mediated cardiomyopathy referred to as *takotsubo syndrome* or *apical ballooning syndrome* **(Chaps. 266–270)**.

Rupture or transection of the aorta, usually just above the aortic valve or at the site of the tethering ligamentum arteriosum, is a common consequence of nonpenetrating chest trauma and is the most common vascular deceleration injury. The clinical presentation may be similar to that of aortic dissection **(Chap. 291)**; the arterial pressure and pulse amplitude may be increased in the upper extremities and decreased in the lower extremities, and chest x-ray may reveal mediastinal widening. Aortic rupture into the left thoracic space is almost universally fatal; however, the rupture may occasionally be contained by the aortic adventitia, resulting in a false, or *pseudo-*, aneurysm that may be discovered months or years after the initial injury.



TREATMENT

Blunt Cardiac Injury

The treatment of BCI depends on the specific injury sustained. Hemodynamically stable patients with a normal ECG and normal serial troponin levels are at low risk for BCI and usually do not require hospital admission for cardiac issues. Patients with an abnormal ECG, including those with conduction disturbances, and/or elevated troponin but normal echocardiogram usually warrant 24–48 h of telemetry monitoring; however, other specific cardiac treatment is not usually required in the absence of the development of arrhythmias, as conduction disturbances are often transient. Patients with mechanical complications (acute valvular insufficiency, myocardial rupture) require urgent operative correction.

PENETRATING CARDIAC INJURY

Penetrating injuries of the heart produced by knife or bullet wounds usually result in rapid clinical deterioration and frequently in death as a result of hemopericardium/pericardial tamponade or massive hemorrhage. Nonetheless, up to half of such patients may survive long enough to reach a specialized trauma center if immediate resuscitation is performed. Prognosis in these patients relates to the mechanism of injury, the specific cardiac chamber(s) involved, and their clinical condition at presentation. In general, gunshot wounds are associated with a higher mortality than are knife wounds. Twenty percent of shooting victims survive versus up to 65% of stabbing victims. This is likely in part because ballistic wounds are more frequently associated with multichamber cardiac injury. As a result of its anterior position in the chest, the right ventricle (RV) is the most frequently injured cardiac chamber,

A B

FIGURE 283-1 Transthoracic echocardiogram demonstrating a traumatic ventricular septal defect. The patient underwent emergent repair of the right ventricle following a self-inflicted stab wound to the chest. Subsequent two-dimensional imaging (***A***) revealed a laceration of the interventricular septum (*arrow*) with color flow Doppler (***B***) demonstrating prominent left-to-right shunting across the defect. LV, left ventricle; RV, right ventricle.

followed by the left ventricle (LV); isolated atrial injury is uncommon. Some studies suggest that RV injuries may be associated with a better prognosis than LV injuries, and most reports indicate that multichamber involvement carries a worse prognosis than single-chamber injury. Patients who are in hemodynamic collapse at presentation to the emergency department have a particularly poor prognosis with a mortality rate approaching 90%, whereas ~75% of patients who are stable enough to be brought to the operating room will survive.

Cardiac perforation of the right atrium, the RV free wall, or the interventricular septum may occur as a complication of cardiac procedures including placement of central venous/intracardiac catheters, insertion of pacemaker/defibrillator leads, or performance of RV endomyocardial biopsies; and coronary arterial perforation can occur during deployment of intracoronary stents. These iatrogenic injuries are associated with a better prognosis than are other forms of penetrating cardiac trauma, likely related to a more limited degree of cardiac injury and the rapid availability of corrective therapies.

Traumatic rupture of a great vessel from penetrating injury is usually associated with hemothorax and, less often, hemopericardium, both of which are associated with significant mortality. Local hematoma formation may compress adjacent vessels and produce ischemic symptoms, and arteriovenous fistulas may develop, occasionally resulting in high-output heart failure.

Some patients with penetrating chest injuries are hemodynamically stable at presentation and without symptoms to suggest cardiac injury; however, as many as 20% of these patients will have occult penetrating cardiac trauma. As a result, there should always be a high index of suspicion for cardiac injury in any patient with penetrating chest trauma, irrespective of clinical stability. TTE should be performed in all of these patients to assess for the presence of pericardial effusion or hematoma.

Occasionally, patients who survive penetrating cardiac injuries may subsequently present days or weeks later with a new cardiac murmur or heart failure as a result of mitral or tricuspid regurgitation or an intracardiac shunt (i.e., ventricular or atrial septal defect, aortopulmonary fistula, or coronary arteriovenous fistula) that was undetected at the time of the initial injury or developed subsequently **(Fig. 283-1)**. Therefore, trauma patients should be examined carefully several weeks after the injury. If a mechanical complication is suspected, it can be confirmed by echocardiography or cardiac catheterization.

TREATMENT

Penetrating Cardiac Injury

Penetrating cardiac injury associated with hemodynamic instability is a surgical emergency and requires immediate resuscitative measures including endotracheal intubation, establishment of large-bore intravenous access to facilitate massive volume resuscitation, and immediate thoracotomy to allow for pericardial drainage and repair of cardiac injuries. Occasionally, cross-clamping of the descending aorta is required to perfuse the heart and brain preferentially until hemodynamic stability can be achieved. Hemodynamically stable patients in whom echocardiography reveals even a small pericardial effusion require urgent surgical exploration to evaluate for occult cardiac perforation. Pericardiocentesis may be lifesaving in patients with tamponade but is usually only a temporizing measure while awaiting definitive surgical therapy. In some survivors of penetrating cardiac injury, the pericardial hemorrhage predisposes to the development of constriction **(Chap. 281)**, which may require surgical decortication.

Section 5 Coronary and Peripheral Vascular Disease

284 Ischemic Heart Disease

Robert P. Giugliano, Elliott M. Antman, Joseph Loscalzo

Ischemic heart disease (IHD) is a condition in which there is an inadequate supply of blood and oxygen to a portion of the myocardium; it typically occurs when there is an imbalance between myocardial oxygen supply and demand. The most common cause of myocardial ischemia is atherosclerotic disease of an epicardial coronary artery (or arteries) sufficient to cause a regional reduction in myocardial blood flow and inadequate perfusion of the myocardium supplied by the involved coronary artery. This chapter focuses on the chronic manifestations and treatment of IHD (sometimes referred to as chronic coronary disease or chronic coronary syndrome), while the subsequent chapters address the acute phases of IHD.

EPIDEMIOLOGY AND GLOBAL TRENDS

IHD causes more deaths and disability and incurs greater economic costs than any other illness in the developed world. IHD is the most common, serious, chronic, life-threatening illness in the United States, where 20.5 million persons have IHD. Although there is regional variation, ~3–4% of the population has sustained a myocardial infarction. Genetic factors, a high-fat and energy-rich diet, smoking, and a sedentary lifestyle are associated with the emergence of IHD. In the United States and Western Europe, IHD is growing among low-income groups, but primary prevention has delayed the disease to later in life across socioeconomic groups. Despite these sobering statistics, it is worth noting that epidemiologic data show a decline in the rate of deaths due to IHD, about half of which is attributable to treatments and half to prevention by risk factor modification.

Obesity, insulin resistance, and type 2 diabetes mellitus are increasing and are powerful risk factors for IHD. These trends are occurring in the general context of population growth and as a result of the increase in the average age of the world's population. With urbanization in countries with emerging economies and a growing middle class, elements of the energy-rich Western diet are being adopted. As a result, the prevalence of risk factors for IHD and the prevalence of IHD itself are both increasing rapidly, so that in analyses of the global burden of disease, there is a shift from communicable to noncommunicable diseases, and it is estimated that globally over 200 million people live with IHD. Population subgroups that appear to be particularly affected are men in South Asian countries, especially India and the Middle East. IHD is a major contributor to the number of disability-adjusted life-years (DALYs) experienced globally.

PATHOPHYSIOLOGY

Central to an understanding of the pathophysiology of myocardial ischemia is the concept of myocardial supply and demand. In normal conditions, for any given level of a demand for oxygen, the myocardium will control the supply of oxygen-rich blood to prevent underperfusion of myocytes and the subsequent development of ischemia and infarction. The major determinants of myocardial oxygen demand (MVO_2) are heart rate, myocardial contractility, and myocardial wall tension (stress). An adequate supply of oxygen to the myocardium requires a satisfactory level of oxygen-carrying capacity of the blood (determined by the inspired level of oxygen, pulmonary function, and hemoglobin concentration and function) and an adequate level of coronary blood flow. Blood flows through the coronary arteries in a phasic fashion, with the majority occurring during diastole. About 75% of the total coronary resistance to flow occurs across three sets of arteries: (1) large epicardial arteries (Resistance 1 = R_1), (2) prearteriolar vessels (R_2), and (3) arteriolar and intramyocardial capillary vessels (R_3). In the absence of significant flow-limiting atherosclerotic obstructions, R_1 is trivial; the major determinant of coronary resistance is found in R_2 and R_3 **(Fig. 284-1)**. The normal coronary circulation is dominated and controlled by the heart's requirements for oxygen. This need is met by the ability of the coronary vascular bed to vary its resistance (and, therefore, blood flow) considerably while the myocardium extracts a high and relatively fixed percentage of oxygen. Normally, intramyocardial resistance vessels demonstrate a great capacity for dilation (R_2 and R_3 decrease). The changing oxygen needs of the heart with exercise and emotional stress affect coronary

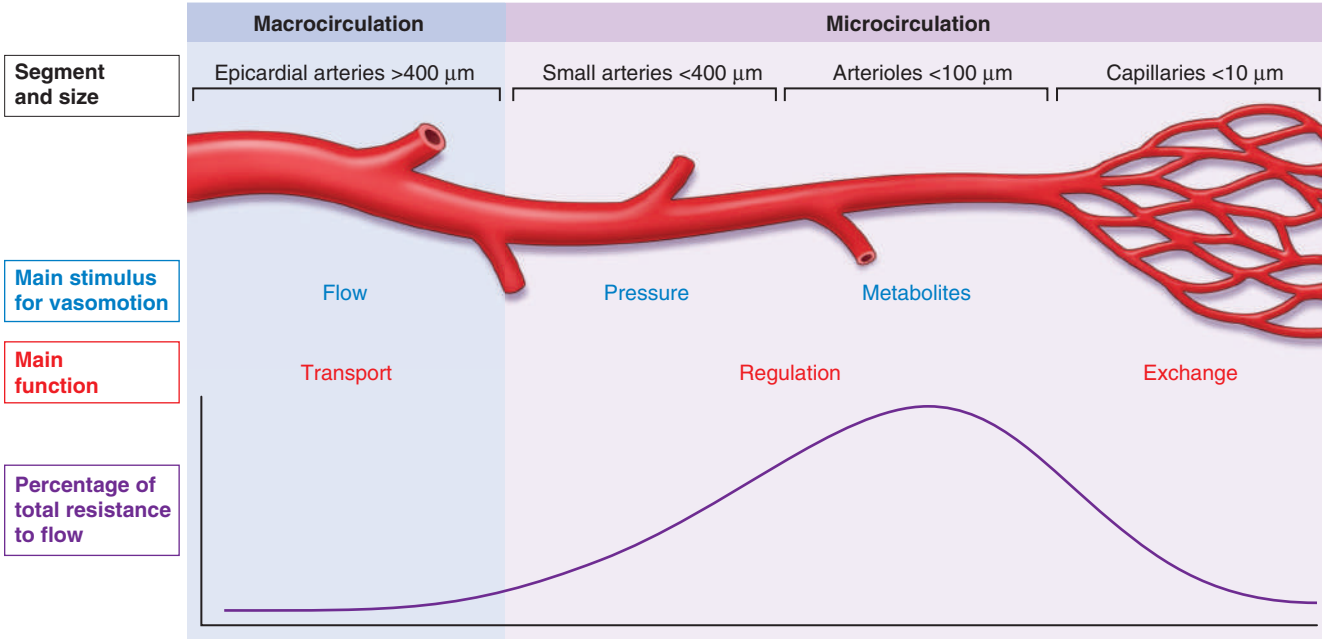

FIGURE 284-1 Macrocirculation and microcirculation across segments and sizes of the arteries. The location and size of the arteries supplying blood to the heart is shown at the top. Vasomotion of the arterial segments occurs in response to the stimuli shown. The main function of each of the arterial segments is shown next, followed by a depiction of the relative resistance to antegrade flow. (*Adapted from J Knuuti et al: 2019 ESC guidelines for the diagnosis and management of chronic coronary syndromes. Eur Heart J 41:407, 2020/.*)

vascular resistance and, in this manner, regulate the supply of oxygen and substrate to the myocardium (*metabolic regulation*). The coronary resistance vessels also adapt to physiologic alterations in blood pressure to maintain coronary blood flow at levels appropriate to myocardial needs (*autoregulation*).

By reducing the lumen of the coronary arteries, atherosclerosis limits appropriate increases in perfusion when the demand for more coronary flow occurs. When the luminal reduction is severe, myocardial perfusion in the basal state is reduced. Coronary blood flow also can be limited by spasm (see vasospastic angina in **Chap. 285**), arterial thrombi, and, rarely, coronary emboli as well as by ostial narrowing due to aortitis. Congenital abnormalities such as the origin of the left anterior descending coronary artery from the pulmonary artery may cause myocardial ischemia and infarction in infancy, but this cause is very rare in adults.

Myocardial ischemia also can occur if myocardial oxygen demands are markedly increased and particularly when coronary blood flow may be limited, as occurs in severe left ventricular hypertrophy (LVH) due to aortic stenosis. The latter can present with angina that is indistinguishable from that caused by coronary atherosclerosis largely owing to subendocardial ischemia **(Chap. 272)**. A reduction in the oxygen-carrying capacity of the blood, as in extremely severe anemia or in the presence of carboxyhemoglobin, rarely causes myocardial ischemia by itself but may lower the threshold for ischemia in patients with moderate coronary obstruction.

Not infrequently, two or more causes of ischemia coexist in a patient, such as an increase in oxygen demand due to LVH secondary to hypertension and a reduction in oxygen supply secondary to coronary atherosclerosis and anemia. Abnormal constriction or failure of normal dilation of the coronary resistance vessels also can cause ischemia. When it causes angina, this condition is referred to as *microvascular angina*.

CORONARY ATHEROSCLEROSIS

Epicardial coronary arteries are the major site of atherosclerotic disease. The major risk factors for atherosclerosis (high levels of plasma low-density lipoprotein [LDL], cigarette smoking, hypertension, and diabetes mellitus) vary in their relative impact on disturbing the normal functions of the vascular endothelium. These functions include local control of vascular tone, maintenance of an antithrombotic surface, and control of inflammatory cell adhesion and diapedesis. The loss of these defenses leads to inappropriate constriction, luminal thrombus formation, and abnormal interactions between blood cells, especially monocytes and platelets, and the activated vascular endothelium. Functional changes in the vascular milieu ultimately result in the subintimal collections of fat, smooth muscle cells, fibroblasts, and intercellular matrix that define the atherosclerotic plaque. Rather than viewing atherosclerosis strictly as a vascular problem, it is useful to consider it in the context of alterations in the nature of the circulating blood (hyperglycemia; increased concentrations of LDL cholesterol, tissue factor, fibrinogen, von Willebrand factor, coagulation factor VII, and platelet microparticles). The combination of a "vulnerable vessel" in a patient with "vulnerable blood" promotes a state of hypercoagulability and hypofibrinolysis. This is especially true in patients with diabetes mellitus.

Atherosclerosis develops at irregular rates in different segments of the epicardial coronary tree and leads eventually to segmental reductions in cross-sectional area, i.e., plaque formation. There is also a predilection for atherosclerotic plaques to develop at sites of increased turbulence in coronary flow, such as at branch points in the epicardial arteries. When a stenosis reduces the diameter of an epicardial artery by 50%, there is a limitation of the ability to increase flow to meet increased myocardial demand. When the diameter is reduced by ~80%, blood flow at rest may be reduced, and further minor decreases in the stenotic orifice area can reduce coronary flow dramatically to cause myocardial ischemia at rest or with minimal stress.

Segmental atherosclerotic narrowing of epicardial coronary arteries is caused most commonly by the formation of a plaque, which is subject to rupture or erosion of the cap separating the plaque from the bloodstream. Upon exposure of the plaque contents to blood, two important and interrelated processes are set in motion: (1) platelets are activated and aggregate, and (2) the coagulation cascade is activated, leading to deposition of fibrin strands. A thrombus composed of platelet aggregates and fibrin strands traps red blood cells and can reduce coronary blood flow, leading to the clinical manifestations of myocardial ischemia.

The location of the obstruction influences the quantity of myocardium rendered ischemic and determines the severity of the clinical manifestations. Thus, critical obstructions in vessels, such as the left main coronary artery and the proximal left anterior descending coronary artery, are particularly hazardous. Chronic severe coronary narrowing and myocardial ischemia frequently are accompanied by the development of collateral vessels, especially when the narrowing develops gradually. When well developed, such vessels can by themselves provide sufficient blood flow to sustain the viability of the myocardium at rest but not during conditions of increased demand.

With progressive worsening of a stenosis in a proximal epicardial artery, the distal resistance vessels (when they function normally) dilate to reduce vascular resistance and maintain coronary blood flow. A pressure gradient develops across the proximal stenosis, and poststenotic pressure falls. When the resistance vessels are maximally dilated, myocardial blood flow becomes dependent on the pressure in the coronary artery distal to the obstruction. In these circumstances, ischemia, manifest clinically by angina or electrocardiographically by ST-segment deviation, can be precipitated by increases in myocardial oxygen demand caused by physical activity, emotional stress, and/or tachycardia. Changes in the caliber of the stenosed coronary artery resulting from physiologic vasomotion, loss of endothelial control of dilation (as occurs in atherosclerosis), pathologic spasm (vasospastic angina), or small platelet-rich plugs also can upset the critical balance between oxygen supply and demand and thereby precipitate myocardial ischemia.

EFFECTS OF ISCHEMIA

During episodes of inadequate perfusion caused by coronary atherosclerosis, myocardial tissue oxygen tension falls and may cause transient disturbances of the mechanical, biochemical, and electrical functions of the myocardium **(Fig. 284-2)**. Coronary atherosclerosis is a focal process that usually causes nonuniform ischemia. During ischemia, regional disturbances of ventricular contractility cause segmental hypokinesia, akinesia, or, in severe cases, bulging (dyskinesia), which can reduce myocardial pump function.

The abrupt development of severe ischemia, as occurs with total or subtotal coronary occlusion, is associated with near instantaneous failure of normal muscle relaxation and then diminished contraction. The relatively poor perfusion of the subendocardium causes more intense ischemia of this portion of the wall (compared with the subepicardial region). Ischemia of large portions of the ventricle causes transient left ventricular (LV) failure, and if the papillary muscle apparatus is involved, mitral regurgitation can occur. When ischemia is transient, it may be associated with angina pectoris; when it is prolonged, it can lead to myocardial necrosis and scarring with or without the clinical picture of acute myocardial infarction **(Chap. 286)**.

A wide range of abnormalities in cell metabolism, function, and structure underlie these mechanical disturbances during ischemia. The normal myocardium metabolizes fatty acids and glucose to carbon dioxide and water. With severe oxygen deprivation, fatty acids cannot be oxidized, and glucose is converted to lactate; intracellular pH is reduced, as are the myocardial stores of high-energy phosphates, i.e., ATP and creatine phosphate. Impaired cell membrane function leads to the leakage of potassium and the uptake of sodium by myocytes as well as an increase in cytosolic calcium. The severity and duration of the imbalance between myocardial oxygen supply and demand determine whether the damage is reversible (≤20 min for total occlusion in the absence of collaterals) or permanent, with subsequent myocardial necrosis (>20 min).

Ischemia also causes characteristic changes in the electrocardiogram (ECG) such as repolarization abnormalities, as evidenced by inversion

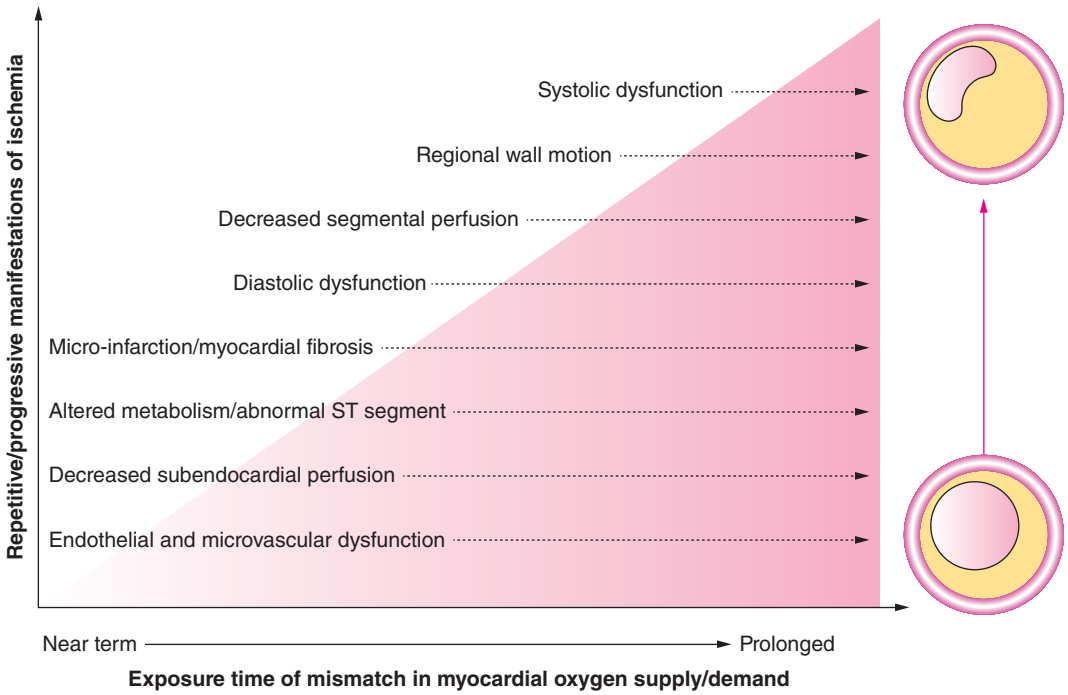

FIGURE 284-2 Cascade of mechanisms and manifestations of ischemia. (*Reproduced with permission from LJ Shaw et al: Women and ischemic heart disease: Evolving knowledge. J Am Coll Cardiol 54:1561, 2009.*)

of T waves and, when more severe, displacement of ST segments (Chap. 247). Transient T-wave inversion probably reflects nontransmural, intramyocardial ischemia; transient ST-segment depression often reflects patchy subendocardial ischemia; and ST-segment elevation is thought to be caused by more severe transmural ischemia. Another important consequence of myocardial ischemia is electrical instability, which may lead to isolated ventricular premature beats or even ventricular tachycardia or ventricular fibrillation (Chaps. 261 and 262). Most patients who die suddenly from IHD do so as a result of ischemia-induced ventricular tachyarrhythmias (Chap. 317).

ASYMPTOMATIC VERSUS SYMPTOMATIC IHD

Although the prevalence is decreasing, postmortem studies of accident victims and military casualties in Western countries show that coronary atherosclerosis can begin before age 20 and is present among adults who were asymptomatic during life. Exercise stress tests in asymptomatic persons may show evidence of silent myocardial ischemia, i.e., exercise-induced ECG changes not accompanied by angina pectoris; coronary angiographic studies of such persons may reveal coronary artery plaques and previously unrecognized obstructions (Chap. 249). Coronary artery calcifications (CACs) may be seen on computed tomography (CT) images of the heart, can be quantified in a CAC score, and may be used as adjunctive information to support a diagnosis of IHD. However, they should not be used as the primary screening modality or as the isolated basis on which to formulate therapeutic decisions. (See further discussion below.) Postmortem examination of patients with such obstructions without a history of clinical manifestations of myocardial ischemia often shows macroscopic scars secondary to myocardial infarction in regions supplied by diseased coronary arteries, with or without collateral circulation. According to population studies, ~25% of patients who survive acute myocardial infarction may not come to medical attention, and these patients have the same adverse prognosis as do those who present with the classic clinical picture of acute myocardial infarction (Chap. 286). Sudden death may be unheralded and is a common presenting manifestation of IHD (Chap. 317).

Patients with IHD also can present with cardiomegaly and heart failure secondary to ischemic damage of the LV myocardium that may have caused no symptoms before the development of heart failure; this condition is referred to as *ischemic cardiomyopathy*. In contrast to the asymptomatic phase of IHD, the symptomatic phase is characterized by chest discomfort due to either angina pectoris or acute myocardial infarction (Chap. 286). Having entered the symptomatic phase, the patient may exhibit a stable or progressive course, revert to the asymptomatic stage, or die suddenly.

STABLE ANGINA PECTORIS

This episodic clinical syndrome is a result of transient myocardial ischemia. Various diseases that cause myocardial ischemia and the numerous forms of discomfort with which it may be confused are discussed in Chap. 15. Males constitute ~70% of all patients with angina pectoris and an even greater proportion of those aged <50 years. It is, however, important to note that descriptions of angina pectoris in women may be different from that in men.

HISTORY

The typical patient with angina is a man >50 years or a woman >60 years of age who complains of episodes of chest discomfort, usually described as heaviness, pressure, squeezing, smothering, or choking and only rarely as frank pain. When the patient is asked to localize the sensation, they typically place a hand over the sternum, sometimes with a clenched fist, to indicate a squeezing, central, substernal discomfort (Levine's sign). Angina is usually crescendo-decrescendo in nature (typically with the severity of the discomfort not at its most intense level at the outset of symptoms), typically lasts 2–5 min, and can radiate to either shoulder and to both arms (especially the ulnar aspects of the forearm and hand). It also can arise in or radiate to the back, interscapular region, root of the neck, jaw, teeth, and epigastrium. Angina is rarely localized below the umbilicus or above the mandible. A useful finding in assessing a patient with chest discomfort is the fact that myocardial ischemic discomfort does not radiate to the trapezius muscles; that radiation pattern is more typical of pericarditis.

Although episodes of angina typically are caused by exertion (e.g., exercise, hurrying, or sexual activity) or emotion (e.g., stress, anger, fright, or frustration) and are relieved by rest, they also may occur at rest and while the patient is recumbent (angina decubitus). The patient may be awakened at night by typical chest discomfort and dyspnea. Nocturnal angina may be due to episodic tachycardia, diminished oxygenation as the respiratory pattern changes during sleep, or expansion of the intrathoracic blood volume that occurs with recumbency; the latter causes an increase in cardiac size (end-diastolic volume), wall

tension, and myocardial oxygen demand that can lead to ischemia and transient LV failure.

The threshold for the development of angina pectoris may vary by time of day and emotional state. Many patients report a fixed threshold for angina, occurring predictably at a certain level of activity, such as climbing two flights of stairs at a normal pace. In these patients, coronary stenosis and myocardial oxygen supply are fixed, and ischemia is precipitated by an increase in myocardial oxygen demand; they are said to have stable exertional angina. In other patients, the threshold for angina may vary considerably within any particular day and from day to day. In such patients, variations in myocardial oxygen supply, most likely due to changes in coronary vasomotor tone, may play an important role in defining the pattern of angina. A patient may report symptoms upon minor exertion in the morning yet by midday be capable of much greater effort without symptoms. Angina may also be precipitated by unfamiliar circumstances, a heavy meal, exposure to cold, or a combination of these factors.

Exertional angina typically is relieved in 1–5 min by slowing or ceasing activities and even more rapidly by rest and sublingual nitroglycerin (see below). Indeed, the diagnosis of angina should be suspect if it does not respond to the combination of these measures. The severity of angina can be conveniently summarized by the Canadian Cardiac Society functional classification **(Table 284-1)**. Its impact on the patient's functional capacity can be described by using the New York Heart Association functional classification (Table 284-1).

Sharp, fleeting chest pain or a prolonged, dull ache localized to the left submammary area is rarely due to myocardial ischemia. However, especially in women and patients with diabetes mellitus, angina pectoris may be atypical in location and not strictly related to provoking factors. In addition, this symptom may exacerbate and remit over days, weeks, or months. Its occurrence can be seasonal, occurring more frequently in the winter in temperate climates. Anginal "equivalents" are symptoms of myocardial ischemia other than angina. They include dyspnea, nausea, fatigue, and faintness and are more common in the elderly and in patients with diabetes mellitus.

TABLE 284-1 Cardiovascular Disease Classification Chart

CLASS	NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION	CANADIAN CARDIOVASCULAR SOCIETY FUNCTIONAL CLASSIFICATION
I	Patients have cardiac disease but *without* the resulting *limitations* of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, *does not cause angina.* Angina present with strenuous or rapid or prolonged exertion at work or recreation.
II	Patients have cardiac disease resulting in *slight limitation* of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.	*Slight limitation* of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, or when under emotional stress or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of stairs at a normal pace and in normal conditions.
III	Patients have cardiac disease resulting in *marked limitation* of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	*Marked limitation* of ordinary physical activity. Walking one to two blocks on the level and climbing one flight of stairs at normal pace.
IV	Patients have cardiac disease resulting in *inability* to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	*Inability* to carry on any physical activity without discomfort—anginal syndrome *may* be present at rest.

Systematic questioning of a patient with suspected IHD is important to uncover the features of an unstable syndrome associated with increased risk, such as angina occurring with less exertion than in the past, occurring at rest, or awakening the patient from sleep. Since coronary atherosclerosis often is accompanied by similar lesions in other arteries, a patient with angina should be questioned and examined for peripheral arterial disease (intermittent claudication **[Chap. 292]**), stroke, or transient ischemic attacks **(Chap. 437)**. It is also important to uncover a family history of premature IHD (<55 years in first-degree male relatives and <65 years in female relatives) and the presence of diabetes mellitus, hyperlipidemia, hypertension, cigarette smoking, and other risk factors for coronary atherosclerosis.

The history of typical angina pectoris establishes the diagnosis of IHD until proven otherwise. Given the importance of the history, clinicians should move beyond unstructured interviews with the patient and consider using a validated questionnaire (e.g., Seattle Angina Questionnaire) to establish the presence and severity of IHD. The coexistence of advanced age, male sex, the postmenopausal state, and risk factors for atherosclerosis increases the likelihood of hemodynamically significant coronary disease. A particularly challenging problem is the evaluation and management of patients with persistent ischemic-type chest discomfort but no flow-limiting obstructions in their epicardial coronary arteries. This situation arises more often in women than in men. Potential etiologies include microvascular coronary disease (detectable on coronary reactivity testing in response to vasoactive agents such as intracoronary adenosine, acetylcholine, and nitroglycerin) and abnormal cardiac nociception. Treatment of microvascular coronary disease should focus on efforts to improve endothelial function, including nitrates, beta blockers, calcium antagonists, statins, and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). Abnormal cardiac nociception is more difficult to manage and may be ameliorated in some cases by imipramine.

PHYSICAL EXAMINATION

The physical examination is often normal in patients with stable angina when they are asymptomatic. However, because of the increased likelihood of IHD in patients with diabetes and/or peripheral or cerebrovascular arterial disease, clinicians should search for evidence of atherosclerotic disease at other sites, such as an abdominal aortic aneurysm, carotid arterial bruits, and diminished arterial pulses in the lower extremities. The physical examination also should include a search for evidence of risk factors for atherosclerosis such as xanthelasmas and xanthomas. Evidence for peripheral and cerebrovascular arterial disease should be sought by evaluating the pulse contour at multiple locations and comparing the blood pressure between the arms and between the arms and the legs (ankle-brachial index). Examination of the fundi may reveal an increased light reflex and arteriovenous nicking as evidence of hypertension. There also may be signs of anemia, thyroid disease, and nicotine stains on the fingertips from cigarette smoking.

Palpation may reveal cardiac enlargement and abnormal contraction of the cardiac impulse (LV dyskinesia). Auscultation can uncover arterial bruits, a third and/or fourth heart sound, and, if acute ischemia or previous infarction has impaired papillary muscle function, an apical systolic murmur due to mitral regurgitation. These auscultatory signs are best appreciated with the patient in the left lateral decubitus position. Aortic stenosis, aortic regurgitation **(Chap. 272)**, pulmonary hypertension **(Chap. 294)**, and hypertrophic cardiomyopathy **(Chaps. 266–270)** must be excluded, since these disorders may cause angina in the absence of coronary atherosclerosis. Examination during an anginal attack is useful, since ischemia can cause transient LV failure with the appearance of a third and/or fourth heart sound, a dyskinetic cardiac apex, mitral regurgitation, and even pulmonary edema. Tenderness of the chest wall, localization of the discomfort with a single fingertip on the chest, or reproduction of the pain with palpation of the

chest makes it unlikely that the pain is caused by myocardial ischemia. A protuberant abdomen may indicate that the patient has the metabolic syndrome and is at increased risk for atherosclerosis.

LABORATORY EXAMINATION

Although the diagnosis of IHD can be made with a high degree of confidence from the history and physical examination, a number of simple laboratory tests can be helpful. The urine should be examined for evidence of diabetes mellitus and renal disease (including microalbuminuria) since these conditions accelerate atherosclerosis. Similarly, examination of the blood should include measurements of lipids (cholesterol—total, LDL, high-density lipoprotein [HDL]—triglycerides, and lipoprotein (a)), glucose (hemoglobin A_{1C}), creatinine, hematocrit, and, if indicated based on the physical examination, thyroid function. A chest x-ray may be helpful in demonstrating the consequences of IHD, i.e., cardiac enlargement, ventricular aneurysm, or signs of heart failure. These signs can support the diagnosis of IHD and are important in assessing the degree of cardiac damage. Evidence exists that an elevated level of high-sensitivity C-reactive protein (CRP) (specifically, between 1 and 3 mg/L) is an independent risk factor for IHD and may be useful in therapeutic decision-making about the initiation of hypolipidemic treatment. The major benefit of high-sensitivity CRP is in reclassifying the risk of IHD in patients in the "intermediate" risk category on the basis of traditional risk factors.

ELECTROCARDIOGRAM

A 12-lead ECG recorded at rest may be normal in patients with typical angina pectoris, but there may also be signs of an old myocardial infarction **(Chap. 247)**. Although repolarization abnormalities, i.e., ST-segment and T-wave changes, as well as LVH and disturbances of cardiac rhythm or intraventricular conduction, are suggestive of IHD, they are nonspecific, since they also can occur in pericardial, myocardial, and valvular heart disease or, in the case of the former, transiently with anxiety, changes in posture, drugs, or esophageal disease. The presence of LVH is a significant indication of increased risk of adverse outcomes from IHD. Of note, even though LVH and cardiac rhythm disturbances are nonspecific indicators of the development of IHD, they may be contributing factors to episodes of angina in patients in whom IHD has developed as a consequence of conventional risk factors. Dynamic ST-segment and T-wave changes that accompany episodes of angina pectoris and disappear thereafter are more specific.

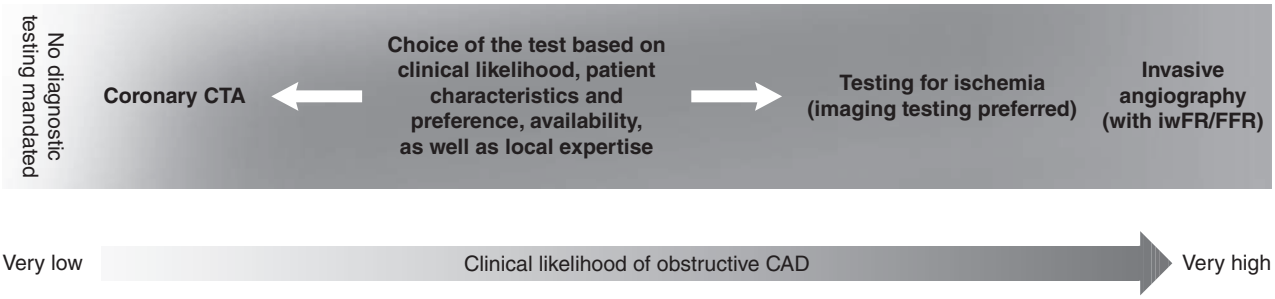
STRESS TESTING

Electrocardiographic The most widely used test for both the diagnosis of IHD and the estimation of risk and prognosis involves recording of the 12-lead ECG before, during, and after exercise, usually on a treadmill **(Fig. 284-3)**. The test consists of a standardized incremental increase in external workload **(Table 284-2)** while symptoms, the ECG, and arm blood pressure are monitored. Exercise duration is usually symptom-limited, and the test is discontinued upon evidence of chest discomfort, severe shortness of breath, dizziness, severe fatigue, ST-segment depression >0.2 mV (2 mm), a fall in systolic blood pressure >10 mmHg, or the development of a ventricular tachyarrhythmia. This test is used to discover any limitation in exercise performance, detect typical ECG signs of myocardial ischemia, and establish their relationship to chest discomfort. The ischemic ST-segment response generally is defined as flat or downsloping depression of the ST segment >0.1 mV below baseline (i.e., the PR segment) and lasting longer than 0.08 s (Fig. 284-2). Upsloping or junctional ST-segment changes are not considered characteristic of ischemia and do not constitute a positive test. Although T-wave abnormalities, conduction disturbances, and ventricular arrhythmias that develop during exercise should be noted, they are also not diagnostic. Negative exercise tests in which the target heart rate (85% of maximal predicted heart rate for age and sex) is not achieved are considered nondiagnostic.

In interpreting ECG stress tests, the probability that coronary artery disease (CAD) exists in the patient or population under study (i.e., pretest probability) should be considered. A positive result on exercise indicates that the likelihood of CAD is 98% in males who are >50 years with a history of typical angina pectoris and who develop chest discomfort during the test. The likelihood decreases if the patient has atypical or no chest pain by history and/or during the test.

The incidence of false-positive tests is significantly increased in patients with low probabilities of IHD, such as asymptomatic men age <40 or premenopausal women with no risk factors for premature atherosclerosis. It is also increased in patients taking cardioactive drugs, such as digitalis and antiarrhythmic agents, and in those with intraventricular conduction disturbances, resting ST-segment and T-wave abnormalities, ventricular hypertrophy, or abnormal serum potassium levels. Obstructive disease limited to the circumflex coronary artery may result in a false-negative stress test since the posterolateral portion of the heart that this vessel supplies is not well represented on the surface 12-lead ECG. Since the overall sensitivity of an exercise stress ECG is only ~75%, a negative result does not exclude CAD, although it makes the likelihood of three-vessel or left main CAD extremely unlikely.

A medical professional should be present throughout the exercise test. It is important to measure total duration of exercise, the times to the onset of ischemic ST-segment change and chest discomfort, the external work performed (generally expressed as the stage of exercise), and the internal cardiac work performed, i.e., by the heart rate–blood pressure product. The depth of the ST-segment depression and the time needed for recovery of these ECG changes are also important. Because the risks of exercise testing are small but real—estimated at one fatality and two nonfatal complications per 10,000 tests—equipment for resuscitation should be available. Modified (heart rate–limited rather than symptom-limited) exercise tests can be performed safely in patients as early as 6 days after uncomplicated myocardial infarction (Table 284-2). Contraindications to exercise stress testing include rest angina within 48 h, unstable rhythm, severe aortic stenosis, acute myocarditis, uncontrolled heart failure, severe pulmonary hypertension, and active infective endocarditis.

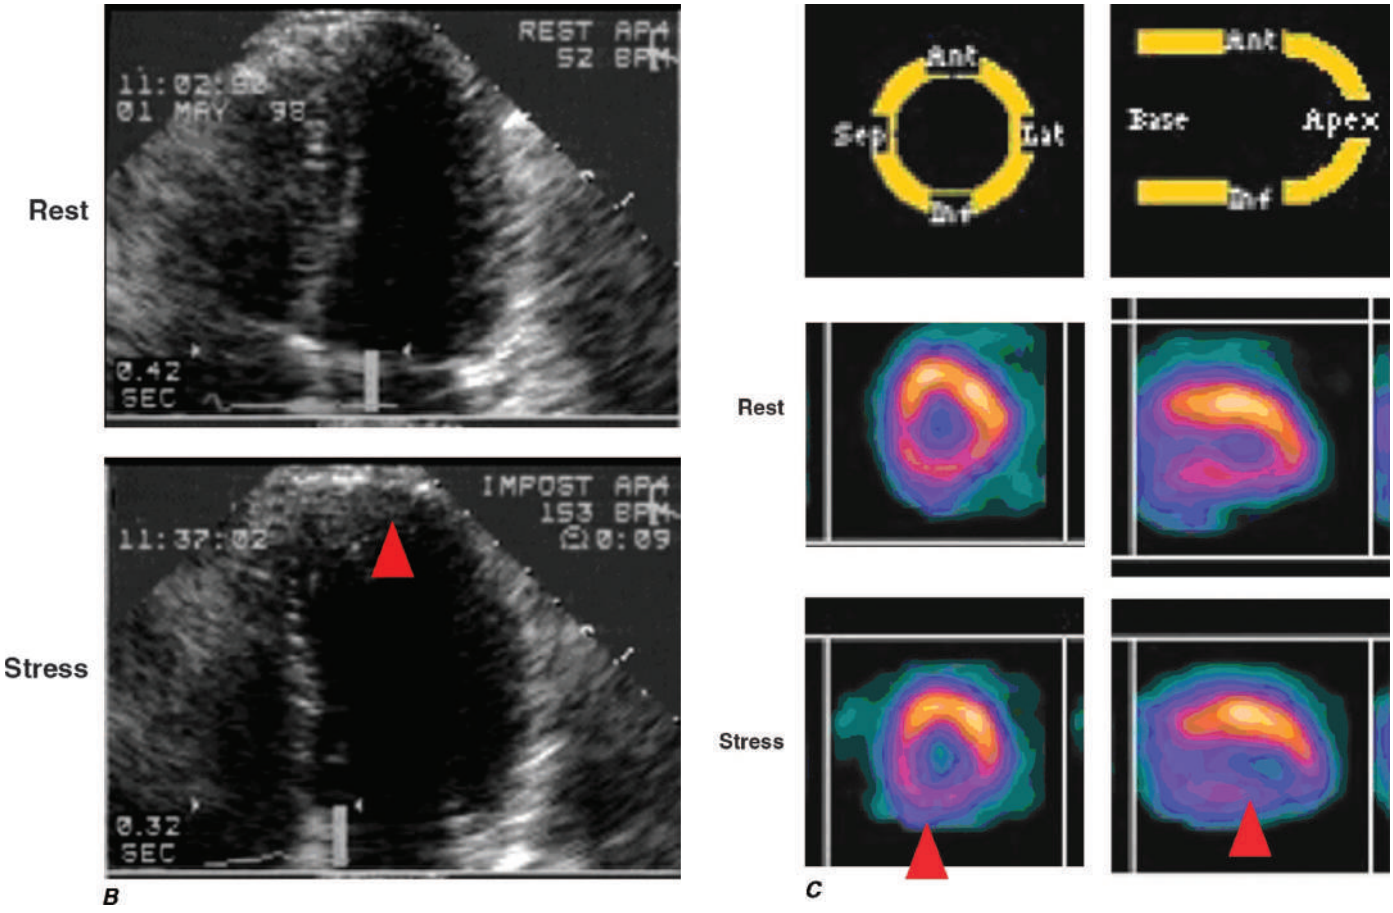


The normal response to graded exercise includes progressive increases in heart rate and blood pressure. Failure of the blood pressure to increase or an actual decrease with signs of ischemia during the test is an important adverse prognostic sign, since it may reflect ischemia-induced global LV dysfunction. The development of angina and/or severe (>0.2 mV) ST-segment depression at a low workload, i.e., before completion of stage II of the Bruce protocol, and/or ST-segment depression that persists >5 min after the termination of exercise increases the specificity of the test and suggests severe IHD and a high risk of future adverse events.

Cardiac Imaging **(See also Chap. 248)** When the resting ECG is abnormal (e.g., preexcitation syndrome, >1 mm of resting ST-segment depression, left bundle branch block, paced ventricular rhythm), information gained from an exercise test can be enhanced by stress myocardial radionuclide perfusion imaging after the intravenous administration of thallium-201 or 99m-technetium sestamibi during exercise (or with pharmacologic) stress. Contemporary data also suggest positron emission tomography (PET) imaging (with exercise or pharmacologic stress) using N-13 ammonia or rubidium-82 as another technique for assessing perfusion. Images obtained immediately after cessation of exercise to detect regional ischemia are compared with those obtained at rest to confirm reversible ischemia and regions of persistently absent uptake that signify infarction.

A sizable fraction of patients who need noninvasive stress testing to identify myocardial ischemia and increased risk of coronary events cannot exercise because of peripheral vascular or musculoskeletal disease, exertional dyspnea, or deconditioning. In these circumstances, an intravenous pharmacologic challenge is used in place of exercise. For example, adenosine can be given to create a coronary "steal" by temporarily increasing flow in nondiseased segments of the coronary vasculature at the expense of diseased segments. Alternatively, a graded incremental infusion of dobutamine may be administered to increase MVO_2. A variety of imaging options are available to accompany these pharmacologic stressors (Fig. 284-3). The development of a transient perfusion defect with a tracer such as thallium-201 or 99m-technetium sestamibi is used to detect myocardial ischemia.

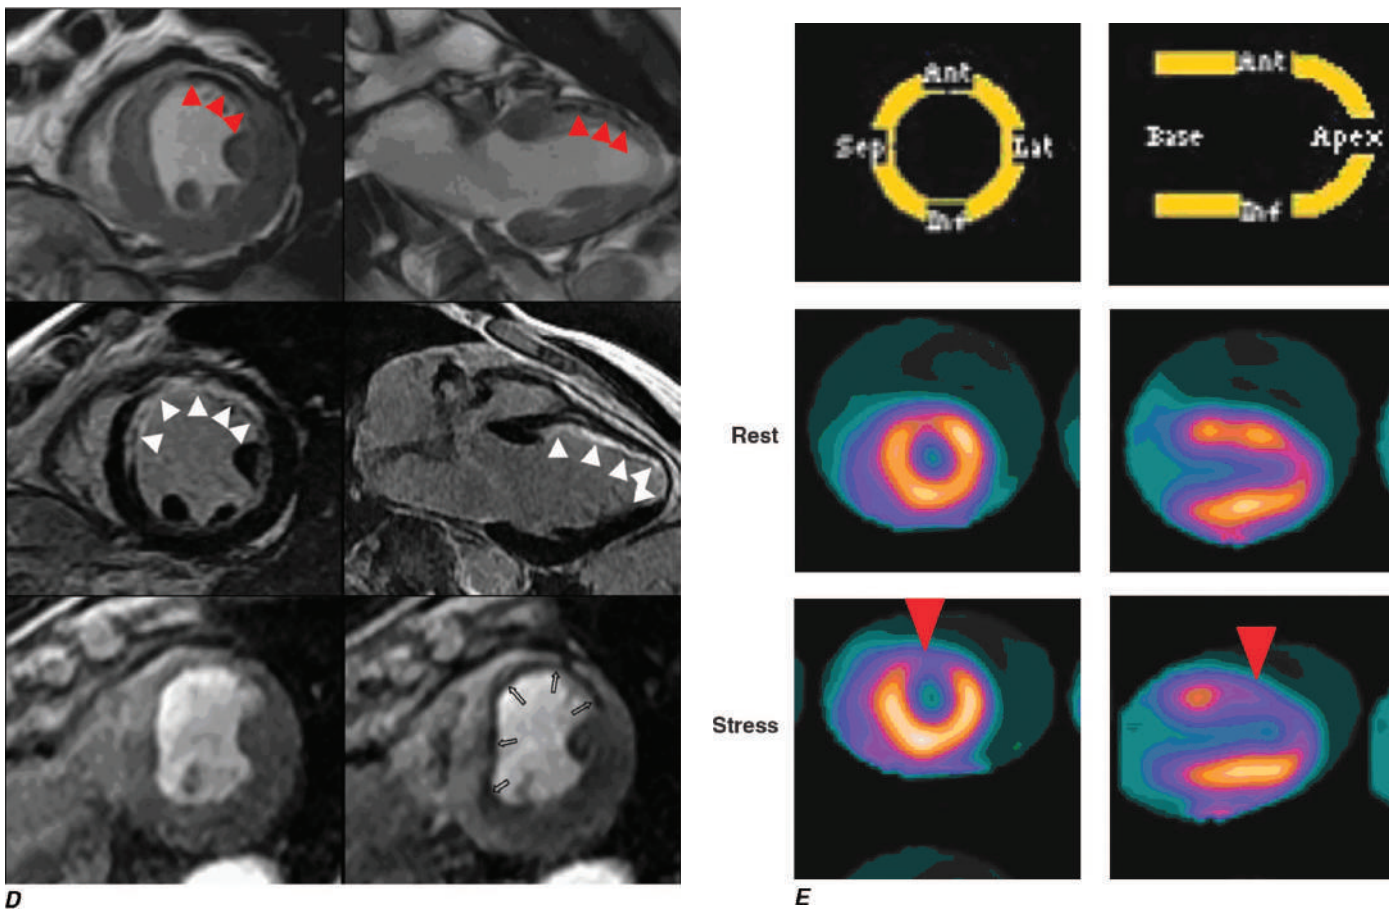
Echocardiography is used to assess LV function in patients with chronic stable angina and patients with a history of a prior myocardial infarction, pathologic Q waves, or clinical evidence of heart failure. Two-dimensional echocardiography can assess both global and regional wall motion abnormalities of the left ventricle that are transient when due to ischemia. Stress (exercise or dobutamine) echocardiography may cause the emergence of regions of akinesis or dyskinesis that are not present at rest. Stress echocardiography, like stress myocardial perfusion imaging, is more sensitive than exercise electrocardiography in the diagnosis of IHD. Cardiac magnetic resonance (CMR) stress testing is also evolving as an alternative to radionuclide, PET, or echocardiographic stress imaging. CMR stress testing performed with dobutamine infusion can be used to assess wall motion abnormalities accompanying ischemia, as well as myocardial perfusion. CMR can be used to provide more complete ventricular evaluation using multislice magnetic resonance imaging (MRI) studies.



Atherosclerotic plaques become progressively calcified over time, and coronary calcification in general increases with age. For this

A

FIGURE 284-3 Selecting appropriate testing patients with angina and suspected coronary artery disease (CAD). On the left of the figure is an algorithm for selecting from among testing options. In patients who are at low risk, in whom prior testing was equivocal, or in whom the diagnosis of is CAD uncertain, noninvasive functional stress testing with imaging for myocardial ischemia or computed tomography angiography (CTA) is reasonable to establish the diagnosis of CAD prior to initiation of treatment. Patients with a high clinical likelihood of CAD, patients with symptoms despite antianginal therapy or with low-level activities, and patients with high-risk features based on the initial clinical evaluation may proceed directly to invasive coronary angiography without further diagnostic testing. *(Adapted from J Knuuti et al: 2019 ESC guidelines for the diagnosis and management of chronic coronary syndromes. Eur Heart J 41:407, 2020.)* Panels ***A–F*** are examples of the data obtained with electrocardiogram (ECG) monitoring and specialized imaging procedures. CMR, cardiac magnetic resonance; EBCT, electron beam computed tomography; ECHO, echocardiography; FFR, fractional flow reserve; IHD, ischemic heart disease; iwFR, instantaneous wave-free ration; MIBI, methoxyisobutyl isonitrite; MR, magnetic resonance; PET, positron emission tomography. ***A.*** Lead V_4 at rest (*top panel*) and after 4.5 min of exercise (*bottom panel*). There is 3 mm (0.3 mV) of horizontal ST-segment depression, indicating a positive test for ischemia. *(Adapted from BR Chaitman, in E Braunwald et al [eds]: Heart Disease, 8th ed, Philadelphia, Saunders, 2008.)* ***B.*** A 45-year-old avid jogger who began experiencing classic substernal chest pressure underwent an exercise echo study. With exercise, the patient's heart rate increased from 52 to 153 beats/min. The left ventricular chamber dilated with exercise, and the septal and apical portions became akinetic to dyskinetic (*red arrow*). These findings are strongly suggestive of a significant flow-limiting stenosis in the proximal left anterior descending artery, which was confirmed at coronary angiography. *(Modified from SD Solomon, in E Braunwald et al [eds]: Primary Cardiology, 2nd ed, Philadelphia, Saunders, 2003.)* ***C.*** Stress and rest myocardial perfusion single-photon emission computed tomography images obtained with 99m-technetium sestamibi in a patient with chest pain and dyspnea on exertion. The images demonstrate a medium-size and severe stress perfusion defect involving the inferolateral and basal inferior walls, showing nearly complete reversibility, consistent with moderate ischemia in the right coronary artery territory (*red arrows*). *(Images provided by Dr. Marcello Di Carli, Nuclear Medicine Division, Brigham and Women's Hospital, Boston, MA.)* ***D.*** A patient with a prior myocardial infarction presented with recurrent chest discomfort. On cardiac magnetic resonance (CMR) cine imaging, a large area of anterior akinesia was noted (marked by the *arrows* in the top left and right images, systolic frame only). This area of akinesia was matched by a larger extent of late gadolinium-DTPA enhancements consistent with a large transmural myocardial infarction (marked by *arrows* in the middle left and right images). Resting (*bottom left*) and adenosine vasodilating stress (*bottom right*) first-pass perfusion images revealed reversible perfusion abnormality that extended to the inferior septum. This patient was found to have an occluded proximal left anterior descending coronary artery with extensive collateral formation. This case illustrates the utility of different modalities in a CMR examination in characterizing ischemic and infarcted myocardium. DTPA, diethylenetriamine penta-acetic acid. *(Images provided by Dr. Raymond Kwong, Cardiovascular Division, Brigham and Women's Hospital, Boston, MA.)* ***E.*** Stress and rest myocardial perfusion PET images obtained with rubidium-82 in a patient with chest pain on exertion. The images demonstrate a large and severe stress perfusion defect involving the mid and apical anterior, anterolateral, and anteroseptal walls and the left ventricular apex, showing complete reversibility, consistent with extensive and severe ischemia in the mid-left anterior descending coronary artery territory (*red arrows*). *(Images provided by Dr. Marcello Di Carli, Nuclear Medicine Division, Brigham and Women's Hospital, Boston, MA.)* ***F.*** A 58-year-old woman with psoriasis presented with chest discomfort and underwent coronary CT angiography (CCTA) for further evaluation. There was a large amount of mostly noncalcified plaque resulting in severe (>70%) stenosis of the mid left anterior descending artery (LAD) and the mid-right coronary artery (RCA). There was minimal plaque in the left circumflex (LCx). CCTA data can be used to reconstruct three-dimensional images to aid visualization. In addition, each coronary artery can be visualized en face by creating a short axis along the length of the coronary segment being visualized. In this case, the stenosis of the LAD is seen in the red box (corresponding to the level of the *dashed red line*) and compared with the proximal normal segment in the green box (corresponding to the level of the *dashed green line*). (*Images provided by Dr. Ron Blankstein, Cardiovascular Division, Brigham and Women's Hospital, Boston, MA.*)



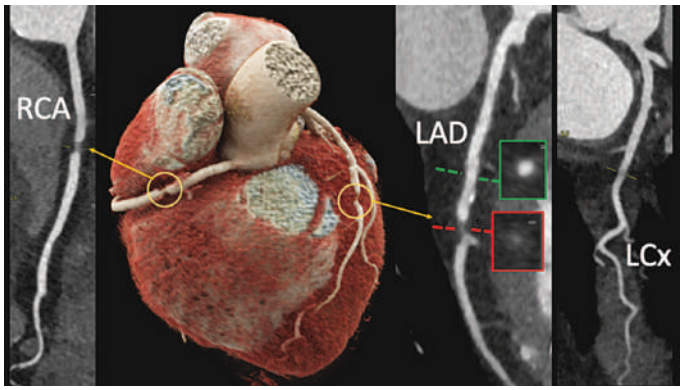


FIGURE 284-3 (Continued)

F

FIGURE 284-3 (Continued)

reason, methods for detecting coronary calcium have been developed as a measure of the presence of coronary atherosclerosis. These methods involve CT applications that achieve rapid acquisition of images (electron beam [EBCT] and multidetector [MDCT] detection). Coronary calcium detected by these imaging techniques most commonly is quantified by using the Agatston score, which is based on the area and density of calcification.

Coronary CT angiography (CCTA) (Fig. 284-3) is helpful in diagnosing the extent and severity of nonobstructive and obstructive IHD, as well as assessing plaque composition. Thus, CCTA is an attractive option when the pretest likelihood of IHD is intermediate in a young patient (< 65 years) with chest pain or less obstructive IHD is suspected. Stress imaging is the preferred diagnostic test when the goal is assessing the adequacy of ischemia-guided management.

CORONARY ARTERIOGRAPHY

(See also Chap. 249) This diagnostic method outlines the lumina of the coronary arteries and can be used to detect or exclude serious coronary obstruction. However, coronary arteriography provides no information about the arterial wall, and severe atherosclerosis that does not encroach on the lumen may go undetected. Of note, atherosclerotic plaques characteristically are scattered throughout the coronary tree, tend to occur more frequently at branch points, and grow progressively in the intima and media of an epicardial coronary artery at first without encroaching on the lumen, causing an outward bulging of the artery—a process referred to as remodeling. Later in the course of the disease, further growth causes luminal narrowing.

Indications The ISCHEMIA trial informs decision-making about referral for coronary arteriography (with intent to perform revascularization) in patients with stable IHD and an ejection fraction >35% even in the presence of moderate-severe ischemia on noninvasive functional testing. Over the course of 4 years of follow-up, early referral for an invasive strategy was not associated with a reduction in the risk of myocardial infarction or death but was more effective than an initial conservative, medical strategy in relieving angina. Thus, coronary arteriography is indicated in (1) patients with chronic stable angina pectoris who are severely symptomatic despite medical therapy and are

TABLE 284-2 Relation of Metabolic Equivalent Tasks (METs) to Stages in Various Testing Protocols

being considered for revascularization, i.e., a percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG); (2) patients with troublesome symptoms that present diagnostic difficulties in whom there is a need to confirm or rule out the diagnosis of IHD; (3) patients with known or possible angina pectoris who have survived cardiac arrest; and (4) patients with angina or evidence of ischemia on noninvasive testing with clinical or laboratory evidence of ventricular dysfunction.

Examples of other indications for coronary arteriography include the following:

1. Patients with chest discomfort suggestive of angina pectoris but a negative or nondiagnostic stress test who require a definitive diagnosis for guiding medical management, alleviating psychological stress, career or family planning, or insurance purposes.
2. Patients who have been admitted repeatedly to the hospital for a suspected acute coronary syndrome **(Chaps. 285 and 286)**, but in whom this diagnosis has not been established and in whom it is considered clinically important to determine the presence or absence of CAD.
3. Patients with careers that involve the safety of others (e.g., pilots, firefighters, police) who have questionable symptoms or suspicious or positive noninvasive tests and in whom there are reasonable doubts about the state of the coronary arteries.
4. Patients with aortic stenosis or hypertrophic cardiomyopathy and angina in whom the chest pain could be due to IHD.
5. Male patients >45 years and females >55 years who are to undergo a cardiac operation such as valve replacement or repair and who may or may not have clinical evidence of myocardial ischemia.
6. Patients after myocardial infarction, especially those who are at high risk after myocardial infarction because of the recurrence of angina or the presence of heart failure, frequent ventricular premature contractions, or signs of ischemia on the stress test.
7. Patients in whom coronary spasm or another nonatherosclerotic cause of myocardial ischemia (e.g., coronary artery anomaly, Kawasaki disease) is suspected.

Noninvasive alternatives to diagnostic coronary arteriography include CT angiography and CMR angiography **(Chap. 248)**. Important aspects of their use that should be noted include the substantially higher radiation exposure with CT angiography compared to conventional diagnostic arteriography and the limitations on CMR imposed by cardiac movement during the cardiac cycle, especially at high heart rates.

PROGNOSIS

The principal prognostic indicators in patients known to have IHD are age, the functional state of the left ventricle, the location(s) and severity of coronary artery narrowing, and the severity or activity of myocardial ischemia. Angina pectoris of recent onset, unstable angina **(Chap. 285)**, early postmyocardial infarction angina, angina that is unresponsive or poorly responsive to medical therapy, and angina accompanied by symptoms of congestive heart failure all indicate an increased risk for adverse coronary events. The same is true for the physical signs of heart failure, episodes of pulmonary edema, transient third heart sounds, and mitral regurgitation and for echocardiographic or radioisotopic (or roentgenographic) evidence of cardiac enlargement and reduced (<0.40) ejection fraction.

Most important, any of the following signs during noninvasive testing indicates a high risk for coronary events: inability to exercise for 6 min, i.e., stage II (Bruce protocol) of the exercise test; a strongly positive exercise test showing onset of myocardial ischemia at low workloads (≥0.1 mV ST-segment depression before completion of stage II, ≥0.2 mV ST-segment depression at any stage, ST-segment depression for >5 min after the cessation of exercise, a decline in systolic pressure >10 mmHg during exercise, or the development of ventricular tachyarrhythmias during exercise); the development of large or multiple perfusion defects or increased lung uptake during stress radioisotope perfusion imaging; and a decrease in LV ejection fraction during exercise on radionuclide ventriculography or during stress echocardiography. Conversely, patients who can complete stage III of the Bruce exercise protocol and have a normal stress perfusion scan or negative stress echocardiographic evaluation are at very low risk for future coronary events. The finding of frequent episodes of ST-segment deviation on ambulatory ECG monitoring (even in the absence of symptoms) is also an adverse prognostic finding.

On cardiac catheterization, elevations of LV end-diastolic pressure and ventricular volume and reduced ejection fraction are the most important signs of LV dysfunction and are associated with a poor prognosis. Patients with chest discomfort but normal LV function and normal coronary arteries have an excellent prognosis. Obstructive lesions of the left main (>50% luminal diameter) or left anterior descending coronary artery proximal to the origin of the first septal artery are associated with a greater risk than are lesions of the right or left circumflex coronary artery because of the greater quantity of myocardium at risk. Atherosclerotic plaques in epicardial arteries with fissuring or filling defects indicate increased risk. These lesions go through phases of inflammatory cellular activity, degeneration, endothelial dysfunction, abnormal vasomotion, platelet aggregation, and fissuring or hemorrhage. These factors can temporarily worsen the stenosis and cause thrombosis and/or abnormal reactivity of the vessel wall, thus exacerbating the manifestations of ischemia. The recent onset of symptoms, the development of severe ischemia during stress testing (see above), and unstable angina pectoris **(Chap. 285)** all reflect episodes of rapid progression in coronary lesions.

With any degree of obstructive CAD, mortality is greatly increased when LV function is impaired; conversely, at any level of LV function, the prognosis is influenced importantly by the quantity of myocardium perfused by critically obstructed vessels. Therefore, it is essential to collect all the evidence substantiating past myocardial damage (evidence of myocardial infarction on ECG, echocardiography, radioisotope imaging, or left ventriculography), residual LV function (ejection fraction and wall motion), and risk of future damage from coronary events (extent of coronary disease and severity of ischemia defined by noninvasive stress testing). The larger the quantity of established myocardial necrosis is, the less the heart is able to withstand additional damage and the poorer the prognosis. Risk estimation must include age, presenting symptoms, all risk factors, signs of arterial disease, existing cardiac damage, and signs of impending damage (i.e., ischemia).

The greater the number and severity of risk factors for coronary atherosclerosis (advanced age [>75 years], hypertension, dyslipidemia, diabetes, morbid obesity, accompanying peripheral and/or cerebrovascular disease, previous myocardial infarction), the worse the prognosis of an angina patient. Evidence exists that elevated levels of CRP in the plasma, extensive coronary calcification on EBCT (see above), and increased carotid intimal thickening on ultrasound examination also indicate an increased risk of coronary events.

TREATMENT

Stable Angina Pectoris

Once the diagnosis of IHD has been made, each patient must be evaluated individually with respect to their level of understanding, expectations and goals, control of symptoms, and prevention of adverse clinical outcomes such as myocardial infarction and premature death. The degree of disability and the physical and emotional stress that precipitates angina must be recorded carefully to set treatment goals. The management plan should include the following components: (1) explanation of the problem and reassurance about the ability to formulate a treatment plan, (2) identification and treatment of aggravating conditions, (3) recommendations for adaptation of activity as needed, (4) treatment of risk factors that will decrease the occurrence of adverse coronary outcomes, (5) drug therapy for angina, and (6) consideration of revascularization. Emphasis should be placed on a patient-centric, team-based approach to care, with recognition of the importance of social determinants of health.

EXPLANATION AND REASSURANCE

Patients with IHD need to understand their condition and realize that a long and productive life is possible even though they have angina pectoris or have experienced and recovered from an acute

myocardial infarction. Offering results of clinical trials showing improved outcomes can be of great value in encouraging patients to resume or maintain activity and return to work. A planned program of rehabilitation can encourage patients to lose weight, improve exercise tolerance, and control risk factors with more confidence.

IDENTIFICATION AND TREATMENT OF AGGRAVATING CONDITIONS

A number of conditions may increase oxygen demand or decrease oxygen supply to the myocardium and may precipitate or exacerbate angina in patients with IHD. LVH, aortic valve disease, and hypertrophic cardiomyopathy may cause or contribute to angina and should be excluded or treated. Obesity, hypertension, and hyperthyroidism should be treated aggressively to reduce the frequency and severity of anginal episodes. Decreased myocardial oxygen supply may be due to reduced oxygenation of the arterial blood (e.g., in pulmonary disease or, when carboxyhemoglobin is present, due to cigarette or cigar smoking) or decreased oxygen-carrying capacity (e.g., in anemia). Correction of these abnormalities, if present, may reduce or even eliminate angina pectoris.

ADAPTATION OF ACTIVITY

Myocardial ischemia is caused by a discrepancy between the demand of the heart muscle for oxygen and the ability of the coronary circulation to meet that demand. Most patients can be helped to understand this concept and utilize it in the rational programming of activity. Many tasks that ordinarily evoke angina may be accomplished without symptoms simply by reducing the speed at which they are performed. Patients must appreciate the diurnal variation in their tolerance of certain activities and reducing their energy requirements in the morning, immediately after meals, and in cold or inclement weather. On occasion, it may be necessary to recommend a change in employment or residence to avoid physical stress.

Physical conditioning usually improves the exercise tolerance of patients with angina and has substantial psychological benefits. A regular program of isotonic exercise that is within the limits of the individual patient's threshold for the development of angina pectoris and that does not exceed 80% of the heart rate associated with ischemia on exercise testing should be strongly encouraged. Based on the results of an exercise test, the number of metabolic equivalent tasks (METs) performed at the onset of ischemia can be estimated (Table 284-2) and a practical exercise prescription can be formulated to permit daily activities that will fall below the ischemic threshold **(Table 284-3)**.

TREATMENT OF RISK FACTORS

A *family history* of premature IHD is an important indicator of increased risk and should trigger a search for treatable risk factors such as hyperlipidemia, hypertension, and diabetes mellitus. *Obesity* impairs the treatment of other risk factors and increases the risk of adverse coronary events. In addition, obesity often is accompanied by three other risk factors: diabetes mellitus, hypertension, and hyperlipidemia. The treatment of obesity and these accompanying risk factors is an important component of any management plan. A diet low in saturated and *trans*-unsaturated fatty acids and a reduced caloric intake to achieve optimal body weight are a cornerstone in the management of chronic IHD. It is especially important to emphasize weight loss and regular exercise in patients with the metabolic syndrome or overt diabetes mellitus.

Cigarette smoking accelerates coronary atherosclerosis in both sexes and at all ages and increases the risk of thrombosis, plaque instability, myocardial infarction, and death. In addition, by increasing myocardial oxygen needs and reducing oxygen supply, it aggravates angina. Smoking cessation studies have demonstrated important benefits with a significant decline in the occurrence of these adverse outcomes. Noncombustible tobacco in the form of electronic cigarettes (nicotine delivery systems) may also increase the frequency of anginal episodes. The physician's message must be clear and strong and supported by programs that achieve and monitor abstinence from all tobacco product use **(Chap. 465)**.

TABLE 284-3 Energy Requirements for Some Common Activities

LESS THAN 3 METs	3–5 METs	5–7 METs	7–9 METs	MORE THAN 9 METs
Self-Care				
Washing/shaving	Cleaning windows	Easy digging in garden	Heavy shoveling	Carrying loads upstairs (objects >90 lb)
Dressing	Raking	Level hand lawn mowing	Carrying objects (60–90 lb)	Climbing stairs (quickly)
Light housekeeping	Power lawn mowing	Carrying objects (30–60 lb)		Shoveling heavy snow
Desk work	Bed making/stripping			
Driving auto	Carrying objects (15–30 lb)			
Occupational				
Sitting (clerical/assembly)	Stocking shelves (light objects)	Carpentry (exterior)	Digging ditches (pick and shovel)	Heavy labor
Desk work	Light welding/carpentry	Shoveling dirt		
Standing (store clerk)		Sawing wood		
Recreational				
Golf (cart)	Dancing (social)	Tennis (singles)	Canoeing	Squash
Knitting	Golf (walking)	Snow skiing (downhill)	Mountain climbing	Ski touring

Hypertension **(Chap. 288)** may coexist with other risk factors for IHD and is associated with an increased risk of adverse clinical events from coronary atherosclerosis as well as stroke. In addition, the LVH that results from sustained hypertension aggravates ischemia. There is evidence that long-term effective treatment of hypertension can decrease the occurrence of adverse coronary events **(Chap. 288)**.

Diabetes mellitus **(Chap. 415)** accelerates coronary, cerebrovascular, and peripheral atherosclerosis and is frequently associated with dyslipidemia and increases in the risk of angina, myocardial infarction, and sudden coronary death. Aggressive control of the dyslipidemia (target LDL cholesterol <70 mg/dL) and hypertension (blood pressure <130/80 mmHg), that are frequently found in patients with diabetes mellitus, is highly effective and therefore essential, as described below. Use of either a sodium-glucose cotransporter 2 (SGLT-2) inhibitor or glucagon-like peptide 1 (GLP-1) receptor agonist in patients with IHD and type 2 diabetes is recommended in current guidelines to reduce the risk of major adverse cardiovascular events.

DYSLIPIDEMIA

The treatment of dyslipidemia is central in aiming for long-term relief from angina, reduced need for revascularization, and reduction in myocardial infarction and death. The control of lipids can be achieved by the combination of a diet low in saturated and *trans*-unsaturated fatty acids, exercise, and weight loss. Nearly always, HMG-CoA reductase inhibitors (statins) are required and can lower LDL cholesterol (25–50%), raise HDL cholesterol (5–9%), and lower triglycerides (5–30%). A powerful treatment effect of statins on atherosclerosis, IHD, and outcomes is seen regardless of the pretreatment LDL cholesterol level. In patients with IHD on a maximally tolerated statin with an LDL cholesterol ≥70 mg/dL, addition of ezetimibe is recommended as the next step, followed by a PCSK9 inhibitor (in patients at very high risk) should the LDL cholesterol goal not be achieved. When these therapies are not sufficient or tolerated, bempedoic acid may be considered for further LDL cholesterol reduction. Icosapent ethyl (purified eicosapentaenoic acid), fibrates, and resin-binding agents can be used to lower triglycerides **(Chap. 419)**, but only icosapent ethyl has been shown to reduce cardiovascular risk in the statin era. Controlled trials with lipid-regulating regimens have shown equal proportional benefit for men, women, the elderly, patients with diabetes mellitus, and smokers. Evidence exists that a high rate of control of LDL over time is associated with a lower cumulative LDL exposure and lower rate of major adverse cardiovascular events.

Compliance with the health-promoting behaviors listed above is generally very poor, and a conscientious physician must not underestimate the major effort required to meet this challenge. Many patients who are discharged from the hospital with proven coronary disease do not receive adequate treatment for dyslipidemia. In light of the proof that treating dyslipidemia brings major benefits, physicians need to establish treatment pathways, monitor compliance, and follow up regularly.

RISK REDUCTION IN WOMEN WITH IHD

The incidence of clinical IHD in premenopausal women is very low; however, after menopause, the atherogenic risk factors increase (e.g., increased LDL) and the rate of clinical coronary events accelerates to the levels observed in men. Diabetes mellitus, which is more common in women, greatly increases the occurrence of clinical IHD and amplifies the deleterious effects of hypertension, hyperlipidemia, and smoking. Cardiac catheterization and coronary revascularization are underused in women and are performed at a later and more severe stage of the disease than in men. When cholesterol lowering, beta blockers after myocardial infarction, and CABG are applied in the appropriate patient groups, women benefit to the same degree as men.

DRUG THERAPY

The commonly used drugs for the treatment of angina pectoris are summarized in **Tables 284-4 through 284-6**. Pharmacotherapy for IHD is designed to reduce the frequency of anginal episodes, myocardial infarction, and coronary death. Trial data emphasize how important medical management is when added to the health-promoting behaviors discussed above. To achieve maximum benefit from medical therapy for IHD, it is frequently necessary to combine agents from different classes and titrate the doses as guided by the individual profile of risk factors, symptoms, hemodynamic responses, and side effects.

TABLE 284-4 Nitrate Therapy in Patients with Ischemic Heart Disease

PREPARATION OF AGENT	DOSE	SCHEDULE
Nitroglycerin[a]		
Ointment	0.5–2 in.	Two or three times daily
Transdermal patch	0.2–0.8 mg/h	Every 24 h; remove at bedtime for 12–14 h
Sublingual tablet	0.3–0.6 mg	As needed, up to three doses 5 min apart
Spray	One or two sprays	As needed, up to three doses 5 min apart
Isosorbide dinitrate[a]		
Oral	10–40 mg	Two or three times daily
Oral sustained release	80–120 mg	Once or twice daily (eccentric schedules)
Isosorbide 5-mononitrate		
Oral	20 mg	Twice daily (given 7–8 h apart)
Oral sustained release	30–240 mg	Once daily

[a]A 10- to 12-h nitrate-free interval is recommended.

NITRATES

The organic nitrates are a valuable class of drugs in the management of angina pectoris (Table 284-4). Their major mechanisms of action include systemic venodilation with concomitant reduction in LV end-diastolic volume and pressure, thereby reducing myocardial wall tension and oxygen requirements; dilation of epicardial coronary vessels; and increased blood flow in collateral vessels. When metabolized, organic nitrates release nitric oxide (NO) that binds to guanylyl cyclase in vascular smooth muscle

TABLE 284-5 Properties of Beta Blockers in Clinical Use for Ischemic Heart Disease

DRUGS	SELECTIVITY	PARTIAL AGONIST ACTIVITY	USUAL DOSE FOR ANGINA
Acebutolol	β_1	Yes	200–600 mg twice daily
Atenolol	β_1	No	50–200 mg/d
Betaxolol	β_1	No	10–20 mg/d
Bisoprolol	β_1	No	10 mg/d
Esmolol (intravenous)[a]	β_1	No	50–300 μg/kg/min
Labetalol[b]	None	Yes	200–600 mg twice daily
Metoprolol	β_1	No	50–200 mg twice daily
Nadolol	None	No	40–80 mg/d
Nebivolol	β_1 (at low doses)	No	5–40 mg/d
Pindolol	None	Yes	2.5–7.5 mg 3 times daily
Propranolol	None	No	80–120 mg twice daily
Timolol	None	No	10 mg twice daily

[a]Esmolol is an ultra-short-acting beta blocker that is administered as a continuous intravenous infusion. Its rapid offset of action makes esmolol an attractive agent to use in patients with relative contraindications to beta blockade. [b]Labetolol is a combined alpha and beta blocker.

Note: This list of beta blockers that may be used to treat patients with angina pectoris is arranged alphabetically. It is preferable to use a sustained-release formulation that may be taken once daily to improve the patient's compliance with the regimen.

Source: Data from RJ Gibbons et al: J Am Coll Cardiol 41:159, 2003.

TABLE 284-6 Calcium Channel Blockers in Clinical Use for Ischemic Heart Disease

DRUGS	USUAL DOSE	DURATION OF ACTION	SIDE EFFECTS
Dihydropyridines			
Amlodipine	5–10 mg qd	Long	Headache, edema
Felodipine	5–10 mg qd	Long	Headache, edema
Isradipine	2.5–10 mg bid	Medium	Headache, fatigue
Nicardipine	20–40 mg tid	Short	Headache, dizziness, flushing, edema
Nifedipine	Immediate release:[a] 30–90 mg daily orally Slow release: 30–180 mg orally	Short	Hypotension, dizziness, flushing, nausea, constipation, edema
Nisoldipine	20–40 mg qd	Short	Similar to nifedipine
Nondihydropyridines			
Diltiazem	Immediate release: 30–80 mg 4 times daily Slow release: 120–320 mg qd	Short Long	Hypotension, dizziness, flushing, bradycardia, edema
Verapamil	Immediate release: 80–160 mg tid Slow release: 120–480 mg qd	Short Long	Hypotension, myocardial depression, heart failure, edema, bradycardia

[a]May be associated with increased risk of mortality if administered during acute myocardial infarction.

Note: This list of calcium channel blockers that may be used to treat patients with angina pectoris is divided into two broad classes, dihydropyridines and nondihydropyridines, and arranged alphabetically within each class. Among the dihydropyridines, the greatest clinical experience has been obtained with amlodipine and nifedipine. After the initial period of dose titration with a short-acting formulation, it is preferable to switch to a sustained-release formulation that may be taken once daily to improve patient compliance with the regimen.

cells, leading to an increase in cyclic guanosine monophosphate, which causes relaxation of vascular smooth muscle. Nitrates also exert antithrombotic activity by NO-dependent activation of platelet guanylyl cyclase, impairment of intraplatelet calcium flux, and platelet activation.

The absorption of these agents is rapid and complete through mucous membranes. For this reason, nitroglycerin is most commonly administered sublingually in tablets of 0.4 or 0.6 mg. Patients with angina should be instructed to take the medication both to relieve angina and also ~5 min before activities that are likely to induce an episode.

Nitrates improve exercise tolerance in patients with chronic angina and relieve ischemia in patients with unstable angina as well as patients with vasospastic variant angina **(Chap. 285)**. A diary of angina and nitroglycerin use may be valuable for detecting changes in the frequency, severity, or threshold for discomfort that may signify the development of unstable angina pectoris and/or herald an impending myocardial infarction.

Long-Acting Nitrates None of the long-acting nitrates is as effective as sublingual nitroglycerin for the acute relief of angina. These organic nitrate preparations can be swallowed, chewed, or administered as a patch or paste by the transdermal route (Table 284-4). They provide effective plasma levels for up to 24 h, but the therapeutic response is highly variable. Different preparations and/or administration during the daytime should be tried only to prevent discomfort while avoiding side effects such as headache and dizziness. Individual dose titration is important to prevent side effects. To minimize the effects of nitrate tolerance, the minimum effective dose should be used and a minimum of 8 h each day kept free of the drug to restore any useful response(s).

Beta-Adrenergic Blockers These drugs represent an important component of the pharmacologic treatment of angina pectoris (Table 284-5). They reduce myocardial oxygen demand by inhibiting the increases in heart rate, arterial pressure, and myocardial contractility caused by adrenergic activation. Beta blockade reduces these variables most strikingly during exercise but causes only small reductions at rest. Long-acting beta-blocking drugs or sustained-release formulations offer the advantage of once-daily dosing (Table 284-5). The therapeutic aims include relief of angina and ischemia. These drugs also can reduce mortality and reinfarction rates in patients after myocardial infarction and are moderately effective antihypertensive agents. Use of beta blockers beyond 1 year after myocardial infarction may be reassessed in the absence of LV systolic dysfunction, angina, arrhythmias, or uncontrolled hypertension, as their long-term benefit in such patients is unclear.

Relative contraindications include asthma and reversible airway obstruction in patients with chronic lung disease, atrioventricular conduction disturbances, severe bradycardia, Raynaud's phenomenon, and a history of mental depression. Side effects include fatigue, reduced exercise tolerance, nightmares, impotence, cold extremities, intermittent claudication, bradycardia (sometimes severe), impaired atrioventricular conduction, LV failure, bronchial asthma, worsening claudication, and intensification of the hypoglycemia produced by oral hypoglycemic agents and insulin. Reducing the dose or even discontinuation may be necessary if these side effects develop and persist. Since sudden discontinuation can intensify ischemia, the doses should be tapered over 2 weeks. Beta blockers with relative β_1-receptor specificity such as metoprolol and atenolol may be preferable in patients with mild bronchial obstruction and insulin-requiring diabetes mellitus.

Calcium Channel Blockers Calcium channel blockers (Table 284-6) are coronary vasodilators that produce variable and dose-dependent reductions in myocardial oxygen demand, contractility, and arterial pressure. These combined pharmacologic effects are advantageous and make these agents as effective as beta blockers in the treatment of angina pectoris. They are indicated when beta blockers are contraindicated, poorly tolerated, or ineffective. Because of differences in the dose-response relationship on cardiac electrical activity between the dihydropyridine and nondihydropyridine calcium channel blockers, verapamil and diltiazem may produce symptomatic disturbances in cardiac conduction and bradyarrhythmias. They also exert negative inotropic actions and are more likely to aggravate LV failure, particularly when used in patients with LV dysfunction, especially if the patients are also receiving beta blockers. Although useful effects usually are achieved when calcium channel blockers are combined with beta blockers and nitrates, individual titration of the doses is essential with these combinations. Vasospastic angina responds particularly well to calcium channel blockers (especially members of the dihydropyridine class), supplemented when necessary by nitrates **(Chap. 285)**.

Verapamil ordinarily should not be combined with beta blockers because of the combined adverse effects on heart rate and contractility. Diltiazem can be combined with beta blockers in patients with normal ventricular function and no conduction disturbances. Amlodipine and beta blockers have complementary actions on coronary blood supply and myocardial oxygen demands. Whereas the former decreases blood pressure and dilates coronary arteries, the latter slows heart rate and decreases contractility. Amlodipine and the other second-generation dihydropyridine calcium antagonists (nicardipine, isradipine, long-acting nifedipine, and felodipine) are potent vasodilators and are useful in the simultaneous treatment of angina and hypertension. Short-acting dihydropyridines should be avoided because of the risk of precipitating infarction, particularly in the absence of concomitant beta blocker therapy.

Choice Between Beta Blockers and Calcium Channel Blockers for Initial Therapy Since beta blockers have been shown to improve life expectancy after acute myocardial infarction **(Chaps. 285 and 286)** and calcium channel blockers have not, the former may also be preferable in patients with angina and a damaged left ventricle. However, calcium channel blockers are indicated in patients with the following: (1) inadequate responsiveness to the combination of beta blockers and nitrates; many of these patients do well with a combination of a beta blocker and a dihydropyridine calcium channel blocker; (2) adverse reactions to beta blockers such as depression, sexual disturbances, and fatigue; (3) angina and a history of asthma or chronic obstructive pulmonary disease; (4) sick-sinus syndrome or significant atrioventricular conduction disturbances; (5) vasospastic angina; or (6) symptomatic peripheral arterial disease.

Ranolazine, a piperazine derivative, may be useful for patients with chronic angina despite standard medical therapy **(Table 284-7)**. Its antianginal action is believed to occur via inhibition of the late inward sodium current (I_{Na}). The benefits of I_{Na} inhibition include limitation of the Na overload of ischemic myocytes and prevention of Ca^{2+} overload via the Na^+–Ca^{2+} exchanger. A dose of 500–1000 mg orally twice daily is usually well tolerated. Ranolazine is contraindicated in patients with hepatic impairment or with conditions or drugs associated with QT_c prolongation, and when drugs that inhibit the CYP3A metabolic system (e.g., ketoconazole, diltiazem, verapamil, macrolide antibiotics, HIV protease inhibitors, and large quantities of grapefruit juice) are being used.

A comparison of the common side effects, contraindications, and potential drug interactions of many of the frequently presented antianginal agents is shown in Table 284-7.

Antiplatelet Drugs Aspirin is an irreversible inhibitor of platelet cyclooxygenase and thereby interferes with platelet activation. Chronic administration of 75–325 mg orally per day has been shown to reduce coronary events in asymptomatic adult men over age 50, patients with chronic stable angina, and patients who have or have survived unstable angina and myocardial infarction. There is a dose-dependent increase in bleeding when aspirin is used chronically. It is preferable to use an enteric-coated formulation in the range of 75–162 mg/d. Administration of this drug should be considered in all patients with IHD in the absence of gastrointestinal bleeding, allergy, or dyspepsia. Clopidogrel (300–600 mg loading and 75 mg/d) is an oral agent that blocks $P2Y_{12}$ ADP receptor–mediated platelet aggregation. It provides benefits similar to those of aspirin in patients with stable chronic IHD and may be substituted for aspirin if aspirin causes the side effects listed above. Clopidogrel combined with aspirin reduces death and coronary ischemic events in patients with an acute coronary syndrome **(Chap. 285)** and also reduces the risk of thrombus formation in patients undergoing implantation of a stent in a coronary artery **(Chap. 287)**. Alternative antiplatelet agents that block the $P2Y_{12}$ platelet receptor such as prasugrel and ticagrelor have been shown to be more effective than clopidogrel for prevention of ischemic events after placement of a stent for an acute coronary syndrome but are associated with an increased risk of bleeding. Although combined treatment with clopidogrel and aspirin for at least a year is recommended in patients with an acute coronary syndrome treated with implantation of a drug-eluting stent, studies have not shown any benefit from the routine addition of clopidogrel to aspirin in patients with chronic stable IHD.

OTHER THERAPIES

ACE inhibitors and ARBs are widely used in the treatment of survivors of myocardial infarction, patients with hypertension or chronic IHD including angina pectoris, and those at high risk of vascular diseases such as diabetes. The benefits of ACE inhibitors and ARBs are most evident in IHD patients at increased risk, especially if diabetes mellitus or LV dysfunction is present, and those who have not achieved adequate control of blood pressure and LDL cholesterol on beta blockers and statins. However, the routine administration of ACE inhibitors or ARBs to IHD patients who have normal LV function and have achieved blood pressure and LDL goals on other therapies does not reduce the incidence of events and therefore is not cost-effective.

Despite treatment with nitrates, beta blockers, calcium channel blockers, and ranolazine, some patients with IHD continue to experience angina, and additional medical therapy is now available to alleviate their symptoms.

Originally introduced for the management of diabetes mellitus, the SGLT-2 inhibitor drugs have emerged as important agents with cardiovascular and renal protective effects. They promote weight loss, lower blood pressure, and reduce plasma volume—all of which are desirable in patients with IHD. In addition, they decrease

TABLE 284-7 Antianginal Agents

AGENT	COMMON SIDE EFFECTS	CONTRAINDICATIONS	POTENTIAL DRUG INTERACTIONS
Agents That Have a Physiologic Effect			
Short-acting and long-acting nitrates	Headache, flushing, hypotension, syncope and postural hypotension, reflex tachycardia, methemoglobinemia	Hypertrophic obstructive cardiomyopathy	Phosphodiesterase type 5 inhibitors (sildenafil and similar agents), beta-adrenergic blockers, calcium channel blockers
Beta blockers	Fatigue, depression, bradycardia, heart block, bronchospasm, peripheral vasoconstriction, postural hypotension, impotence, masked signs of hypoglycemia	Low heart rate or heart conduction disorder, cardiogenic shock, asthma, severe peripheral vascular disease, decompensated heart failure, vasospastic angina; use with caution in patients with COPD (cardioselective beta blockers may be used if patient receives adequate treatment with long-acting beta agonists)	Heart rate–lowering calcium channel blockers, sinus node or AV conduction depressors
Calcium-channel blockers			
Heart rate–lowering agents	Bradycardia, heart conduction defect, low ejection fraction, constipation, gingival hyperplasia	Cardiogenic shock, severe aortic stenosis, obstructive cardiomyopathy	CYP3A4 substrates (digoxin, simvastatin, cyclosporine)
Dihydropyridine	Headache, ankle swelling fatigue, flushing, reflex tachycardia	Low heart rate or heart rhythm disorder, sick-sinus syndrome, congestive heart failure, low blood pressure	Agents with cardiodepressant effects (beta blockers, flecainide), CYP3A4 substrates
Agents That Affect Myocardial Metabolism			
Ranolazine	Dizziness, constipation, nausea, QT interval prolongation	Liver cirrhosis	CYP3A4 substrates (digoxin, simvastatin, cyclosporine), drugs that prolong the corrected QT interval

Abbreviations: AV, atrioventricular; COPD, chronic obstructive pulmonary disease; CYP3A4, cytochrome P450 3A4.

Source: Data from SE Husted: Lancet 386:691, 2015, and EM Ohman: N Engl J Med 374:1167, 2016.

intraglomerular hypertension and hyperfiltration. Evidence exists that they are helpful in patients with and without diabetes who have a reduced LV ejection fraction.

Colchicine exhibits a number of broad cellular effects (interferes with chemotaxis and phagocytosis of inflammatory cells, reduces the expression of adhesion molecules, modifies cytokine production) that result in an anti-inflammatory effect and may favorably affect the progression of atherosclerosis. In placebo-controlled randomized trials after myocardial infarction, low-dose colchicine (0.5 mg daily) prevented future cardiovascular events; however because it has a narrow therapeutic window, has a long half-life dependent upon renal clearance, is metabolized by CYP3A4, and is a substrate for P-glycoprotein (both of which that may result in drug-drug interactions), additional monitoring is required.

In contrast, nonsteroidal anti-inflammatory drug (NSAID) use in patients with IHD may be associated with a small but finite increased risk of myocardial infarction and mortality. For this reason, they generally should be avoided in IHD patients. If they are required for symptom relief, it is advisable to coadminister aspirin and strive to use an NSAID associated with the lowest risk of cardiovascular events, in the lowest dose required, and for the shortest period of time.

Nicorandil opens ATP-sensitive potassium channels in myocytes, leading to a reduction of free intracellular calcium ions. It is typically administered orally in a dose of 20 mg twice daily for prevention of angina. Nicorandil is not available for use in the United States but is used in several other countries and is recommended as second-line treatment in the European chronic coronary disease (CCD) guidelines. Similarly, trimetazidine, which improves mitochondrial metabolism through inhibition of myocardial fatty acid uptake and oxidation and consequent stimulation of glucose oxidation, is recommended as a second-line antianginal in CCD and is available in many countries outside the United States.

Ivabradine (2.5–7.5 mg orally twice daily) is a specific sinus node inhibiting agent that may be helpful for preventing cardiovascular events in patients with IHD who have a resting heart rate ≥70 beats/min (alone or in combination with a beta blocker) *and* LV systolic dysfunction. However, the data are mixed regarding its clinical benefit, with the most recent U.S. CCD guideline recommending against its use in patients with normal LV function due to an increased risk of death or myocardial infarction).

Angina and Heart Failure Transient LV failure with angina can be controlled by the use of nitrates. For patients with established congestive heart failure, the increased LV wall tension raises myocardial oxygen demand. See **Chap. 265** for the "pillars" of treatment for heart failure. Treatment of congestive heart failure **(Chap. 264)** reduces heart size, wall tension, and myocardial oxygen demand, which helps control angina and ischemia. If the symptoms and signs of heart failure are controlled, an effort should be made to use beta blockers not only for angina but because trials in heart failure have shown significant improvement in survival. A trial of the intravenous ultra-short-acting beta blocker esmolol may be useful to establish the safety of beta blockade in selected patients. Nocturnal angina often can be relieved by the treatment of heart failure.

The combination of congestive heart failure and angina in patients with IHD usually indicates a poor prognosis and warrants serious consideration of cardiac catheterization and coronary revascularization.

CORONARY REVASCULARIZATION

Clinical trials have confirmed that with the initial diagnosis of stable IHD, it is first appropriate to initiate a medical regimen as described above. Revascularization should be considered in the presence of unstable phases of the disease, intractable symptoms, high-risk coronary anatomy, diabetes, and impaired LV function. *Revascularization should be employed in conjunction with but not replace the continuing need to modify risk factors and assess medical therapy.* An algorithm for integrating medical therapy and revascularization options in patients with IHD is shown in **Fig. 284-4**.

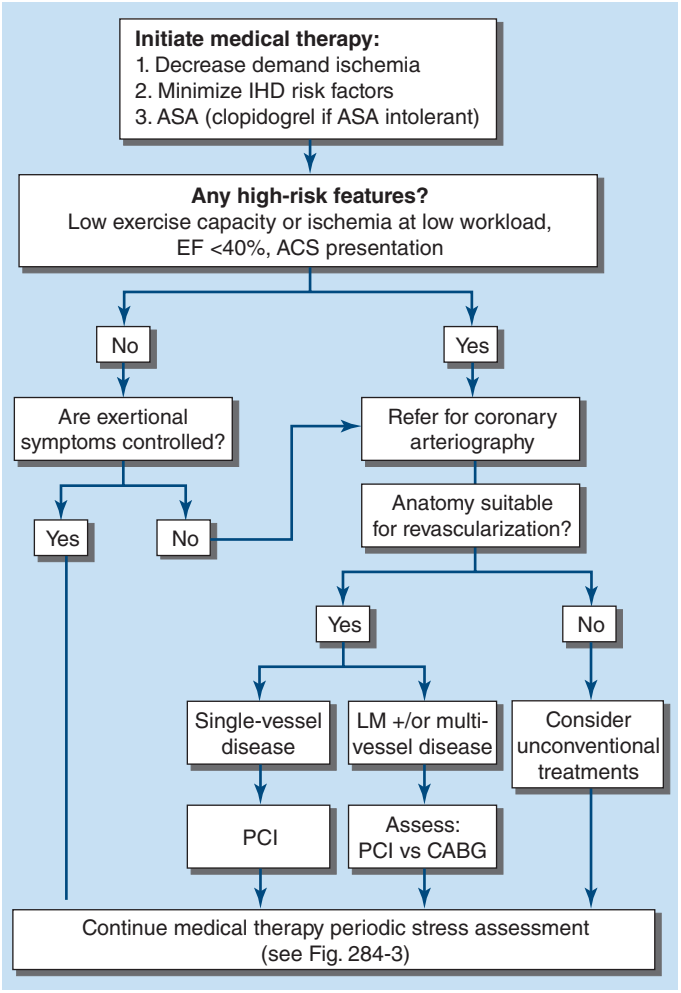

FIGURE 284-4 Algorithm for management of a patient with ischemic heart disease. All patients should receive the core elements of medical therapy as shown at the top of the algorithm. If high-risk features are present, as established by the clinical history, exercise test data, and imaging studies, the patient should be referred for coronary arteriography. Based on the number and location of the diseased vessels and their suitability for revascularization, the patient is treated with a percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery or should be considered for unconventional treatments. See text for further discussion. ACS, acute coronary syndrome; ASA, aspirin; EF, ejection fraction; IHD, ischemic heart disease; LM, left main.

PERCUTANEOUS CORONARY INTERVENTION

(See also Chap. 287) PCI involving balloon dilatation usually accompanied by coronary stenting is widely used to achieve revascularization of the myocardium in patients with symptomatic IHD and suitable stenoses of epicardial coronary arteries. Whereas patients with stenosis of the left main coronary artery and those with three-vessel IHD (especially with diabetes and/or impaired LV function) who require revascularization are best treated with CABG, PCI is widely employed in patients with symptoms and evidence of ischemia due to stenoses of one or two vessels and even in selected patients with three-vessel disease (and, perhaps, in some patients with left main disease) and may offer many advantages over surgery.

Indications and Patient Selection The most common clinical indication for PCI is symptom-limiting angina pectoris, despite medical therapy, accompanied by evidence of ischemia during a stress test. PCI is more effective than medical therapy for the relief of angina. PCI improves outcomes in patients with unstable angina or when used early in the course of myocardial infarction with and without cardiogenic shock. However, in patients with stable exertional angina, clinical trials

have confirmed that PCI does not reduce the occurrence of death or myocardial infarction compared to optimum medical therapy. PCI can be used to treat stenoses in native coronary arteries as well as in bypass grafts in patients who have recurrent angina after CABG.

Risks When coronary stenoses are discrete and symmetric, two and even three vessels can be treated in sequence. However, case selection is essential to avoid a prohibitive risk of complications, which are usually due to dissection or thrombosis with vessel occlusion, uncontrolled ischemia, and ventricular failure **(Chap. 287)**. Oral aspirin, a $P2Y_{12}$ antagonist, and an antithrombin agent are given to reduce coronary thrombus formation. Left main coronary artery stenosis generally is regarded as a lesion that should be treated with CABG. In selected cases such as patients with prohibitive surgical risks, PCI of an unprotected left main can be considered, but such a procedure should be performed only by a highly skilled operator; importantly, there are regional differences in the use of this approach internationally.

Efficacy Primary success, with relief of angina, is achieved in >95% of cases. In diseased vein grafts, procedural success has been improved by the use of an embolic protection device, when feasible, to prevent ischemia and infarction. The use of current-generation drug-eluting stents that locally deliver antiproliferative drugs have a lower rate of restenosis (<5%) than the initial bare metal stents and are now the standard of care in PCI. Of note, however, the delayed endothelial healing in the region of a drug-eluting stent also extends the period during which the patient is at risk for subacute stent thrombosis. Aspirin should be administered indefinitely and a $P2Y_{12}$ antagonist daily (dual antiplatelet therapy [DAPT]) ideally for 1 year after implantation of a drug-eluting stent. Evidence exists of a benefit of continuing DAPT for up to 30 months, albeit at the cost of a higher risk of bleeding. Shorter courses of DAPT may be used in patients who are at high bleeding risk **(see Chap. 69)** or who have a long-term indication for oral anticoagulation **(see Chap. 121)**.

Efforts are underway to develop new antithrombotic regimens to reduce the risk of bleeding. These include (1) shortening the duration of DAPT by eliminating aspirin after 1 or 3 months and continuing a $P2Y_{12}$ antagonist alone, (2) de-escalating from a potent $P2Y_{12}$ inhibitor (i.e., prasugrel, ticagrelor) after 1 month to clopidogrel or reduced-dose prasugrel 5 mg daily, and (3) switching from DAPT to dual pathway inhibition with an antiplatelet agent and a low-dose direct oral anticoagulant. While each of these has been compared to standard DAPT regimens, such studies tend to be unpowered for ischemic events, and these alternative strategies have not been compared to one another.

When a situation arises in which temporary discontinuation of antiplatelet therapy is necessary, the clinical circumstances should be reviewed with the operator who performed the PCI and a coordinated plan should be established for minimizing the risk of late stent thrombus; central to this plan is the discontinuation of antiplatelet therapy for the shortest acceptable period. The risk of stent thrombosis is dependent on stent size and length, complexity of the lesions, age, diabetes, and technique. However, compliance with DAPT and individual responsiveness to platelet inhibition are very important factors as well.

Successful PCI produces effective relief of angina in >95% of cases. The majority of patients with symptomatic IHD who require revascularization can be treated initially by PCI. Successful PCI is less invasive and expensive than CABG and permits savings in the *initial* cost of care. Successful PCI avoids the risk of stroke associated with CABG surgery and allows earlier return to work and resumption of an active life. However, the early health-related and economic benefits of PCI are reduced over time because of the greater need for follow-up and the increased need for repeat procedures. When directly compared in patients with diabetes or three-vessel or left main CAD, CABG was superior to PCI in preventing major adverse cardiac or cerebrovascular events over a 12-month follow-up.

CORONARY ARTERY BYPASS GRAFTING

Anastomosis of one or both of the internal mammary arteries or a radial artery to the coronary artery distal to the obstructive lesion is the preferred procedure. For additional obstructions that cannot be bypassed by an artery, a section of a vein (usually the saphenous) is used to form a venous bypass conduit between the aorta and the coronary artery distal to the obstructive lesion.

Although some indications for CABG are controversial, certain areas of agreement exist:

1. The operation is relatively safe, with mortality rates <1% in patients without serious comorbid disease and normal LV function and when the procedure is performed by an experienced surgical team.
2. Intraoperative and postoperative mortality rates increase with the severity of ventricular dysfunction, comorbidities, age ≥80 years, and lack of surgical experience. The effectiveness and risk of CABG vary widely depending on case selection and the skill and experience of the surgical team.
3. Occlusion of *venous* grafts is observed in 10–20% of patients during the first postoperative year and in ~2% per year during 5- to 7-year follow-up and 4% per year thereafter. Long-term patency rates are considerably higher for internal mammary and radial artery implantations than for saphenous vein grafts. In patients with left anterior descending coronary artery obstruction, survival is better when coronary bypass involves the internal mammary artery rather than a saphenous vein. Graft patency and outcomes are improved by meticulous treatment of risk factors, particularly dyslipidemia.
4. Angina is abolished or greatly reduced in ~90% of patients after complete revascularization. Although this usually is associated with graft patency and restoration of blood flow, the pain may also have been alleviated as a result of infarction of the ischemic segment, denervation due to median sternotomy, or a placebo effect.
5. Survival may be improved by operation in patients with stenosis of the left main coronary artery as well as in patients with three- or two-vessel disease with significant obstruction of the proximal left anterior descending coronary artery. The survival benefit is greater in patients with abnormal LV function (ejection fraction <35). Survival *may* also be improved in the following patients: (a) patients with obstructive CAD who have survived sudden cardiac death or sustained ventricular tachycardia; (b) patients who have undergone previous CABG and have multiple saphenous vein graft stenoses, especially of a graft supplying the left anterior descending coronary artery; and (c) patients with recurrent stenosis after PCI and high-risk criteria on noninvasive testing.
6. Minimally invasive CABG through a small thoracotomy and/or off-pump surgery can reduce morbidity and shorten convalescence in suitable patients but does not appear to reduce significantly the risk of neurocognitive dysfunction postoperatively.
7. Among patients with type 2 diabetes mellitus and multivessel coronary disease, CABG surgery plus optimal medical therapy is superior to optimal medical therapy alone in preventing major cardiovascular events, a benefit mediated largely by a significant reduction in nonfatal myocardial infarction. The benefits of CABG are especially evident in patients with diabetes mellitus treated with an insulin-sensitizing strategy as opposed to an insulin-providing strategy. CABG has also been shown to be superior to PCI (including the use of drug-eluting stents) in preventing death, myocardial infarction, and repeat revascularization in patients with diabetes mellitus and multivessel IHD.

Indications for CABG usually are based on the severity of symptoms, coronary anatomy, and ventricular function. The ideal candidate has no other complicating disease and has troublesome or disabling angina that is not adequately controlled by medical therapy or does not tolerate medical therapy. Great symptomatic benefit can be anticipated if a patient wishes to lead a more active life and has severe stenoses of two or three epicardial coronary arteries with objective evidence of myocardial ischemia as a cause of the chest discomfort. Congestive heart failure and/or LV dysfunction, advanced age (≥80 years), reoperation, urgent need for surgery, and the presence of diabetes mellitus are all associated with a higher perioperative mortality rate.

LV dysfunction can be due to noncontractile or hypocontractile segments that are viable but are chronically ischemic (hibernating myocardium). As a consequence of chronic reduction in myocardial blood flow, these segments downregulate their contractile function.

They can be detected by using radionuclide scans of myocardial perfusion and metabolism, PET, cardiac MRI, or delayed scanning with thallium-201 or by improvement of regional functional impairment provoked by low-dose dobutamine. In such patients, revascularization improves myocardial blood flow, can return function, and can improve survival.

The Choice Between PCI and CABG All the clinical characteristics of each individual patient must be used to decide on the method of revascularization (e.g., LV function, diabetes, lesion complexity). A number of randomized clinical trials have compared PCI and CABG in patients with multivessel CAD who were suitable technically for both procedures. The redevelopment of angina requiring repeat coronary angiography and repeat revascularization is higher with PCI. This is a result of restenosis in the stented segment (a problem largely solved with drug-eluting stents) and the development of new stenoses in unstented portions of the coronary vasculature. It has been argued that PCI with stenting focuses on culprit lesions, whereas a bypass graft to the target vessel also provides a conduit around future culprit lesions proximal to the anastomosis of the graft to the native vessel **(Fig. 284-5)**. By contrast, stroke rates are lower with PCI.

Based on available evidence, it is now recommended that patients with lifestyle-limiting angina despite guideline-directed medical management and therapy be considered for coronary revascularization. Patients with single- or two-vessel disease with normal LV function and anatomically suitable lesions ordinarily are advised to undergo PCI **(Chap. 287)**. For patients who are poor candidates for surgery, it is reasonable to choose PCI over CABG to improve symptoms and reduce major adverse cardiac events.

In patients with left main disease associated with high-complexity CAD, CABG remains preferred to PCI to improve survival. Similarly, in patients with diabetes and multivessel disease involving the left anterior descending artery, CABG (with a left internal mammary conduit) is preferred over PCI, although in patients with low- or intermediate-complexity CAD, PCI may be considered.

Patients with three-vessel disease (or two-vessel disease that includes the proximal left descending coronary artery) and impaired global LV function (LV ejection fraction <50%) or diabetes mellitus and those with left main CAD or other lesions unsuitable for catheter-based procedures should be considered for CABG as the initial method of revascularization. In light of the complexity of the decision-making, it is desirable to have a multidisciplinary team, including a cardiologist and a cardiac surgeon in conjunction with the patient's primary care physician, provide input along with ascertaining the patient's preferences before committing to a particular revascularization option.

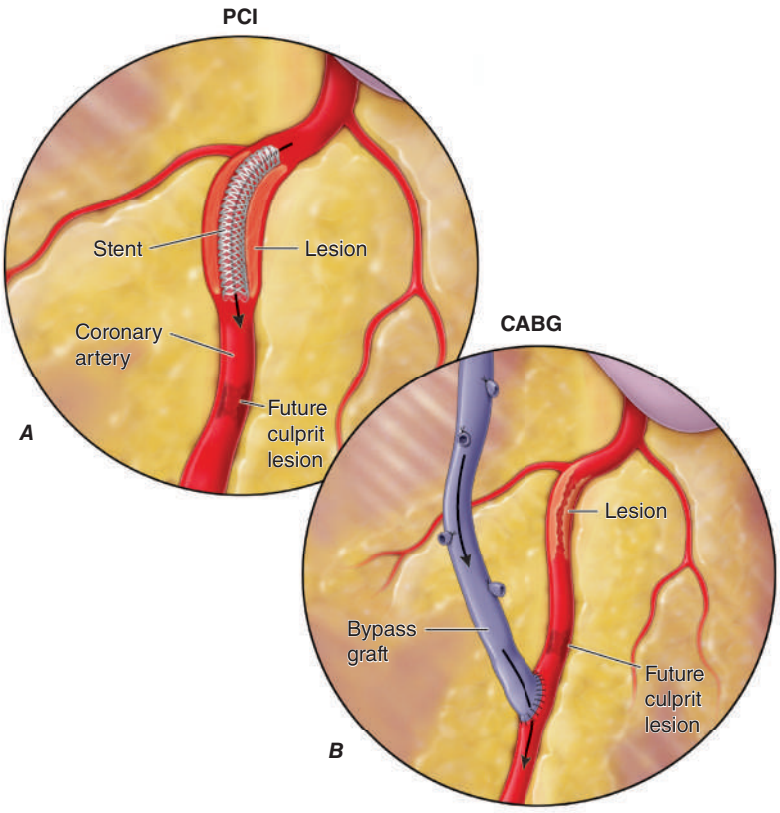

FIGURE 284-5 Difference in the approach to the lesion with percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG). PCI is targeted at the "culprit" lesion or lesions, whereas CABG is directed at the epicardial vessel, including the culprit lesion or lesions and future culprits, proximal to the insertion of the vein graft, a difference that may account for the superiority of CABG, at least in the intermediate term, in patients with multivessel disease. (*From The New England Journal of Medicine, Quantitative Determinants of the Outcome of Asymptomatic Mitral Regurgitation, M Enriquez-Sarano et al. 352, 2235. Copyright © 2005. UNCONVENTIONAL TREATMENTS FOR IHD

On occasion, clinicians will encounter a patient who has persistent, disabling angina despite maximally tolerated medical therapy and for whom revascularization is not an option (e.g., small diffusely diseased vessels not amenable to stent implantation or acceptable targets for bypass grafting). In such situations, unconventional treatments should be considered.

Enhanced external counterpulsation utilizes pneumatic cuffs on the lower extremities to provide diastolic augmentation and systolic unloading of blood pressure to decrease cardiac work and oxygen consumption while enhancing coronary blood flow. Clinical trials have shown that regular application improves angina, exercise capacity, and regional myocardial perfusion.

Neuromodulation (e.g., spinal cord simulation, transcutaneous or subcutaneous electrical neural stimulation, sympathectomy) and coronary sinus constriction (using a reducer device) have shown promise in small studies. Experimental approaches, such as stem cell therapies and cardiac repair with small noncoding RNA molecules (miRNA), are also under active study.

ASYMPTOMATIC (SILENT) ISCHEMIA

Obstructive CAD, acute myocardial infarction, and transient myocardial ischemia can occur in the absence of symptoms. During continuous ambulatory ECG monitoring, the majority of ambulatory patients with typical chronic stable angina are found to have objective evidence of myocardial ischemia (ST-segment depression) during episodes of chest discomfort while they are active outside the hospital. In addition, many of these patients also have more frequent episodes of asymptomatic ischemia. Frequent episodes of ischemia (symptomatic and asymptomatic) during daily life appear to be associated with an increased likelihood of adverse coronary events (death and myocardial infarction). In addition, patients with asymptomatic ischemia after a myocardial infarction are at greater risk for a second coronary event. The widespread use of exercise ECG during routine examinations has also identified some of these previously unrecognized patients with asymptomatic CAD. Longitudinal studies have demonstrated an increased incidence of coronary events in asymptomatic patients with positive exercise tests.

TREATMENT

Asymptomatic Ischemia

The management of patients with asymptomatic ischemia must be individualized. When coronary disease has been confirmed, the aggressive treatment of hypertension and dyslipidemia is essential and will decrease the risk of infarction and death. In addition, the physician should consider the following: (1) the degree of positivity

of the stress test, particularly the stage of exercise at which ECG signs of ischemia appear; the magnitude and number of the ischemic zones of myocardium on imaging; and the change in LV ejection fraction that occurs on radionuclide ventriculography or echocardiography during ischemia and/or during exercise; (2) the ECG leads showing a positive response, with changes in the anterior precordial leads indicating a less favorable prognosis than changes in the inferior leads; and (3) the patient's age, occupation, and general medical condition.

Most would agree that an asymptomatic 45-year-old commercial airline pilot with significant (0.4-mV) ST-segment depression in leads V_1 to V_4 during mild exercise should undergo coronary arteriography, whereas an asymptomatic, sedentary 85-year-old retiree with 0.1-mV ST-segment depression in leads II and III during maximal activity need not. However, there is no consensus about the most appropriate approach in the large majority of patients for whom the situation is less extreme. Asymptomatic patients with silent ischemia, three-vessel CAD, and impaired LV function may be considered appropriate candidates for CABG.

The treatment of risk factors, particularly lipid lowering and blood pressure control as described above, and the use of aspirin, statins, and beta blockers after infarction have been shown to reduce events and improve outcomes in asymptomatic as well as symptomatic patients with ischemia and proven CAD. Although the incidence of asymptomatic ischemia can be reduced by treatment with beta blockers, calcium channel blockers, and long-acting nitrates, it is not clear whether this is necessary or desirable in patients who have not had a myocardial infarction.

285 Non-ST-Segment Elevation Acute Coronary Syndrome (Non-ST-Segment Elevation Myocardial Infarction and Unstable Angina)

Robert P. Giugliano, Christopher P. Cannon, Eugene Braunwald

Patients with acute coronary syndrome (ACS) are commonly classified into two groups to facilitate evaluation and management, namely patients with acute myocardial infarction (MI) with ST-segment elevation (STEMI) on their presenting electrocardiogram (ECG) **(see Chap. 286)** and those with non-ST-segment elevation acute coronary syndrome (NSTE-ACS). The latter include patients with non-ST-segment elevation MI (NSTEMI), who, by definition, have evidence of myocyte necrosis, and those with unstable angina (UA), who do not **(Fig. 285-1)**.

The incidence of NSTEMI is rising due to the increasing burden of obesity, diabetes, and chronic kidney disease in an aging population and the increasing detection of myocardial necrosis by troponin (see below), whereas the incidence of STEMI is declining due to greater use of aspirin, statins, and less smoking. Among patients with NSTE-ACS, the proportion with NSTEMI is increasing while that with UA is falling because of the wider use of highly sensitive troponin (hsTn) assays (see below) with enhanced detection of myocyte necrosis, thereby reclassifying UA to NSTEMI.

PATHOPHYSIOLOGY

NSTE-ACS is caused by an imbalance between myocardial oxygen supply and demand, most commonly resulting from one or more of three processes that lead to coronary arterial thrombosis: (1) plaque fissure with inflammation—the inflammatory response is reflected by an increased activity of effector T cells as part of an adaptive immunity dysregulation; (2) plaque fissure without inflammation; and (3) plaque erosion, which is present in at least one-third of ACS and is recognized with increasing frequency **(Fig. 285-2)**. The so-called "vulnerable plaques" responsible for ACS may show an eccentric stenosis with scalloped or overhanging edges and a narrow neck on coronary angiography. Such plaques usually are composed of a lipid-rich core with a thin fibrous cap. Patients with NSTE-ACS frequently have multiple such plaques that are at risk of disruption. A fourth process, without thrombosis, may be caused by epicardial or microvascular spasm or increased myocardial oxygen demand, typically in the presence of fixed epicardial coronary obstruction.

Among patients with NSTE-ACS studied at angiography, <10% have stenosis of the left main coronary artery, and approximately 35% have three-vessel coronary artery disease, 25% have two-vessel disease, 20% have single-vessel disease, and 10% have no apparent critical epicardial coronary artery stenosis; some of the latter may have obstruction of the coronary microcirculation and/or spasm of the epicardial vessels.

CLINICAL PRESENTATION

Diagnosis The diagnosis of NSTE-ACS is based largely on a combination of the history and clinical findings (age, ECG, and circulating troponin) **(Table 285-1, Fig. 285-3)**.

History and Physical Examination Typically, chest discomfort is severe and has at least one of three features: (1) occurrence at rest (or with minimal exertion), lasting >10 min; (2) of relatively recent onset (i.e., within the prior 2 weeks); and/or (3) a crescendo pattern, i.e., distinctly more severe, prolonged, or frequent than previous episodes.

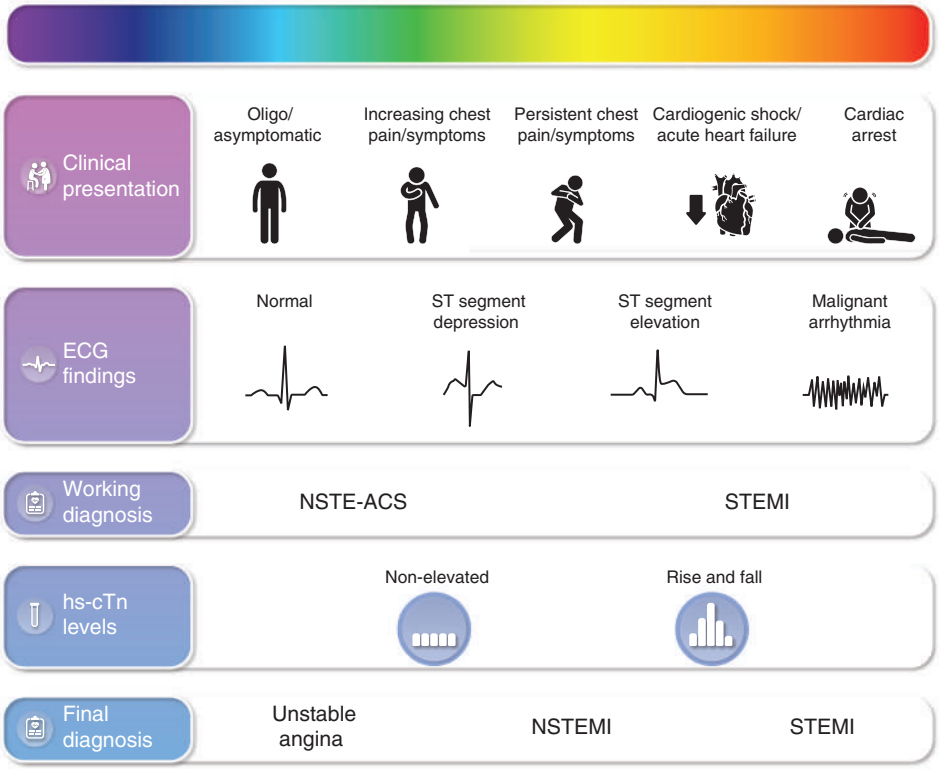

FIGURE 285-1 Spectrum of acute coronary syndromes. The spectrum of clinical presentations, electrocardiographic findings, and high-sensitivity cardiac troponin levels in patients with acute coronary syndrome. ACS, acute coronary syndrome; ECG, electrocardiogram; hs-cTn, high-sensitivity cardiac troponin; NSTE-ACS, non-ST-segment elevation acute coronary syndrome; NSTEMI, non-ST-segment elevation myocardial infarction; STEMI, ST-segment elevation myocardial infarction. *(RA Byrne et al: 2023 ESC guideline for the management of acute coronary syndromes. Eur Heart J 44:3720, 2023, by permission of Oxford university Press.)*

The diagnosis of NSTEMI is established if a patient with any of these features (without ECG ST-segment elevations) develops evidence of myocardial necrosis, as reflected in abnormally elevated levels of circulating troponin, in the absence of another explanation (see below). The chest discomfort is typically located in the substernal region and radiates to the left arm, left shoulder, and/or superiorly to the neck and jaw. Anginal equivalents such as dyspnea, epigastric discomfort, nausea, or weakness may occur instead of chest discomfort. These equivalents are more frequently reported by women, the elderly, and patients with diabetes mellitus. The physical examination resembles that in patients with stable angina **(see Chap. 284)** and may be unremarkable. However, if the patient has a large area of myocardial ischemia or a large NSTEMI, the physical findings can include diaphoresis; pale, cool skin; sinus tachycardia; a third and/or fourth heart sound; basilar rales; hypotension; and in severe cases, cardiogenic shock. An important goal of the physical examination is to identify potential alternative life-threatening diagnoses, e.g., pulmonary embolism **(see Chap. 290)**, aortic dissection **(see Chap. 291)**, and cardiac tamponade **(see Chap. 281)**,

given the vastly different treatment plans required to avoid major morbidity and death.

Electrocardiogram New ST-segment depression occurs in about one-third of patients with NSTE-ACS. It may be transient but can persist for as long as several days following NSTEMI. T-wave changes are more common but are a less specific sign of ischemia unless they are new and deep T-wave inversions (≥0.3 mV).

Cardiac Biomarkers Patients with NSTEMI have elevated biomarkers of necrosis, such as cardiac troponin (cTn) I or T (cTnI or cTnT). High-sensitive (hs) cTns are sensitive, relatively specific, and the preferred markers of myocardial necrosis. Elevated levels of cTn with a dynamic early change distinguish patients with NSTEMI from those with UA. In patients with NSTEMI, there is a characteristic temporal rise of the plasma concentration, peaking at 12–24 h after onset of symptoms and gradually decreasing thereafter. There is a direct relationship between the degree of elevation and mortality. The 1-h rapid rule-out MI algorithm (no abnormal elevation of hsTn at 0 or 1 h after presentation) has been recommended by recent practice guidelines. It is important to distinguish myocardial injury from myocardial necrosis; the former is defined by elevations of cTn >99th percentile of the upper reference limit in patients *without* a clear clinical history or ECG features of acute myocardial ischemia. Myocardial injury may be caused by a variety of noncardiac and cardiac conditions other than MI (Table 285-2).

RISK STRATIFICATION

Patients with documented NSTE-ACS exhibit a wide spectrum of early (30 days) risk of death, ranging from 1 to 10%, and a recurrent ACS rate of 5–15% during the first year. Assessment of risk can be accomplished by one of several clinical risk scoring systems, including those developed from the Thrombolysis in Myocardial Infarction (TIMI) Trials, the Global Registry of Acute Coronary Event (GRACE), and the HEART (*h*istory, *e*lectrocardiogram, *a*ge, *r*isk factors, *t*roponin) score (Fig. 285-3). Multimarker strategies including hsTn and brain natriuretic peptides are now gaining favor, both to define more fully the pathophysiologic mechanisms underlying a patient's presentation and to stratify the patient's risk further. Early risk assessment is useful in identifying patients who would derive the greatest benefit from an early invasive strategy (see below).

TABLE 285-2 Reasons for the Elevation of Cardiac Troponin Values as a Result of Myocardial Injury

Myocardial injury related to acute myocardial infarction
Atherosclerotic plaque disruption or erosion with thrombosis
Myocardial injury related to acute myocardial ischemia because of oxygen supply/demand imbalance
Reduced myocardial perfusion
• Coronary artery spasm, microvascular dysfunction
• Coronary embolism
• Coronary artery dissection
• Sustained bradyarrhythmia
• Hypotension or shock
• Respiratory failure
• Severe anemia
Increased myocardial oxygen demand
• Sustained tachyarrhythmia
• Severe hypertension
Other causes of myocardial injury
Cardiac conditions
• Heart failure
• Myocarditis
• Cardiomyopathy (any type)
• Takotsubo syndrome
• Recent coronary revascularization
• Cardiac procedure other than revascularization
• Catheter ablation
• Defibrillator shocks
• Cardiac contusion
Systemic conditions
• Sepsis
• Chronic kidney disease
• Stroke, subarachnoid hemorrhage
• Pulmonary embolism
• Infiltrative diseases, e.g., amyloidosis, sarcoidosis
• Chemotherapeutic agents
• Critical illness
• Strenuous exercise

TREATMENT

Non-ST-Segment Elevation Acute Coronary Syndrome

Patients with a low likelihood of ischemia can usually be managed in an emergency department or a dedicated "chest pain unit." Evaluation of such patients includes clinical monitoring for recurrent ischemic discomfort and continuous monitoring of ECGs, serial monitoring of hsTn at presentation, 1 h, and, if necessary, 3 h. In patients for whom there is diagnostic uncertainty or intermediate-risk patients, stress testing to detect and grade ischemia or cardiac computed tomography angiography to assess epicardial coronary artery obstruction may be considered **(see Chaps. 248 and 284)**.

MEDICAL TREATMENT

Patients who "rule-in" for NSTE-ACS by clinical features, hsTn, or ST-T–wave changes on the ECG should be admitted to the hospital. Patients should be placed on bed rest with continuous ECG monitoring for ST-segment deviation and cardiac arrhythmias, preferably on a specialized cardiac unit. Ambulation is permitted if the patient shows no recurrence of ischemia (symptoms or ECG changes) and does not develop an elevation of cTn for 24 h.

Medical therapy consists of an acute phase focused on the clinical symptoms and stabilization of the culprit lesion(s) and a longer-term phase that involves therapies directed at the prevention of disease progression and future recurrent NSTE-ACS.

ANTI-ISCHEMIC TREATMENT (TABLE 285-3)

To provide relief of pain and discomfort, initial treatment, in addition to bed rest, includes nitrates, β-adrenergic blockers, and inhaled oxygen in patients with hypoxemia (arterial O_2 saturation <90%) and/or in those with heart failure and rales.

Nitrates Nitroglycerin should first be given sublingually or by buccal spray (0.3–0.6 mg) if the patient is experiencing ischemic discomfort. If symptoms persist after three doses given 5 min apart, intravenous nitroglycerin (5–10 μg/min, using nonabsorbing tubing) is recommended. The infusion rate may be increased by 10 μg/min every 3–5 min until symptoms are relieved, systolic arterial pressure falls to <90 mmHg, or the dose reaches 200 μg/min. Topical or oral nitrates **(see Chap. 284)** can be used when the pain has resolved, or they may replace intravenous nitroglycerin when the patient has been symptom-free for 12–24 h. The only absolute contraindications to the use of nitrates are hypotension or the recent use of a phosphodiesterase type 5 (PDE-5) inhibitor, sildenafil or vardenafil (within 24 h), or tadalafil (within 48 h).

β-Adrenergic Blockers and Other Agents Beta blockers are the other mainstay of anti-ischemic treatment because they reduce myocardial oxygen needs. They may be started by the intravenous route in patients with severe ischemia but should be avoided in the presence of acute or severe heart failure, low cardiac output,

TABLE 285-3 Recommendations for Anti-Ischemic Drugs in the Acute Phase of NSTE-ACS

THERAPY	RECOMMENDATION	WHEN TO AVOID
Nitrates	• Use sublingual or intravenous nitrates to relieve angina • Use intravenous nitrates if recurrent angina, uncontrolled hypertension, or signs of heart failure • Consider in patients with vasospastic angina	• Recent use of a PDE-5 inhibitor[a] • Hypotension • Right ventricular infarct • Severe aortic stenosis
Beta blockers	• Initiate early for ischemic symptoms • Continue chronic therapy	• PR interval >0.24 s • 2nd or 3rd atrioventricular block • Heart rate <50 beats/min • Systolic pressure <90 mmHg • Shock or Killip class III or IV heart failure • Severe reactive airways disease
Calcium channel blockers	• Consider in patients with vasospastic angina • Consider in patients with contraindications to beta blockers	• Systolic pressure <90 mmHg • Pulmonary edema • Left ventricular dysfunction[b] • Avoid short-acting nifedipine
Morphine or other narcotic analgesics[c]	• Continued severe angina despite 3 sublingual nitroglycerin tablets • Recurrent ischemia despite adequate anti-ischemic therapy	• Hypotension • Respiratory depression • Confusion or obtundation

[a]Sildenafil or vardenafil <24 h or tadalafil <48 h. [b]Diltiazem or verapamil. [c]Concomitant administration may delay the absorption and blunt the antiplatelet effect of oral $P2Y_{12}$ inhibitors.

Abbreviations: NSTE-ACS, non-ST-segment elevation acute coronary syndrome; PDE-5, phosphodiesterase type 5.

Source: Modified from M Roffi et al: Eur Heart J 37:267, 2017.

hypotension, or contraindications (e.g., high-degree atrioventricular block, active bronchospasm). Ordinarily, oral beta blockade targeted to a heart rate of 50–60 beats/min is recommended.

Heart rate–slowing calcium channel blockers, e.g., verapamil or diltiazem, are recommended for patients who have persistent symptoms or ECG signs of ischemia after treatment with full-dose nitrates and beta blockers and in patients with contraindications to either class of these agents. Patients who have continuing severe chest pain despite maximal anti-ischemic therapy and are without contraindications to morphine may receive this drug intravenously (1–5 mg every 5–30 min). Additional medical therapy includes angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers. Early administration of intensive HMG-CoA reductase inhibitors (statins), such as atorvastatin 80 mg/d or rosuvastatin 40 mg/d, prior to percutaneous coronary intervention (PCI), and continued thereafter has been shown to reduce both early and late recurrent ischemic events. In patients who do not have an adequate response to maximally tolerated statin (i.e., <50% decrease in low-density lipoprotein cholesterol [LDL-C]), addition of ezetimibe 10 mg daily and/or a PCSK9 inhibitor (alirocumab, evolocumab) early after ACS have been shown to further reduce the LDL-C and prevent future cardiovascular events.

ANTITHROMBOTIC THERAPY

Antithrombotic therapy consisting of antiplatelet and anticoagulant drugs represents the second major cornerstone of treatment **(Table 285-4)**.

Antiplatelet Drugs (See Chap. 123) Initial treatment should begin with the cyclooxygenase inhibitor aspirin with a dose of 150–325 mg of an oral non-enteric-coated preparation or 75–250 mg intravenously. Thereafter, lower oral doses (75–100 mg/d) are recommended since they maintain efficacy while causing less bleeding. Contraindications are severe active bleeding and aspirin allergy.

In the absence of a high risk for bleeding, patients with NSTE-ACS, irrespective of whether an invasive or conservative strategy (see below) is selected, should also receive a platelet $P2Y_{12}$ receptor blocker to inhibit platelet activation. There are now three oral and one intravenous $P2Y_{12}$ inhibitors available. The thienopyridine clopidogrel is an inactive prodrug that is converted into an active metabolite that causes irreversible blockade of the platelet $P2Y_{12}$ receptor. The loading dose of clopidogrel is 300–600 mg, whereas the maintenance dose is 75 mg daily. When clopidogrel is added to aspirin, so-called dual antiplatelet therapy (DAPT), in patients with NSTE-ACS, it confers a 20% relative reduction in cardiovascular death, MI, or stroke, compared to aspirin alone but is associated with a moderate (absolute 1%) increase in major bleeding.

Two other $P2Y_{12}$ inhibitors have been shown to be superior to clopidogrel in preventing recurrent cardiac ischemic events but both increase bleeding. Prasugrel, also a thienopyridine, achieves a more rapid onset and higher level of irreversible platelet inhibition than clopidogrel. Compared to clopidogrel, prasugrel significantly reduced the combined risk of cardiovascular death, MI, stroke, and stent thrombosis, but increased bleeding, in patients with ACS with scheduled PCI. It has been approved for ACS patients following angiography when PCI is planned; it should be administered at a loading dose of 60 mg followed by 10 mg/d. Prasugrel is contraindicated in patients with prior stroke or transient ischemic attack or at high risk for bleeding, and should be administered once the coronary anatomy is known (i.e., post coronary angiography).

Ticagrelor, a potent, *reversible* platelet $P2Y_{12}$ inhibitor, reduces the risk of cardiovascular death, total mortality, or MI compared to clopidogrel across a broad spectrum of patients with ACS. After a loading dose of 180 mg, 90 mg bid is administered as maintenance. Like prasugrel, ticagrelor increases the risk of bleeding. Unlike prasugrel, ticagrelor demonstrated benefit whether patients were managed conservatively or with an early invasive strategy (see below). Some patients may develop dyspnea soon after administration, although the symptoms are often transient and infrequently serious.

Up to one-third of patients have an inadequate response to clopidogrel, and a substantial proportion of these cases are related to a genetic variant of the cytochrome P450 system involving the *2C19* gene that leads to reduced conversion of clopidogrel into its active metabolite. Thus, alternate $P2Y_{12}$ blockers (prasugrel or ticagrelor) should be considered in patients with NSTE-ACS who develop a new coronary event while receiving clopidogrel and aspirin. An intravenous, direct, and rapidly acting $P2Y_{12}$ inhibitor, cangrelor, has also shown benefit relative to clopidogrel in patients who underwent PCI following a NSTE-ACS and reduced the risk of cardiovascular ischemic events, but at the expense of increased major bleeding events.

In the 1990s and early 2000s, several trials of glycoprotein IIb/IIIa inhibitors in patients with NSTE-ACS had shown modest benefit counterbalanced by an increase in major bleeding. However, the majority of earlier studies were performed without concomitant $P2Y_{12}$ inhibitor treatment, and more recent studies in patients receiving the latter failed to show a benefit of routine early initiation of a glycoprotein IIb/IIIa inhibitor. Because of the increased risk of bleeding, the addition of a glycoprotein IIb/IIIa inhibitor to aspirin and a $P2Y_{12}$ inhibitor (i.e., triple antiplatelet therapy) should be reserved for patients undergoing PCI with a high coronary thrombus burden on angiography or thrombotic complications of PCI.

Long-term DAPT should continue preferably for 12 months in patients with NSTE-ACS without an indication for long-term

TABLE 285-4 Clinical Use of Antithrombotic Therapy

Oral Antiplatelet Therapy	
Aspirin	Loading dose of 150–325 mg orally of nonenteric formulation followed by 75–100 mg/d of an enteric or a nonenteric formulation
Clopidogrel	Loading dose of 600 mg (if PCI planned) or 300 mg (if no PCI planned), followed by 75 mg/d
Prasugrel	Pre-PCI: Loading dose of 60 mg followed by 10 mg/d In patient with body weight <60 kg or >75 years old, maintenance dose of 5 mg/d
Ticagrelor	Loading dose of 180 mg followed by 90 mg twice daily
Intravenous Antiplatelet Therapy at the Time of PCI	
Cangrelor	30 μg/kg bolus followed by 4 μg/kg/min infusion for 2 h or duration of procedure
Eptifibatide	180 μg/kg bolus followed in 10 min by second bolus of 180 μg/kg with infusion of 2.0 μg/kg/min for up to 18 h
Tirofiban	25 μg/kg per min over 3 minutes, followed by infusion of 0.15 μg/kg/min for up to 18 h
Parenteral Anticoagulants[a]	
Unfractionated heparin	Bolus 70–100 U/kg (maximum 5000 U) IV followed by infusion of 12–15 U/kg per h titrated to ACT 250–300 s
Enoxaparin	0.5 mg/kg IV bolus at the time of PCI *or* 1 mg/kg subcutaneous every 12 h; the first dose may be preceded by a 30-mg IV bolus; renal adjustment to 1 mg/kg once daily if creatine clearance <30 mL/min
Bivalirudin	Initial IV bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg per h
Fondaparinux	2.5 mg subcutaneously daily (only prior to PCI)
Oral Anticoagulant Drugs (concomitant treatment after PCI)	
VKA	Dosing based on INR value and the respective clinical indication
Apixaban	Maintenance dose 5 mg (dose reduced to 2.5 mg) twice daily
Dabigatran	Maintenance dose 150 mg (dose reduced to 75 mg) twice daily in the United States; outside the United States, either 110 or 150 mg twice daily may be used
Edoxaban	Maintenance dose 60 mg (dose reduced to 30 mg) once daily
Rivaroxaban	Maintenance dose 20 mg (dose reduced to 15 mg) once daily In patients without atrial fibrillation or venous thromboembolism 2.5 mg bid may be used

Note: All dose reductions for patients meeting criteria. **(See also Chap. 123.)**

Abbreviations: ACT, activated clotting time; INR, international normalized ratio; PCI, percutaneous coronary intervention; VKA, vitamin K antagonists (e.g., warfarin).

Source: Modified from FJ Neumann: Eur Heart J 40:137, 2019.

full-dose anticoagulation; the duration of DAPT is dependent upon the risk of bleeding versus thrombosis. Clinicians should select the antiplatelet regimen that provides the best balance between efficacy and safety based on the individual patient characteristics and clinical scenario. A shorter duration of DAPT may be considered for patients at high risk of bleeding who are not high at high ischemic risk (see below). Longer duration DAPT, i.e., >12 months, is favored in patients with high atherothrombotic risk (e.g., due to stenting of the left main coronary artery or proximal left anterior descending or proximal bifurcating coronary arteries, recurrent MI, stent thrombosis).

Anticoagulants (See Chap. 123) Four parenteral options are available for anticoagulant therapy to be added to antiplatelet agents: (1) unfractionated heparin (UFH), long the mainstay of therapy; (2) the low-molecular-weight heparin (LMWH) enoxaparin, which has been shown to be superior to UFH in reducing recurrent cardiac events, especially in patients managed by a conservative strategy (however, it is accompanied by a modest increase in bleeding); (3) bivalirudin, a direct thrombin inhibitor that is similar in efficacy to either UFH or LMWH and is used just prior to and/or during PCI; and (4) fondaparinux, a synthetic factor Xa inhibitor that is equivalent in efficacy to enoxaparin but has a lower risk of major bleeding. While UFH and enoxaparin have been widely studied in patients managed either with an early conservative or invasive strategy, bivalirudin is rarely used in conservatively managed patients, while fondaparinux requires supplemental UFH to prevent procedure-related thrombosis. In patients who develop NSTE-ACS while receiving treatment with a direct oral anticoagulant (DOAC), the DOAC **(see Chap. 123)** should be held when one of the four parenteral anticoagulants is begun.

If an early invasive strategy is indicated (see below), radial arterial access is recommended to reduce the risk of bleeding. Excessive bleeding is the most important adverse effect of all antithrombotic agents, including both antiplatelet agents and anticoagulants. Therefore, attention must be directed to the doses of antithrombotic agents, accounting for age, body weight, creatinine clearance, and a previous history of excessive bleeding. Patients who have experienced a stroke are at higher risk of intracranial bleeding with potent antiplatelet agents and combinations of antithrombotic drugs. In patients with atrial fibrillation (including patients with NSTE-ACS) treated with an oral anticoagulant who undergo PCI, the duration of DAPT should be shortened (e.g., stop aspirin after hospital discharge or at most at 1 month after PCI, except in patients at very high risk for ischemic events), and continue $P2Y_{12}$ inhibitor plus DOAC for 1 year. After 1 year, the majority of patients should be transitioned to oral anticoagulation monotherapy without concomitant antiplatelet treatment.

INVASIVE VERSUS CONSERVATIVE STRATEGY (FIG. 285-4)

In an invasive strategy, following initiation of anti-ischemic and antithrombotic agents as described above, coronary arteriography is recommended within 2 h of presentation for patients are unstable or within 24 h in high-risk stable patients, followed by coronary revascularization (PCI or coronary artery bypass grafting), depending on the coronary anatomy (Fig. 285-4). Multiple clinical trials have demonstrated the benefit of this strategy in high-risk patients (i.e., patients with multiple clinical risk factors, ST-segment deviation, and/or positive biomarkers). Two studies comparing an immediate invasive strategy (median time to intervention of 1.4 and 4.7 h after presentation) reduced the rate of death or new MI compared to a delayed invasive strategy (median time of intervention of 61 and 62 h), with a greater benefit among patients with a high-risk score. In patients at low risk, the outcomes from an

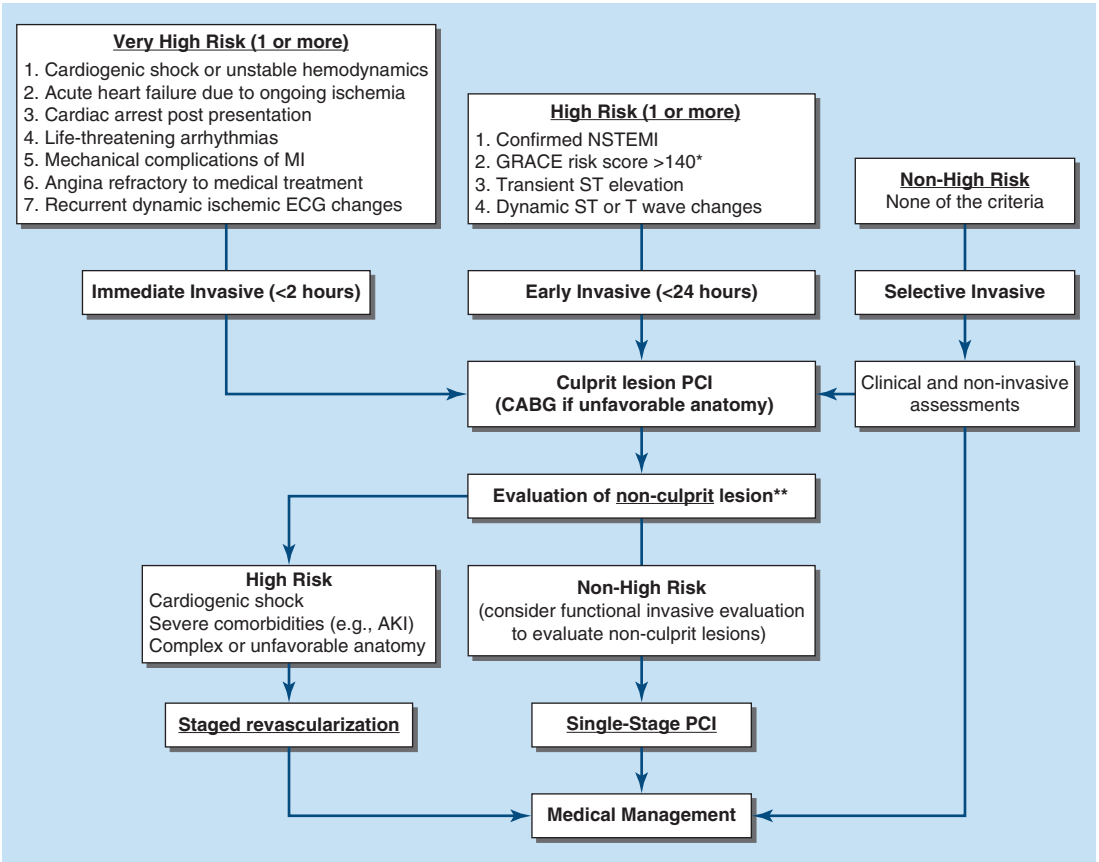

FIGURE 285-4 Selection, timing, and staging of invasive strategy in patients with non-ST-elevation acute coronary syndrome. AKI, acute kidney injury; CABG, coronary artery bypass grafting; GRACE, Global Registry of Acute Coronary Syndrome Events; PCI, percutaneous coronary intervention. Patients with non-ST-elevations acute coronary syndrome who have one or more very-high risk features should undergo immediate invasive strategy with coronary angiography as soon as possible (within 2 hours), unless absolute contraindications exist. An early invasive strategy should be considered within 24 hours in stable patients with one or more high risk features. Stable patients with no very-high or high risk features should be managed with a selective invasive approach in which clinical, non-invasive assessments, and patient preferences are used to guide management. *Fox KA, BMJ Open 2014;4:e004425. https://doi.org/10.1136/bmjopen-2013-004425. **In patients with multivessel disease, single-stage PCI during the index procedure to achieve complete coronary revascularization should be considered in the absence of cardiogenic shock, severe comorbidities such as AKI, or coronary anatomy that is unfavorable or high risk requiring evaluation for The Heart Team for CABG vs complex coronary intervention.

invasive strategy are similar to those obtained from a conservative strategy. The latter consists of anti-ischemic and antithrombotic therapy followed by a "selective invasive approach," in which the patient is observed closely and coronary arteriography is conducted if coronary computed angiography shows the presence of epicardial coronary stenosis, rest pain or ST-segment changes recur, a biomarker of necrosis becomes positive, or there is evidence of severe ischemia on a stress test.

LONG-TERM MANAGEMENT

The time of hospital discharge is a "teachable moment" for the patient with NSTE-ACS, when the caregiver can review and optimize the medical regimen. Risk factor modification is crucial, and the importance of smoking cessation, following an appropriate diet, achieving and maintaining optimal weight, daily exercise, an LDL-C <55 mg/dL, blood pressure control, and control of hyperglycemia should be emphasized. There is evidence of benefit with long-term therapy with several classes of drugs. Beta blockers, intensive lipid-lowering therapies (high-intensity statin, ezetimibe, and if needed, adding a PCSK9 inhibitor or bempedoic acid) to achieve an LDL-C <55 mg/dL, ACE inhibitors or angiotensin receptor blockers, and sodium-glucose cotransporter 2 or glucagon-like peptide 1 receptor agonists in selected patients with type 2 diabetes mellitus (see Chap. 416) are recommended. The recommended antiplatelet regimen consists of the combination of low-dose (75–100 mg/d) aspirin and a $P2Y_{12}$ inhibitor (prasugrel or ticagrelor is favored over clopidogrel) for 12 months unless there is a high risk of bleeding. After 12 months, antiplatelet monotherapy with a single antiplatelet should be continued thereafter (see Chap. 284), unless long-term full-dose anticoagulation is indicated, in which case anticoagulant without antiplatelet therapy is recommended long-term (see above).

Several trials have explored shorter courses and less intensive DAPT in patients not on anticoagulation who are at high risk of bleeding and low risk of ischemic events. Recent guidelines support a shorter-duration DAPT regimens of 3–6 months in these patients, followed by stopping aspirin and continuing with $P2Y_{12}$ inhibitor alone. Another option is de-escalation of $P2Y_{12}$ intensity (i.e., switching from prasugrel or ticagrelor to clopidogrel at 3 months) while continuing aspirin. De-escalation of DAPT is not recommended in the first 30 days following ACS as this has been associated with increased risk of ischemic events.

In patients who require long-term anticoagulation (e.g., patients with atrial fibrillation), the duration of so-called "triple therapy" consisting of aspirin, clopidogrel, and an oral anticoagulant should be kept to a minimum. In these patients, aspirin should be discontinued at discharge or 1 week, and oral anticoagulation and clopidogrel continued until month 12, followed thereafter by oral anticoagulant alone. Conversely, in patients at high ischemic risk (e.g., those with prior MI, diabetes mellitus, coronary vein graft, heart failure) who are also at low risk of bleeding and not on an anticoagulant, continuation of DAPT for up to 3 years has been shown to be beneficial. If ticagrelor is used, the dose should be reduced to 60 mg twice daily 1 year after ACS as this reduces bleeding without an increase in ischemic events.

Registries have shown that women and racial minorities, as well as patients with NSTE-ACS at high risk, including the elderly and patients with diabetes or chronic kidney disease, are less likely to receive evidence-based pharmacologic and interventional therapies with resultant poorer clinical outcomes and quality of life. Special attention should be directed to these groups.

VASOSPASTIC ANGINA

In 1959, Prinzmetal and colleagues described a syndrome of severe ischemic pain that usually occurs at rest and is associated with ST-segment elevation originally known as Prinzmetal's variant angina, but since renamed vasospastic angina (VA). VA is caused by focal spasm of an epicardial coronary artery with resultant transmural ischemia and abnormalities in left ventricular function that may lead to acute MI, ventricular tachycardia or fibrillation, and sudden cardiac death. The cause of the spasm is not well defined, but it may be related to hypercontractility of coronary arterial smooth muscle due to adrenergic vasoconstrictors, leukotrienes, or serotonin. For reasons that are not clear, the prevalence of VA has decreased substantially during the past few decades, although it remains much more frequent in Japan than in North America or Western Europe.

Clinical and Angiographic Manifestations Patients with VA are generally younger and, except for cigarette smoking, have fewer coronary risk factors than do patients with NSTE-ACS. Cardiac examination is usually unremarkable in the absence of ischemia. However, a minority of patients have a generalized vasospastic disorder associated with migraine and/or Raynaud's phenomenon. The clinical diagnosis of VA is made by the detection of transient ST-segment *elevation* with rest pain, although many patients may also exhibit episodes of silent ischemia.

Coronary angiography demonstrates transient coronary spasm as the diagnostic hallmark of VA. Atherosclerotic plaques in at least one proximal coronary artery occur in about half of patients. Hyperventilation and intracoronary acetylcholine have been used to provoke focal coronary stenosis on angiography or to provoke rest angina with ST-segment elevation to establish the diagnosis. In patients with no obstructive coronary atherosclerosis and suspected coronary vasomotor abnormalities, a positive provocative test for spasm has been shown to be safe, identifies a high-risk subgroup, and is endorsed by guidelines since it permits selection of therapy most appropriate for the underlying pathophysiology.

TREATMENT

Vasospastic Angina

Calcium channel blockers are the main therapeutic agents. Nitroglycerin, either sublingual or intravenous, is effective to relieve coronary arterial spasm and angina, but the efficacy of long-term nitrates is limited by nitrate tolerance. Aspirin may actually increase the severity of ischemic episodes, possibly as a result of the sensitivity of coronary tone to modest changes in the synthesis of prostacyclin, and should be used only in patients with significant atherosclerosis. Statin therapy has been shown to reduce the risk of major adverse events, although the precise mechanism is not established. The response to beta blockers is variable. Cilostazol and nicorandil (not available in the United States) may also prevent recurrent episodes. Coronary revascularization may be helpful in patients who also have discrete, flow-limiting, proximal fixed obstructive lesions. Patients who have had ischemia-associated ventricular fibrillation despite maximal medical therapy should receive an implantable cardioverter-defibrillator.

Prognosis Many patients with VA pass through an acute, active phase, with frequent episodes of angina and cardiac events during the first 6 months after presentation, after which there may be a tendency for symptoms and cardiac events to diminish over time. Survival at 5 years is excellent (~90–95%), but as many as 20% of patients experience an MI. Patients with no or mild fixed coronary obstruction experience a lower incidence of cardiac death or MI compared to patients with associated severe obstructive lesions. Patients with VA who develop serious arrhythmias during spontaneous episodes of pain are at a higher risk for sudden cardiac death. In most patients who survive an infarction or the initial 3- to 6-month period of frequent episodes, there is a tendency for symptoms and cardiac events to diminish over time.

GLOBAL CONSIDERATIONS

Ischemic heart disease (IHD) and its most dangerous manifestation, ACS, remain the most frequent cause of death and disability worldwide. In the mid-twentieth century, these conditions were most common in high-income countries. Although improvements in primary prevention and treatment of ACS have reduced cardiovascular morbidity and mortality due to IHD over the past 70 years, these advances have not affected all population groups equally. In Europe, there remains a northeast to southwest gradient, with higher prevalence in northern Russia and the Baltic nations and considerably lower prevalence in Spain, France, and Italy. In the United States, there remain racial and economic disparities, with poorer outcomes in minorities and low-income populations.

Simultaneous with these important advances in the high-income countries, the low- and middle-income countries have moved in the opposite direction. Improvements in agriculture, nutrition, sanitation, prevention and treatment of infections, and management of maternal/early childhood disorders, urbanization, and a reduction of physical labor have, in combination, led to marked increases in coronary risk factors—hypertension, cigarette smoking, obesity, diabetes mellitus, and elevations of circulating LDL-C. These changes have been most prominent in Central and South Asia, as well as in the more developed regions of sub-Saharan Africa and the Middle East.

The current challenge is to apply what was learned in high-income countries to the large populations in the low- and middle-income countries that are now at high risk. This will require large educational efforts directed at both the populations and their caregivers. An additional challenge will be to provide the trained specialized personnel, facilities, drugs, and devices to deal with these threats. The successful implementation of these measures is now principally a socio-politico-economic issue. One mitigating factor is that many of the important drugs to prevent and treat these disorders, such as statins, ezetimibe, ACE inhibitors, diuretics, beta blockers, and calcium antagonists, are off patent and are now inexpensive.

286 ST-Segment Elevation Myocardial Infarction

David A. Morrow, Elliott M. Antman, Joseph Loscalzo

Acute myocardial infarction (AMI) is a common diagnosis in hospitalized patients in industrialized countries. In the United States, ~605,000 patients experience a new AMI and 200,000 experience a recurrent AMI each year. About half of AMI-related deaths occur before the stricken individual reaches the hospital. The in-hospital mortality rate after admission for AMI has declined from 10 to ~5%. The 1-year mortality rate after AMI is ~15%. Mortality is approximately fourfold higher in patients aged >75 years as compared with younger patients.

When patients with prolonged ischemic discomfort at rest are first seen, the working clinical diagnosis is that they are suffering from an acute coronary syndrome **(Fig. 286-1)**. The 12-lead electrocardiogram (ECG) is a pivotal diagnostic and triage tool because it is at the center of the decision pathway for management, permitting distinction of those patients presenting with ST-segment elevation from those presenting without ST-segment elevation. Circulating cardiac biomarkers of myocardial injury are measured to distinguish unstable angina (UA) from non-ST-segment elevation myocardial infarction (NSTEMI) and to estimate preliminarily the magnitude of myocardial necrosis in an ST-segment elevation myocardial infarction (STEMI). Epidemiologic studies indicate there has been a shift in the pattern of AMI over the past several decades with more patients with NSTEMI than STEMI. This chapter focuses on the evaluation and management of patients with STEMI, while **Chap. 286** discusses UA/NSTEMI.

PATHOPHYSIOLOGY: ROLE OF ACUTE PLAQUE RUPTURE/EROSION

STEMI usually occurs when coronary blood flow decreases abruptly after a thrombotic occlusion of a coronary artery previously affected by atherosclerosis. Slowly developing, high-grade coronary artery stenoses do not typically precipitate STEMI because of the development of a rich collateral network over time. Instead, STEMI occurs when a coronary artery thrombus develops rapidly at a site of vascular injury. This injury is produced or facilitated by factors such as cigarette smoking, hypertension, lipid accumulation, and inflammation. In most cases, STEMI occurs when the surface of an atherosclerotic plaque becomes disrupted either through erosion or rupture (exposing its contents to the blood) and conditions (local or systemic) favor thrombogenesis. Histologic studies indicate that the coronary plaques prone to disruption are those with a rich lipid core and a thin fibrous cap. However, current clinical data have demonstrated that less than 5% of such thin-capped fibroatheromas are a nidus for AMI during long-term follow-up. Other morphologic characteristics associated with rupture-prone plaque include expansive remodeling, neovascularization (angiogenesis), plaque hemorrhage, adventitial inflammation, and a "spotty" pattern of calcification.

A mural thrombus forms at the site of plaque disruption, and the involved coronary artery becomes occluded. After an initial platelet monolayer forms at the site of the disrupted plaque, various agonists (collagen, ADP, epinephrine, serotonin) promote platelet activation. After agonist stimulation of platelets, thromboxane A_2 (a potent local vasoconstrictor) is released, further platelet activation occurs, and potential resistance to fibrinolysis develops.

In addition to the generation of thromboxane A_2, activation of platelets by agonists promotes a conformational change in the glycoprotein IIb/IIIa receptor **(Chap. 120)**. Once converted to its functional state, this receptor develops a high affinity for soluble adhesive proteins (i.e., integrins) such as fibrinogen. Since fibrinogen is a multivalent molecule, it can bind to two different platelets simultaneously, resulting in platelet cross-linking and aggregation.

The coagulation cascade is activated on exposure of tissue factor in damaged endothelial cells at the site of the disrupted plaque. Factors VII and X are activated, ultimately leading to the conversion of prothrombin to thrombin, which then converts fibrinogen to fibrin **(Chap. 121)**. Fluid-phase and clot-bound thrombin participate in an autoamplification reaction, leading to further activation of the coagulation cascade. The culprit coronary artery eventually becomes occluded by a thrombus containing platelet aggregates and fibrin strands **(Fig. 286-2)**.

In rare cases, STEMI may be due to coronary artery occlusion caused by coronary emboli, congenital coronary abnormalities, coronary spasm, or spontaneous coronary artery dissection. The amount of myocardial damage caused by coronary occlusion depends on (1) the territory supplied by the affected vessel, (2) whether or not the vessel becomes totally occluded, (3) the duration of coronary occlusion, (4) the quantity of blood supplied by collateral vessels to the affected tissue, (5) the demand for oxygen of the myocardium whose blood supply has been suddenly limited, (6) endogenous factors that can produce early spontaneous lysis of the occlusive thrombus, and (7) the adequacy of myocardial perfusion in the infarct zone when flow is restored in the occluded epicardial coronary artery.

Patients at increased risk for developing STEMI include those with multiple coronary risk factors and those with UA **(Chap. 285)**. Less

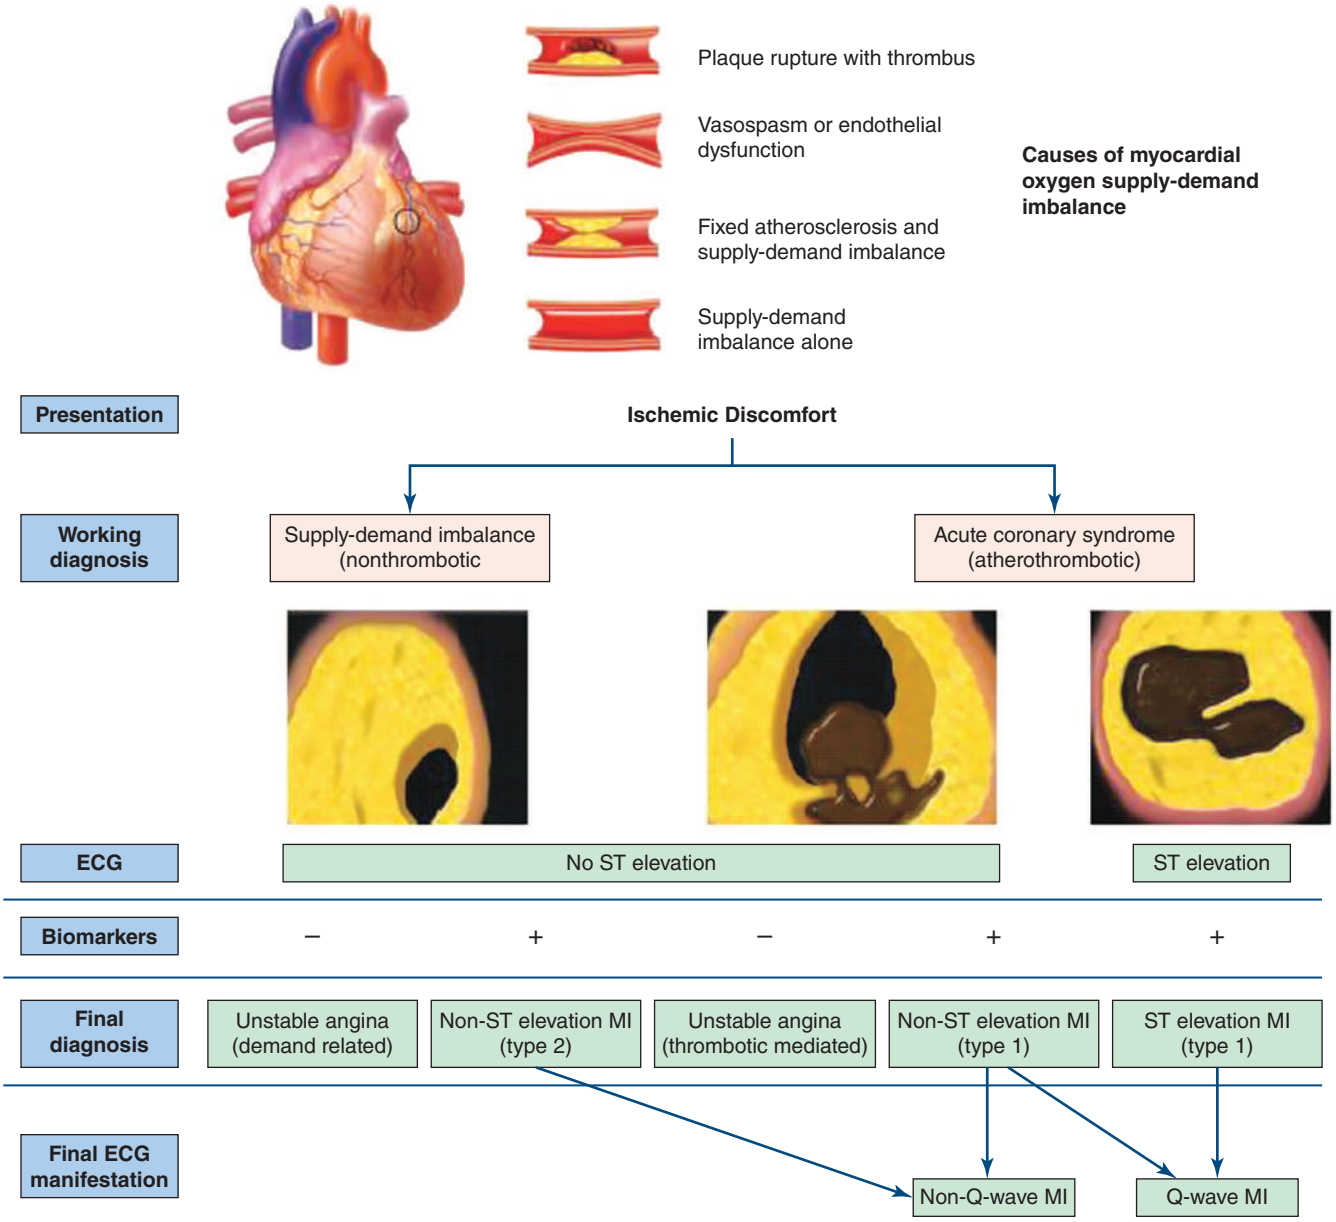

FIGURE 286-1 Acute coronary syndromes. Following disruption of a vulnerable plaque, patients experience ischemic discomfort resulting from a reduction of flow through the affected epicardial coronary artery. The flow reduction may be caused by a completely occlusive thrombus (*right*) or subtotally occlusive thrombus (*middle*). Patients with ischemic discomfort may present with or without ST-segment elevation. Of patients with ST-segment elevation, the majority ultimately develop a Q wave on the electrocardiogram (ECG; Q-wave myocardial infarction [MI]), while a minority do not develop Q waves and, in the past, were said to have sustained a non-Q-wave MI (NQMI). Patients who present without ST-segment elevation are suffering from either unstable angina or a non-ST-segment elevation MI (NSTEMI), a distinction that is ultimately made based on the presence or absence of a biomarker of myocardial injury such as cardiac troponin detected in the blood. *(Reproduced with permission from Hamm Scirica BM, Libby P, Morrow DA: ST-elevation myocardial infarction: Pathophysiology and clinical evolution, in Braunwald's Heart Disease, 12th ed, Libby P et al (eds). New York, Elsevier, 2022, Figure 37-1, pp 636-661.)*

common underlying medical conditions predisposing patients to STEMI include hypercoagulability, collagen vascular disease, systemic inflammatory diseases, cocaine abuse, and intracardiac thrombi or masses that produce coronary emboli.

There have been major advances in the management of STEMI with recognition that the "chain of survival" involves a highly integrated system starting with prehospital care and extending to early hospital management so as to provide expeditious implementation of a reperfusion strategy.

CLINICAL PRESENTATION

In up to one-half of cases, a precipitating factor appears to be present before STEMI, such as vigorous physical exercise, emotional stress, or a medical or surgical illness. Although STEMI may commence at any time of the day or night, circadian variations have been reported such that clusters are seen in the morning within a few hours of awakening.

Pain is the most common presenting complaint in patients with STEMI. The pain is deep and visceral; adjectives commonly used to describe it are *heavy*, *squeezing*, and *crushing*; although, occasionally, it is described as stabbing or burning **(Chap. 15)**. It is similar in character to the discomfort of angina pectoris **(Chap. 284)** but commonly occurs at rest, is usually more severe, and lasts longer. Typically, the pain involves the central portion of the chest and/or the epigastrium, and, on occasion, it radiates to the arms. Less common sites of radiation include the abdomen, back, lower jaw, and neck. The frequent location of the pain beneath the xiphoid and epigastrium and the patients' denial that they may be suffering a heart attack are chiefly responsible for the common mistaken impression of indigestion. The pain of STEMI may radiate as high as the occipital area but not below the umbilicus. It is often accompanied by sweating, nausea, vomiting, anxiety, and a sense of impending doom. The pain may commence when the patient is at rest, but when it begins during a period of exertion, it does not usually subside with cessation of activity, in contrast to angina pectoris.

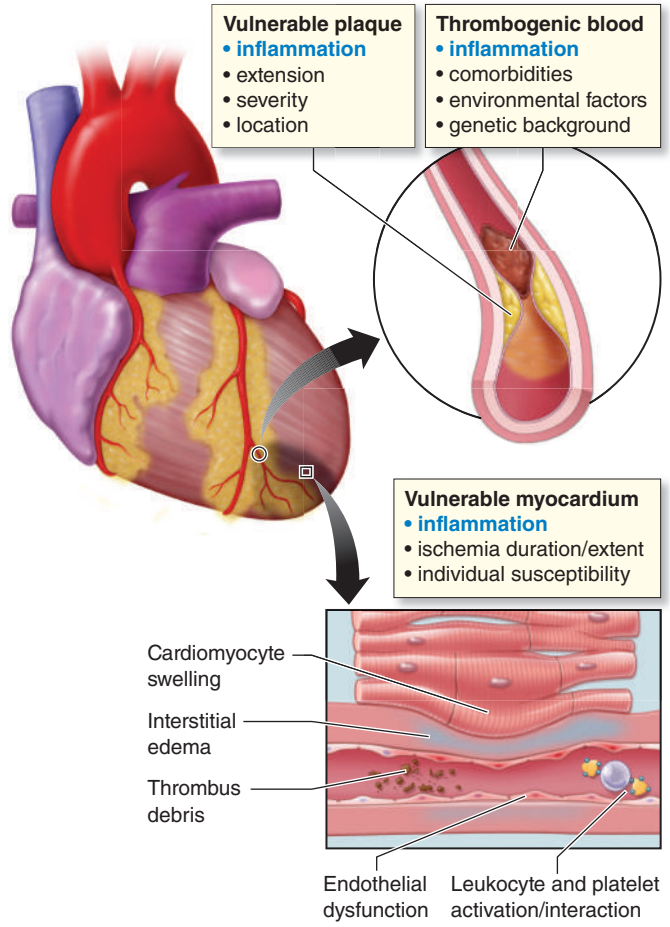

FIGURE 286-2 Critical determinants of myocardial infarction injury. The overlapping of vulnerable plaque and thrombogenic blood are critical determinants for myocardial infarction occurrence and extension. In addition, myocardial vulnerability, which is largely due to coronary microvascular dysfunction, contributes to extension and severity of ischemic injury. In the most severe form (known as no-reflow), structural and functional impairments sustain vascular obstruction. Endothelial dysfunction triggers leukocyte and platelet activation/interaction, whereas thrombotic debris may worsen the obstruction. Furthermore, cardiomyocyte swelling, interstitial edema, and tissue inflammation promote extravascular compression. *(Modified from F Montecucco, F Carbone, TH Schindler. Pathophysiology of ST-segment elevation myocardial infarction: Novel mechanisms and treatments. Eur Heart J 37:1268, 2016.)*

The pain of STEMI can simulate pain from acute pericarditis (Chap. 281), pulmonary embolism (Chap. 290), acute aortic dissection (Chap. 291), costochondritis, and gastrointestinal disorders. These conditions should therefore be considered in the differential diagnosis. Radiation of discomfort to the trapezius is not seen in patients with STEMI and may be a useful distinguishing feature that suggests pericarditis is the correct diagnosis. However, *pain is not uniformly present in patients with STEMI*. The proportion of painless STEMIs is greater in patients with diabetes mellitus, and it increases with age. STEMI may present as sudden-onset breathlessness. Other less common presentations, with or without pain, include sudden loss of consciousness, a confusional state, a sensation of profound weakness, the appearance of an arrhythmia, evidence of peripheral embolism, or merely an unexplained drop in arterial pressure.

PHYSICAL FINDINGS

Most patients are anxious and restless, attempting unsuccessfully to relieve the pain by moving about in bed, altering their position, and stretching. Pallor associated with perspiration and coolness of the extremities occurs commonly. The combination of substernal chest pain persisting for >30 min and diaphoresis strongly suggests STEMI. Although many patients have a normal pulse rate and blood pressure within the first hour of STEMI, patients with anterior infarction may have manifestations of sympathetic nervous system hyperactivity (tachycardia and/or hypertension), and those with inferior infarction may show evidence of parasympathetic hyperactivity (bradycardia and/or hypotension).

The precordium is usually quiet, and the apical impulse may be difficult to palpate. Other physical signs of ventricular dysfunction include fourth and third heart sounds, decreased intensity of the first heart sound, and paradoxical splitting of the second heart sound (Chap. 246). A transient midsystolic or late systolic apical systolic murmur due to dysfunction of the mitral valve apparatus may be present. A pericardial friction rub may be heard in patients with transmural STEMI at some time in the course of the illness. The carotid pulse is often decreased in volume, reflecting reduced stroke volume. Temperature elevations up to 38°C may be observed during the first week after STEMI.

LABORATORY FINDINGS

STEMI progresses through the following temporal stages: (1) acute (first few hours–7 days), (2) healing (7–28 days), and (3) healed (≥29 days). The myocardium undergoes a series of cellular responses in the infarct zone, beginning with recruitment of polymorphonuclear leukocytes (for removal of dead cells and clearance of extracellular macromolecules) followed by monocytes. Experimental work has now detailed this sequence of accumulation of subpopulations of mononuclear phagocytes with an initial wave of monocytes characterized by high proteolytic and phagocytic capacity and elaboration of proinflammatory cytokines followed by the repair monocytes that release a mediators that stimulate angiogenesis and extracellular matrix production (Fig. 286-3). New microvessels and fibrosis are key constituents of forming granulation tissue, and these processes establish a foundation for myocardial scar formation, ventricular remodeling, and infarct healing. In addition, emerging evidence reveals a role for an "emergency hematopoiesis" that mobilizes leukocyte progenitor cells that ultimately participate in myocardial healing.

When evaluating the results of diagnostic tests for STEMI, the temporal phase of the infarction must be considered. The tests of value in confirming the diagnosis may be divided into four groups: (1) ECG, (2) blood-based cardiac biomarkers, (3) cardiac imaging, and (4) nonspecific indices of tissue necrosis and inflammation.

ELECTROCARDIOGRAM

The electrocardiographic manifestations of STEMI are described in Chap. 247. During the initial stage, total occlusion of an epicardial coronary artery produces ST-segment elevation. Most patients initially presenting with ST-segment elevation ultimately evolve Q waves on the ECG. However, Q waves in the leads overlying the infarct zone may vary in magnitude and appear only transiently, depending on the reperfusion status of the ischemic myocardium and restoration of transmembrane potentials over time. A small proportion of patients initially presenting with ST-segment elevation will not develop Q waves when the obstructing thrombus is not totally occlusive, obstruction is transient, or a rich collateral network is present. Among patients presenting with ischemic discomfort but *without* ST-segment elevation, if a cardiac biomarker of necrosis (see below) is detected, the diagnosis of NSTEMI is ultimately made (Fig. 286-1). A minority of patients who present initially without ST-segment elevation may develop a Q-wave myocardial infarction (MI). Previously, it was believed that transmural MI is present if the ECG demonstrates Q waves or loss of R waves, and nontransmural MI may be present if the ECG shows only transient ST-segment and T-wave changes. However, electrocardiographic-pathologic correlations are far from perfect, and terms such as *Q-wave MI*, *non-Q-wave MI*, *transmural MI*, and *nontransmural MI* have been replaced by STEMI and NSTEMI (Fig. 286-1). Contemporary studies using magnetic resonance imaging (MRI) suggest that the development of a Q wave on the ECG is more dependent on the volume of infarcted tissue rather than the transmurality of infarction.

CARDIAC BIOMARKERS OF MYOCARDIAL INJURY

Certain proteins, referred to as cardiac biomarkers, are released from necrotic heart muscle after STEMI. The rate of liberation of specific

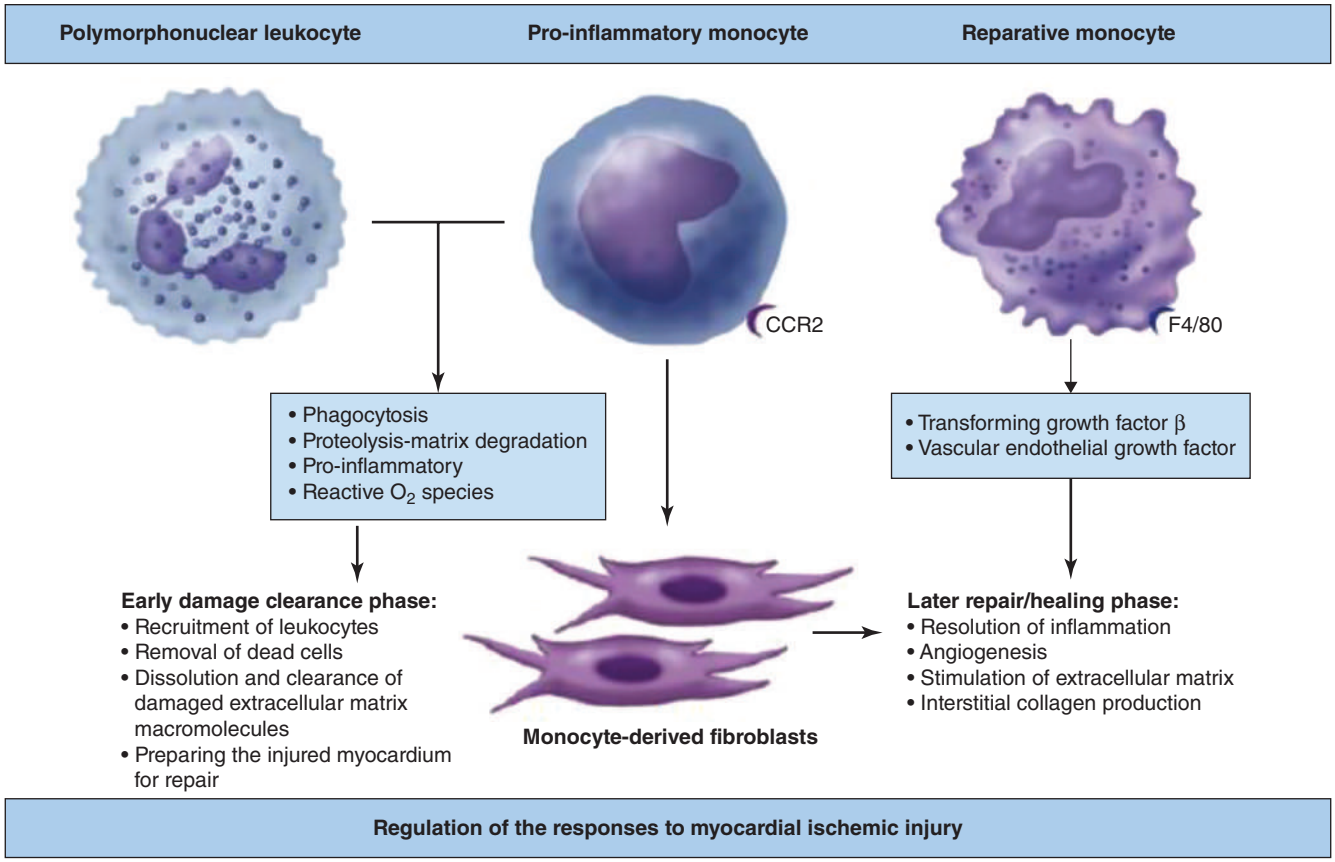

FIGURE 286-3 Phases of myocardial injury and healing. Immediate recruitment of polymorphonuclear leukocytes precedes the accumulation of proinflammatory monocytes (typically bearing the chemokine receptor 2 [CCR2]). These phagocytic cells release the mediators of the early phase response to ischemic injury by clearing dead cells and debris and prompting additional inflammatory cells to enter the injured area. Reparative monocytes stimulate the production of extracellular matrix macromolecules that reinforce the cardiac skeleton during healing as well as microvessel formation characteristic of granulation tissue. Monocyte-derived fibroblasts are capable of interstitial collagen synthesis that reinforces repair of the myocardial skeleton, potentially mitigating expansive remodeling of the infarct and promoting healing with less risk for chronic heart failure. *(Reproduced with permission from P Libby et al: The myocardium: More than just myocytes. J Am Coll Cardiol 74:3137, 2019.)*

proteins differs depending on their intracellular location, their molecular weight, and the local blood and lymphatic flow. Cardiac biomarkers become detectable in the peripheral blood once the capacity of the cardiac lymphatics to clear the interstitium of the infarct zone is exceeded and spillover into the venous circulation occurs. The criteria for AMI require a rise and/or fall in cardiac biomarker values with at least one value above the 99th percentile of the upper reference limit for normal individuals.

Cardiac-specific troponin T (cTnT) and *cardiac-specific troponin I* (cTnI) have amino-acid sequences that differ from those of the skeletal muscle forms of these proteins. These differences permitted the development of quantitative assays for cTnT and cTnI using highly specific monoclonal antibodies. cTnT and cTnI may increase after STEMI to levels many times higher than the upper reference limit (set at the 99th percentile of values in a reference population). The measurement of cTnT or cTnI is of considerable diagnostic usefulness, and they are now the preferred biochemical markers for MI when measured with high-sensitivity assays **(Fig. 286-4 and Chap. 15)**. In practical terms, the high-sensitivity troponin assays are of less immediate value in patients with STEMI. Contemporary urgent reperfusion strategies necessitate making a decision (based largely on a combination of clinical and ECG findings) before the results of blood tests have returned from the laboratory. Levels of cTnI and cTnT typically remain elevated for at least 7–10 days after STEMI.

Historically, creatine phosphokinase (CK) and its MB isoenzyme (CK-MB) were used for the diagnosis of AMI. A ratio (relative index) of CK-MB mass to CK activity ≥2.5 suggests but is not diagnostic of a myocardial rather than a skeletal muscle source for the CK-MB elevation. It is *not* cost-effective to measure both a cardiac-specific troponin and CK-MB. Because of its more rapid decline after the onset of AMI, CK-MB may be useful for the discrimination of early reinfarction during the period that cardiac troponin remains elevated following the index event (Fig. 286-3).

While it has long been recognized that the total quantity of protein released correlates with the size of the infarct, the peak protein concentration correlates only weakly with infarct size. Recanalization of a coronary artery occlusion (either spontaneously or by mechanical or pharmacologic means) in the early hours of STEMI causes earlier peaking of biomarker measurements (Fig. 286-4) because of a rapid washout from the interstitium of the infarct zone, quickly overwhelming lymphatic clearance of the proteins.

The *nonspecific reaction* to myocardial injury is associated with polymorphonuclear leukocytosis, which appears within a few hours after the onset of pain and persists for 3–7 days; the white blood cell count often reaches levels of 12,000–15,000/μL. The erythrocyte sedimentation rate rises more slowly than the white blood cell count, peaking during the first week and sometimes remaining elevated for 1 or 2 weeks.

CARDIAC IMAGING

Abnormalities of wall motion on *two-dimensional echocardiography* **(Chap. 248)** are almost universally present in patients with STEMI. Although acute STEMI cannot be distinguished from an old myocardial scar or from acute severe ischemia by echocardiography, the ease and safety of the procedure make its use appealing as a screening tool in the emergency department. When the ECG is not diagnostic of STEMI, early detection of the presence or absence of wall motion abnormalities by echocardiography can aid in management decisions, such as whether the patient should receive reperfusion therapy (e.g., percutaneous coronary intervention [PCI] or fibrinolysis). Echocardiographic estimation of left ventricular (LV) function is useful prognostically; detection of reduced function serves as an indication for

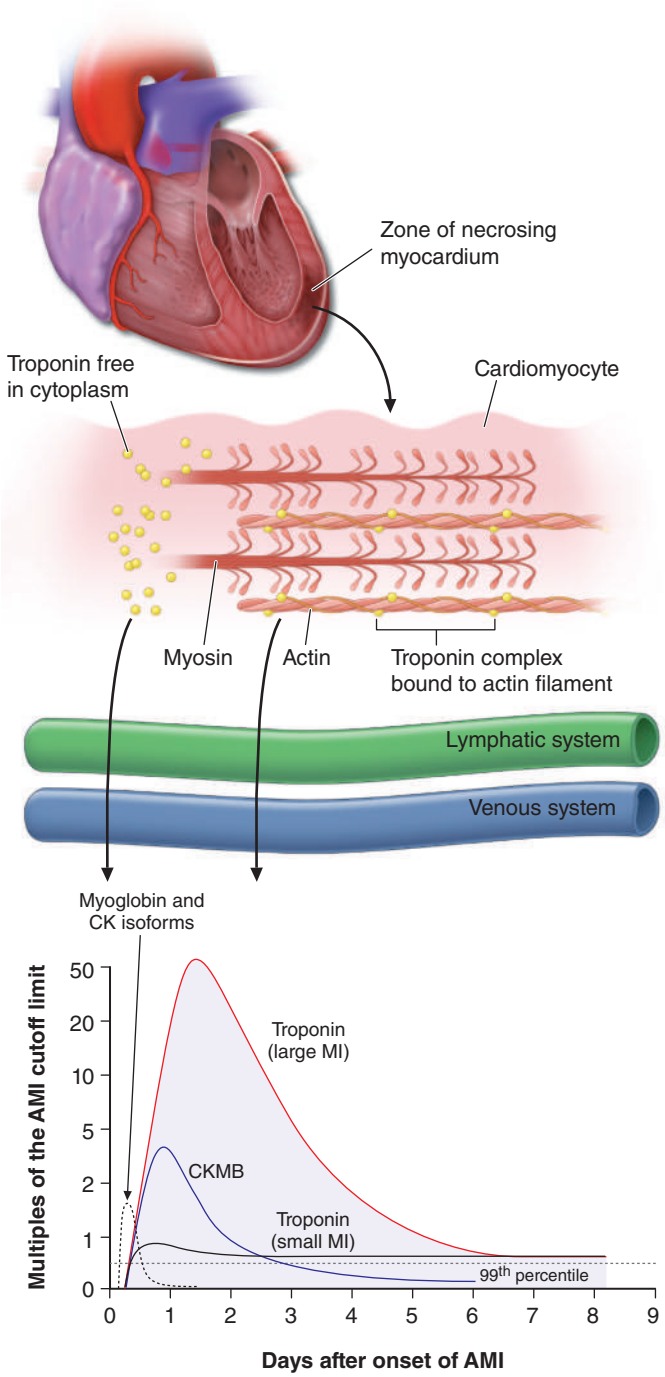

FIGURE 286-4 The zone of necrosing myocardium is shown at the top of the figure, followed in the middle portion of the figure by a diagram of a cardiomyocyte that is in the process of releasing biomarkers. The biomarkers that are released into the interstitium are first cleared by lymphatics followed subsequently by spillover into the venous system. After disruption of the sarcolemmal membrane of the cardiomyocyte, the cytoplasmic pool of biomarkers is released first (*left-most arrow in bottom portion of figure*). Markers such as myoglobin and CK isoforms are rapidly released, and blood levels rise quickly above the cutoff limit; this is then followed by a more protracted release of biomarkers from the disintegrating myofilaments that may continue for several days. Cardiac troponin levels rise to about 20–50 times the upper reference limit (the 99th percentile of values in a reference control group) in patients who have a "classic" acute myocardial infarction (MI) and sustain sufficient myocardial necrosis to result in abnormally elevated levels of the MB fraction of creatine kinase (CK-MB). Clinicians can now diagnose episodes of microinfarction by sensitive assays that detect cardiac troponin elevations above the upper reference limit, even though CK-MB levels may still be in the normal reference range (not shown). CV, coefficient of variation. *(Modified from EM Antman: Decision making with cardiac troponin tests. N Engl J Med 346:2079, 2002, and; bottom image: Reproduced with permission from AS Jaffe: Biomarkers in acute cardiac disease: The present and the future. J Am Coll Cardiol 48:1, 2006.)*

therapy with an inhibitor of the renin-angiotensin-aldosterone system. Echocardiography may also identify the presence of right ventricular (RV) infarction, ventricular aneurysm, pericardial effusion, and LV thrombus. In addition, Doppler echocardiography is useful in the detection and quantitation of a ventricular septal defect and mitral regurgitation, two serious complications of STEMI.

Radionuclide imaging techniques **(Chap. 248)** are available but rarely used for evaluating patients with suspected STEMI. Myocardial perfusion imaging with [^{99m}Tc]-sestamibi, which is distributed in proportion to myocardial blood flow and concentrated by viable myocardium **(Chap. 285)**, reveals a defect ("cold spot") in most patients during the first few hours after development of a transmural infarct. However, the technique cannot distinguish acute infarcts from chronic scars and, thus, is not specific for the diagnosis of *acute* MI.

An Expert Consensus Task Force for the Universal Definition of Myocardial Infarction has provided a comprehensive set of criteria for the definition of MI that integrates the clinical and laboratory findings discussed earlier as well as a classification of MI into five types that reflect the clinical circumstances in which it may occur **(Table 286-1)**.

INITIAL MANAGEMENT

PREHOSPITAL CARE

The prognosis in STEMI in the era of primary PCI is largely related to the occurrence of two general classes of complications: (1) electrical complications (arrhythmias) and (2) mechanical complications ("pump failure"). Most out-of-hospital deaths from STEMI result from the sudden development of ventricular fibrillation. The vast majority of deaths due to ventricular fibrillation occur within the first 24 h of the onset of symptoms, and of these, over half occur in the first hour. Therefore, the major elements of prehospital care of patients with suspected STEMI include (1) recognition of symptoms by the patient and prompt seeking of medical attention; (2) rapid deployment of an emergency medical team capable of performing resuscitative maneuvers, including defibrillation; (3) expeditious transportation of the patient to a hospital facility that is continuously staffed by physicians and nurses skilled in managing arrhythmias and providing advanced cardiac life support; and (4) expeditious implementation of reperfusion therapy. The greatest delay usually occurs not during transportation to the hospital but, rather, between the onset of pain and the patient's decision to call for help. This delay can best be reduced by health care professionals educating the public concerning the significance of chest discomfort and the importance of seeking early medical attention. Regular office visits with patients having a history of, or who are at risk for, ischemic heart disease are important "teachable moments" for clinicians to review the symptoms of AMI and the appropriate action plan.

Increasingly, monitoring and treatment are carried out by trained personnel in the ambulance, further shortening the time between the onset of the infarction and appropriate treatment. In areas remote from PCI centers, fibrinolytic therapy may be administered prehospital. General guidelines for initiation of fibrinolysis in the prehospital setting include the ability to transmit 12-lead ECGs to confirm the diagnosis, the presence in the ambulance of personnel trained in the interpretation of ECGs and management of STEMI, and online medical command and control that can authorize the initiation of treatment in the field.

MANAGEMENT IN THE EMERGENCY DEPARTMENT

In the emergency department, the goals for the management of patients with suspected STEMI include control of cardiac discomfort, rapid identification of patients who are candidates for urgent reperfusion therapy, triage of lower-risk patients to the appropriate location in the hospital, and avoidance of inappropriate discharge of patients with STEMI. Many aspects of the treatment of STEMI are initiated in the emergency department and then continued during the in-hospital phase of management. The overarching goal is to minimize the time from first medical contact to initiation of reperfusion therapy **(Fig. 286-5)**. This may involve transfer from a non-PCI hospital to one

TABLE 286-1 Definitions of Myocardial Injury and Infarction

Criteria for Myocardial Injury

The term *myocardial injury* should be used when there is evidence of elevated cardiac troponin (cTn) levels with at least one value above the 99th percentile upper reference limit (URL). The myocardial injury is considered acute if there is a rise and/or fall of cTn values.

Criteria for Acute Myocardial Infarction (types 1, 2, and 3 MI)

The term *acute myocardial infarction* (MI) should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischemia and with detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and at least one of the following:

- Symptoms of myocardial ischemia
- New ischemic electrocardiographic (ECG) changes
- Development of pathologic Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology
- Identification of a coronary thrombus by angiography or autopsy (not for types 2 or 3 MIs)

Postmortem demonstration of acute atherothrombosis in the artery supplying the infarcted myocardium meets criteria for *type 1 MI*. Evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute atherothrombosis meets criteria for *type 2 MI*. Cardiac death in patients with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes before cTn values became available or abnormal meets criteria for *type 3 MI*.

Criteria for Coronary Procedure–Related MI (types 4 and 5 MI)

Percutaneous coronary intervention (PCI)–related MI is termed *type 4a MI*.

Coronary artery bypass grafting (CABG)–related MI is termed *type 5 MI*. Coronary procedure–related MI <48 h after the index procedure is arbitrarily defined by an elevation of cTn values >5 times for *type 4a MI* and >10 times for *type 5 MI* of the 99th percentile URL in patients with normal baseline values. Patients with elevated preprocedural cTn values, in whom the preprocedural cTn levels are stable (<20% variation) or falling, must meet the criteria for a >5- or >10-fold increase and manifest a change from the baseline value of >20%. In addition, they must have at least one of the following:

- New ischemic ECG changes (this criterion is related to *type 4a MI* only)
- Development of new pathologic Q waves
- Imaging evidence of loss of viable myocardium that is presumed to be new and in a pattern consistent with an ischemic etiology
- Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or graft, side-branch occlusion-thrombus, disruption of collateral flow, or distal embolization

Isolated development of new pathologic Q waves meets the *type 4a MI* or *type 5 MI* criteria with either revascularization procedure if cTn levels are elevated and rising, but less than the prespecified thresholds for PCI and CABG.

Other types of type 4 MI include *type 4B MI* stent thrombosis and *type 4C MI* restenosis that both meet *type 1 MI* criteria.

Postmortem demonstration of a procedure-related thrombus meets the *type 4a MI* and *type 5 MI* criteria if associated with a stent.

Criteria for Prior or Silent/Unrecognized MI

Any one of the following criteria meets the diagnosis for prior or silent/unrecognized MI:

- Abnormal Q waves with or without symptoms in the absence of nonischemic causes
- Imaging evidence of loss of viable myocardium in a pattern consistent with ischemic etiology
- Pathoanatomical findings of a prior MI

Source: Reproduced with permission from K Thygesen et al: Fourth universal definition of myocardial infarction (2018). Circulation 138:e618, 2018.

that is PCI capable, with a goal of initiating PCI within 120 min of first medical contact (Fig. 286-5).

Aspirin is essential in the management of patients with suspected STEMI and is effective across the entire spectrum of acute coronary syndromes. Rapid inhibition of cyclooxygenase-1 in platelets followed by a reduction of thromboxane A_2 levels is achieved by buccal absorption of a chewed 160–325-mg tablet in the emergency department. This measure should be followed by daily oral administration of aspirin in a dose of 75–162 mg.

In patients whose arterial oxygen (O_2) saturation is normal, supplemental O_2 is not recommended. However, when hypoxemia is present (O_2 saturation <90%), O_2 should be administered to correct the hypoxemia; the patient should then be reassessed to determine if there is a continued need for such treatment.

CONTROL OF DISCOMFORT

Sublingual *nitroglycerin* can be given safely to most patients with STEMI. Up to three doses of 0.4 mg should be administered at about 5-min intervals in patients with persistent ischemic symptoms. In addition to diminishing or abolishing chest discomfort, nitroglycerin may be capable of both decreasing myocardial O_2 demand (by lowering preload) and increasing myocardial O_2 supply (by dilating infarct-related coronary vessels or collateral vessels and by improving subendocardial perfusion). In patients whose initially favorable response to sublingual nitroglycerin is followed by the return of chest discomfort, particularly if accompanied by other evidence of ongoing ischemia such as further ST-segment or T-wave shifts, the use of intravenous nitroglycerin may be considered. Therapy with nitrates should be avoided in patients who present with low systolic arterial pressure (<90 mmHg) or in whom there is clinical suspicion of RV infarction (inferior infarction on ECG, elevated jugular venous pressure, clear lungs, and hypotension). Nitrates should not be administered to patients who have taken a phosphodiesterase-5 inhibitor for erectile dysfunction within the preceding 24 h because it may potentiate the hypotensive effects of nitrates. An idiosyncratic reaction to nitrates, consisting of sudden marked hypotension, sometimes occurs but can usually be reversed promptly by the rapid administration of intravenous atropine.

Morphine is a very effective analgesic for the pain associated with STEMI. However, it may reduce sympathetically mediated arteriolar and venous constriction, and the resulting venous pooling may reduce cardiac output and arterial pressure. These hemodynamic disturbances usually respond promptly to elevation of the legs, but in some patients, volume expansion with intravenous saline is required. The patient may experience diaphoresis and nausea, but these events usually pass and are replaced by a feeling of well-being associated with the relief of pain. Morphine also has a vagotonic effect and may cause bradycardia or advanced degrees of heart block, particularly in patients with inferior infarction. These side effects usually respond to atropine (0.5 mg intravenously). Morphine may also slow the gastrointestinal absorption of oral medicines, which may delay the onset of action of orally administered antiplatelet therapy; however, currently available clinical data have not demonstrated an increase in the risk of adverse clinical outcomes as a result of any interaction between morphine and antiplatelet agents. Therefore, it is reasonable to use morphine in patients with STEMI to relieve pain. Morphine is administered by repetitive (every 5 min) intravenous injection of small doses (2–4 mg).

Intravenous *beta blockers* are also useful in mitigating the ischemic pain of STEMI. These drugs control pain effectively in some patients, presumably by diminishing myocardial O_2 demand and hence ischemia. More important, there is evidence that intravenous beta blockers reduce the risks of reinfarction and ventricular fibrillation (see "Beta-Adrenoceptor Blockers" below). A commonly employed regimen is metoprolol, 5 mg every 2–5 min for a total of three doses, provided the patient has a heart rate >60 beats/min, systolic pressure >100 mmHg, a PR interval <0.24 s, and no signs of acute heart failure.

Patient selection is important when considering beta blockers for STEMI. Oral beta blocker therapy should be initiated in the first 24 h for patients who do *not* have any of the following: (1) signs of acute heart failure, (2) evidence of a low-output state, (3) increased risk for cardiogenic shock, or (4) other relative contraindications to beta blockade (bradycardia, PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease). In eligible patients, 15 min after the last intravenous dose, an oral regimen is initiated with 50 mg every 6 h for 48 h, followed by 100 mg every 12 h.

Unlike beta blockers, calcium antagonists are of little value in the acute setting, and there is evidence that short-acting dihydropyridines may be associated with an increased mortality risk.

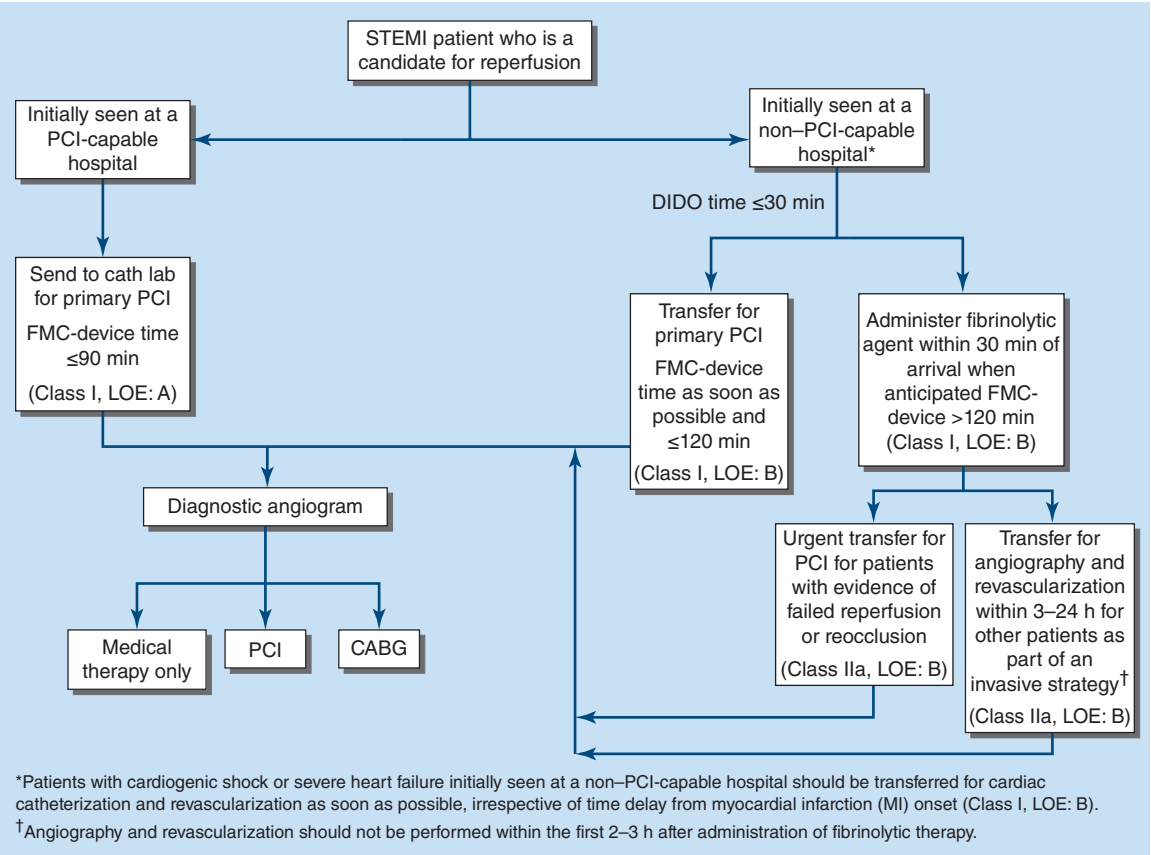

FIGURE 286-5 Reperfusion therapy for patients with ST-segment elevation myocardial infarction (STEMI). Performance of percutaneous coronary intervention (PCI) is dictated by an anatomically appropriate culprit stenosis. Circulation 127:e362, 2013.)*

MANAGEMENT STRATEGIES

The primary tool for screening patients and making triage decisions is the initial 12-lead ECG. When ST-segment elevation meeting the Universal Definition of MI criteria **(Table 286-2)** is present, a patient should be considered a candidate for *reperfusion therapy* (Figs. 286-1 and 286-5). The process of selecting patients for fibrinolysis versus primary PCI **(Chap. 287)** is discussed below. In the absence of ST-segment elevation, fibrinolysis is not helpful, and evidence exists suggesting that it may be harmful.

LIMITATION OF INFARCT SIZE

The quantity of myocardium that becomes necrotic as a consequence of a coronary artery occlusion is determined by factors other than just the location of occlusion. While the central zone of the infarct contains necrotic tissue that is irretrievably lost, the fate of the surrounding ischemic myocardium (ischemic penumbra) may be improved by timely restoration of coronary perfusion, reduction of myocardial O_2 demands, prevention of the accumulation of noxious metabolites, and blunting of the impact of mediators of reperfusion injury (e.g., calcium overload and oxygen-derived free radicals). Up to one-third of patients with STEMI may achieve *spontaneous* reperfusion of the infarct-related coronary artery within 24 h and experience improved healing of infarcted tissue.

TABLE 286-2 Electrocardiographic Criteria for ST-Elevation Myocardial Infarction

New ST-elevation at the J-point in 2 contiguous leads with the cut-point:

- In all leads other than leads V_2–V_3: ≥0.1 mV (1 mm on standard scale)
- In leads V_2–V_3:
  - ≥0.2 mV (2 mm) in men ≥40 years old
  - ≥0.25 mV (2.5 mm) in men <40 years
  - ≥0.15 mV (1.5 mm) in women regardless of age

Source: Reproduced from K Thygesen et al: Fourth universal definition of myocardial infarction (2018). Circulation 138:e618, 2018.

Reperfusion, either pharmacologically (by fibrinolysis) or by primary PCI, accelerates the opening of infarct-related arteries in those patients in whom spontaneous fibrinolysis ultimately would have occurred and also greatly increases the number of patients in whom restoration of flow in the infarct-related artery is accomplished. Timely restoration of flow in the epicardial infarct–related artery combined with improved perfusion of the downstream zone of infarcted myocardium results in a limitation of infarct size. Protection of the ischemic myocardium by the maintenance of an optimal balance between myocardial O_2 supply and demand through pain control, treatment of heart failure (HF), and minimization of tachycardia and hypertension extends the "window" of time for the salvage of myocardium by reperfusion strategies.

Glucocorticoids and nonsteroidal anti-inflammatory agents, with the exception of aspirin, should be avoided in patients with STEMI. They can impair infarct healing and increase the risk of myocardial rupture, and their use may result in a larger infarct scar. In addition, they can increase coronary vascular resistance, thereby potentially reducing flow to ischemic myocardium.

PRIMARY PERCUTANEOUS CORONARY INTERVENTION

(See also Chap. 287) PCI, usually stenting without preceding fibrinolysis, referred to as *primary PCI*, is effective in restoring perfusion in STEMI when carried out on an emergency basis in the first few hours of MI. It has the advantage of being applicable to patients who have contraindications to fibrinolytic therapy (see below) but otherwise are considered appropriate candidates for reperfusion. Primary PCI is more effective than fibrinolysis in opening occluded coronary arteries and, *when performed by experienced teams in dedicated medical centers*, is associated with better short-term and long-term clinical outcomes. Compared with fibrinolysis, primary PCI is preferred unless the time to delivery of the first coronary device is anticipated to be longer than 120 min. Primary PCI is also preferred when the diagnosis is in doubt, cardiogenic shock is present, bleeding risk is high, or symptoms have

been present for longer than 2–3 h, at which time the clot is less easily lysed by fibrinolytic drugs. Contemporary studies (PRAMI, CvLPRIT, COMPLETE) provide evidence that, in patients with STEMI without shock, performing PCI on nonculprit coronary vessels, either during the index procedure or within 45 days, results in a lower rate of cardiovascular events and a lower need for subsequent ischemia-driven revascularization. In contrast, among patients with cardiogenic shock, routine PCI of nonculprit arteries during the initial primary PCI is contraindicated due to an increase in the rate of death or severe renal failure compared with culprit-only PCI.

FIBRINOLYSIS

If timely primary PCI is not available and no contraindications are present (see below), fibrinolytic therapy should ideally be initiated within 30 min of presentation (i.e., door-to-needle time ≤30 min). The principal goal of fibrinolysis is prompt restoration of full coronary arterial patency. The fibrinolytic agents tissue plasminogen activator (tPA), streptokinase, tenecteplase (TNK), and reteplase (rPA) have been approved by the U.S. Food and Drug Administration for intravenous use in patients with STEMI. These drugs all act by promoting the conversion of plasminogen to plasmin, which subsequently lyses fibrin thrombi. Although considerable emphasis was first placed on a distinction between more fibrin-specific agents, such as tPA, and non-fibrin-specific agents, such as streptokinase, it is now recognized that these differences are only relative, as some degree of systemic fibrinolysis occurs with the former agents. TNK and rPA are referred to as *bolus fibrinolytics* since their administration does not require a prolonged intravenous infusion.

When assessed angiographically, flow in the culprit coronary artery is described by a simple qualitative scale called the *Thrombolysis in Myocardial Infarction (TIMI) grading system*: grade 0 indicates complete occlusion of the infarct-related artery; grade 1 indicates some penetration of the contrast material beyond the point of obstruction, but without perfusion of the distal coronary bed; grade 2 indicates perfusion of the entire infarct vessel into the distal bed, but with flow that is delayed compared with that of a normal artery; and grade 3 indicates full perfusion of the infarct vessel with normal flow. The latter is the goal of reperfusion therapy, because full perfusion of the infarct-related coronary artery yields far better results in terms of limiting infarct size, maintenance of LV function, and reduction of both short- and long-term mortality rates.

tPA and the other relatively fibrin-specific plasminogen activators, rPA and TNK, are more effective than streptokinase at restoring full perfusion—i.e., TIMI grade 3 coronary flow—and have a small edge in improving survival as well. The recommended regimen of tPA consists of a 15-mg bolus followed by 50 mg intravenously over the first 30 min, followed by 35 mg over the next 60 min. Streptokinase is administered as 1.5 million units (MU) intravenously over 1 h. rPA is administered in a double-bolus regimen consisting of a 10-MU bolus given over 2–3 min, followed by a second 10-MU bolus 30 min later. TNK is given as a single weight-based intravenous bolus of 0.53 mg/kg over 10 s. In addition to the fibrinolytic agents discussed earlier, pharmacologic reperfusion typically involves adjunctive antiplatelet and antithrombotic drugs, as discussed subsequently.

Clear contraindications to the use of fibrinolytic agents include a history of cerebrovascular hemorrhage at any time, a nonhemorrhagic stroke or other cerebrovascular event within the past year, marked hypertension (a reliably determined systolic arterial pressure >180 mmHg and/or a diastolic pressure >110 mmHg) at any time during the acute presentation, suspicion of aortic dissection, and active internal bleeding (excluding menses). While advanced age is associated with an increase in hemorrhagic complications, the benefit of fibrinolytic therapy in the elderly appears to justify its use if no other contraindications are present, the amount of myocardium in jeopardy appears to be substantial, and timely access to primary PCI is not available.

Relative contraindications to fibrinolytic therapy, which require assessment of the risk-to-benefit ratio, include current use of anticoagulants (international normalized ratio ≥2), a recent (<2 weeks) invasive or surgical procedure or prolonged (>10 min) cardiopulmonary resuscitation, known bleeding diathesis, pregnancy, a hemorrhagic ophthalmic condition (e.g., hemorrhagic diabetic retinopathy), active peptic ulcer disease, and a history of severe hypertension that is currently adequately controlled. Because of the risk of an allergic reaction, patients should not receive streptokinase if that agent had been received within the preceding 5 days to 2 years.

Allergic reactions to streptokinase occur in ~2% of patients who receive it. While a minor degree of hypotension occurs in 4–10% of patients given this agent, marked hypotension occurs, although rarely, in association with severe allergic reactions.

Hemorrhage is the most frequent and potentially the most serious complication. Because bleeding episodes that require transfusion are more common when patients require invasive procedures, unnecessary venous or arterial interventions should be avoided in patients receiving fibrinolytic agents. Hemorrhagic stroke is the most serious complication and occurs in ~0.5–0.9% of patients being treated with these agents. This rate increases with advancing age, with patients >70 years experiencing roughly twice the rate of intracranial hemorrhage as those <65 years. Large-scale trials have suggested that the rate of intracranial hemorrhage with tPA or rPA is slightly higher than with streptokinase.

INTEGRATED REPERFUSION STRATEGY

Timely performance of PCI is the preferred reperfusion strategy in the management of STEMI. Prior approaches that segregated the pharmacologic and catheter-based approaches to reperfusion have now been replaced with an integrated approach to triage and transfer STEMI patients to receive PCI (Fig. 286-5). To achieve the degree of integration required to care for a patient with STEMI, all communities should create and maintain a regional system of STEMI care that includes assessment and continuous quality improvement of emergency medical services and hospital-based activities.

In patients who have been treated with a fibrinolytic, urgent coronary angiography should be performed if there is evidence of either (1) failure of reperfusion (persistent chest pain and ST-segment elevation >90 min), in which case a *rescue PCI* should be considered; or (2) coronary artery reocclusion (re-elevation of ST segments and/or recurrent chest pain) or the development of recurrent ischemia. Moreover, transfer to a PCI-capable center is recommended in all patients immediately after fibrinolysis with intent for angiography and PCI of the infarct-related artery, if indicated, between 3 and 24 h after successful fibrinolysis. Coronary artery bypass surgery should be reserved for patients whose coronary anatomy is unsuited to PCI but in whom revascularization appears to be advisable because of extensive jeopardized myocardium or recurrent ischemia.

HOSPITAL PHASE MANAGEMENT

CARDIAC INTENSIVE CARE UNITS

These units, previously described as coronary care units, are routinely equipped with continuous monitoring of the cardiac rhythm of each patient and hemodynamic monitoring in selected patients. Equally important is the organization of a highly trained team of nurses who can recognize arrhythmias and perform cardiac resuscitation, including electroshock, when necessary. The availability of electrocardiographic monitoring and trained personnel outside the coronary care unit has made it possible to admit lower-risk patients (e.g., those not hemodynamically compromised and without active arrhythmias) to "intermediate care units." However, it remains reasonable to admit patients with STEMI to a cardiac intensive care unit when high-risk features are present (e.g., hemodynamic or electrical instability) or when suitably equipped and staffed intermediate care units are not available.

The duration of stay in the coronary care unit is dictated by the ongoing need for intensive care. In general, patients with STEMI who remain at low risk (no persistent chest discomfort, HF, hypotension, or cardiac arrhythmias) may be safely transferred out of the coronary care unit within 24–48 h.

Activity Factors that increase the work of the heart during the initial hours of infarction may increase the size of the infarct. Therefore, patients with STEMI should generally be kept at bed rest for the first 6–12 h. However, in the absence of complications, patients should be encouraged, under supervision, to resume an upright posture by dangling their feet over the side of the bed and sitting in a chair within the first 24 h. This practice is psychologically beneficial and usually results in a reduction in the pulmonary capillary wedge pressure. In the absence of hypotension and other complications, patients typically are ambulating with increasing duration, anticipating that they may be discharged after 3–5 days.

Diet Because of the risk of emesis and aspiration soon after STEMI, patients should receive either nothing or only clear liquids by mouth for the first 4–12 h. The typical diet after AMI should provide ≤30% of total calories as fat and have a cholesterol content of ≤300 mg/d. Complex carbohydrates should make up 50–55% of total calories. Portions should not be unusually large, and the menu should be enriched with foods that are high in potassium, magnesium, and fiber, but low in sodium. Diabetes mellitus and hypertriglyceridemia are managed by restriction of concentrated sweets in the diet.

PHARMACOTHERAPY

ANTITHROMBOTIC AGENTS

The use of antiplatelet and anticoagulant therapy during the initial phase of STEMI is based on extensive laboratory and clinical evidence that thrombosis plays an important role in the pathogenesis of this condition. The primary goal of treatment with antiplatelet and anticoagulant agents is to maintain patency of the infarct-related artery, in conjunction with reperfusion strategies. A secondary goal is to reduce the patient's tendency to thrombosis and, thus, the likelihood of mural thrombus formation or deep-venous thrombosis. The degree to which antiplatelet and anticoagulant therapy achieves these goals partly determines how effectively it reduces the risk of mortality from STEMI.

As noted previously (see "Management in the Emergency Department" earlier), aspirin is the standard antiplatelet agent for patients with STEMI. The most compelling evidence for the benefits of antiplatelet therapy (mainly with aspirin) in STEMI is found in the comprehensive overview by the Antiplatelet Trialists' Collaboration. Data from nearly 20,000 patients with MI enrolled in 15 randomized trials were pooled and revealed a relative reduction of 27% in the mortality rate, from 14.2% in control patients to 10.4% in patients receiving antiplatelet agents.

Inhibitors of the $P2Y_{12}$ ADP receptor prevent activation and aggregation of platelets. The addition of the $P2Y_{12}$ inhibitor clopidogrel to background treatment with aspirin to STEMI patients reduces the risk of clinical events (death, reinfarction, stroke) and, in patients receiving fibrinolytic therapy, has been shown to prevent reocclusion of a successfully reperfused infarct artery. Third-generation oral $P2Y_{12}$ ADP receptor antagonists, such as prasugrel and ticagrelor, are more effective than clopidogrel in preventing ischemic complications in STEMI patients undergoing PCI but are associated with an increased risk of bleeding. Glycoprotein IIb/IIIa receptor inhibitors may be used when thrombotic complications occur during PCI.

The anticoagulant agent most commonly used in clinical practice is unfractionated heparin (UFH). Use of UFH is recommended in patients with STEMI undergoing primary PCI. In addition, the available data suggest that when UFH is added to a regimen of aspirin and a non-fibrin-specific thrombolytic agent such as streptokinase, additional mortality benefit occurs (about 5 lives saved per 1000 patients treated). The immediate administration of intravenous UFH, in addition to a regimen of aspirin and relatively fibrin-specific fibrinolytic agents (tPA, rPA, or TNK), helps to maintain patency of the infarct-related artery. This effect is achieved at the cost of a small increased risk of bleeding. The recommended dose of UFH is an initial bolus of 60 U/kg (maximum 4000 U) followed by an initial infusion of 12 U/kg per h (maximum 1000 U/h). The activated partial thromboplastin time during maintenance therapy should be 1.5–2 times the control value.

Alternatives to UFH for anticoagulation of patients with STEMI are the low-molecular-weight heparin (LMWH) preparations, a synthetic version of the critical pentasaccharide sequence (fondaparinux), and the direct antithrombin bivalirudin. Advantages of LMWHs include high bioavailability permitting administration subcutaneously, reliable anticoagulation without monitoring, and greater anti-Xa:IIa activity. Enoxaparin has been shown to reduce significantly the composite endpoints of death/nonfatal reinfarction and death/nonfatal reinfarction/urgent revascularization compared with UFH in STEMI patients who receive fibrinolysis. Treatment with enoxaparin is associated with higher rates of serious bleeding, but net clinical benefit—a composite endpoint that combines efficacy and safety—still favors enoxaparin over UFH. Interpretation of the data on fondaparinux is difficult because of the complex nature of the pivotal clinical trial evaluating it in STEMI (OASIS-6). Fondaparinux appears superior to placebo in STEMI patients not receiving reperfusion therapy, but its relative efficacy and safety compared with UFH are less certain. Owing to the risk of catheter thrombosis, fondaparinux should not be used alone at the time of coronary angiography and PCI but should be combined with another anticoagulant with antithrombin activity such as UFH or bivalirudin. Trials of bivalirudin used an open-label design to evaluate its efficacy and safety compared with UFH plus a glycoprotein IIb/IIIa inhibitor. Bivalirudin was associated with a lower rate of bleeding, largely driven by reductions in vascular access site hematomas ≥5 cm or the administration of blood transfusions. Bivalirudin is an alternative to UFH in patients undergoing primary PCI.

Patients with an anterior location of the infarction, severe LV dysfunction, HF, a history of embolism, or two-dimensional echocardiographic evidence of mural thrombus are at increased risk of systemic or pulmonary thromboembolism. Patients with suspected mural thrombus should receive full therapeutic levels of anticoagulant therapy (LMWH or UFH) while hospitalized, followed by at least 3 months of oral anticoagulant therapy. It is reasonable to consider extended oral anticoagulant therapy (i.e., up to 3 months after presentation with STEMI) in patients with a high risk of developing systemic thromboembolism because of a large area of akinetic myocardium.

BETA-ADRENOCEPTOR BLOCKERS

The benefits of beta blockers in patients with STEMI can be divided into those that occur immediately when the drug is given acutely and those that accrue over the long term when the drug is given for secondary prevention after an infarction. Acute intravenous beta blockade, although no longer routinely recommended because of the risk of precipitating heart failure, improves the myocardial O_2 supply-demand relationship, decreases pain, reduces infarct size, and decreases the incidence of serious ventricular arrhythmias. In patients who undergo fibrinolysis soon after the onset of chest pain, no incremental reduction in mortality rate is seen with beta blockers, but recurrent ischemia and reinfarction are reduced.

Oral beta-blocker therapy after STEMI is useful for most patients (including those treated with an angiotensin-converting enzyme [ACE] inhibitor) except those in whom it is specifically contraindicated (patients with HF or severely compromised LV function, heart block, orthostatic hypotension, or a history of asthma) and perhaps those whose excellent long-term prognosis (defined as an expected mortality rate of <1% per year, patients <55 years, no previous MI, with normal ventricular function, no complex ventricular ectopy, and no angina) markedly diminishes any potential benefit.

INHIBITION OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

ACE inhibitors reduce the mortality rate after STEMI, and the mortality benefits are additive to those achieved with aspirin and beta blockers. The maximum benefit is seen in high-risk patients (those who have an anterior infarction, a prior infarction, and/or globally depressed LV function), but evidence suggests that a short-term benefit occurs when ACE inhibitors are prescribed unselectively to all hemodynamically stable patients with STEMI (i.e., those with a systolic pressure >100 mmHg). The mechanism involves a reduction in ventricular remodeling after infarction (see

"Ventricular Dysfunction" later) with a subsequent reduction in the risk of HF. The rate of recurrent infarction may also be lower in patients treated chronically with ACE inhibitors after infarction.

ACE inhibitors should be continued indefinitely in patients who have clinically evident HF, in patients in whom an imaging study shows a reduction in global LV function or a large regional wall motion abnormality, or in those who are hypertensive.

Angiotensin receptor blockers (ARBs) should be administered to STEMI patients who are intolerant of ACE inhibitors and who have either clinical or radiologic signs of HF. Long-term mineralocorticoid receptor inhibition (spironolactone, eplerenone) should be prescribed for STEMI patients who are already receiving therapeutic doses of an ACE inhibitor, have an LV ejection fraction ≤40%, and have either symptomatic HF or diabetes mellitus and do not have significant renal dysfunction (creatinine ≥2.5 mg/dL in men and ≥2.0 mg/dL in women) or hyperkalemia (potassium ≥5.0 mEq/L).

Although angiotensin receptor–neprilysin inhibition with sacubitril/valsartan is more effective than ACE inhibitor therapy in patients with symptomatic HF with a reduced ejection fraction, sacubitril/valsartan was not more effective than an ACE inhibitor in preventing the development of incident HF in patients early post-MI.

OTHER AGENTS

Favorable effects on the ischemic process and ventricular remodeling (see below) previously led many physicians to routinely use *intravenous nitroglycerin* (5–10 μg/min initial dose and up to 200 μg/min as long as hemodynamic stability is maintained) for the first 24–48 h after the onset of infarction. However, a subsequent large, randomized trial demonstrated no benefit of intravenous nitroglycerin with respect to major outcomes in patients with STEMI. Use of intravenous nitroglycerin may be considered in patients with STEMI who have persistent hypertension, HF, or ongoing ischemia.

Results of multiple trials of different calcium antagonists have failed to establish a role for these agents in the treatment of most patients with STEMI. Therefore, the routine use of calcium antagonists cannot be recommended. Targeted control of blood glucose in diabetic patients with STEMI has been shown to reduce the mortality rate. Serum magnesium should be measured in all patients on admission, and any demonstrated deficits should be corrected to minimize the risk of arrhythmias.

COMPLICATIONS AND THEIR MANAGEMENT

Recognition and management of the complications of STEMI are essential elements of the care of this patient population **(Table 286-3)**.

VENTRICULAR DYSFUNCTION

After STEMI, the left ventricle undergoes a series of changes in shape, size, and thickness in both the infarcted and noninfarcted segments. This process is referred to as *ventricular remodeling* and generally precedes the development of clinically evident HF in the months to years after infarction. Soon after STEMI, the left ventricle begins to dilate. Acutely, this results from expansion of the infarct, i.e., slippage of muscle bundles, disruption of normal myocardial cells, and tissue loss within the necrotic zone, resulting in disproportionate thinning and elongation of the infarct zone. Later, lengthening of the noninfarcted segments occurs as well. The overall chamber enlargement that occurs is related to the size and location of the infarct, with greater dilation following infarction of the anterior wall and apex of the left ventricle and causing more marked hemodynamic impairment, more frequent HF, and a poorer prognosis. Progressive dilation and its clinical consequences may be ameliorated by therapy with ACE inhibitors. In patients with an ejection fraction <40%, regardless of whether or not HF is present, ACE inhibitors or ARBs, and eventually a beta blocker, should be prescribed (see "Inhibition of the Renin-Angiotensin-Aldosterone System" earlier).

HEMODYNAMIC ASSESSMENT

Pump failure is now the primary cause of in-hospital death from STEMI. The extent of infarction correlates well with the degree of pump failure and with mortality, both early (within 10 days of infarction) and later. The most common clinical signs are pulmonary rales and an S_3 gallop sound. Pulmonary congestion is also frequently seen on the chest roentgenogram. Elevated LV filling pressure and elevated pulmonary artery pressure are the characteristic hemodynamic findings, but these findings may result from a reduction of ventricular compliance (diastolic failure) and/or a reduction of stroke volume with secondary cardiac dilation (systolic failure) **(Chap. 264)**.

A classification originally proposed by Killip divides patients into four groups: class I, no signs of pulmonary or venous congestion; class II, moderate HF as evidenced by rales at the lung bases, S_3 gallop, tachypnea, or signs of failure of the right side of the heart, including venous and hepatic congestion; class III, severe HF and pulmonary edema; and class IV, shock with systolic pressure <90 mmHg and evidence of peripheral vasoconstriction, peripheral cyanosis, mental confusion, and oliguria. When this classification was established in 1967, the expected hospital mortality rate of patients in these classes was as follows: class I, 0–5%; class II, 10–20%; class III, 35–45%; and class IV, 85–95%. With advances in management, the mortality rate in each class has fallen, perhaps by as much as

TABLE 286-3 Mechanical Complications of ST-Elevation Myocardial Infarction

CHARACTERISTIC	VENTRICULAR SEPTAL RUPTURE	RUPTURE OF THE VENTRICULAR FREE WALL	PAPILLARY MUSCLE RUPTURE
Incidence	0.2–3% without reperfusion therapy, 0.2–0.34% with fibrinolytic therapy, 3.9% in patients with cardiogenic shock	Approximately 0.3–1%; fibrinolytic therapy does not reduce risk; primary PCI seems to reduce risk	Approximately 0.1–1% (posteromedial more frequent than anterolateral papillary muscle rupture)
Time course	Bimodal peak; within 24 h and 3–5 days; range, 1–14 days	Bimodal peak; within 24 h and 3–5 days; range, 1–14 days	Bimodal peak; within 24 h and 3–5 days; range, 1–14 days
Clinical manifestations	Chest pain, shortness of breath, hypotension	Anginal, pleuritic, or pericardial chest pain; syncope; hypotension; restlessness; sudden death	Abrupt onset of shortness of breath and pulmonary edema; hypotension
Physical findings	Harsh holosystolic murmur, thrill, S_3, accentuated S_2, pulmonary edema, RV and LV failure, cardiogenic shock	Jugular venous distention (29% of patients), pulsus paradoxus (47%), electromechanical dissociation, cardiogenic shock	A soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema, cardiogenic shock
Echocardiographic findings	Ventricular septal rupture, left-to-right shunt on color flow Doppler echocardiography through the ventricular septum, pattern of RV overload	>5 mm pericardial effusion not visualized in all cases; layered, high-acoustic echoes within the pericardium (blood clot); direct visualization of tear; signs of tamponade	Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe mitral regurgitation on color flow Doppler echocardiography
Right-heart catheterization	Increase in oxygen saturation from the RA to RV, large *v* waves	Ventriculography insensitive, classic signs of tamponade not always present (equalization of diastolic pressures in the cardiac chambers)	No increase in oxygen saturation from the RA to RV, large *v* waves, very high PCWP

Abbreviations: LV, left ventricle; PCI, percutaneous coronary intervention; PCWP, pulmonary capillary wedge pressure; RA, right atrium; RV, right ventricle.

Source: Reproduced with permission from Bohula EA, Morrow DA: ST-elevation myocardial infarction: Management, in *Braunwald's Heart Disease,* 12th ed, Libby P et al (eds). New York, Elsevier, 2022, pp 662-713.

one-third to one-half. However, the mortality rate for patients with cardiogenic shock (class IV) has plateaued without additional improvement for the past 25 years.

Hemodynamic evidence of abnormal global LV function appears when contraction is seriously impaired in 20–25% of the left ventricle. Infarction of ≥40% of the left ventricle usually results in cardiogenic shock **(Chap. 316)**. Positioning of a balloon flotation (Swan-Ganz) catheter in the pulmonary artery permits monitoring of LV filling pressure as well as estimation of the cardiac output; this technique may be useful in patients who exhibit hypotension and/or clinical evidence of HF. With the addition of intraarterial pressure monitoring, systemic vascular resistance can be calculated as a guide to adjusting vasopressor and vasodilator therapy. Some patients with STEMI have markedly elevated LV filling pressures (>22 mmHg) and normal cardiac indices (2.6–3.6 L/[min/m^2]), while others have relatively low LV filling pressures (<15 mmHg) and reduced cardiac indices. The former patients usually benefit from diuresis, while the latter may respond to volume expansion.

HYPOVOLEMIA

This is an easily corrected condition that may contribute to the hypotension and vascular collapse associated with STEMI in some patients. It may be secondary to previous diuretic use, to reduced fluid intake during the early stages of the illness, and/or to vomiting associated with pain or medications. Consequently, hypovolemia should be identified and corrected in patients with STEMI and hypotension by cautious fluid administration during continuous monitoring of oxygenation before more vigorous forms of therapy are begun. Eventually, the cardiac output plateaus, and further increases in LV filling pressure only increase congestive symptoms and decrease systemic oxygenation without raising arterial pressure.

TREATMENT

Heart Failure

The management of HF in association with STEMI is similar to that of acute HF secondary to other forms of heart disease (avoidance of hypoxemia, diuresis, afterload reduction, inotropic support) **(Chap. 264)**, except that the benefits of digitalis administration to patients with STEMI are unimpressive. By contrast, diuretic agents are extremely effective, as they diminish pulmonary congestion in the presence of systolic and/or diastolic HF. LV filling pressure falls, and orthopnea and dyspnea improve after the intravenous administration of furosemide or other loop diuretics. Nitrates in various forms may be used to decrease preload and congestive symptoms. Oral isosorbide dinitrate, topical nitroglycerin ointment, and intravenous nitroglycerin all have the advantage over a diuretic of lowering preload through venodilation without decreasing the total plasma volume. In addition, nitrates may improve ventricular compliance if ischemia is present, as ischemia causes an elevation of LV filling pressure. Vasodilators must be used with caution to prevent serious hypotension. As noted earlier, ACE inhibitors are an ideal class of drugs for management of ventricular dysfunction after STEMI, especially for the long term. (See "Inhibition of the Renin-Angiotensin-Aldosterone System" earlier.)

CARDIOGENIC SHOCK

Prompt reperfusion, efforts to reduce infarct size, and treatment of ongoing ischemia and other complications of MI appear to have reduced the incidence of cardiogenic shock from 20 to ~7%. Among those who exhibit cardiogenic shock, only 10% of patients with this condition present with it on admission, while 90% develop it during hospitalization. Typically, patients who develop cardiogenic shock have severe multivessel coronary artery disease with evidence of "piecemeal" necrosis extending outward from the original infarct zone. **The evaluation and management of cardiogenic shock after STEMI are discussed in detail in Chap. 316.**

RIGHT VENTRICULAR INFARCTION

Approximately one-third of patients with inferior infarction demonstrate at least a minor degree of RV necrosis. An occasional patient with inferoposterior LV infarction also has extensive RV infarction, and rare patients present with infarction limited primarily to the RV. Clinically significant RV infarction causes signs of severe RV failure (jugular venous distention, Kussmaul's sign, hepatomegaly **[Chap. 246]**) with or without hypotension. ST-segment elevations of right-sided precordial ECG leads, particularly lead V_4R, are frequently present in the first 24 h in patients with RV infarction. Two-dimensional echocardiography is helpful in determining the degree of RV dysfunction. Catheterization of the right side of the heart often reveals a distinctive hemodynamic pattern resembling constrictive pericarditis (steep right atrial "y" descent and an early diastolic dip and plateau in RV waveforms) **(Chap. 281)**. Therapy consists of volume expansion to maintain adequate RV preload and efforts to improve LV performance with attendant reduction in pulmonary capillary wedge and pulmonary arterial pressures.

ARRHYTHMIAS

(See also Chaps. 251 and 253) The incidence of arrhythmias after STEMI is higher in patients seen early after the onset of symptoms. The mechanisms responsible for infarction-related arrhythmias include autonomic nervous system imbalance, electrolyte disturbances, ischemia, and slowed conduction in zones of ischemic myocardium. An arrhythmia can usually be managed successfully if trained personnel and appropriate equipment are available when it develops. Since most deaths from arrhythmia occur during the first few hours after infarction, the effectiveness of treatment relates directly to the speed with which patients come under medical observation. The prompt management of arrhythmias constitutes a significant advance in the treatment of STEMI.

Ventricular Premature Beats Infrequent, sporadic ventricular premature depolarizations occur in almost all patients with STEMI and do not require therapy. Whereas in the distant past, frequent, multifocal, or early diastolic ventricular extrasystoles (so-called warning arrhythmias) were routinely treated with antiarrhythmic drugs to reduce the risk of development of ventricular tachycardia and ventricular fibrillation, pharmacologic therapy is now reserved for patients with sustained ventricular arrhythmias. Prophylactic antiarrhythmic therapy (either intravenous lidocaine early or oral agents later) is contraindicated for ventricular premature beats in the absence of clinically important ventricular tachyarrhythmias because such therapy may increase the mortality rate. Beta-adrenoceptor blocking agents are effective in abolishing ventricular ectopic activity in patients with STEMI and in the prevention of ventricular fibrillation. As described earlier (see "Beta-Adrenoceptor Blockers"), they should be used routinely in patients without contraindications. In addition, hypokalemia and hypomagnesemia are risk factors for ventricular fibrillation in patients with STEMI; to reduce the risk, the serum potassium concentration should be adjusted to ~4.5 mmol/L and magnesium to ~2.0 mmol/L.

Ventricular Tachycardia and Fibrillation Sustained ventricular tachycardia that is well tolerated hemodynamically should be treated with an intravenous regimen of amiodarone (bolus of 150 mg over 10 min, followed by infusion of 1.0 mg/min for 6 h and then 0.5 mg/min). A less desirable but alternative regimen is procainamide (bolus of 15 mg/kg over 20–30 min; infusion of 1–4 mg/min). If ventricular tachycardia does not stop promptly, electrical cardioversion should be used **(Chap. 253)**. An unsynchronized discharge of 200 J (biphasic waveform) is used immediately in patients with ventricular fibrillation or when ventricular tachycardia causes hemodynamic deterioration. Ventricular tachycardia or fibrillation that is refractory to electroshock may be more responsive after the patient is treated with amiodarone (150-mg bolus).

Ventricular arrhythmias, including the unusual form of ventricular tachycardia known as *torsades des pointes* **(Chaps. 259 and 261)**, may occur in patients with STEMI as a consequence of ongoing ischemia or

other concurrent problems (e.g., hypoxia, hypokalemia, or other electrolyte disturbances) or of the toxic effects of a QT-prolonging agent being administered to the patient. A search for such secondary causes should always be undertaken.

Although the in-hospital mortality rate is increased, the long-term survival is excellent in patients who survive to hospital discharge after *primary* ventricular fibrillation; i.e., ventricular fibrillation that is a primary response to acute ischemia that occurs during the first 48 h and is not associated with predisposing factors such as HF, shock, bundle branch block, or ventricular aneurysm. This natural history is in sharp contrast to the poor prognosis for patients who develop ventricular fibrillation *secondary* to severe pump failure. For patients who develop ventricular tachycardia or ventricular fibrillation late in their hospital course (i.e., after the first 48 h), the mortality rate is increased both in-hospital and during long-term follow-up. Such patients should be considered for implantation of a cardioverter-defibrillator (ICD) **(Chap. 259)**. A more challenging issue is the prevention of sudden cardiac death from ventricular fibrillation late after STEMI in patients who have not exhibited sustained ventricular tachyarrhythmias during their index hospitalization. An algorithm for selection of patients who warrant prophylactic implantation of an ICD is shown in **Fig. 286-6**.

Accelerated Idioventricular Rhythm Accelerated idioventricular rhythm (AIVR, "slow ventricular tachycardia"), a ventricular rhythm with a rate of 60–100 beats/min, often occurs transiently during fibrinolytic therapy at the time of reperfusion. For the most part, AIVR, whether it occurs in association with fibrinolytic therapy or spontaneously, is benign, and does not presage the development of classic ventricular tachycardia. Most episodes of AIVR do not require treatment if the patient is monitored carefully, as degeneration into a more serious arrhythmia is rare; overly aggressive treatment can lead to complete heart block.

Supraventricular Arrhythmias Sinus tachycardia is the most common supraventricular arrhythmia. If it occurs secondary to another cause (such as anemia, fever, HF, or a metabolic derangement), the primary problem should be treated first. However, if it appears to be due to sympathetic overstimulation (e.g., as part of a hyperdynamic state), then treatment with a beta blocker is indicated. Other common arrhythmias in this group are atrial flutter and atrial fibrillation, which are often secondary to LV failure. Digoxin may be considered for supraventricular arrhythmias if HF with reduced ejection fraction is present. If left ventricular systolic dysfunction is absent, beta blockers, verapamil, and diltiazem are suitable alternatives for controlling the ventricular rate, as they may also help to control ischemia. If the abnormal rhythm persists for a prolonged period with a high ventricular rate (e.g., >120 beats/min) or if tachycardia induces HF, shock, or ischemia (as manifested by recurrent pain or ECG changes), a synchronized electroshock should be used.

Accelerated junctional rhythms have diverse causes but may occur in patients with inferoposterior infarction. Digitalis excess must be ruled out. In some patients with severely compromised LV function, the loss of appropriately timed atrial systole results in a marked reduction of cardiac output. Right atrial or coronary sinus pacing is indicated in such instances.

Sinus Bradycardia Treatment of sinus bradycardia is indicated if hemodynamic compromise results from the slow heart rate. Atropine is the most useful drug for increasing heart rate and should be given intravenously in doses of 1.0 mg initially. If the rate remains

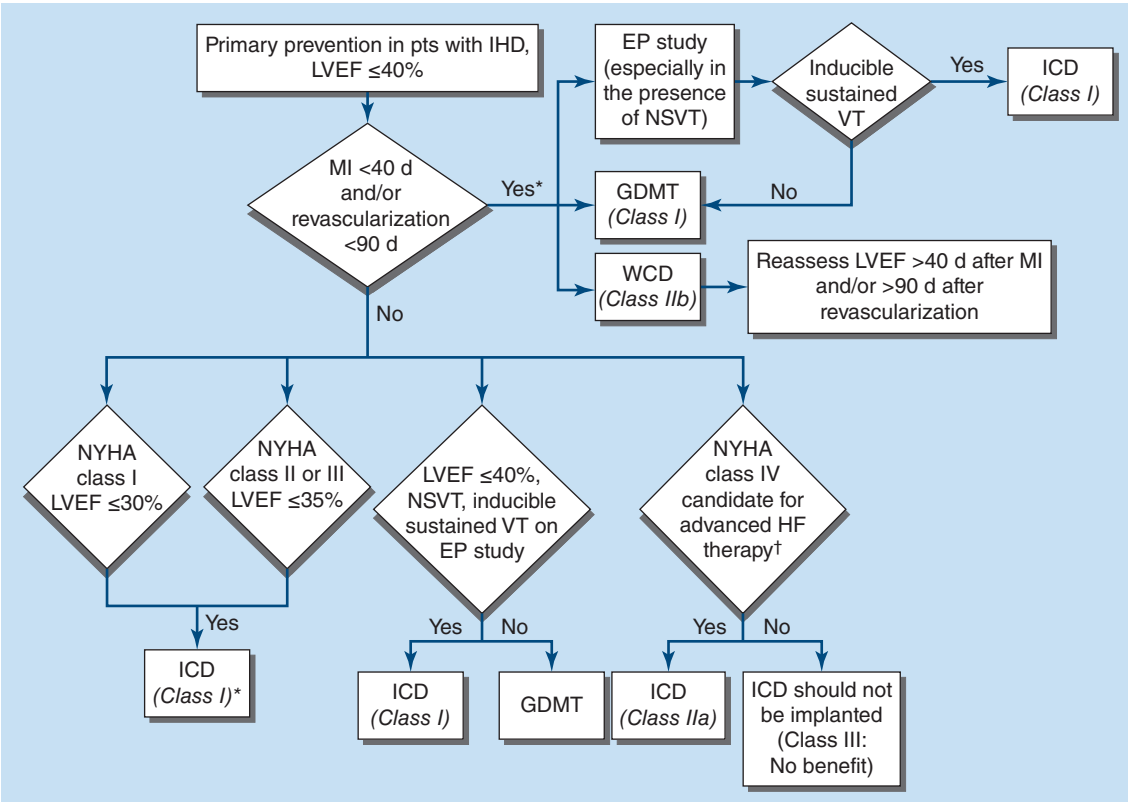

FIGURE 286-6 Primary prevention of SCD in patients with ischemic heart disease, including recent MI. *Scenarios exist for early ICD placement in select circumstances such as patients with a pacing indication or syncope. †Advanced HF therapy includes CRT, cardiac transplant, and left ventricular assist device. CRT, cardiac resynchronization therapy; EP, electrophysiologic; GDMT, guideline-directed management and therapy; HF, heart failure; ICD, implantable cardioverter-defibrillator; IHD, ischemic heart disease, LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSVT, nonsustained ventricular tachycardia; NYHA, New York Heart Association; pts, patients; SCD, sudden cardiac death; VT, ventricular tachycardia; WCD, wearable cardioverter-defibrillator. The available evidence does not suggest there is a survival advantage to the use of an ICD early after MI, and the WCD is a potential option while waiting until the ejection fraction is reassessed (see figure). While the WCD appears to be effective in patients who wear the device, it is associated with frequent alarms, skin irritation, and emotional distress, which results in reduced wear time in a large number of patients. *(Reproduced with permission from SM Al-Khatib et al: 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death. Circulation 138:e272, 2018.)*

<50–60 beats/min, additional doses, up to a total of 3.0 mg, may be given. Persistent bradycardia (<40 beats/min) despite atropine may be treated with electrical pacing.

Atrioventricular and Intraventricular Conduction Disturbances (See also Chap. 251) Both the in-hospital mortality rate and the post-discharge mortality rate of patients who have complete atrioventricular (AV) block in association with anterior infarction are markedly higher than those of patients who develop AV block with inferior infarction. This difference is related to the fact that heart block in inferior infarction is commonly a result of increased vagal tone and/or the release of adenosine and, therefore, is transient. In anterior wall infarction, however, heart block is usually related to ischemic malfunction of the conduction system, which is commonly associated with extensive myocardial necrosis.

Temporary electrical pacing provides an effective means of increasing the heart rate of patients with bradycardia due to AV block. However, acceleration of the heart rate may have only a limited impact on prognosis in patients with anterior wall infarction and complete heart block in whom the large size of the infarct is the major factor determining outcome. It should be carried out if it improves hemodynamics. Pacing does appear to be beneficial in patients with inferoposterior infarction who have complete heart block associated with HF, hypotension, marked bradycardia, or significant ventricular ectopic activity. A subgroup of these patients, those with RV infarction, often respond poorly to ventricular pacing because of the loss of the atrial contribution to ventricular filling. In such patients, dual-chamber AV sequential pacing may be required.

External noninvasive pacing electrodes should be positioned in a "demand" mode for patients with sinus bradycardia (rate <50 beats/min) that is unresponsive to drug therapy, Mobitz II second-degree AV block, third-degree heart block, or bilateral bundle branch block (e.g., right bundle branch block plus left anterior fascicular block). Retrospective studies suggest that permanent pacing may reduce the long-term risk of sudden death due to bradyarrhythmias in the rare patient who develops combined persistent bifascicular and transient third-degree heart block during the acute phase of MI.

OTHER COMPLICATIONS

Recurrent Chest Discomfort Because recurrent or persistent ischemia often heralds extension of the original infarct or reinfarction in a new myocardial zone and is associated with a near tripling of mortality after STEMI, patients with these symptoms should be referred for prompt coronary arteriography and mechanical revascularization. Administration of a fibrinolytic agent is an alternative to early mechanical revascularization in patients with recurrent ischemic ST-segment elevation.

Pericarditis (See also Chap. 281) Pericardial friction rubs and/or pericardial pain are frequently encountered in patients with STEMI involving the epicardium. This complication can usually be managed with aspirin (650 mg four times daily). It is important to diagnose the chest pain of pericarditis accurately because failure to recognize it may lead to the erroneous diagnosis of recurrent ischemic pain and/or infarct extension, with resulting inappropriate use of anticoagulants, nitrates, beta blockers, or coronary arteriography. When it occurs, complaints of pain radiating to either trapezius muscle is helpful because such a pattern of discomfort is typical of pericarditis but rarely occurs with ischemic discomfort. Anticoagulants potentially could cause tamponade in the presence of acute pericarditis (as manifested by either pain or persistent rub) and therefore should not be used unless there is a compelling indication.

Thromboembolism Clinically apparent thromboembolism complicates STEMI in ~10% of cases, but embolic lesions are found in 20% of patients in necropsy series, suggesting that thromboembolism is often clinically silent. Thromboembolism is considered to be an important contributing cause of death in 25% of patients with STEMI who die after admission to the hospital. Arterial emboli originate from LV mural thrombi, while most pulmonary emboli arise in the leg veins.

Thromboembolism typically occurs in association with large infarcts (especially anterior), HF, and an LV thrombus detected by echocardiography. The incidence of arterial embolism from a clot originating in the ventricle at the site of an infarction is small but real. Two-dimensional echocardiography reveals LV thrombi in about one-third of patients with anterior wall infarction but in few patients with inferior or posterior infarction. Arterial embolism often presents as a major complication, such as hemiparesis when the cerebral circulation is involved. When a thrombus has been clearly demonstrated by echocardiographic or other techniques, systemic anticoagulation should be undertaken (in the absence of contraindications), as the incidence of embolic complications appears to be markedly lowered by such therapy. The appropriate duration of therapy is unknown, but 3–6 months is reasonable.

Left Ventricular Aneurysm The term *ventricular aneurysm* is usually used to describe *dyskinesis* or local expansile paradoxical wall motion. Normally functioning myocardial fibers must shorten more if stroke volume and cardiac output are to be maintained in patients with ventricular aneurysm; if they cannot, overall ventricular function is impaired. True aneurysms are composed of scar tissue and neither predispose to nor are associated with cardiac rupture.

The complications of LV aneurysm do not usually occur for weeks to months after STEMI; they include HF, arterial embolism, and ventricular arrhythmias. Apical aneurysms are the most common and the most easily detected by clinical examination. The physical finding of greatest value is a double, diffuse, or displaced apical impulse. Ventricular aneurysms are readily detected by two-dimensional echocardiography, which may also reveal a mural thrombus in an aneurysm.

Rarely, myocardial rupture may be contained by a local area of pericardium, along with organizing thrombus and hematoma. Over time, this *pseudoaneurysm* enlarges, maintaining communication with the LV cavity through a narrow neck. Because a pseudoaneurysm often ruptures spontaneously, it should be surgically repaired if recognized.

POSTINFARCTION RISK STRATIFICATION AND MANAGEMENT

Many clinical and laboratory factors have been identified that are associated with an increase in cardiovascular risk after initial recovery from STEMI. Some of the most important factors include persistent ischemia (spontaneous or provoked), depressed LV ejection fraction (<40%), rales above the lung bases on physical examination or congestion on chest imaging, and symptomatic ventricular arrhythmias. Other features associated with increased risk include a history of previous MI, age >75, diabetes mellitus, prolonged sinus tachycardia, hypotension, ST-segment changes at rest without angina ("silent ischemia"), an abnormal signal-averaged ECG, nonpatency of the infarct-related coronary artery (if angiography is undertaken), and persistent advanced heart block or a new intraventricular conduction abnormality on the ECG. Therapy must be individualized on the basis of the relative importance of the risk(s) present.

The goal of preventing reinfarction, pump failure, and death after recovery from STEMI has led to strategies to evaluate risk after infarction. The risk of early recurrent ischemic events has diminished substantially in the era of primary PCI, with further reduction in the setting of current practice recommendations for routine revascularization of suitable severely stenosed nonculprit coronary arteries. In contrast, in stable patients after fibrinolysis who have not undergone revascularization, submaximal exercise stress testing may be carried out before hospital discharge to detect residual ischemia and ventricular ectopy and to provide the patient with a guideline for exercise in the early recovery period. Alternatively, or in addition, a maximal (symptom-limited) exercise stress test may be carried out 4–6 weeks after infarction. Patients in whom angina is induced at relatively low workloads, those who have a large reversible defect on perfusion imaging, those with demonstrable ischemia, and those in whom exercise provokes symptomatic ventricular arrhythmias should be considered at high risk for recurrent MI or death from arrhythmia. Cardiac catheterization with coronary angiography and/or invasive electrophysiologic evaluation is advised.

Evaluation of LV function should be performed in all patients with STEMI. Recognition of a depressed LV ejection fraction by echocardiography, cardiac magnetic resonance imaging (MRI), or nuclear myocardial perfusion imaging **(Chap. 248)** identifies patients who should receive medications to inhibit the renin-angiotensin-aldosterone system. Cardiac MRI **(Chap. 248)** can provide high-resolution imaging of the extent of myocardial injury. A standard imaging agent (gadolinium) is administered, and images are obtained after a 10-min delay. Since little gadolinium enters the normal myocardium, where there are tightly packed myocytes, but does percolate into the intercellular region of the infarct zone, there is a bright signal in areas of infarction that appears in stark contrast to the dark areas of normal myocardium.

In many hospitals, a cardiac rehabilitation program with progressive exercise is initiated in the hospital and continued after discharge. Such programs should include an educational component that informs patients about their disease and its risk factors. Exercise testing performed at entry into cardiac rehabilitation also aids in formulating an individualized exercise prescription.

The usual duration of hospitalization for an uncomplicated STEMI is about 3–5 days. The remainder of the convalescent phase may be accomplished at home. During the first 1–2 weeks, the patient should be encouraged to increase activity by walking about the house and outdoors in good weather. Normal sexual activity may be resumed during this period. After 2 weeks, the physician should regulate the patient's activity on the basis of exercise tolerance. Most patients will be able to return to work within 2–4 weeks.

SECONDARY PREVENTION

Various secondary preventive measures are at least partly responsible for the improvement in the long-term mortality and morbidity rates after STEMI. Long-term treatment with an antiplatelet agent (usually aspirin) after STEMI is associated with a 25% reduction in the risk of recurrent infarction, stroke, or cardiovascular mortality (36 fewer events for every 1000 patients treated). Dual antiplatelet therapy with aspirin and a $P2Y_{12}$ receptor antagonist (clopidogrel, prasugrel, or ticagrelor) is recommended for 12 months after a STEMI, in the absence of high bleeding risk or the occurrence of bleeding complications. ACE inhibitors or ARBs and, in appropriate patients, aldosterone antagonists should be used indefinitely by patients with clinically evident HF, a reduced LV ejection fraction, or a large regional wall motion abnormality to prevent late ventricular remodeling and recurrent ischemic events.

After several decades of evaluation, there is substantial evidence that suggests that administration of an anticoagulant for secondary prevention has a favorable effect on late mortality, stroke, and reinfarction in patients hospitalized with STEMI. Nevertheless, given the multiple alternatives for antithrombotic therapy, including potent antiplatelet agents, for this indication, clinicians must weigh the potential benefits of treatment with an oral anticoagulant based on established indications for anticoagulation, the use of other antithrombotic therapies, including long-term dual antiplatelet therapy, and the risk for bleeding.

The chronic routine use of oral beta-adrenoceptor blockers for at least 1 year after STEMI is supported by well-conducted, placebo-controlled trials.

Anti-inflammatory therapy with low-dose colchicine (0.5 mg once daily) may be considered as part of a secondary preventive regimen for patients with STEMI, particularly if the patient has had a recurrent atherosclerotic vascular event despite guideline-directed medical therapy.

Finally, risk factors for *atherosclerosis* **(Chap. 244)** should be discussed with the patient and, when possible, favorably modified.

287 Percutaneous Coronary Interventions and Other Interventional Procedures

Deepak L. Bhatt, Pinak B. Shah

Percutaneous transluminal coronary angioplasty (PTCA) was first introduced by Andreas Gruentzig in 1977 as an alternative to coronary bypass surgery. The concept was initially demonstrated by Charles Dotter in 1964 in peripheral vessels. The development of a small inelastic balloon catheter by Gruentzig allowed expansion of the technique into smaller peripheral and coronary vessels. Initial coronary experience was limited to single-vessel coronary disease and discrete proximal lesions due to the technical limitations of the equipment. Advances in technology with smaller profile balloon catheters and movable steerable guidewires and greater operator experience allowed the procedure to grow rapidly with expanded use in patients with more complex lesions and multivessel disease. The introduction of coronary stents in 1994 was one of the major advances in the field. These devices reduced acute complications and reduced by half the significant problems of acute thrombosis and late restenosis (or recurrence of stenosis). Further reductions in restenosis were achieved by the introduction of drug-eluting stents in 2003. These stents slowly release antiproliferative drugs directly into the plaque over a few months. Percutaneous coronary intervention (PCI) is the most common revascularization procedure in the United States and is performed more than twice as often as coronary artery bypass surgery: >900,000 patients a year.

Interventional cardiology is a separate discipline that began with coronary interventions. The discipline has now expanded to include interventions for structural heart disease including treatment of congenital heart disease and valvular heart disease; it also includes interventions to treat peripheral vascular disease, including atherosclerotic and nonatherosclerotic lesions in the carotid, renal, aortic, and peripheral arterial and venous circulations.

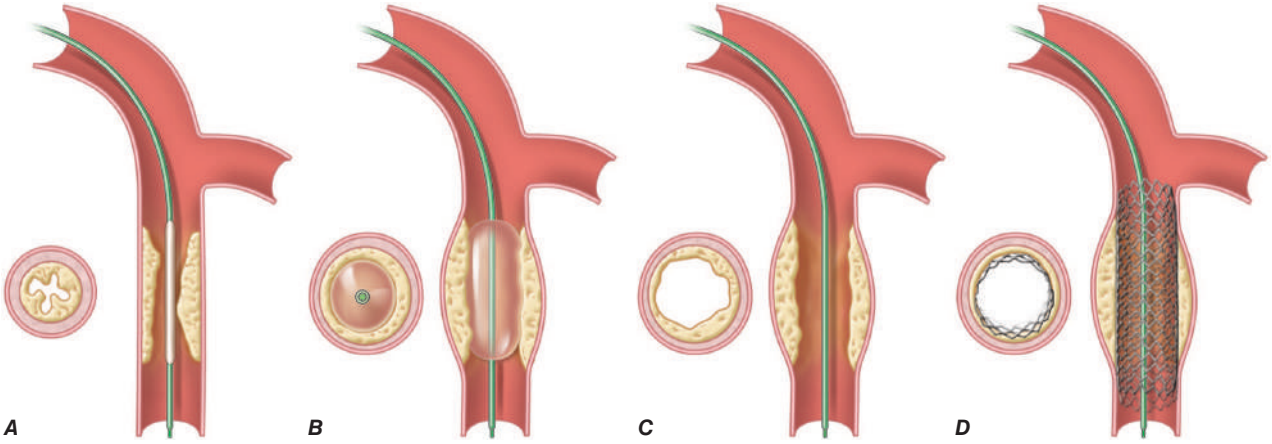

FIGURE 287-1 Schematic diagram of the primary mechanisms of balloon angioplasty and stenting. ***A.*** A balloon angioplasty catheter is positioned into the stenosis over a guidewire under fluoroscopic guidance. ***B.*** The balloon is inflated, temporarily occluding the vessel. ***C.*** The lumen is enlarged primarily by stretching the vessel, often resulting in small dissections in the neointima. ***D.*** A stent mounted on a deflated balloon is placed into the lesion and pressed against the vessel wall with balloon inflation (not shown). The balloon is deflated and removed, leaving the stent permanently against the wall acting as a scaffold to hold the dissections against the wall and prevent vessel recoil. *(Reproduced with permission from EJ Topol: Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2002.)*

TECHNIQUE

The initial procedure is performed in a similar manner as a diagnostic cardiac catheterization **(Chap. 249)**. Arterial access is obtained via the radial or femoral artery. To prevent thrombotic complications during the procedure, patients who are anticipated to need PCI are given aspirin (325 mg) and may be given a platelet $P2Y_{12}$ inhibitor such as clopidogrel (loading dose of 600 mg), prasugrel (loading dose of 60 mg), or ticagrelor (loading dose of 180 mg) before the procedure. Cangrelor, a potent IV $P2Y_{12}$ inhibitor, is approved for use in patients who have not received an oral agent prior to the procedure. During the procedure, anticoagulation is achieved by administration of unfractionated heparin, enoxaparin (a low-molecular-weight heparin), or bivalirudin (a direct thrombin inhibitor). In patients with ST-segment elevation myocardial infarction (STEMI), high-risk acute coronary syndrome, or a large thrombus in the coronary artery, an intravenous glycoprotein IIb/IIIa inhibitor (tirofiban or eptifibatide) may also be given, although cangrelor appears to be as effective with less bleeding risk.

Following placement of an introducing sheath into the artery, preformed guiding catheters are used to cannulate selectively the origins of the coronary arteries. Through the guiding catheter, a flexible, steerable guidewire is negotiated into the coronary artery lumen using fluoroscopic guidance; it is then advanced through the stenosis and into the vessel beyond. This guidewire then serves as a "rail" over which angioplasty balloons, stents, or other therapeutic devices can be advanced to enlarge the narrowed segment of coronary artery. The artery is usually dilated with a balloon catheter followed by placement of a stent. The catheters and introducing sheath are removed and the artery manually held, or in the case of radial access, an inflatable cuff is used. One of several femoral arterial closure devices can also be used to achieve hemostasis. Because PCI is usually performed under local anesthesia and mild sedation, procedural recovery is generally less than 24 h. Most patients undergoing elective PCI can be discharged the same day of the procedure.

Balloon angioplasty works by stretching the artery and displacing the plaque away from the lumen, enlarging the entire vessel **(Figs. 287-1 and 287-2)**. The procedure rarely results in embolization of atherosclerotic material. Owing to inelastic elements in the plaque, the stretching of the vessel by the balloon results in small, localized dissections that can protrude into the lumen and be a nidus for acute thrombus formation. If the dissections are severe, then they can obstruct the lumen or induce a thrombotic occlusion of the artery (acute closure). Stents have largely prevented this complication by holding the dissection flaps up against the vessel wall (Fig. 287-1).

Stents are currently used in >90% of coronary angioplasty procedures. Stents are wire meshes (usually made of stainless steel or other

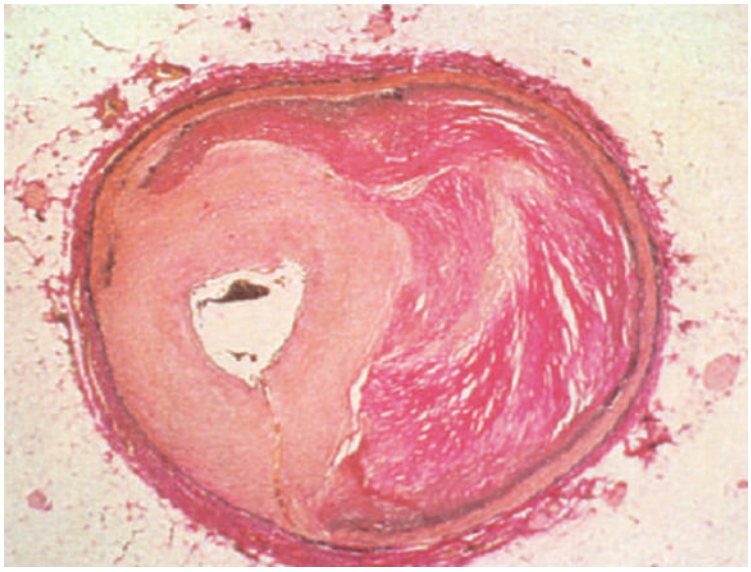

FIGURE 287-2 An example of neointimal hyperplasia and restenosis showing narrowing of the vessel. *(Reprinted from CE Essed, M Van den Brand, AE Becker: Transluminal coronary angioplasty and early restenosis. Fibrocellular occlusion after wall laceration. Br Heart J 49:393, 1983; with permission.)*

metals, such as cobalt chromium or nitinol) that are compressed over a deflated angioplasty balloon. When the balloon is inflated, the stent is enlarged to approximate the "normal" vessel lumen. The balloon is then deflated and removed, leaving the stent behind to provide a permanent scaffold in the artery. Owing to the design of the struts, these devices are flexible, allowing their passage through diseased and tortuous coronary vessels. Stents are rigid enough to prevent elastic recoil of the vessel and have dramatically improved the success and safety of the procedure as a result.

Drug-eluting stents (DESs) further enhanced the efficacy of PCI. An antiproliferative agent is attached to the metal stent by use of a thin polymer coating. The antiproliferative drug elutes from the stent over a 1- to 3-month period or longer after implantation. DESs have been shown to reduce clinical restenosis by 50%, so that in uncomplicated lesions, symptomatic restenosis occurs in 5–10% of patients. Not surprisingly, this benefit led to the rapid acceptance of these devices, and given their safety profile, nearly 100% of stents placed today are DESs. The first-generation DESs were coated with either sirolimus or paclitaxel. Second-generation DESs use newer agents such as everolimus, biolimus, and zotarolimus. These second-generation DESs appear to be more effective with fewer complications, such as early or late stent thrombosis, than the first-generation devices and, therefore, have replaced the first-generation stents. Biodegradable polymers that are used to attach the drugs to the stents may be theoretically superior to permanent polymers in preventing late stent thrombosis. In addition, the first-generation everolimus-eluting biodegradable vascular scaffold (BVS) stent had been shown to be reasonably safe with gradual degradation over several years, although concerns about late and very late stent thrombosis ultimately prevented introduction into clinical practice in the United States. Additional bioresorbable stents are under investigation. Drug-coated balloons (DCBs) are covered with an antiproliferative drug that can also reduce restenosis and are used primarily to treat in-stent restenosis.

Other interventional devices include atherectomy devices, thrombectomy catheters, and intravascular lithotripsy (IVL). These devices are designed to modify complex plaque or thrombus to facilitate and optimize stent placement. Rotational atherectomy is the most commonly used adjunctive device and is modeled after a dentist's drill, with small round burrs of 1.25–2.5 mm at the tip of a flexible wire shaft. The burr is passed over the guidewire up to the stenosis and drills atherosclerotic material. Because the atherosclerotic particles are ≤25 μm, they pass through the coronary microcirculation and rarely result in complications. The device is particularly useful in heavily calcified plaques that are resistant to balloon dilatation. Orbital atherectomy is a newer approach to calcified lesions that also relies on a spinning burr. IVL catheters emit pressure waves that fracture calcium within vessel walls, thereby increasing the compliance of the vessel and enhancing stent deployment. In acute STEMI, specialized catheters without a balloon can be used to aspirate thrombus in order to prevent embolization down the coronary vessel and to improve blood flow before angioplasty and stent placement. Current studies show that manual catheter thrombus aspiration should not be used routinely but, in certain cases of a large thrombus burden, can improve blood flow in primary PCI.

PCI of degenerated saphenous vein graft lesions has been associated with a significant incidence of distal embolization of atherosclerotic material, unlike PCI of native vessel disease. A number of distal protection devices have been shown to significantly reduce embolization and myocardial infarction in this setting. Most devices work by using a collapsible wire filter at the end of a guidewire that is expanded in the distal vessel before PCI. If atherosclerotic debris is dislodged, the basket captures the material, and at the end of the PCI, the basket is pulled into a delivery catheter, and the debris safely removed from the patient.

Intravascular imaging is an adjunct to angiographic imaging for PCI that provides information regarding optimal treatment strategy and improves the long-term durability and safety of PCI. There are two modalities available for intravascular imaging: intravascular ultrasound (IVUS) and optical coherence tomography (OCT). IVUS catheters have piezoelectric ultrasound transducers at the distal end that can provide an image from within the vessel, as well as provide information regarding plaque morphology. OCT utilizes near-infrared light to provide intraluminal imaging of the vessel. The resolution of OCT is better than IVUS; however, both modalities have been shown in meta-analyses of clinical trials to optimize stent diameters and reduce the likelihood of delayed complications, such as in-stent restenosis and stent thrombosis.

SUCCESS AND COMPLICATIONS

A successful procedure (angiographic success), defined as a reduction of the stenosis to less than a 20% diameter narrowing, occurs in 95–99% of patients. Lower success rates are seen in patients with tortuous, small, or calcified vessels or chronic total occlusions. Chronic total occlusions have the lowest success rates, and their recanalization is significantly better if the occlusion is recent (within 3 months) or there are favorable anatomic features. Improvements in equipment and complex antegrade and retrograde wire crossing techniques have increased the success rates of recanalization of chronic total occlusions to 70–80%.

Serious complications are rare but include a mortality rate of 0.1–0.3% for elective cases, a large myocardial infarction in <3%, and stroke in 0.1–0.4%. Patients who are older (>65 years), undergoing an emergent or urgent procedure, have chronic kidney disease, present with STEMI, or are in shock have significantly higher risk. Scoring systems can help to estimate the risk of the procedure. Myocardial infarction during PCI can occur for multiple reasons including an acute occluding thrombus, severe coronary dissection, embolization of thrombus or atherosclerotic material with resulting (micro) vascular occlusion, or closure of a side branch vessel at the site of angioplasty or stent placement. Most myocardial infarctions are small and only detected by a rise in the creatine phosphokinase (CPK) or troponin level after the procedure. Only those with significant enzyme elevations (>10 times the upper limit of normal) are associated with a less favorable long-term outcome. Coronary stents have largely prevented occlusive coronary dissections from angioplasty due to the scaffolding effect of the stent.

All types of stents are prone to stent thrombosis (1–3%), either acute (<24 h) or subacute (1–30 days), which can be ameliorated by greater attention to full initial stent deployment and the use of dual antiplatelet therapy (DAPT) (aspirin plus a platelet $P2Y_{12}$ receptor blocker [clopidogrel, prasugrel, or ticagrelor]). Late (30 days–1 year) and very late (>1 year) stent thromboses occur very infrequently with stents but are slightly more common with first-generation DESs. Use of the second-generation stents is associated with lower rates of late and very late stent thromboses, and shorter durations of DAPT (6 months) are recommended for the stent, although longer durations may be useful depending on the underlying atherothrombotic and bleeding risks. Longer durations of DAPT up to 1 year should also be considered for patients undergoing PCI for acute coronary syndromes. Premature discontinuation of DAPT, particularly in the first month after implantation, is associated with a significantly increased risk for stent thrombosis (three- to nine-fold greater). Stent thrombosis results in death in 10–20% and myocardial infarction in 30–70% of patients. Elective surgery that requires discontinuation of antiplatelet therapy after DES implantation should be postponed until after 3 months and preferably after 6 months, if at all possible.

Restenosis, or renarrowing of the dilated coronary stenosis, is the most common complication of PCI and occurs in 20–50% of patients with balloon angioplasty alone, 10–30% of patients with bare metal stents, and 5–15% of patients with DESs within the first year. The fact that stent placement provides a larger acute luminal area than balloon angioplasty alone reduces the incidence of subsequent restenosis. DESs further reduce restenosis through a reduction in excessive neointimal growth over the stent. If restenosis does not occur, the long-term outcome is excellent **(Fig. 287-3)**. Clinical restenosis is recognized by recurrence of angina or symptoms within 12 months of the procedure. Less frequently, patients with restenosis can present with non-ST-segment elevation myocardial infarction (NSTEMI) (10%) or STEMI (2%) as well. Very late stent thrombosis and restenosis after 1 year are more likely to be due to neoatherosclerosis than intimal hyperplasia seen within the first year. Clinical restenosis requires confirmation of a significant stenosis at the site of the prior PCI. The

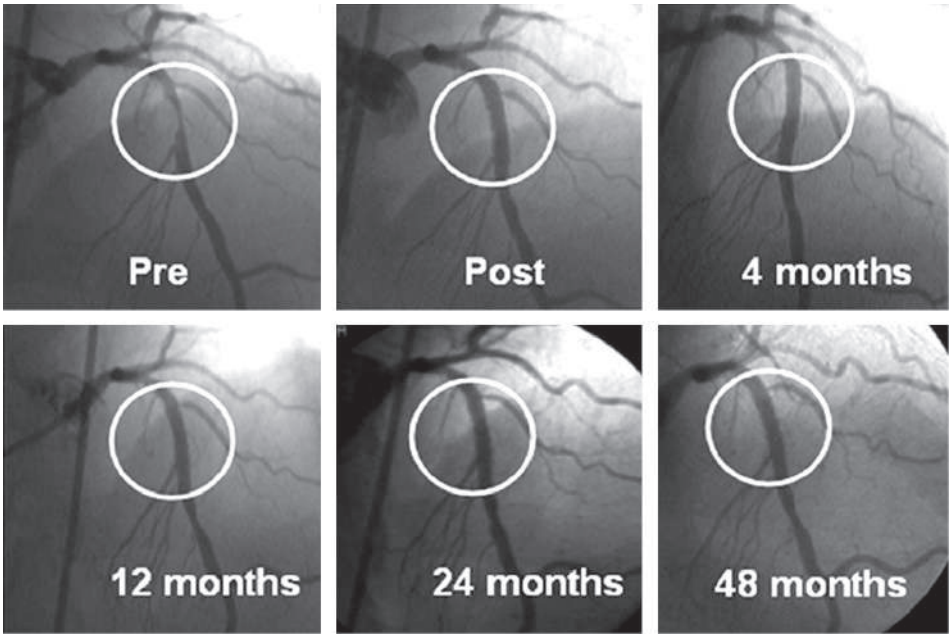

FIGURE 287-3 Long-term results from one of the first patients to receive a sirolimus-eluting stent from early Sao Paulo experience. *(From GW Stone, in D Baim [ed]: Cardiac Catheterization, Angiography and Intervention, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2006; with permission.)*

management of clinical restenosis is usually to repeat the PCI with balloon dilatation and placement of another DES. Once a patient has had restenosis, the risk of a second restenosis is further increased. The risk factors for restenosis are diabetes, myocardial infarction, long lesions, small-diameter vessels, and suboptimal initial PCI result. Treatments for symptomatic recurrent restenosis include re-stenting, brachytherapy, DCBs, or coronary bypass surgery.

INDICATIONS

The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines extensively review the indications for PCI in patients with stable angina, unstable angina, NSTEMI, and STEMI and should be referred to for a comprehensive discussion of the indications. Briefly, the two principal indications for coronary revascularization in patients with *chronic stable angina* **(Chap. 284)** are (1) to improve angina symptoms in patients who remain symptomatic despite adequate medical therapy and (2) to reduce mortality rates in patients with severe and extensive coronary disease. In patients with stable angina who are well controlled on medical therapy, studies such as the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) and Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trials have shown that initial revascularization does not lead to better outcomes (death or myocardial infarction) and can be safely delayed until symptoms worsen or evidence of severe ischemia on noninvasive testing occurs. The International Study of Comparative Health Effectiveness with Medical and Invasive Approaches (ISCHEMIA) trial was the largest trial comparing optimal medical therapy to revascularization with PCI or coronary artery bypass grafting (CABG) in stable patients with moderate ischemia on stress testing but without left main disease or reduced left ventricular function (<35% ejection fraction). It showed that optimal medical therapy was similar to revascularization in a composite of cardiovascular death or hospitalization or in cardiovascular death and myocardial infarction at a median of 3.3 years. This trial confirms prior studies and supports conservative management in most stable patients. When revascularization is indicated due to unacceptable symptoms, the choice of PCI or CABG depends on a number of clinical and anatomic factors.

The Synergy between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX) trial compared PCI with the paclitaxel DES to CABG in 1800 patients with three-vessel coronary disease or left main disease. The study found no difference in death or myocardial infarction at 1 year, but repeat revascularization was significantly higher in the stent-treated group (13.5 vs 5.9%), while stroke was significantly higher in the surgical group (2.2 vs 0.6%). The primary endpoint of death, myocardial infarction, stroke, or revascularization was significantly better with CABG, particularly in those with the most extensive coronary artery disease such as three-vessel disease. The 10-year results confirm these findings. The Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial randomized 1900 patients with diabetes and multivessel disease and found a significantly lower primary endpoint of death, myocardial infarction, or stroke with CABG than PCI. Recent trials comparing PCI with CABG have shown similar outcomes for those with less extensive disease, but a better outcome with CABG when the coronary disease is severe and extensive. These studies support CABG for those with the most severe left main and three-vessel disease or those with diabetes. Lesser degrees of multivessel disease in patients with or without diabetes have an equal outcome with PCI, including left main disease with favorable angiographic characteristics.

The choice of PCI versus CABG is also related to the anticipated procedural success and complications of PCI and the risks of CABG. For PCI, the characteristics of the coronary anatomy are critically important. The location of the lesion in the vessel (proximal or distal), the degree of tortuosity, and the size of the vessel are considered. In addition, the lesion characteristics, including the degree of the stenosis, the presence of calcium, lesion length, and presence of thrombus, are assessed. The most common reason to decide not to do PCI is that the lesion(s) felt to be responsible for the patient's symptoms is not treatable. This is most commonly due to the presence of a chronic total occlusion (>3 months in duration) with unfavorable characteristics. A lesion classification to characterize the likelihood of success or failure of PCI has been developed by the ACC/AHA. Lesions with the highest success are called type A lesions (such as proximal noncalcified subtotal lesions), and those with the lowest success or highest complication rate are type C lesions (such as chronic total occlusions). Intermediate lesions are classified as type B1 or B2 depending on the number of unfavorable characteristics. Approximately 25–30% of patients will not be candidates for PCI due to unfavorable anatomy, whereas only 5% of CABG patients will not be candidates for surgery due to coronary anatomy. The primary reason for being considered inoperable with CABG is the presence of severe comorbidities such as advanced age, frailty, severe chronic obstructive pulmonary disease (COPD), poor left ventricular function or lack of suitable surgical conduits, or poor distal targets for bypass.

Another consideration in choosing a revascularization strategy is the degree of revascularization needed. In patients with multivessel disease, bypass grafts can usually be placed to all vessels >2 mm with significant stenosis, whereas PCI may be able to treat only some of the lesions due to the presence of unfavorable anatomy. Assessment of the significance of intermediate lesions using fractional flow reserve (FFR) or the instantaneous wave-free ratio (iFR) **(Chap. 249)** can assist in determining which lesions should be revascularized. The Fractional Flow Reserve versus Angiography for Multivessel Evaluation (FAME) trial showed a 30% reduction in adverse events when revascularization by PCI was restricted to those lesions that were hemodynamically significant (FFR ≤0.80) rather than when guided by angiography alone. Trials have shown that iFR is as predictive as FFR but is quicker and easier to perform, especially if there are sequential lesions or multivessel disease. Thus, complete revascularization of all functionally significant lesions should be favored and considered when choosing the optimal revascularization strategy. Given the multiple factors that need to be considered in choosing the best revascularization for an individual patient with multivessel disease, it is optimal to have a discussion among the cardiac surgeon, interventional cardiologist, and the physicians caring for the patient (so-called heart team) to weigh the choices properly.

Patients with acute coronary syndrome are at excess risk of short- and long-term mortality. Randomized clinical trials have shown that PCI is superior to intensive medical therapy in reducing mortality and myocardial infarction, with the benefit largely confined to those patients who are high risk. High-risk non-ST-segment elevation acute coronary syndrome patients are defined as those with any one of the following: refractory ischemia, recurrent angina, positive cardiac-specific enzymes, new ST-segment depression, transient ST-segment elevation, low ejection fraction, severe arrhythmias, or a recent PCI or CABG. PCI is preferred over surgical therapy in most high-risk patients with acute coronary syndromes unless they have severe multivessel disease or the culprit lesion responsible for the unstable presentation cannot be adequately determined or treated. In STEMI, thrombolysis and PCI (primary PCI) are effective methods to restore coronary blood flow and salvage myocardium within the first 12 h after onset of chest pain. Because PCI is more effective in restoring flow than thrombolysis, it is preferred if readily available within 90 min of presentation to the hospital. PCI is also performed following thrombolysis to facilitate adequate reperfusion or as a rescue procedure in those who do not achieve reperfusion from thrombolysis, who cannot be rapidly transferred to a hospital that can perform primary PCI, or who develop cardiogenic shock. The Complete Versus Culprit-Only Revascularization Strategies to Treat Multivessel Disease After Early PCI for STEMI (COMPLETE) trial supports complete revascularization of nonculprit lesions in STEMI either in the hospital or in the few weeks after discharge.

OTHER INTERVENTIONAL TECHNIQUES

STRUCTURAL HEART DISEASE

Interventional treatment for structural heart disease (adult congenital heart disease and valvular heart disease) is a significant and growing component of the field of interventional cardiology.

The most common adult congenital lesion to be treated with percutaneous techniques is closure of atrial septal defects **(Chap. 280)**. The procedure is done as in a diagnostic right heart catheterization with the passage of a catheter up the femoral vein into the right atrium. With echo and fluoroscopic guidance, the size and location of the defect can be accurately defined, and closure is accomplished using one of several approved devices. All devices use a left atrial and right atrial wire mesh or covered disk that are pulled together to capture the atrial septum around the defect and seal it off. The Amplatzer Septal Occluder (AGA Medical, Minneapolis, MN) and the Gore ASD Occluder (W.L. Gore, Flagstaff, AZ) are the most commonly used devices in the United States **(Fig. 287-4)**. The success rate in selected patients is 85–95%, and the device complications are rare and include device embolization, infection, or erosion. Closure of patent foramen ovale (PFO) is done in a similar fashion. PFO closure may be considered in patients who have had recurrent paradoxical stroke or transient ischemic attack (TIA) despite adequate medical therapy including anticoagulation or antiplatelet therapy or who are at high risk for recurrent stroke. Ten-year follow-up from the Randomized Evaluation of Recurrent Stroke Comparing PFO Closure to Established Current Standard of Care Treatment (RESPECT) trial showed a benefit of closure in reducing the risk for recurrent cryptogenic stroke, as have the REDUCE and CLOSE trials. The use in the treatment of migraine is not supported by the current data.

Similar devices can also be used to close patent ductus arteriosus and ventricular septal defects. Other congenital diseases that can be treated percutaneously include coarctation of the aorta, pulmonic stenosis, peripheral pulmonary stenosis, and other abnormal communications between the cardiac chambers or vessels.

The treatment of valvular heart disease is the most rapidly growing area in interventional cardiology. In the past, the only available techniques were balloon valvuloplasty for the treatment of aortic, mitral, or pulmonic stenosis **(Chap. 272)**. Mitral valvuloplasty is the preferred treatment for symptomatic patients with rheumatic mitral stenosis

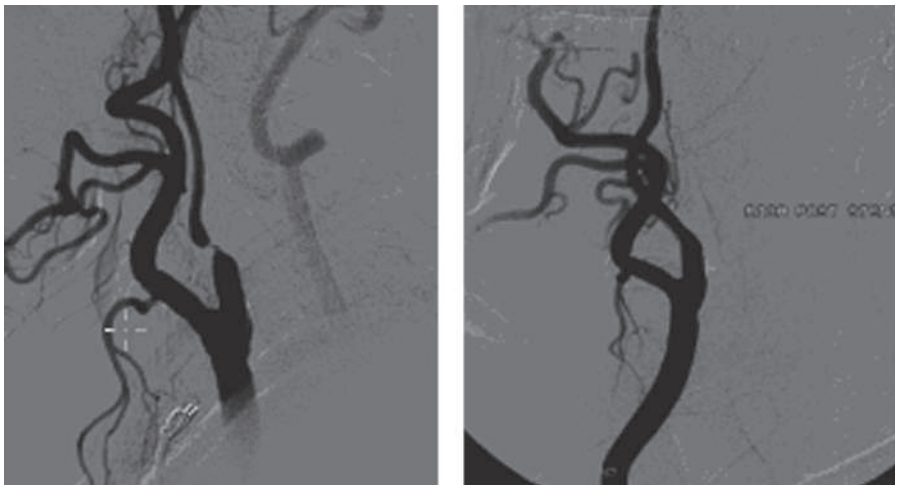
who have favorable anatomy. The outcome in these patients is equal to that of surgical commissurotomy. The success is highly related to the echocardiographic appearance of the valve. The most favorable setting is commissural fusion without calcification or subchordal fusion and the absence of significant mitral regurgitation. Access is obtained from the femoral vein using a transseptal technique in which a long metal catheter with a needle tip is advanced from the femoral vein through the right atrium and atrial septum at the level of the foramen ovale into the left atrium. A balloon-dilatation catheter is negotiated across the mitral valve and inflated to a predetermined size to enlarge the valve. The most commonly used dilatation catheter is the Inoue balloon. The technique splits the commissural fusion and commonly results in a doubling of the mitral valve area. The success of the procedure in favorable anatomy is 95%, and severe complications are rare (1–2%). The most common complications are tamponade due to puncture into the pericardium during the transseptal puncture or the creation of severe mitral regurgitation due to damage to the valve leaflets.

Severe mitral regurgitation can be treated percutaneously using transcatheter edge-to-edge repair (TEER). There are two devices approved for TEER including the MitraClip (Abbott, Abbott Park, IL) and the PASCAL device (Edwards Lifescience, Irvine, CA) (Fig. 287-4). The procedure involves the passage of a catheter into the left atrium using the transseptal technique. A special catheter with a metallic clasping device on the end is passed through the mitral valve and retracted to catch and bring together the mid portion of the anterior and posterior mitral valve leaflets. The device creates a double opening in the mitral valve and thereby reduces mitral regurgitation similar to the surgical Alfieri repair. In the Endovascular Valve Edge-to-Edge Repair Study (EVEREST II) trial, the MitraClip device was less effective than surgical repair or replacement but was shown to be safe. Subsequent trials have shown it to be reasonably effective for patients who are not good candidates for surgical repair, particularly when the regurgitation is due to functional causes. The Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional Mitral Regurgitation (COAPT) trial showed that, in patients with heart failure and functional mitral regurgitation who were carefully selected based on clinical and echocardiographic features, the procedure can reduce mortality.

At the present time, there are no approved devices for transcatheter mitral valve replacement (TMVR of native mitral valves). There are many devices presently in clinical trials. TMVR device development has been challenging due to the interior location of the mitral valve, the large size of the mitral valve, and potential for left ventricular outflow tract obstruction.

Severe aortic stenosis can be treated with balloon valvuloplasty as well. In this setting, the valvuloplasty balloon catheter is placed retrograde across the aortic valve from the femoral artery and briefly inflated to stretch open the valve. The success is much less favorable, with only 50% achieving an aortic valve area of >1 cm^2 and a restenosis rate of 25–50% after 6–12 months. This poor success rate has limited its use to patients who are not surgical candidates or as a bridge to surgery or transcatheter aortic valve replacement (TAVR). In this setting, the intermediate-term mortality rate of the procedure is high (10%). Repeat aortic valvuloplasty as a treatment for aortic valve restenosis has been reported.



TAVR has been shown to be an effective treatment for low-, intermediate-, and high-risk patients and inoperable patients with aortic stenosis. Currently, three valve devices are approved in the United States: the Edwards SAPIEN valve (Edwards Lifescience, Irvine, CA), the Evolut platform (Medtronic, Minneapolis, MN), and the Navitor system (Abbott Cardiovascular, Plymouth, MN) (Fig. 287-4). Data to date show excellent durability of the valves, although long-term outcomes of 10 years are not yet available. The Evolut and Navitor valves are self-expanding, whereas the Sapien valve is balloon expanded. The cannulas are large (14–18 French), and retrograde access via the femoral artery is most commonly utilized. In patients with peripheral artery disease, access via the axillary or carotid artery may be utilized. The valve is positioned across the valve and deployed, occasionally requiring postdeployment balloon inflation to ensure full contact with the aortic annulus. The success rate is >90%, and the 30-day mortality rate is 2–15% based on preoperative risk. The Placement of Aortic Transcatheter Valve (PARTNER) randomized trial of the Edwards valve showed a 55% reduction in 1-year mortality and major adverse events in the extreme-risk group randomized to TAVR compared with medical therapy. In separate randomized trials comparing the Sapien platform to surgery and the Evolut platform to surgery, low-, moderate-, and high-risk patients had similar outcomes to surgical valve replacement at 1 year. As a result, these valves have been approved for low-, intermediate-, high-, and extreme-risk patients with severe symptomatic aortic stenosis. At the present time, the Navitor platform is only approved for patients at high risk for surgery.

Aortic and mitral bioprosthetic valve degeneration can be treated with repeat surgery or, in high-risk patients, with a transcatheter valve-in-valve procedure where a percutaneous valve is placed inside of the prior surgical valve. It has been shown to be effective for aortic and mitral valves.

Pulmonic stenosis can also be effectively treated with balloon valvuloplasty and percutaneously replaced with the Melody valve (Medtronic). Tricuspid valve interventions are increasingly being performed utilizing TEER and tricuspid valve replacement devices, which are now approved for use.

PERIPHERAL ARTERY INTERVENTIONS

The use of percutaneous interventions to treat symptomatic patients with arterial obstruction in the carotid, renal, aortic, and peripheral vessels is an effective alternative to vascular surgery. Randomized clinical trial data support the use of carotid stenting in patients at high risk of complications from carotid endarterectomy **(Fig. 287-5)**. Recent trials suggest similar outcomes with carotid stenting and carotid endarterectomy in patients at average risk, although depending on the patient's risk for periprocedural stroke or myocardial infarction, one procedure may be preferred over the other. The success rate of peripheral artery interventional procedures has been improving, including treatment for long segments of occlusive disease historically treated by peripheral bypass surgery **(Fig. 287-6)**. The use of DCBs and DESs has been shown to reduce restenosis when compared with balloon angioplasty alone. Peripheral intervention is increasingly part of the training of an interventional cardiologist, and most programs now require an additional year of training after the interventional cardiology training year. The techniques and outcomes are described in detail in the chapter on peripheral vascular disease **(Chap. 292)**.

CIRCULATORY SUPPORT TECHNIQUES

The use of circulatory support techniques is indicated for the management of patients with shock or hemodynamic instability and occasionally is needed in order to safely perform PCI on hemodynamically unstable patients. It also can be useful in helping to stabilize patients before surgical interventions. The most commonly used device is the percutaneous intraaortic balloon pump developed in the early 1960s. A 7- to 8-French, 25- to 50-mL balloon catheter is placed retrograde from the femoral artery into the descending aorta between the aortic arch and the abdominal aortic bifurcation. It is connected to a helium gas inflation system that synchronizes the inflation to coincide with early diastole with deflation by mid-diastole. As a result, it increases early diastolic pressure, lowers systolic pressure, and lowers late diastolic pressure through displacement of blood from the descending aorta (counterpulsation). This results in an increase in coronary blood flow and a decrease in afterload. It is contraindicated in patients with aortic regurgitation, aortic dissection, or severe peripheral artery disease. The major complications are vascular and thrombotic. Intravenous heparin is given in order to reduce thrombotic complications.

Another support device is the Impella (Abiomed, Danvers, MA). The Impella CP catheter is placed percutaneously from the femoral artery into the left ventricle. The catheter has a small microaxial pump at its tip that can pump up to 2.5–5 L/min from the left ventricle to the aorta. The larger Impella 5.5 device provides greater support for longer periods of time but requires surgical implantation typically through the axillary artery. Patients can also be placed on peripheral extracorporeal membrane oxygenation (ECMO) using large cannulas placed in the femoral artery and vein. This technique can be performed emergently or electively in the catheterization laboratory and is useful for support of patients with acute respiratory failure or cardiac failure.

INTERVENTIONS FOR PULMONARY EMBOLISM

The treatment of deep vein thrombosis is intravenous anticoagulation, with placement of an inferior vena cava filter if recurrent pulmonary emboli (PE) occur or anticoagulation is not possible. Postphlebitic syndrome is a serious condition due to chronic venous obstruction that can lead to chronic leg edema and venous ulcers. Randomized data show that mechanical treatments may have a selective role in treatment of large iliofemoral deep-vein thrombosis.

PE should be treated with fibrinolytic agents if massive and in some cases if submassive. Surgical pulmonary embolectomy is an option for the treatment of massive PE with hemodynamic instability in patients who have contraindications for systemic fibrinolysis or those in whom it has failed. Catheter-based therapies for submassive and massive PEs are still evolving, but studies have shown promise. The techniques employed include catheter directed thrombolysis with intraclot infusion of a thrombolytic agent, potentially enhanced with ultrasound-assisted catheter-directed thrombus fragmentation. The success of these techniques has been reported to be 80–90%, with major complications occurring in 2–4% of patients. Thrombus removal with large-bore aspiration devices include the FlowTriever (Inari Medical, Irvine, CA) and the CAT12 (Penumbra, Alameda, CA).

INTERVENTIONS FOR REFRACTORY HYPERTENSION

The recent recognition of the importance of the renal sympathetic nerves in modulating blood pressure has led to a technique to selectively denervate renal sympathetic nerves in patients with refractory hypertension. The procedure involves applying low-power radiofrequency treatment via a catheter along the length of both renal arteries. Despite promising nonrandomized data, in the randomized Symplicity HTN-3 trial, renal denervation did not significantly reduce blood pressure compared with medical therapy. Further optimization of the technique is ongoing with some evidence from small, randomized trials of modest efficacy, which was sufficient to lead to regulatory approval.

CONCLUSION

Interventional cardiology continues to expand its borders. Treatment for coronary artery disease, including complex anatomic subsets, continues to advance. Technological advances such as DESs, now already in their second generation, are improving the results of PCI. PCI is the treatment of choice for patients with acute coronary syndromes. For patients with stable coronary disease, PCI is effective in symptom alleviation. Use of a Heart Team is the best way to make decisions concerning which revascularization—PCI or CABG—is best for an individual patient. Treatment of peripheral and cerebrovascular disease can be effective with percutaneous techniques. Structural heart disease is increasingly being treated with percutaneous options, with interventional approaches such as TAVR becoming preferred over surgical aortic valve replacement. Further growth of invasive procedures is anticipated in years to come.

288 Hypertension

Paul K. Whelton

High blood pressure (BP) is a leading risk factor for cardiovascular disease (CVD), including ischemic and hemorrhagic stroke, coronary heart disease (CHD), heart failure (HF), peripheral arterial disease (PAD), chronic kidney disease (CKD)/end-stage kidney disease (ESKD), dementia, and all-cause mortality. Hypertension, a subset of high BP, is very common no matter how it is defined and results in a huge burden due to death, morbidity, disability, social and workplace disruption, and cost to the individual and society. According to data from the National Ambulatory Medical Care Survey (NAMCS), hypertension is a component for more than one-third of all visits to office-based physicians by U.S. adults. Likewise, global estimates have ranked hypertension as the most common reason for primary care visits worldwide. Hypertension is often associated with other CVD risk factors, resulting in a higher risk of complications and related burden of illness. The optimal approach to high BP is to prevent its development, but diagnosis, treatment, and control of hypertension also provide an effective means to reduce the risk of BP-related CVD. Unfortunately, both strategies are poorly implemented worldwide, resulting in a high burden of preventable disease.

BLOOD PRESSURE PHYSIOLOGY AND PATHOPHYSIOLOGY

Complex and incompletely understood mechanisms control blood flow in individual organs and the arteriolar system. At the most basic level, arterial BP is controlled by cardiac output and peripheral resistance **(Fig. 288-1)**. However, arterial pressure is largely thought to be controlled by a renal-volume-endocrine pressure control system, in which the blood volume and total peripheral resistance are manipulated slowly to adjust arterial BP.

Cardiac output is influenced by stroke volume and heart rate, with stroke volume being related to myocardial contraction and the size of the intravascular compartment. Changes in cardiac output play an important role in acute BP responses to stressors. Peripheral vascular resistance is determined by functional and anatomic changes in small arteries and arterioles. The vascular endothelium is composed of a single layer of endothelial cells that constitute the inner cellular lining of arterioles. It serves as a direct contact with circulating blood and regulates exchanges between the bloodstream and surrounding tissues. Endothelial cells control vascular tone and, thereby, blood flow by synthesizing and releasing relaxing and contracting factors such as nitric oxide; metabolites of arachidonic, lipoxygenase, and cytochrome pathways; peptides, including endothelin; adenosine; purines; and reactive oxygen species; and by generating endothelial enzymes that produce vasoactive hormones such as angiotensin II. Endothelial dysfunction may play an important role in the initiation or progression of hypertension and atherosclerosis. A wide variety of systems interplay to keep cardiac output and peripheral resistance in balance, including sodium handling, primarily by the kidney, and many neural and hormonal systems that influence peripheral resistance by stimulating vascular constriction (e.g., the sympathetic system and the renin-angiotensin-aldosterone system [RAAS]) or inducing vasodilation (e.g., bradykinin system), and by modulating hormones that result in excretion or retention of sodium (natriuretic peptides and aldosterone, respectively).

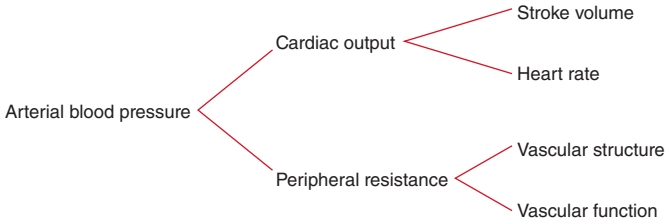

FIGURE 288-1 Schematic depiction of factors that influence the control of blood pressure.

Most vascular beds have the capacity to autoregulate blood flow. When peripheral arterial resistance is increased, the autoregulatory systems tend to increase vascular resistance within the vascular bed to maintain constant blood flow. During the 1960s, Arthur Guyton hypothesized that the capacity of the kidney to excrete sodium ultimately dictates long-term changes in levels of BP. Although the Guyton model has been challenged and alternatives proposed, it has had a profound influence on the understanding of BP regulation. A commonly accepted theory is that initial elevation of BP is due to increased cardiac output and expanded intravascular volume; peripheral resistance increases and cardiac output reverts toward normal over time. Whether or not this is the typical sequence of events in the pathogenesis of hypertension, salt can activate a number of neural, endocrine, paracrine, and vascular mechanisms that have the potential to increase arterial pressure. As arterial pressure increases in response to a high intake of sodium chloride, urinary sodium excretion increases, and sodium balance is maintained at the expense of an increase in arterial pressure. The mechanism for this "pressure-natriuresis" phenomenon may involve a subtle increase in glomerular filtration rate (GFR), decreased sodium absorption capacity in the renal tubules, and hormonal factors such as atrial natriuretic factor. In individuals with an impaired capacity to excrete sodium, greater increases in arterial pressure are required to achieve natriuresis and sodium balance.

Many of the drugs used to manage high BP work though influences on the various BP control mechanisms. For example, direct vasodilators and calcium channel blockers (CCBs) work by inducing arteriolar vasodilation. Agents that block the RAAS, such as angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and renin inhibitors, act by blocking the vasoconstricting effects of angiotensin II and sodium-retaining effects of aldosterone. ACEIs also inhibit inactivation of the vasodilator bradykinin, resulting in angioedema in some patients treated with this agent. Beta blockers tend to affect BP by impairing the action of sympathetic system neurotransmitters that stimulate vasoconstriction and heart rate. For example, beta blockers can antagonize the neurotransmitter acetylcholine as well as epinephrine and norepinephrine. In addition to being the most important site for the effect of agents that block the RAAS activity, many drugs affect electrolyte and fluid exchange in the kidneys. Carbonic anhydrase inhibitors have a diuretic effect in the proximal tubules, but due to side effects and diminishing efficacy over time, they are rarely used for BP control. Thiazide and thiazide-like diuretics work to enhance sodium excretion in the distal convoluted tubule and are a mainstay of drug therapy for BP control. They work by reducing intravascular volume, but over the long term, their effect on BP is through reducing peripheral arteriolar resistance. Loop diuretics are more potent diuretics that produce sodium excretion in the loop of Henle. They tend to be relatively short-acting agents that are better suited for sodium excretion than BP reduction. Mineralocorticoid receptor antagonists (MRAs) or aldosterone antagonists are diuretic drugs that work in the distal tubule of the kidney, including the distal convoluted tubule, connecting the tubule and cortical collecting duct, to antagonize the action of aldosterone at mineralocorticoid

receptor sites. These are examples of presumed principal mechanisms of action, but many drugs have other effects on the control of vascular tone and cardiac output that play a role in their effects on BP.

BLOOD PRESSURE MEASUREMENT

Commonly, BP measurements are used to estimate an individual's average level of BP; estimate their risk of CVD, in combination with other indicators; and determine the need for hypertension prevention or treatment. Office and clinic BP measurements are among the most common procedures in clinical practice and arguably provide the best assessment of BP because they have been used in almost all of the landmark BP-CVD risk prediction cohort studies and hypertension prevention and treatment trials. The need for standardization of the BP measurement procedure was recognized by early advocates of BP assessment. Subsequently, the effects of factors that can systematically (predictably) result in falsely high or low BP estimates were quantified, which formed the basis for BP measurement recommendations by professional societies and clinical practice guideline committees. BP also varies randomly (nonpredictably) within and between visits, resulting in corresponding recommendations to rely on an average of repeated readings obtained at more than one visit for classification of an individual's average level of BP. For many years, U.S. clinical practice guidelines have recommended using an average of two or more BP measurements obtained at two or more visits to estimate the usual level of BP. The most important elements for obtaining accurate office BP measurements are visually depicted in **Fig. 288-2** and outlined below.

- Instruct the patient to avoid a full bladder and abstain from caffeine, smoking, alcohol, or exercise for 30 min prior to the measurements.
- Use a quiet room with a comfortable ambient temperature.
- Explain the procedure to the patient, including the number of readings.
- Instruct the patient to rest for 3–5 min prior to the first measurement and avoid talking or distractions such as cell phone use during the rest period and subsequent BP measurements.
- Seat the patient in a chair with upright back support. The patient's feet should be flat on the ground and the measurement arm comfortably supported such that the cuff is at heart level.
- Use a clinically validated, preferably automated BP measurement device. Choose a cuff that is the correct size for the patient's arm, and measure their BP at the mid-brachial level.
- The BP measurements should be obtained by a trained, preferably certified, member of the health care team using the arm with the highest pressure at the first visit.

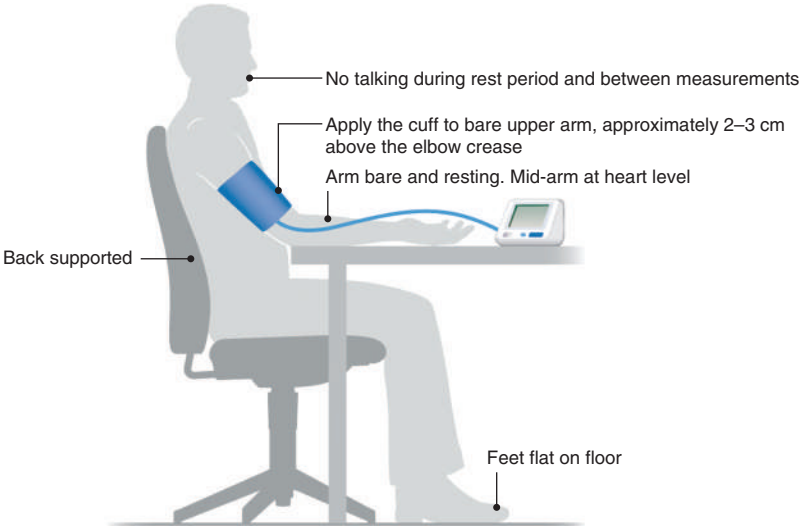

FIGURE 288-2 Schematic depiction of the important elements for accurate measurement of office blood pressure. *(Reproduced with permission from AK Cheung et al: International consensus on standardized clinic blood pressure measurement: A call to action. Am J Med 136:438, 2023.)*

TABLE 288-1 American College of Cardiology/American Heart Association Blood Pressure Classification System in Adults

BP CATEGORY	SYSTOLIC BP, mmHg		DIASTOLIC BP, mmHg
Normal BP	<120	and	<80
Elevated BP	120–129	and	<80
Stage 1 hypertension	130–139	or	80–89
Stage 2 hypertension	≥140	or	≥90

Abbreviation: BP, blood pressure.

- Use an average of two or more readings at two or more visits to estimate the patient's usual level of BP.
- Provide the patient with the results and an interpretation of their clinical implications.

Most clinical practice guidelines recommend use of a clinically validated oscillometric BP measurement device, a method that eliminates several sources of measurement error and does not require periodic recalibration. Several websites provide a listing of BP measurement devices that have been clinically validated to international standards. These include the Validate BP website in the United States (*https://www.validatebp.org/*) and the STRIDE BP website in Europe (*https://stridebp.org/bp-monitors*). Similarly, many free office and home BP measurement training and certification courses are available, including an easy-to-access course sponsored by the Pan American Health Organization, World Hypertension League, and others (*https://campus.paho.org/en/node/29166*).

DEFINITION OF HYPERTENSION

BP classifications systems differ by country and have changed substantially over time. The current classification proposed by the American College of Cardiology (ACC) and American Heart Association (AHA) for office/clinic BP measurements in U.S. adults is displayed in **Table 288-1**.

Correct classification presumes accurate BP measurement and averaging of two or more readings obtained at two or more occasions. When the systolic BP (SBP) and diastolic BP (DBP) readings are in different categories of BP, the higher classification should be chosen. In children and adolescents <13 years of age, hypertension is generally based on a comparison with age-, sex-, and height-specific normative data. Hypertension is defined as an average of three SBP or DBP readings at or above the 95th percentile or an SBP or DBP ≥130 or 80 mmHg, respectively. This chapter is focused on BP in adults ≥18 years.

Despite the importance and relative simplicity of accurate BP readings, errors in BP measurement are common in routine clinical practice. Generally, SBP is overestimated by an average of ~7 mmHg, which results in a 15–20% overestimation of hypertension prevalence. However, underestimation of BP and failure to diagnose hypertension are also common. Clinical practice errors vary by level of BP and practice settings and are inconsistent over time, making it impossible to use formulae to correct the errors. For those who aspire to practice evidence-based medicine, the only solution is to follow the recommendations for accurate and precise BP measurements that are advocated by the AHA, ACC, and many other organizations. Having a trained nonphysician staff member obtain routine BP measurements provides an efficient and cost-effective means of obtaining high-quality observations. This is the common practice in research studies and in many large U.S. systems of care.

OUT-OF-OFFICE BLOOD PRESSURE MEASUREMENT

Office BP measurements provide a limited and potentially biased depiction of an individual's usual level of BP. Guidelines commonly recommend complementing office BP readings with out-of-office BP measurements to confirm high office readings and to probe for higher or lower BPs

outside the office. White coat hypertension, in which office BPs meet the criteria for hypertension but out-of-office BPs are nonhypertensive, and masked hypertension, in which office BPs are nonhypertensive but out-of-office BPs meet the criteria for hypertension, are common, with prevalence estimates of 15–25% for both conditions. Adults with white coat hypertension have a CVD risk profile that is more like those without than those with sustained high BPs in and out of the office and they may be best treated with nonpharmacologic interventions, with careful monitoring to recognize a transition to sustained hypertension. In contrast, adults with masked hypertension have a CVD risk profile that is like those with sustained hypertension and may be better treated with a combination of antihypertensive drugs in addition to nonpharmacologic therapy. Masked hypertension should be suspected especially in adults with an elevated but nonhypertensive office BP and evidence of end-organ damage such as left ventricular hypertrophy or proteinuria. Home BP measurements provide the most practical approach to obtaining out-of-office BP readings and provide the additional benefit of engaging patients in their own care. When home BP measurements are desired, patients should be instructed to use a clinically validated BP measurement device and trained to measure their BPs accurately and precisely using the same approaches outlined for measurement of office BPs. Most guidelines recommend using an average of two to three measurements obtained in the morning (before taking antihypertensive medications) and evening. In the United States, obtaining home BP measurements for about 3 days prior to an office visit represents a reasonable and practical option for estimating a patient's usual level of home BP. The BP for recognition of hypertension is the same for office and home BP measurements (SBP ≥130 and DBP ≥80 mmHg). Likewise, the BP control is defined as an SBP/DBP <130/80 mmHg in both settings. Many home BP measurement devices allow for storage of the readings on a memory chip and for transfer to the physician's office by use of telemetry. This approach thwarts the potential for the bias of more favorable readings that can occur with written patient self-reports. Ambulatory BP measurements are best obtained by practitioners with special expertise in this technique and interpretation of the results. The equivalent SBP/DBP readings for an office average of 130/80 mmHg are 130/80, 110/65, and 125/75 mmHg for daytime, nighttime, and 24-h ambulatory readings, respectively. Ambulatory BP measurements provide the potential for scrutiny of nighttime readings, which may provide the best BP prediction of CVD risk. Specifically, those whose BPs fail to follow the usual pattern of a pronounced decrement during the nighttime (nondippers) tend to have a higher risk of CVD. BP nondipping is more common in non-Hispanic blacks than the other major racial/ethnic groups in the United States. Ambulatory BP measurement is relatively expensive and intrusive. Patients in the United States are usually reluctant to undergo repeat ambulatory BP measurements, making this measurement method most useful in confirming the diagnosis of hypertension, especially where uncertainty is a special concern. Wearable devices, including watches, hold great promise for the provision of convenient ways to obtain a more comprehensive assessment of daytime and nighttime BPs, but none of the currently available options are clinically valid.

PREVALENCE OF HYPERTENSION

Prevalence estimates vary depending on the criteria for definition of hypertension, the methods for BP measurement, and the population being studied; hypertension is very common, especially at older age. Age-related increases in BP are noted in almost all countries. Generally, SBP increases progressively until about the eighth decade of life. DBP also increases with age, but less steeply than SBP, until about the fifth decade of life and remains stable or declines thereafter. Isolated systolic hypertension is common late in life due to a widening of the pulse pressure (difference between SBP and DBP). Generally, those who have the highest or lowest BPs early in life tend to "track" in the same extremes of BP over life, with high pressures early in life providing a crude opportunity to identify those at higher risk for hypertension in adulthood. Little or no age-related change in BP has been observed in many isolated populations and in subsets of populations in countries where age-related increases in BP are common. This observation indicates that there is no biological necessity for the commonly observed age-related increase in BP and underscores the value of interventions aimed at prevention of hypertension. Migrant studies that have tracked isolated populations from their native environment to nonnative settings have uniformly reported progression to the more common pattern of age-related increases in BP. These BP changes have been associated with increases in dietary sodium and decreases in potassium intake, consumption of a less healthy diet, decreased physical activity, increases in body weight, and increased intake of alcohol.

Based on the ACC/AHA criteria for diagnosis, >103 million adults in the United States have hypertension, making it one of the most common health conditions reported. Hypertension is present in ~20–30% of U.S. adults aged 20–44 years, but the prevalence increases to 80–85% in those aged 75 years or older. The overall prevalence of hypertension in U.S. adults has remained fairly stable in recent decades (~46% overall). Men have slightly higher BPs compared to women during the first half of life, but the opposite is true in later life. In the United States, non-Hispanic black adults have a prevalence of hypertension (59%) that is substantially higher compared to whites (45%), Hispanics (47%), or Asians (46%). Adjusted estimates of hypertension in adult non-Hispanic black men and women are reported to be 59 and 56%, respectively, whereas the corresponding estimates for non-Hispanic white men and women are 47 and 41%, respectively. In addition, hypertension in non-Hispanic black adults tends to begin at a younger age and result in more CVD and kidney complications compared to the other major racial/ethnic groups in the United States. The prevalence of hypertension and CVD complications (especially stroke) is higher in the southeastern United States compared to other regions of the country, especially the northwest. No matter how defined, hypertension is very common in all parts of the world, with a progressively increasing prevalence in low- and middle-income countries and a slight decline in high-income countries. Using the hypertension definition of SBP ≥140 mmHg, DBP ≥90 mmHg, or taking antihypertensive medication, the prevalence in adults was estimated to be 31.5% (1.04 billion) in low- and middle-income countries and 28.5% (349 million) in high-income countries in 2010. As in the United States, hypertension prevalence is very age-dependent and varies by region, race/ethnicity, and other factors, including importantly socioeconomic factors, in most countries.

LABORATORY AND OTHER INVESTIGATIONS

In patients with newly diagnosed hypertension, basic laboratory testing is indicated to (1) recognize the presence and extent of target organ damage; (2) facilitate the identification of secondary causes of hypertension, including kidney disease and primary aldosteronism; (3) recognize comorbid conditions, including diabetes mellitus and hyperlipidemia; (4) estimate atherosclerotic CVD (ASCVD) risk in patients without a history of a CVD; and (5) assist in the optimal choice of antihypertensive drug therapy. At a minimum, a complete blood count, serum electrolytes (sodium, potassium, calcium), serum creatinine and estimated GFR (eGFR), lipid profile, glycemic status (hemoglobin A_{1c} or fasting blood glucose), thyroid-stimulating hormone level, urinalysis and urine albumin-to-creatinine ratio, and 12-lead electrocardiogram (ECG) should be obtained. These basic tests can be complemented by other evaluations as clinically indicated. In some countries, it is not possible to obtain the minimally recommended laboratory results. Guidelines written for clinicians in such countries, including the 2021 World Health Organization (WHO) guideline for the treatment of hypertension in adults, recommend that this should not be an impediment to BP reduction.

ESTIMATION OF CARDIOVASCULAR DISEASE RISK

Abundant studies have shown that BP is associated with CVD risk in a continuous, progressive, log-linear fashion from low to high levels of SBP and DBP. For SBP, the risk relationship has been documented from as low as 90 mmHg to more than 180 mmHg, suggesting relatively low levels of BP, if physiological, may be optimal to prevent the genesis of BP-related atherosclerotic complications. It also suggests that

one might reasonably expect a "lower BP is better" finding in antihypertensive randomized controlled treatment (RCT) trials. In addition to CVD, the level of BP is strongly associated with other diseases, including CKD, ESKD, and dementia. The BP-CVD risk association in observational studies is equally true for men and women. The BP-related slope for relative risk of CVD is steeper at younger age when BP elevation is often an isolated risk predictor. In older adults, the corresponding slope for CVD risk is less steep, but the absolute risk of CVD is far higher because other CVD risk factors are common in those with an elevated BP. At any level of BP, the risk of a CVD complication varies dramatically with more than a 30-fold difference in 10-year predicted risk of CVD for those with an isolated elevation of BP compared to their counterparts with multiple CVD risk factors in addition to an elevated BP. This observation has special relevance for clinical decision-making in patients with a usual SBP between 130 and 139 mmHg. In individuals with stage 1 hypertension as an isolated CVD risk factor, the 5- or 10-year risk of a CVD event may be quite small and limit enthusiasm for introducing antihypertensive drug therapy. However, when stage 1 hypertension is accompanied by other CVD risk factors, the corresponding risk of ASCVD may be quite high and make prescription of antihypertensive drug therapy much more appealing. In antihypertensive clinical trials, the relative risk reductions for CVD events are similar in groups with different levels of underlying CVD risk, but the absolute benefit is much greater in the groups at higher risk for ASCVD. For both these reasons, CVD risk assessment should be part of the initial evaluation.

Patients with a history of a prior CVD complication are known to be at high risk for recurrent CVD events. In those without a history of prior CVD, ASCVD risk should be estimated using a risk calculator. For U.S. adults 40–75 years of age, use of the ACC/AHA pooled cohort equations estimator is recommended because it has been validated in non-Hispanic white and black adults. Those with a 10-year risk of ASCVD ≥10% should be considered at high risk. PREVENT is an updated risk predicting model that is based on a larger and more current dataset than that used for the pooled cohort equations model. It incorporates an assessment of kidney (glomerular) function and allows for inclusion of urinary albumin/creatinine ratio, zip code for assessment of the social determinants of health, and hemoglobin A_{1c} where indicated and has been introduced by the AHA as a replacement for the pooled cohort equations. It can be used in U.S. adults aged 30–70 years to predict 10- and 30-year CVD risk. It includes the prediction of heart failure risk, an important feature in the care of patients with hypertension. Over time, the PREVENT instrument is expected to replace the current pooled cohort equations risk prediction model.

CAUSES OF HYPERTENSION

PRIMARY HYPERTENSION

Most adults have "primary" hypertension, with no obvious underlying anatomic cause of their high BP. Adoption, twin, clinical, and family studies provide evidence for a heritable component of high BP and hypertension. However, much of this may be due to a shared environment because, with rare exceptions, genetic investigations have only identified modest polygenic associations between multiple genes and BP. While genetic research remains an important area for investigation, the clinical implications of genetic studies for diagnosis and management of high BP are currently very limited.

Strong associations with level of BP have been reported for several general environmental exposures, including heavy metals such as lead, mercury, cadmium, and arsenic. Several indicators of air pollution, commonly including levels of particulate matter with a diameter of 2.5 microns ($PM_{2.5}$) or less, have been associated with higher levels of SBP and DBP. In most studies, the increase in SBP has been ~3–5 mmHg, but the magnitude can vary depending on quantity and duration of the exposure. Air pollution is a challenge worldwide, but the level of exposure to pollutants varies widely by geography, climate, season, and extent of economic development. In addition to air pollution, clinically important changes in BP are recognized in geographic regions that experience large seasonal variations in ambient temperature, with lower and higher BPs during the warmest and coldest seasons, respectively. BP also tends to be higher in those who are acutely exposed to high altitudes, possibly due to a combination of hypoxia and cold temperatures.

Personal environmental exposures related to components of diet, physical activity, and alcohol consumption seem to be responsible for much of the age-related increases in BP that are common in most countries. A large body of ecological, migrant, and longitudinal cohort studies have documented higher BPs in those who consume unhealthy diets, have an excessive intake of sodium or an inadequate intake of potassium, are physically inactive, are overweight or obese, or consume alcohol. Many of these exposures have also been linked to CVD complications. For example, insufficient dietary intake of potassium has been identified as a risk factor for stroke in many studies. Stress and other psychosocial indicators have also been associated with higher BPs and CVD events. The six personal exposures identified in **Table 288-2** (diet quality, body weight, excessive dietary sodium intake, insufficient dietary potassium intake, physical inactivity, and alcohol consumption) are all highly prevalent and strongly associated with higher BP and age-related increases in BP. About half of U.S. adults report attempts to eat a heart healthy diet, but this is likely to represent an overestimate. Almost all adults worldwide exceed the intake of dietary sodium and fail to meet the level of dietary potassium recommended by the WHO and national organizations. Likewise, excess body weight is very common in many countries. For example, approximately three-quarters of U.S. adults are either overweight (body mass index [BMI] 25–29 kg/m^2) or obese (BMI ≥30 kg/m^2). More than a quarter of U.S. adults report no physical activity outside their workplace, and about half report less than the recommended level of physical activity (≥150 min of aerobic exercise/week). About 85% of U.S. adults report consumption of alcohol at some point during their life, with >60% reporting alcohol consumption during the previous year and 25% reporting binge drinking during the previous month. Thus, these six exposures are not only closely related to level of BP and targets for interventions aimed at BP lowering but also extremely common exposures.

SECONDARY HYPERTENSION

A minority of patients have "secondary" hypertension, with an overt underlying anatomic or biochemical cause for their high BP. Secondary hypertension should be considered during the evaluation of all patients with new-onset hypertension and in selected patients with prevalent hypertension who have indicators that suggest the possibility of a complicating secondary cause of hypertension, including (1) treatment-resistant hypertension; (2) abrupt worsening of hypertension; (3) disproportionate target organ damage for level of BP; and (4) laboratory or diagnostic findings such as unprovoked hypokalemia, proteinuria, or left ventricular hypertrophy. The approximate prevalence, pathophysiology, possible clinical and physical examination findings, common screening and confirmatory tests, and potential treatments for the six most common causes of secondary hypertension are summarized in **Table 288-3**.

Obstructive Sleep Apnea Obstructive sleep apnea (OSA) is probably the most common cause of secondary hypertension. It is closely associated with overweight, obesity, and other comorbidities. The reported prevalence of OSA varies substantially depending on the criteria used for definition and methods of ascertainment. However, it is very common and may be present in as many as 15–30% of adult men and 10–15% of adult women in the United States. More than half of U.S. adults with OSA have hypertension and >30% of U.S. adults with hypertension have OSA. OSA and hypertension share many common pathophysiologic features, including being overweight, obesity, unhealthy lifestyles, and abnormalities of the renin-angiotensin system and fluid distribution. Sympathetic system activation due to intermittent hypoxia is also an important component of the underlying pathophysiology in OSA. Almost three-quarters of patients with OSA are overweight or obese. In general, there is a direct association between the severity of OSA and an individual's level of BP as well as their resistance to antihypertensive therapy. Resistant hypertension,

TABLE 288-2 Summary Information for the Six Best Proven Nonpharmacologic Interventions That Lower Blood Pressure

CHARACTERISTIC	BP ASSOCIATION	INTERVENTION	REGIMEN	EXPECTED CHANGE IN BP
Diet	BPs are lower in those who consume heart-healthy diets.	Consumption of a heart-healthy diet, especially the Dietary Approaches to Stop Hypertension (DASH) diet.	DASH diet meal plans are readily available.	With good adherence to the DASH diet plan, an average SBP reduction of about 5 mmHg can be expected in patients with and 2–3 mmHg in those without hypertension.
Body weight	Increased body weight is directly associated with SBP/DBP. Almost 75% of U.S. adults are overweight (BMI 25–<30 kg/m^2; 31%) or obese (BMI ≥30 kg/m^2; 42%).	In most patients, weight loss should be achieved by behavioral counseling. In a minority, drug therapy should be considered. Bariatric surgery should be confined to adults with a BMI ≥40 kg/m^2 or ≥35 kg/m^2 and hypertension or another obesity-related comorbidity.	Behavioral interventions are aimed at a combination of calorie reduction and increased physical activity.	Generally, SBP is reduced by ~1 mmHg for every kilogram reduction in body weight. In high-quality RCTs, an average reduction of about 10 lb (4.5 kg) has been common at 6–12 months.
Sodium intake	Dietary sodium is directly associated with SBP, and excessive intake may be important in age-related increases in BP.	Behavioral counseling, use of salt substitutes, public health messaging, and policy to reduce the amount of sodium added during food processing and commercial preparation.	The sodium-BP dose response is almost linear, so any reduction in sodium intake is beneficial. Optimal target recommendations vary from <1500 to 2300 mg sodium intake per day.	In high-quality behavior change trials, average sodium intake is reduced by ~25% and SBP by ~5 mmHg and 2–3 mmHg for adults with and without hypertension, respectively. Use of salt substitutes has resulted in prevention of stroke (14%), CVD (13%), and all-cause mortality (12%) in addition to BP lowering.
Potassium intake	Potassium intake is inversely associated with BP and a lower risk of CVD, especially stroke.	Dietary or pill supplementation, but the former is preferred. An additional intake of 2000 mg/d (~50 mmol/d).	The recommended intake of potassium in adults is ~3500 mg/d. A dose-response meta-analysis suggests supplementing usual intake by ~1200 mg/d may be optimal. Potassium supplementation is contraindicated in patients with hyperkalemia or advanced kidney disease or who are taking medicines that increase the risk of hyperkalemia.	Clinical trial meta-analyses have repeatedly shown that potassium supplementation by diet or pill use lowers BP. The average reduction in SBP has been ~5 and 3 mmHg in adults with and without hypertension, respectively. Greater reductions are observed in adult black patients and those consuming large amounts of dietary sodium.
Physical activity	Observational studies identify a strong inverse association between physical activity and BP, hypertension, and CVD.	Aerobic, dynamic resistance, and isometric resistance exercises.	Most trials have evaluated aerobic exercise interventions, and this type of exercise is commonly prescribed. Most guidelines recommend ≥150 min of aerobic exercise per week. However, any increase in physical activity and any type of exercise are likely to be be beneficial.	In adults with hypertension, aerobic exercise is likely to reduce SBP by ~5 mmHg and, when combined with dynamic resistance exercise, by ~7 mmHg. The extent of BP lowering depends on the starting level of BP and success of the intervention.
Alcohol consumption	Alcohol intake is associated with BP and hypertension in a direct and roughly linear fashion, with no threshold for the association.	Most commonly, substitution of lower alcoholic or nonalcoholic beverages, but behavioral counseling and abstinence, without access to alcohol, have been used in some trials.	Most interventions have targeted a reduction in alcohol consumption, often to ≤2 and ≤1 standard drinks per day in men and women, respectively. However, any reduction in alcohol consumption is helpful.	The extent of BP lowering depends on the starting level of alcohol consumption and the magnitude of the reduction in alcohol intake. Commonly, alcohol reduction trials have resulted in an SBP reduction of >5 mmHg in adults with hypertension.

Abbreviations: BMI, body mass index; BP, blood pressure; CVD, cardiovascular disease; DASH, Dietary Approaches to Stop Hypertension; DBP, diastolic BP; RCT, randomized controlled trials; SBP, systolic BP.

snoring, poor quality sleep, breathing pauses during sleep, and daytime sleepiness are common clinical indicators of OSA. Several simple questionnaire-based tests are available to screen for those who should be evaluated more carefully with a sleep study (polysomnography). Lifestyle improvements, especially those resulting in weight loss, are an important component of treatment for both OSA and any associated hypertension. OSA-specific treatment includes continuous positive airway pressure (CPAP), but meta-analyses demonstrate limited BP lowering due to CPAP treatment. As a result, hypertension in patients with OSA should be treated with antihypertensive drug therapy in addition to nonpharmacologic therapy.

Medication and Other Substances Prescription and over-the-counter medications, herbal and food additives, and illegal substances are often identified as secondary causes of new-onset hypertension or diminished BP control in patients being treated for hypertension. Typically, the increase in BP results from a direct pressor effect of the agents, but these exposures can also have an indirect effect on BP as a result of drug-drug or drug-nondrug exposure interactions. Some of the most common prescription drugs that can increase BP include amphetamines, angiogenesis inhibitors, antidepressants and antipsychotic agents, decongestants, oral contraceptives, nonsteroidal anti-inflammatory drugs (NSAIDs), and systemic corticosteroids. Examples of illicit drugs that can result in a higher BP include cocaine, marijuana, amphetamines, and methylenedioxymethamphetamine. Herbal treatments that have been reported to raise BP include arnica, ephedra (Ma-Huang), ginseng, guarana, consumption of large quantities of licorice, and St. John's wort. Finally, caffeine and several anesthetic agents can result in short-term elevation of BP. A careful history will identify most of these agents and will allow for use of alternatives or a reduced dosage in most patients. The exact prevalence of exposure to any of these agents is uncertain but high. For example, in the nationally representative 1999–2004 National Health and Nutrition Examination Survey (NHANES), >26% of U.S. adults reported regular NSAID use, and the percentage was much higher in older adults and in non-Hispanic whites.

TABLE 288-3 Summary Description of the Most Common Secondary Causes of Hypertension

CAUSE	PREVALENCE	PATHOPHYSIOLOGY	CLINICAL INDICATORS	PHYSICAL EXAMINATION	SCREENING TESTS	CONFIRMATORY TESTS	TREATMENT
Obstructive sleep apnea (OSA)	OSA is very common (10–30% of U.S. adults). More than 50% of U.S. adults with OSA have hypertension, and ~30% with hypertension have OSA.	OSA and hypertension share many common pathophysiologic features, including overweight and obesity. Activation of the sympathetic system due to intermittent hypoxia is an important component of the pathophysiology for OSA.	Resistant hypertension, snoring, poor quality sleep, breathing pauses during sleep, daytime sleepiness, overweight and obesity	Obesity and signs of upper airway narrowing	OSA screening questionnaires (several have been validated)	Polysomnography (sleep study)	Lifestyle improvement, especially aimed at weight loss, is indicated for both OSA and associated hypertension. Antihypertensive drug therapy. Continuous positive airway pressure (CPAP) treatment for OSA has little effect on BP.
Medication and other substances	High prevalence. Numerous potential exposures. For NSAID alone, >26% of U.S. adults reporting regular use.	Varies depending on exposure.	Usually exposure best detected by medical history report	Occasionally, specific physical exam findings, e.g., signs suggesting cocaine use	History taking	History taking	Discontinuation, substitution of alternative therapy, or maintenance of exposure but management of high BP.
Renal parenchymal disease.	One of the most common causes of secondary hypertension (>5%).	Various kidney diseases, including polycystic renal disease, chronic glomerulonephritis, diabetic and hypertensive kidney disease, recurrent stones, and kidney infections.	Resistant hypertension, fatigue, edema, report of hematuria	Proteinuria, renal mass	Serum creatinine, albuminuria, glucose abnormality	Imaging by sonography, CT, or MRI Renal biopsy	Treatment of ASCVD risk factors, including hypertension. Management of the specific kidney disease, if feasible.
Primary aldosteronism	One of the more common causes of secondary hypertension, responsible for the high BP in ~5% of adults with hypertension.	Idiopathic bilateral adrenal hyperplasia (60–70%) Benign adrenal adenoma (30–40%) Occasionally, familial Rarely due to other causes	Severe or resistant hypertension Hypokalemia Nonspecific fatigue, muscle cramps, or weakness Incidental finding of adrenal adenoma Obstructive sleep apnea Family history of early-onset hypertension or stroke	No specific findings on clinical examination	High plasma aldosterone/renin ratio, when measured under standardized conditions CT of the abdomen	Saline suppression test or captopril challenge test are helpful, but adrenal vein sampling for aldosterone levels is generally accepted as the gold standard test.	Adrenalectomy (laparoscopic or surgical) for many patients with an adrenal adenoma. Hypertension due to adrenal hyperplasia best treated medically, with inclusion of a mineralocorticoid receptor antagonist, and lifestyle changes to reduce sodium intake and body weight.
Renovascular disease	Generally reported to approximate 5%.	Usually unilateral disease due to ASCVD (90%) with >70% arterial lumen narrowing. About 10% due to fibromuscular disease, typically occurring in middle-aged white women.	Early, abrupt-onset hypertension (consider fibromuscular disease) Rapidly worsening or resistant hypertension in older adults (consider ASCVD)	Bruits, especially abdominal renal artery bruit	Various imaging options, including Doppler ultrasonography, magnetic resonance, or CT angiography	Digital subtraction angiography	PTA may cure or substantially improve hypertension in patients with discrete fibromuscular disease lesions. Medical treatment is preferred in patients with ASCVD and those with very diffuse fibromuscular disease.
Hypertensive disorders of pregnancy	During pregnancy, approximate prevalence of hypertension 10%, preeclampsia 3%, and eclampsia 0.1–0.3%.	Varies depending on whether the hypertension is new onset or chronic. New-onset hypertension seems to result from reduced placental perfusion and subsequent elevation in peripheral resistance, which usually disappears after delivery.	High BP Preeclampsia if high BP is accompanied by proteinuria or other evidence of target organ damage	High BP, with or without proteinuria	No specific screening tests	Diagnosis by recognition of high BP, based on an average of ≥2 accurately measured BP readings taken on ≥2 occasions	Lifestyle counseling and antihypertensive medication. ACEIs and ARBs should not be used. Initial use of the β-blocker labetalol and/or the CCB nifedipine is commonly recommended because of their safety record and known efficacy in pregnancy.

Abbreviations: ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; ASCVD, atherosclerotic cardiovascular disease; BP, blood pressure; CCB, calcium channel blocker; CT, computed tomography; MRI, magnetic resonance imaging; NSAID, nonsteroidal anti-inflammatory drug; PTA, percutaneous transluminal angioplasty.

Renal Parenchymal Disease This is also relatively common and probably accounts for >5% of all non-OSA and medication-related secondary causes of hypertension. It can result from almost any type of underlying kidney disease but is somewhat more common with glomerular than interstitial disorders. Most patients with CKD disease have hypertension. Importantly, it is often difficult to determine the extent to which a patient's high BP is the cause or a consequence of their kidney disease. Activation of the RAAS is often a part of the underlying pathophysiology that leads to hypertension. Clinical indicators of hypertension due to renal parenchymal disease include treatment resistance, fatigue, palpation of a renal mass, hematuria, proteinuria, elevated creatinine, or hyperglycemia. Imaging with sonography, computed tomography (CT), or magnetic resonance imaging (MRI) can be helpful for the diagnosis of some forms of underlying kidney disease. Renal biopsy is most helpful when glomerulonephritis is suspected. Most patients with CKD have a variety of both conventional and novel risk factors for ASCVD placing them at high risk for CVD complications. Improvement of CVD risk factors, including hypertension, is an essential element of treating patients with CKD. Often, control of hypertension may require use of three or more antihypertensive agents in addition to lifestyle management. Diuretics and RAAS inhibitors such as ACEIs and ARBs are obvious components of the antihypertensive drug treatment regimen. Traditionally, thiazide and thiazide-like diuretics were thought to be relatively ineffective for the management of patients with a serum creatinine >3 mg/dL, but a recent well-conducted trial documented substantial BP and albuminuria reduction in patients with advanced CKD who were treated with the long-acting diuretic chlorthalidone. Finerenone, a newer MRA, has also been shown to enhance BP reduction in patients with advanced CKD. Gliflozins or sodium-glucose cotransporter 2 (SGLT2 inhibitors), which are often very useful in the management of patients with CKD, are diuretics and may provide a small reduction in BP. If possible, the underlying kidney disease should be treated with specific therapy.

Primary Aldosteronism A relatively common cause of secondary hypertension, primary aldosteronism may be the underlying cause of high BP in ~5% of adults with non-OSA and medication-related secondary hypertension. However, the reported prevalence varies widely depending on the criteria for diagnosis and the population studied. Most patients with primary aldosteronism (60–70%) have idiopathic bilateral adrenal hyperplasia but ~30–40% have a benign adenoma, usually unilateral. Often, the clinical presentation is subtle with no more than resistant hypertension or nonspecific symptoms. However, in some patients with more pronounced aldosteronism, unprovoked hypokalemia or hypokalemia-related cardiac arrhythmias, such as atrial fibrillation, may be present. Common screening tests for primary aldosteronism include abdominal imaging by CT to detect an adenoma and measurement, under standardized conditions, of a high aldosterone/renin ratio in conjunction with high plasma aldosterone levels. Several noninvasive investigations, including the saline suppression and captopril challenge tests, can provide more definitive evidence of primary aldosteronism, but adrenal vein aldosterone sampling is generally accepted as the gold standard test for diagnosis. The most important goal is to recognize the minority of patients with a benign unilateral adenoma whose hypertension can be cured or substantially improved by adrenalectomy. The latter can be accomplished by minimally invasive laparoscopy or by use of traditional surgical techniques. Medical management of hypertension in patients with aldosteronism should include the use of MRA agents. In most patients, spironolactone is well tolerated but occasionally adverse effects, including hyperkalemia, breast tenderness, or gynecomastia in men, require the substitution of newer, more expensive, alternative MRAs. The screening tests and especially the more definitive diagnostic tests for primary aldosteronism require careful attention to detail and are generally best conducted by those who have specialized experience in the evaluation of patients who may have primary aldosteronism. Likewise, most adrenal adenomas are very small, and removal by laparoscopy or surgery is most successful when performed by an experienced treatment team. Rarely, primary aldosteronism can be caused by an adrenal carcinoma, ectopic malignancy, or rare genetic disorders.

Renovascular Hypertension Renovascular obstructions that result in substantial and hemodynamically important occlusion of the renal artery can result in hypertension and impaired renal function. Renovascular disease is found in as many as 25% of patients at autopsy, but renovascular hypertension only accounts for ~1% of the high BP in all patients with hypertension. In ~90% of patients with renovascular hypertension, renal artery obstruction is caused by atherosclerosis. Commonly, atherosclerotic renovascular disease is unilateral and the principal obstruction tends to present as a discrete lesion found close to the origin of the renal artery. Patients with atherosclerotic renovascular disease tend to be older and have other indications of ASCVD, including an abnormal risk factor profile and atherothrombotic lesions in other vascular beds. At times, a bruit can be heard over the renal artery or over the carotid or femoral arteries. A minority of patients with renovascular disease have fibromuscular disease. They tend to be younger, mostly white, women. Their renal artery lesions are more diffuse, with an irregular sawtooth appearance, and they are frequently located in more distal parts of the renal artery compared with atherosclerotic lesions. In addition, bilateral real artery disease is more common in patients with fibromuscular disease than is the case for renovascular disease due to ASCVD. Fibromuscular disease should be suspected in any patient with abrupt-onset hypertension, especially in young white women, and in those with resistant hypertension, or recent worsening of hypertension. Underlying atherosclerosis should be suspected in older patients with other indications of ASCVD and in those with otherwise unexplained worsening of kidney function. The threshold for additional diagnostic investigations should be lower when fibromuscular disease is suspected.

A variety of screening tests, including renal ultrasound studies, CT and magnetic resonance angiography imaging studies, renograms, and standardized measurement of plasma renin activity, can be used to exclude other causes of hypertension and to screen for evidence of renovascular disease. Renal angiography provides more definitive evidence of the extent and type of renovascular disease and is currently considered to be the gold standard diagnostic test. Skilled interventional radiologists can employ digital subtraction angiography to generate high-quality studies with less contrast exposure compared to standard angiography. Hypertension due to renovascular disease is more likely in patients with lesions that occlude >70% of the vessel lumen. For many years, renal venous renin sampling was a gold standard diagnostic test but is now rarely performed due to a high frequency of false-positive and false-negative results.

In many patients with hypertension due to fibromuscular disease, percutaneous transluminal angioplasty results in a cure for their hypertension or substantially improves the control of their high BP. For this reason, the most important goal in evaluating patients with suspected renovascular hypertension is to recognize individuals with underlying fibromuscular disease. As is the case for some other forms of secondary hypertension, screening, diagnosis, and treatment results tend to be better when conducted by teams with experience in caring for patients with renovascular disease. Several well-conducted randomized controlled trials, with relatively large sample sizes, have failed to demonstrate any special benefit for BP control or renal preservation following percutaneous transluminal angioplasty or renovascular surgery compared to medical care in patients with atherosclerotic renovascular hypertension. Most patients with suspected atherosclerotic renovascular hypertension should be managed using a combination of nonpharmacologic and antihypertensive drug therapy, including the use of agents that block the RAAS. In rare instances, arteritis and other inflammatory disease can be the underlying cause of renovascular hypertension. The underlying cause should be treated in addition to medical management of hypertension.

Hypertensive Disorders of Pregnancy Hypertension occurs in >10% of pregnancies in the United States and about 3–5% are complicated by preeclampsia, in which hypertension is accompanied by proteinuria or other evidence of target organ damage. The HELLP

syndrome, in which hypertension is accompanied by hemolysis, elevated liver enzymes, and low platelets, represents a more severe form of preeclampsia. Progression to eclampsia, with seizures as the cardinal feature, occurs in <1% of women with mild and about 3% of those with severe preeclampsia. Hypertension during pregnancy is associated with a higher rate of fetal complications and of hypertension and CVD complications for the mother later in life. Hypertensive disorders of pregnancy include the following: (1) chronic hypertension, in which the high BP proceeds pregnancy; (2) gestational hypertension, in which new-onset hypertension is recognized after 20 weeks of gestation; (3) preeclampsia potentially culminating in eclampsia; and (4) chronic hypertension with superimposed preeclampsia. Management of hypertension in pregnancy often includes bed rest, nonpharmacological interventions, and pharmacotherapy. Clinical trials and meta-analyses provide strong evidence that antihypertensive therapy during pregnancy reduces the risk of progression to more severe hypertension, compared to placebo, but less convincing evidence for prevention of preeclampsia and other fetal complications. ACEI and ARB therapy should be avoided due to the potential for teratogenic side effects. Few high-quality studies have compared the benefits and risks of treatment with other commonly used antihypertensive drugs during pregnancy. Usually, treatment with the beta blocker labetalol, the CCB nifedipine, or the centrally acting α_2-adrenergic agonist methyldopa is recommended as providing safe first-line antihypertensive drug therapy, with one trial suggesting that labetalol and nifedipine may be superior to methyldopa for prevention of preeclampsia. A review of prescribing habits in the United States identified labetalol, nifedipine, and the direct vasodilator hydralazine as the three most commonly used antihypertensive agents during pregnancy. Clinical trials have failed to demonstrate a benefit for more intensive therapy to a SBP/DBP <130/80 mmHg compared to <140/90 mmHg.

Less Common Causes of Secondary Hypertension There are many other secondary causes of hypertension, but they tend to be infrequent and are generally best considered when patients are referred to consultants with expertise in recognizing rare causes of secondary hypertension. These include Cushing's syndrome in which large amounts of cortisol are produced in response to excessive levels of adrenocorticotropic hormone (ACTH) produced by a pituitary gland adenoma or ectopic ACTH-producing tumor, an adrenal adenoma, or treatment with glucocorticoids. Clinical signs of note include weight gain in the face (moon face) and trunk, a fatty lump between the shoulders (buffalo hump), thin arms and legs, pink or purple stretch marks on the stomach, hips, thighs, breasts, and underarms, easy bruising, slow healing, and acne. Screening and diagnosis are usually based on an assessment of 24-h urinary corticosteroid levels, imaging tests, and an overnight dexamethasone-suppression test. More than 75% of patients with Cushing's syndrome have hypertension. Treatment depends on the underlying cause of the syndrome. *Pheochromocytoma* is another rare form of secondary hypertension and is caused by excessive production of catecholamines, usually due to a benign neuroendocrine tumor composed of chromaffin cells located in the adrenal medulla (80–85%) or in extra-adrenal paraganglion tissue (paraganglioma). Most patients with pheochromocytoma present with hypertension at a relatively young age (often 30–50 years). Many have nonspecific signs and symptoms, but some have paroxysmal attacks characterized by high BP, sweating, headaches, and cardiac arrhythmias. Screening and diagnosis are usually based on blood and 24-h urinary catecholamine values and abdominal CT, MRI, or positron emission tomography imaging studies. Typically, pheochromocytomas are treated by complete or partial adrenalectomy using minimally invasive surgical techniques. A small minority of patients with pheochromocytoma have an inherited genetic predisposition such as multiple endocrine neoplasia type 2 (MEN 2), von Hippel-Landau disease, neurofibromatosis, and hereditary paraganglioma syndromes. Coarctation of the aorta is the most common congenital cause of hypertension and results from a birth defect in which a portion of the aorta is narrower than usual. When the defect is severe, the coarctation is likely to be detected early in life and may be associated with other congenital abnormalities. When the defect is mild, the disorder may not be recognized until early adulthood. The classical physical examination findings are delayed and diminished femoral and distal pulses. A systolic mummer may be heard in the posterior intrascapular area, and signs of left ventricular hypertrophy may be detected. Screening and diagnostic tests include imaging studies such as echocardiography, CT, and angiography. Treatment options include balloon angioplasty, surgery, and medical management. Other rare causes of hypertension include hyper- and hypothyroidism, acromegaly, and hypercalcemia.

PREVENTION AND TREATMENT OF PRIMARY HYPERTENSION

Both nonpharmacologic interventions, mostly lifestyle improvements, and antihypertensive medication play a role in the management of high BP.

The overall approach to prevention and treatment of hypertension, which is depicted in **Fig. 288-3**, is to encourage a healthy lifestyle in adults with a normal BP (SBP/DBP <120/80 mmHg) and actively advise nonpharmacologic therapy in adults with an elevated BP (SBP 120–129 mmHg and DBP <80 mmHg). Adults with stage 2 hypertension (SBP ≥140 mmHg or DBP ≥90 mmHg) should be treated with a combination of nonpharmacologic and antihypertensive drug therapy. Most adults with stage 1 hypertension (SBP 130–139 mmHg or DBP 80–89 mmHg) should be managed by active application of nonpharmacologic interventions, but in the minority (~30% in the United States) who have a history of CVD or are at high risk for ASCVD, antihypertensive medication should be added to the nondrug approaches to lower BP. In RCTs, low-dose pharmacotherapy has been effective for BP lowering, prevention of hypertension, regression of left ventricular mass, and prevention of left ventricular hypertrophy in nonhypertensive patients. However, drug therapy is not recommended for this purpose in any major clinical practice guideline. The next two sections provide a more detailed guide to the selection and application of nonpharmacologic and antihypertensive drug treatments.

NONPHARMACOLOGICAL INTERVENTIONS TO PREVENT AND TREAT HYPERTENSION

Many nondrug interventions have been reported to lower BP. Most of them are based on changing personal exposures associated with higher BP. The best proven approaches to nonpharmacologic lowering of BP are displayed in Table 288-2.

Generally, the nonpharmacologic interventions used in clinical practice settings require a change in behavior. However, pill supplementation to enhance potassium intake, renal denervation therapy in selected patients with resistant hypertension, and baroreceptor activation therapy are examples of nonpharmacologic treatments that are not primarily based on achieving behavior change. For the nonpharmacologic interventions based on behavior modification, the difficulty of achieving the desired changes varies by intervention and patient, but generally, behavior change can be hard to achieve and maintain over long periods of time. Behavior change interventions are most successful when patients accept the need for change, pledge to embrace the behavioral changes that are necessary, and can be counseled by a member of the health care team who is knowledgeable in the techniques for behavior change. For weight loss, abstinence from alcohol, physical activity, and high-quality counseling programs that are available in convenient locations close to a patient's home or workplace may provide an alternative option to office/clinic-based counseling. Behavior change can be successful in any patient but is especially likely in those with or at high risk for CVD and in patients who have the time, resources, and desire to concentrate on improving their health behaviors. Not surprisingly, older adults and those with higher socioeconomic status (SES) tend to be more successful than their younger and lower SES counterparts. The following are brief summaries of specific aspects of the six interventions identified in Table 288-2.

Diet Quality Heart healthy diets tend to lower BP and improve other diet-related CVD risk factors, such as low-density lipoprotein cholesterol and blood glucose. For example, a reduction in BP has

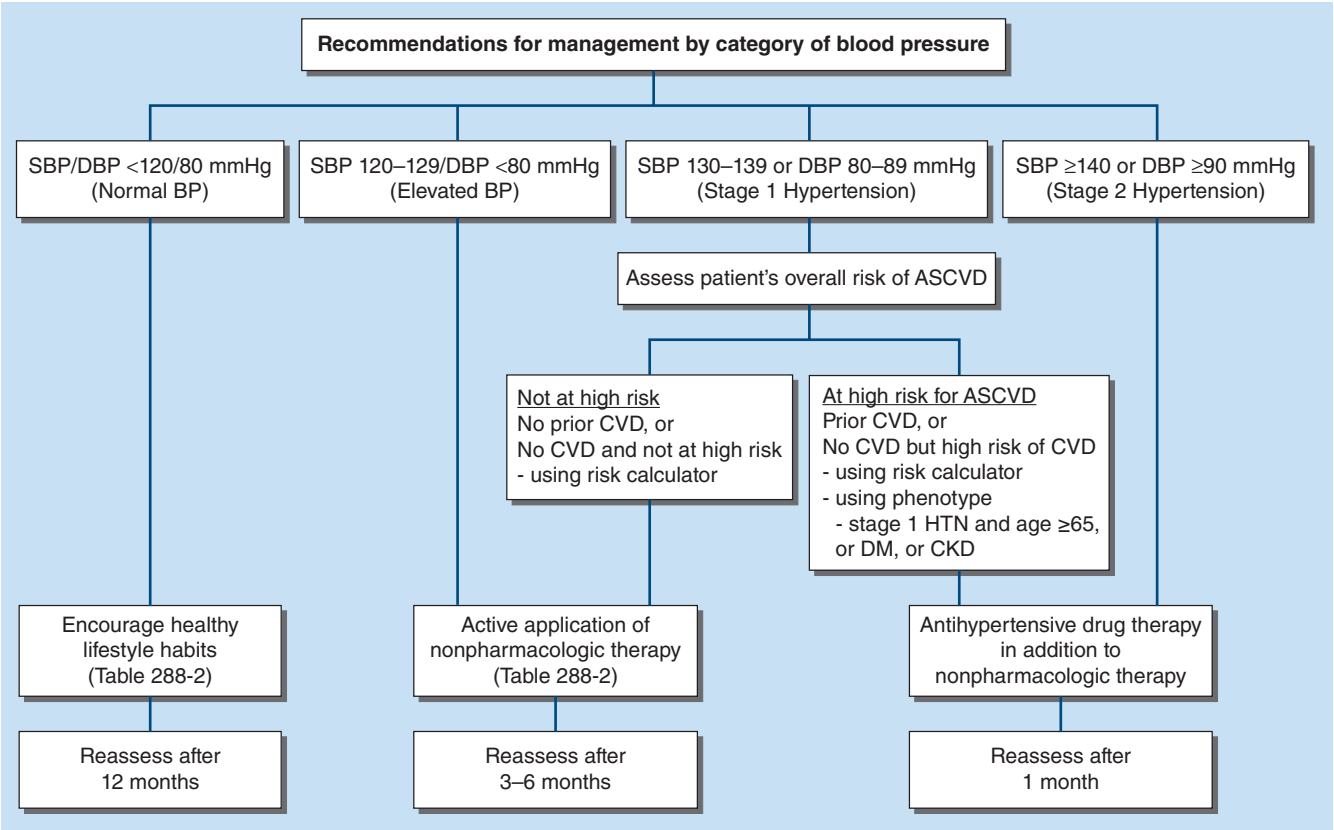

FIGURE 288-3 Recommendations for nonpharmacologic and antihypertensive drug therapy by category of blood pressure. ASCVD, atherosclerotic CVD; BP, blood pressure; CKD, chronic kidney disease; CVD, cardiovascular disease; DBP, diastolic BP; DM, diabetes mellitus; HTN, hypertension; SBP, systolic BP.

been a consistent finding in trials that have evaluated the Mediterranean diet, low-carbohydrate diets, and vegetarian and vegan diets. The DASH (Dietary Approaches to Stop Hypertension) diet is a heart-healthy diet that was specifically formulated to lower BP. The DASH diet is high in vegetables, fruits, whole grains, and low-fat dairy products and low in fats, saturated fats, and cholesterol. It has been extensively evaluated, and many DASH resources and support systems are readily available to health care providers and the public. For these reasons, it is commonly recommended as the best heart-healthy diet choice for BP reduction. Many of the DASH evaluation trials have been conducted as feeding studies in which patients are given specially prepared foods as a replacement for their usual diet. Compared to trials based on behavior change, feeding studies require less effort by the patient, achieve greater intervention change, and generally report a greater reduction in BP. However, the results of feeding trials are less generalizable to clinical practice where provision of patient meals is infeasible. The DASH trials that have employed a behavior change strategy provide a better indication of what can be expected in clinical practice settings. In the original short-term (8-week) feeding trial, the DASH diet reduced SBP/DBP by 5.5/3.0 mmHg compared with the usual U.S. diet. In longer-term (6-month) behavior change trials, the DASH diet combined with other established nonpharmacologic recommendations for BP lowering reduced SBP and DBP by ~4 mmHg and 3 mmHg, respectively, compared to an advice-only intervention, and by 0.6 mmHg and 0.9 mmHg, respectively, compared to other established recommendations on their own. With good adherence, one could reasonably expect use of the DASH diet on its own to result in an average SBP reduction of ~5 mmHg in patients with and 2–3 mmHg in patients without hypertension. Community-based trials have demonstrated that the DASH diet components can be purchased at supermarket locations without the need for patients to pay for higher priced specialty food products. The DASH diet can be combined with other nonpharmacologic interventions such as weight loss, sodium reduction, or increased physical activity. Likewise, the DASH diet eating plan can be customized to meet an individual's other dietary requirements, meal preferences, and lifestyle.

Weight Loss Weight loss not only lowers BP but can also improve lipid levels and is effective for prevention and management of diabetes mellitus. It can be achieved through a combination of calorie reduction and increased physical activity. The most sustainable approach to weight loss is targeting gradual and progressive loss in weight. As with all behavior change strategies, weight loss can be difficult to achieve and even more difficult to maintain over long periods of follow-up. However, it can be successful, especially in motivated patients who receive high-quality counseling and clinician reinforcement. In addition to clinic-based interventions, many commercial and noncommercial providers offer weight loss programs. The commercial programs usually provide some or all of the recommended meals. The optimal goal is achievement of an ideal body weight, but any weight reduction is beneficial. Application of high-quality weight loss counseling usually results in 6- to12-month weight loss of ~10 lb (4.5 kg). Typically, a 1-mmHg reduction in SBP can be expected for about every kilogram of weight loss. This translates to a 6- to 12-month average reduction in SBP of ~5 mmHg. The average reduction varies depending on the success of the intervention and the starting level of BP, with SBP reductions in those with and without hypertension tending to be about 5 and 2–3 mmHg, respectively. Several medications can be used to assist in weight loss, but some of the most popular agents, like sodium-glucose cotransporter 2 (SGLT2) inhibitors, are off-label options and are best reserved for U.S. Food and Drug Administration (FDA)-approved indications. Injectable glucagon-like peptide 1 (GLP-1) receptor agonists are equivalent agents that have been approved for weight loss by the FDA and have been shown to reduce weight in clinical trials. Certain patients with hypertension and a body mass index ≥35 kg/m^2 may be candidates for bariatric surgery. Selection of candidates for bariatric surgery is best conducted by multidisciplinary teams with experience in managing morbid obesity.

Dietary Sodium Reduction Many RCTs have demonstrated reductions in BP following decreases in dietary sodium intake. In a large dose-response meta-analysis of RCTs, there was a striking almost linear relationship between reduction in dietary sodium intake and

the corresponding decreases in BP. This finding was quite robust, being noted for every subgroup studied. An SBP/DBP difference of ~15/10 mmHg was noted between those with the highest (~7000 mg/d) and lowest (<1000 mg/d) intakes of sodium. An average reduction of ~5.5 mmHg was noted for every 2300-mg (100-mmol) decrement in dietary sodium intake. As expected, the effect was greater in adults with compared to those without hypertension and in SBP compared with DBP. The results were consistent with a "lower is better than higher" conclusion for intake of dietary sodium. In healthy U.S. adults, consumption of a diet with 1500 mg sodium provides adequate opportunity to meet the other recommended dietary requirements. Recommendations for daily sodium intake in adults vary considerably. The U.S. federal *Dietary Guidelines for Americans* recommends a daily sodium intake <2300 mg, whereas the World Health Organization recommends <2000 mg and others recommend much lower intakes. More than 95% of U.S. adults exceed the 2000 mg/d threshold, and almost 100% exceed the 1500 mg/d threshold. However, any reduction in dietary sodium intake is likely to be beneficial.

The traditional approach to reducing dietary sodium intake in clinical settings is by means of behavior change interventions. In addition to helping patients estimate and track their sodium intake, trying to avoid high-sodium foods and maximizing home preparations using fresh, natural foods are desirable. In countries like the United States, where most of the population consume commercial food products, >80% of an individual's sodium intake is generally due to sodium added during food processing or commercial preparation of foods and only ~10% is due to naturally occurring sources of sodium. Careful scrutiny of food labels for packaged foods while shopping, reducing meal portion size, choosing condiments and seasonings with low sodium content, salt substitution using herbs and spices, and use of salt substitutes that replace ~25% of the sodium content with potassium are other well-proven strategies to reduce dietary sodium intake. Salt substitutes provide a relatively easy and well-accepted way to achieve a modest reduction in sodium intake and an increase in potassium intake, especially in those who primarily eat foods prepared in the home and/or add a lot of salt at the table. A large cluster-designed clinical trial conducted in Chinese adults with stroke or at high risk for stroke demonstrated an impressive and statistically significant 14% reduction in stroke (the primary outcome), other major CVD events, and all-cause mortality in adults randomized to use a salt with 25% substitution of potassium for sodium compared to those who used regular salt. There was no evidence of a difference in hyperkalemic events in the two treatment groups. Public health messaging based on simple educational and action recommendations is also useful. Policy aimed at reducing the amount of sodium added to foods has great potential but has been difficult to implement in the United States. Long-term follow-up for 10–15 years in participants who had been randomized to a behavioral change sodium reduction intervention or usual care has also suggested a significant reduction of 30% in new-onset CVD events.

Potassium Supplementation A higher intake of potassium is associated with a lower BP and a reduced risk of CVD, especially stroke. U.S. Dietary Reference Intake committees have not made a dietary allowance intake recommendation due to insufficient evidence but have identified 2600 and 3400 mg/d in women and men, respectively, as adequate intake levels. Individual RCTs and meta-analyses provide strong evidence that potassium supplementation reduces BP. This has been achieved with pill therapy and dietary supplementation, with the latter being the preferred approach in clinical practice because this usually results in consumption of a more heart-healthy diet and a lower intake of dietary sodium. In most RCTs, routine potassium intake has been supplemented by about 2300 mg (60 mmol) per day, and the average reduction in SBP has been ~5 mmHg in trials with a successful intervention (net change in urinary potassium ≥20 mmol [870 mg] per day). As expected, the SBP reduction is greater in adults with (~5 mmHg) than without hypertension (~2 mmHg) trials. The SBP lowering is almost three times greater in black compared with white adults. Finally, there is a strong linear association between BP reduction with potassium supplementation and consumption of dietary sodium, possibly reflecting the well-known natriuretic effects of potassium. A dose-response meta-analysis has suggested a U-shaped BP response to potassium intake, with an optimal supplemental intake of ~1200 mg/d. However, the unexpected BP response findings at the upper and lower end of the U-shaped curve were based on indirect estimates and a relatively small number of trials.

Many foods contain potassium, but fruits, vegetables, legumes, and leafy greens are especially high in potassium content. By design, the DASH diet targets provision of 4700 mg of potassium per day, exceeding the recommended intake of 3500 mg/d in U.S. adults. Potassium supplementation is contraindicated in patients with hyperkalemia or advanced kidney disease and in those taking pills that can block the urinary excretion of potassium, including potassium-sparing diuretics, inhibitors of the RAAS, and MRA agents, such as aldosterone, eplerenone, and finerenone.

Physical Activity Observational studies identify a strong inverse association between physical activity (leisure time or total) and BP as well as CVD. In like manner, high-quality RCTs have demonstrated that increased physical activity lowers BP in adults with and without hypertension. Most of the trials have been based on aerobic exercise interventions such as brisk walking, swimming, or dancing. Meta-analyses of aerobic exercise RCTs have been consistent in documenting substantial BP-lowering efficacy, but the quantitative estimates for average reduction in BP have varied considerably, with reports of 5–10 mmHg for SBP in studies restricted to adults with hypertension and 3–5 mmHg for studies in those without hypertension. Dynamic resistance exercises such as climbing stairs, push-ups, weightlifting, and squats have also been shown to lower BP and are often employed concurrently with aerobic exercise. Isometric resistance exercises, during which muscles or muscle groups are tightened without any visible movement of the surrounding joints, include yoga poses, wall sit, plank, and bench press exercises. Fewer high-quality RCTs have assessed the efficacy of isometric resistance exercise, but individual trials and meta-analyses indicate this approach is effective for BP lowering. In the largest meta-analysis (~400 trials) of physical activity, aerobic exercise reduced SBP by ~5 mmHg in adults with hypertension and when combined with dynamic resistance exercise by ~6.5 mmHg. In trials that allowed for a direct comparison with antihypertensive drug therapy, physical activity yielded an almost identical level of BP lowering. Most guidelines recommend moderate-intensity aerobic exercise as the principal approach to lowering BP but acknowledge that dynamic and isometric resistance exercises are a useful complement. Based on clinical trial evidence, an aerobic exercise duration of 40–60 min three or more times per week for a total ≥150 min per week may be optimal. Although more intensive physical activity may be ideal for overall cardiac fitness, less intensive physical activity is sufficient for BP reduction. Less frequent but more intensive physical activity (e.g., "weekend warrior" exercise) has been shown to lower BP.

Alcohol Consumption Alcohol has long been known to be a pressor. Observational dose-response meta-analyses demonstrate a roughly linear association between alcohol consumption and both BP and hypertension, with no threshold for the association. For each 14-mg increased intake of alcohol (amount in a U.S. standard alcoholic drink), SBP is ~1.5 mmHg higher. RCTs have studied the efficacy of reducing alcohol intake on BP by substitution of lower-alcohol or no-alcohol drinks, use of behavior change interventions, or abstinence without access to alcohol. The overall effect of alcohol reduction on SBP in the largest meta-analysis was a reduction of ~5.5 mmHg. However, the magnitude of the effect is greatly influenced by baseline level of BP and alcohol intake and by the success of the intervention. Most current U.S. guidelines recommend an alcohol intake goal of ≤2 and ≤1 standard drinks per day for men and women, respectively. In part, this reflects the possibility that a modest intake of alcohol may favorably influence other CVD risk factors, such as high-density lipoprotein cholesterol. The WHO recommends abstinence from alcohol.

Summary for Nonpharmacologic Interventions to Lower BP In summary, a strong body of evidence supports the value of

interventions based on the six exposures highlighted in Table 288-2. In general, the interventions exhibit a linear-type dose-response for BP reduction. Consequently, more successful interventions result in greater BP reduction, and even smaller than desired changes in the exposure are likely to be beneficial. In addition, greater BP lowering can be expected in adults with compared to adults without hypertension, in those who start with more abnormality in the exposure, and when two or more interventions are combined. For example, a greater reduction in BP can be expected when the intervention combines the DASH diet with weight loss or sodium reduction. However, the behavioral changes needed for combination interventions are typically more challenging and require a greater commitment by the therapist and patient. Finally, nonpharmacologic interventions often enhance the effect of antihypertensive medications. This has been especially well demonstrated for reductions in sodium intake. A practical approach is to focus initially on the behavior that is most abnormal and most amenable to change, with a longer-term goal of more comprehensive improvements. With the exception of salt substitution, change in BP has been the primary outcome in most of the nonpharmacologic treatment trials, but some have demonstrated improvements in intermediate CVD outcomes, especially left ventricular mass and left ventricular hypertrophy. In addition, randomized comparisons following long periods of posttrial follow-up have suggested CVD benefits for both sodium reduction and weight loss.

PHARMACOLOGIC THERAPY TO PREVENT CARDIOVASCULAR DISEASE

Efficacy of Pharmacologic Therapy in Uncomplicated Primary Hypertension In most adults, primary hypertension is uncomplicated and relatively easy to manage. The introduction of diuretics in the late 1950s and early 1960s revolutionized pharmacotherapy of high BP, and these drugs were the principal agents in the early antihypertensive drug treatment trials. The first antihypertensive drug RCT reported a substantial benefit of active therapy compared to placebo in 1966, but it was quickly superseded by two larger placebo-controlled multicenter Veterans Administration Cooperative Group RCT analyses. The first analysis was for adults with an average DBP between 115 and 129 mmHg, and this component was stopped early due to benefit and published in 1967. The second analysis, for adults with an average DBP between 90 and 114 mmHg, was published in 1970. Both analyses demonstrated that antihypertensive drug therapy resulted in a dramatic CVD benefit compared to placebo. Subsequent trials confirmed these findings and documented benefits when SBP reductions were targeted, either in combination with an elevated DBP or as an isolated elevation of SBP in older adults. In a group meta-analysis of 123 trials, active treatment resulted in a reduction of major CVD (20%), CHD (17%), stroke (27%), HF (28%), and all-cause mortality (13%). In this and other meta-analyses, the relative reduction in risk has been almost identical for those with or without prior CVD, albeit only adults at high risk for CVD could participate in the included trials, and benefit has accrued to those with a baseline SBP from 130 to 139 mmHg and above.

Choice of Antihypertensive Drug Classes Characteristics of the 11 most commonly used classes of antihypertensive medication, including examples, usual daily dosage, frequency of administration, proposed mechanism of action, approximate BP lowering compared to placebo, most common side effects, frequency of adverse events, and special aspects of the drug class are shown in **Table 288-4**.

Initial therapy with agents from five classes of drug therapy (diuretics, beta blockers, CCB, ACEI, and ARB) has been shown to prevent CVD compared to placebo. However, in head-to-head RCTs, beta blockers have been inferior to agents from the other four antihypertensive drug classes, especially for prevention of stroke. CCBs are good for prevention of stroke but inferior for prevention of HF, especially compared to diuretics. Generally, meta-analyses have identified diuretics as being the "best in class" for first-step prevention of CVD. Recognizing these differences in antihypertensive drug classes, RCTs and meta-analyses also provide evidence that BP lowering, however achieved, is more important than the drugs used to achieve it. Most clinical practice guidelines, including the U.S. ACC/AHA BP guideline, recommend an approach similar to that outlined in **Fig. 288-4** in which diuretics, CCBs, and ACEIs or ARBs, alone or in combination, are used for initial drug therapy in patients without a compelling indication for use of a beta blocker.

One or more nonpharmacologic therapies should be used to manage adults with stage 1 hypertension who are not at high risk for CVD (no CVD and a calculated 10-year risk of ASCVD <10% based on use of the ACC/AHA pooled cohort equations calculator). If BP cannot be controlled to an SBP/DBP <130/80 mmHg after 6 months of nonpharmacologic therapy, it may be reasonable to add an antihypertensive medication, especially in younger adults with a high lifetime risk of ASCVD. The latter can be estimated using a calculator that is readily available on the ACC website and elsewhere. Antihypertensive drug therapy should be used in addition to nonpharmacologic therapy in adults with stage 1 hypertension who are at high risk for ASCVD and for all individuals with stage 2 hypertension. A minority of such persons with an average SBP/DBP close to 130/80 mmHg can be managed successfully with single antihypertensive agent combined with nonpharmacologic therapy. However, most patients with hypertension require treatment with more than one antihypertensive agent. This is especially the case for adults with stage 2 hypertension with an SBP ≥140 mmHg and all non-Hispanic black adults with hypertension.

In clinical practice settings, it is common for patients with hypertension to have other comorbid conditions, including diabetes mellitus, CHD, and CKD, requiring use of agents from other drug classes that concurrently lower BP. Longer-acting versions of the recommended four first-step drug classes should be used to ensure the adequacy of once-daily treatment. For example, longer-acting diuretics such as chlorthalidone or indapamide are preferred over shorter acting agents such as hydrochlorothiazide because the long half-life of these agents is better suited for the provision of nighttime as well as daytime control of BP and because chlorthalidone has been used in almost all of the landmark U.S. trials of antihypertensive drug treatment. The most common side effects with thiazide and thiazide-like diuretics are biochemical changes, such as hypokalemia and slight increases in blood glucose. Potassium-sparing agents, such as amiloride or triamterene, can be combined with diuretics to counter these effects. The biochemical changes with diuretics are generally mild and do not counteract their well-proven CVD benefits. Although there are differences between individual ACEI agents, their clinical effects are more similar than different. Use of longer-acting agents such as lisinopril is preferred. The most common problematic side effect with ACEIs is a dry cough. This side effect is usually resolved quickly by switching to a corresponding dosage of an ARB. Side effects with ARBs are rare. ACEIs and ARBs should not be used in combination because this unnecessarily increases the risk of hyperkalemia, especially in vulnerable patients and provides little if any additional benefit over using either drug class on its own. Neither an ACEI nor an ARB should be used in pregnancy or planned pregnancy due to the risk of teratogenic side effects in the fetus. In contrast to the other antihypertensive drug classes, there are substantial clinical differences between dihydropyridine and nondihydropyridine CCB agents, with the former being primarily vasoactive and the latter having greater effect on the heart. Typically, dihydropyridine CCBs should be used in the treatment of hypertension. Peripheral edema occurs in ~10% of patients taking dihydropyridine CCBs but is often mild and can be minimized by dose reduction or eliminated by switching to an agent from another class. Nondihydropyridine CCBs should rarely be employed to treat hypertension unless there is another compelling indication for their use. Particular caution is necessary in patients at risk for bradycardia, heart block, or HF.

The earliest beta blocker drugs were relatively nonselective blockers of β-adrenergic receptors, including the heart (β_1 receptors) and lungs (β_2 receptors). They are rarely prescribed for hypertension due to the potential for bronchospasm. The second class of beta blocker agents, including metoprolol, contain more cardioselective and longer-acting drugs. Although cardioselective, atenolol is not recommended because several meta-analyses have reported that it has been less

TABLE 288-4 Summary Information for the Major Antihypertensive Drug Classes Used to Manage High Blood Pressure

CLASS	EXAMPLES	DOSE RANGE, mg	DOSE FREQUENCY/D	METHOD OF ACTION	SBP REDUCTION VERSUS PLACEBO, mmHg (APPROXIMATE)	MOST COMMON ADVERSE EFFECTS	FREQUENCY OF ADVERSE EVENTS	COMMENTS
First-Step Drugs								
Diuretics (thiazide and thiazide-like).	Chlorthalidone Hydrochlorothiazide Indapamide	12.5–25 12.5–50 1.25–2.5	1 1 1	Block sodium reabsorption in distal convoluted tubule	12	Hyponatremia Hypokalemia Hypercalcemia Hyperuricemia Hyperglycemia Dyslipidemia	Similar to placebo	Chlorthalidone preferred due to long half-life and use in most U.S. trials
ACE inhibitors	Enalapril Lisinopril Benazepril Ramipril Trandolapril	5–40 10–40 10–40 2.5–20 1–4	1 or 2 1 1 or 2 1 1	Inhibit ACE activity and Ang II production	12.0	Cough Hyperkalemia in CKD AKF in severe bilateral RAS Hypotension Angioedema	Similar to placebo	Do not use in combination with ARB; contraindicated in pregnancy
ARB	Losartan Valsartan Azilsartan Candesartan Olmesartan	50–100 80–320 40–80 8–32 20–40	1 or 2 1 1 1 1	Block Ang II binding to Ang receptors	12	Hyperkalemia in CKD Reduced GFR AKF in severe bilateral RAS Hypotension	Similar to placebo	Do not use in combination with ACE inhibitor; contraindicated in pregnancy
CCB (DHP)	Amlodipine Felodipine Nifedipine LA	2.5–10 2.5–10 30–90	1 1 1	Blocks calcium from entering cells, primarily inhibiting vasoconstriction	10	Peripheral edema (dose-dependent) Gingival hyperplasia	Similar to placebo	Amlodipine may be preferred CCB if tolerated Not recommended in HFrEF
CCB (non-DHP)	Diltiazem ER Verapamil ER	120–360 100–300	1 1 (evening administration recommended)	Blocks calcium from entering cells, reducing heart rate and vasoconstriction	9.0	Bradycardia Nausea Constipation.	Similar to placebo	Do not use in combination with β-blockers Do not use in HFrEF or in high-grade AV or SA block
Other Drugs								
β-Blocker	Metoprolol Carvedilol Nebivolol	50–200 20–80 5–40	1 1 1	Block β-adrenergic receptors	10	Asthma Bradycardia Fatigue Exercise intolerance Impaired concentration	Similar to placebo	First-step drugs when clinically indicated, e.g., in IHD and HF Contraindicated in high-grade heart block
MRA	Spironolactone Eplerenone Finerenone	25–100 50–100 10–20	1 2 1	Block distal tubule mineralocorticoid receptor activity	9	Hyperkalemia, especially in CKD and with potassium-sparing agents Spironolactone may cause tender breasts, gynecomastia, and erectile dysfunction in men	9–20%	Especially useful in resistant hypertension and low-renin states
K^+-sparing diuretics	Amiloride Triamterene	5–10 50–100	1 or 2 1 or 2	Block distal tubule sodium reabsorption	NA	Hyperkalemia, especially in CKD or with other agents that favor potassium retention	Similar to placebo	Minimal effect on BP Used to counteract hypokalemic effect of diuretics

TABLE 288-4 Summary Information for the Major Antihypertensive Drug Classes Used to Manage High Blood Pressure (Continued)

CLASS	EXAMPLES	DOSE RANGE, mg	DOSE FREQUENCY/D	METHOD OF ACTION	SBP REDUCTION VERSUS PLACEBO, mmHg (APPROXIMATE)	MOST COMMON ADVERSE EFFECTS	FREQUENCY OF ADVERSE EVENTS	COMMENTS
Loop diuretics	Furosemide Torsemide	20–80 5–10	2 1	Inhibits reabsorption of sodium in loop of Henle	NA	Hypokalemia Volume depletion Hyperuricemia	Infrequent	Preferred in CKD with GFR <30, in symptomatic HF, and when using potent direct vasodilator minoxidil
α_1-Receptor blockers	Doxazosin	1–16	1	Inhibit α_1-adrenergic receptors	5	Orthostatic hypotension, especially in older adults	9%	Less cardioprotective than diuretics Mostly used in men with prostrate hypertrophy
Direct vasodilator	Hydralazine Minoxidil	100–200 5–100	2 or 3 1–3	Dilate peripheral arterioles	NA	Reflex tachycardia Fluid retention Hydralazine-induced lupus syndrome (rare) Minoxidil-induced hirsutism in women	Up to 80%	Potent antihypertensive agents Usually reserved for fourth- or fifth-step treatment in resistant hypertension Usually combined with diuretic (loop agents for minoxidil) and β-blocker to minimize side effects
Central α_2-agonist and other centrally acting drugs	Clonidine (oral) Clonidine patch Guanfacine Methyldopa	0.1–0.8 0.1–0.3 0.5–2.0 250–1000	2 1/wk 1 2–3	Stimulate central nervous system α_2-adrenergic receptors	NA	Sedation Dry mouth Bradycardia Fatigue Constipation Orthostatic hypotension.	6–20%	Infrequently used due to side effects and potential for hypertensive crisis following abrupt withdrawal Methyldopa has a good safety record in pregnancy

Note: Adverse event estimates based on U.S. Food and Drug Administration labeling at *http://dailymed.nlm.nih.gov/dailymed/index.cfm*. Estimates of BP lowering versus placebo are "artificially" higher with older agents than with newer agents because the former were compared to placebo alone, whereas the latter were evaluated in patients who were already being treated with other antihypertensive medications.

Abbreviations: ACE, angiotensin-converting enzyme; AKF, acute kidney failure; Ang II, angiotensin II; ARB, angiotensin receptor blocker; AV, atrioventricular; BP, blood pressure; CCB, calcium channel blocker; CKD, chronic kidney disease; DHP, dihydropyridine; ER, extended release; GFR, glomerular filtration; HF, heart failure; HFrEF, heart failure with reduced ejection fraction; IHD, ischemic heart disease; LA, long acting; MRA, mineralocorticoid receptor antagonist; NA, not applicable; RAS, renal artery stenosis; SA, sinoatrial.

cardioprotective than other drug classes, including diuretics, when used for treatment of hypertension. The third-generation beta blocker drugs are cardioselective and have additional vasodilatory properties (nebivolol), used alone or in combination with α-receptor blockade (carvedilol). No RCT has documented improved CVD event protection with use of the newer agents. The remaining agents in Table 288-4 are covered in other sections of this chapter.

It has become increasingly clear that starting with lower doses of a two-drug combination provides superior BP control and results in fewer side effects compared to use of a single drug at a high dose. Initial therapy is especially important because surveys of clinical practice have repeatedly demonstrated that the initial drug choice is often materially unaltered due to therapeutic inertia despite unsatisfactory BP control. RCTs using stepped-care drug therapy, in which antihypertensive medications are added sequentially if BP control has not been achieved at full doses of the proceeding drugs, demonstrate that this approach can be successful if well applied. However, initial combination drug therapy has proven to be more effective for rapid achievement of target BP and medication adherence compared to the stepped-care approach.

Antihypertensive drug combinations should be based on use of drugs with complementary physiologic actions. For example, a diuretic or CCB combined with an ACEI or ARB is suitable for dual therapy and a diuretic combined with a CCB and an ACEI or ARB for triple-therapy combinations. Use of single-pill combinations results in better adherence compared to treatment with multiple drugs. In RCTs, the average number of drugs to achieve an SBP/DBP <140/90 mmHg has been two and to achieve an SBP/DBP <130/80 mmHg has been three.

Antihypertensive Treatment Blood Pressure Target Many clinical trials have reported better prevention of CVD in groups randomized to lower compared with higher achieved treatment BPs. Meta-analyses of RCTs to compare different achieved BPs have typically pooled the experience in trials that compared active versus placebo treatments, more versus less intensive treatments, and groups randomized to different BP targets. Most of these meta-analyses have reported greater benefit for a lower versus higher achieved BP, with the benefit being greatest for those who start at a higher BP and achieve a greater reduction in BP that their counterparts who achieve the

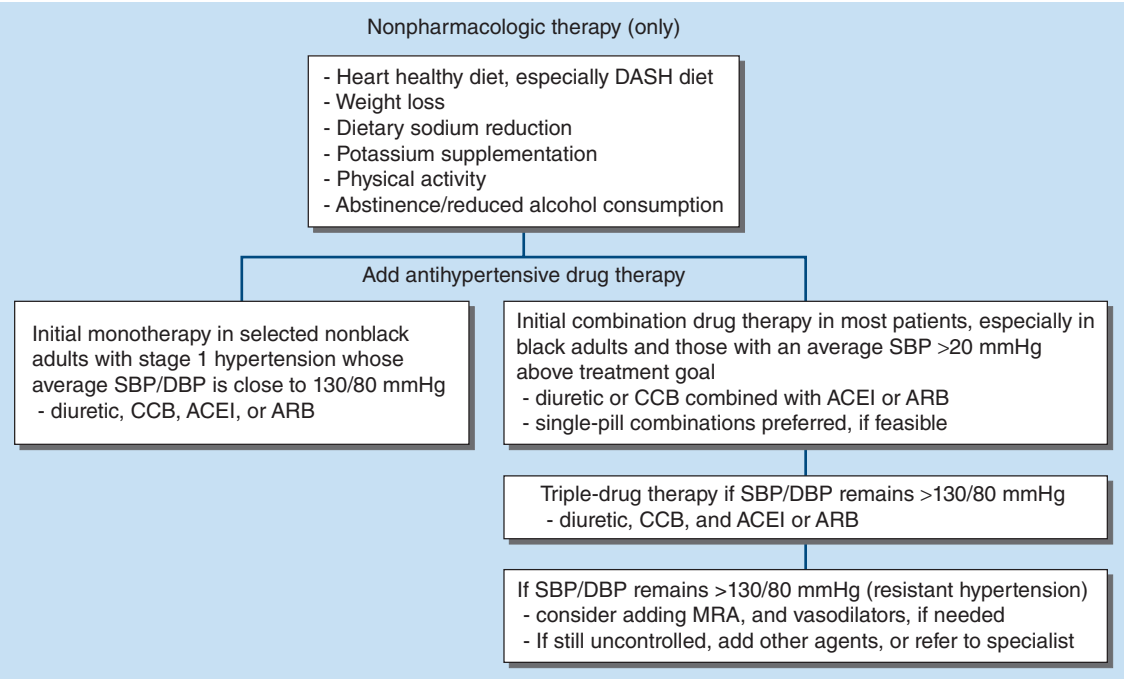

FIGURE 288-4 Overview of specific antihypertensive treatments in adults with uncomplicated hypertension. ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; DASH, Dietary Approaches to Stop Hypertension; DBP, diastolic BP; MRA, mineralocorticoid receptor antagonists; SBP, systolic BP.

same BP but start from a lower level of BP. As one would expect from the observational association between BP and CVD, the incremental benefit for CVD protection diminishes as the category of achieved BP gets progressively lower. Almost all of the meta-analyses, including one conducted for the ACC/AHA BP clinical practice guideline committee, have reported that an achieved SBP of <130 mmHg is superior to higher categories of achieved SBP. The major English-language clinical practice guidelines recommend SBP treatment targets that vary from 120 to 135 mmHg in adults with hypertension and a high risk of ASCVD. Surveys indicate that almost all patients with hypertension who are seen in clinical practice are at high risk for ASCVD. At the current time, an SBP/DBP treatment goal of 130/80 mmHg in adults with hypertension, as recommended in the ACC/AHA BP guideline, seems reasonable. The only exception is in noninstitutionalized community-dwelling older adults, arbitrarily defined as ≥65 years, where the goal should be to achieve an SBP <130 mmHg. For older adults with hypertension and a high burden of comorbidity who have a limited life expectancy, clinical judgment and patient preference should form the basis for decisions regarding the potential value and intensity of BP treatment. An SBP/DBP treatment goal of <130/80 mmHg should not preclude the possibility of achieving a greater reduction in BP in those who tolerate their BP-lowering treatment without evidence of adverse effects. In all four of the RCTs that have compared randomization to an SBP goal of 120 versus 140 mmHg, fewer CVD complications have been noted in the group assigned to the lower BP, albeit this has only been statistically significant in two of the four trials. Three additional large 120 versus 140 mmHg RCTs are expected to report in the near future, which should result in more definitive guidance for a 120 versus 130 mmHg SBP target.

Resistant Hypertension Failure to control SBP/DBP to <130/80 mmHg with three antihypertensive medications, preferably including a diuretic, or taking four or more antihypertensive medications to achieve an SBP/DBP <130/80 mmHg is designated as apparent resistant hypertension. A general approach to the investigation and management of apparent resistant hypertension is outlined in Fig. 288-5.

First, pseudo-resistance due to inaccurate BP measurement should be excluded. Next, accurately measured out-of-office BP readings should be obtained to exclude white coat hypertension. After this important issue is addressed, lifestyle, OSA, use of medications that raise BP, and other secondary causes of hypertension should be excluded. Management of resistant hypertension starts with confirmation of adherence to the prescribed treatment regimen because lack of adherence to lifestyle change advice and medication nonadherence are common explanations for apparent resistant hypertension. It is also important to ensure that the medication regimen is based on use of long-acting, once-daily agents. This is especially true for diuretics, where shorter acting agents such as hydrochlorothiazide should be replaced by chlorthalidone or indapamide. If the antihypertensive medications have been prescribed as separate pills, conversion to a single pill combination is highly desirable. After this issue is addressed, an MRA such as spironolactone should be added to the regimen (Table 288-4). Most patients tolerate spironolactone, but in a minority, laboratory abnormalities such as hyperkalemia or side effects such as dizziness, leg cramps, and gynecomastia can be troublesome, especially in men. Many of the spironolactone side effects can be avoided by use of newer but more expensive MRA agents such as eplerenone and, especially, the nonsteroidal finerenone. In 2023, the U.S. FDA approved the use of ultrasound and radiofrequency renal denervation therapy as adjunctive treatments in patients with resistant hypertension. Consideration of renal nerve denervation (RDN) should be restricted to patients with true resistant hypertension and an office SBP ≥160 mmHg.

Treatment of Hypertension in Special Groups Certain patient groups have characteristics that warrant special attention. The following are some of the more important groups.

PATIENTS WITH CVD The combination of hypertension and CVD is very common. Choice of antihypertensive agents is commonly influenced by the specific type of CVD, but use of ACEI, ARB, or beta blockers is common, often accompanied by diuretics, CCB, and MRA. Additional treatment with SGLT2 inhibitors may be indicated, especially in those with HF and diabetes mellitus. Nondihydropyridines should be used with caution in patients with bradycardia or the potential for heart block. In general, the standard treatment goal of SBP/DBP <130/80 mmHg is indicated if well tolerated.

KIDNEY DISEASE Hypertension is very common in patients with CKD, becoming more prevalent with increasing severity of CKD, such that 80–85% of those with advanced kidney disease have concurrent hypertension. High BP is a risk factor for CKD and ESKD, but the interaction between BP and kidney disease is complex, making it difficult

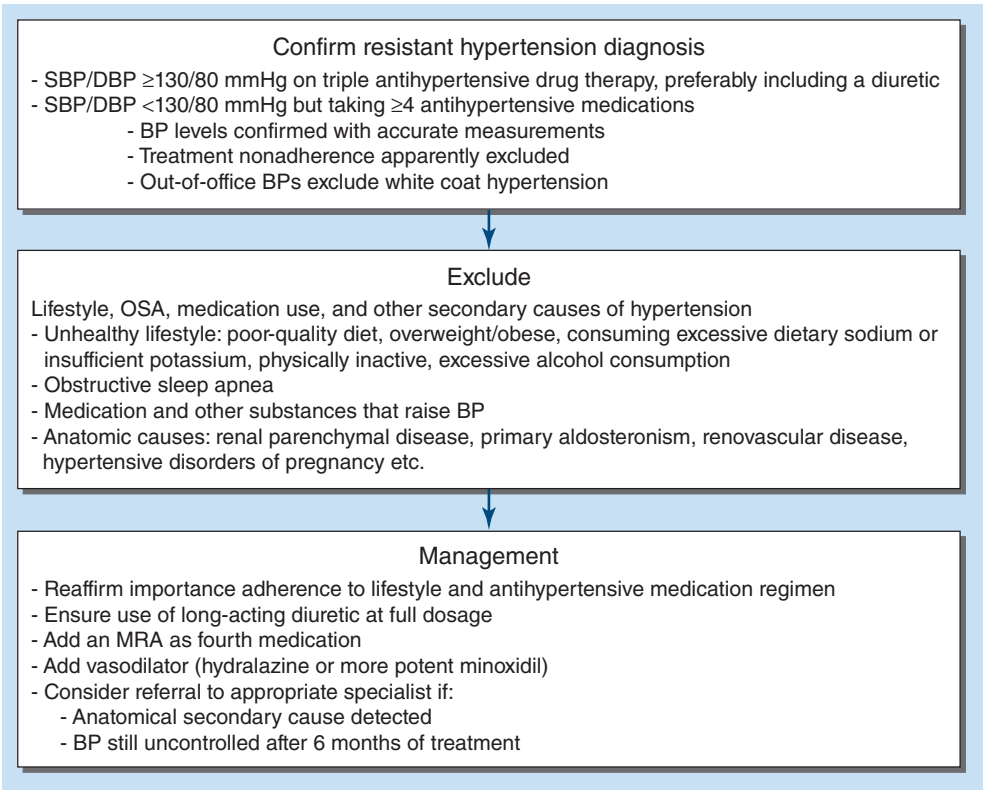

FIGURE 288-5 Confirmation and management of resistant hypertension. BP, blood pressure; DBP, diastolic blood pressure; MRA, mineralocorticoid receptor antagonist; OSA, obstructive sleep apnea; SBP, systolic blood pressure.

to determine cause and effect. Patients with kidney disease have a high prevalence of both traditional and novel risk factors for CVD, including markers of inflammation and endothelial dysfunction. As a result, the burden of CVD complications is high in adults with kidney disease, and patients with ESKD are more likely to die from CVD than from other complications of kidney failure. Managing hypertension in adults with advanced kidney disease can be difficult because they frequently have a combination of increased vascular resistance and intravascular volume overload and can exhibit vascular instability with wide swings in BP that complicates management. Normally, preglomerular vasoconstriction decreases the pressure to which the glomerulus is exposed and optimizes filtration without damaging the glomerulus. The efferent glomerular arteriole can play a supplementary role, as needed, to regulate intraglomerular pressure. When kidney disease is present, the ability to regulate intraglomerular pressure is diminished, with the result that it rises and results in physical damage, a pathophysiologic process that often manifests in proteinuria and diminished glomerular filtration as the number of functioning nephrons declines.

Generally, patients with kidney disease and hypertension require several antihypertensive agents in addition to nonpharmacologic counseling, especially focused on sodium reduction. Antihypertensive drugs that block the RAAS such as ACEIs and ARBs play a central role because they can preserve glomerular function by inducing efferent arteriolar dilatation and reducing intraglomerular pressure. They are particularly important in patients with proteinuria and advanced kidney disease. Diuretics also play an important role because they can concurrently reduce peripheral resistance and intravascular volume. Traditionally, loop diuretics have been recommended in place of thiazide or thiazide-like diuretics in patients with an eGFR of ~30 mL/min per 1.73 m^2 or lower, but a recent high-quality RCT in patients with stage 4 kidney disease (average eGFR <23 mL/min per 1.73 m^2) demonstrated substantially lower (10.5 mmHg) reduction in ambulatory BP and a halving of urinary albumin/creatinine ratio in those randomized to chlorthalidone (12.5–50 mg) compared to placebo. Although CCBs tend to dilate the preglomerular afferent artery, they have a good safety record in kidney disease patients when used in combination with an ACEI or ARB. Single-pill antihypertensive combinations are especially useful in patients with kidney disease because they are usually taking a large number of medications. Electrolyte levels should be monitored carefully, especially serum potassium levels, in kidney disease patients who are treated with potassium-sparing agents, including ACEI, ARB, and MRA drugs. Dual therapy with an ACEI, ARB, or ACEI-ARB combination is dangerous because of the risk of hyperkalemia and decline in kidney function.

PATIENTS WITH DIABETES MELLITUS The combination of hypertension and diabetes is common, resulting in a substantial risk for CVD and kidney disease. In patients with longstanding severe diabetes mellitus, autonomic neuropathy or volume depletion can cause orthostatic hypotension (10 mmHg difference in SBP between sitting and upright pressures), making management of hypertension difficult and requiring careful monitoring. Symptomatic hypotension (syncope) is a more important finding and may require a stepdown in antihypertensive therapy. Numerous RCTs in adults with diabetes have demonstrated that antihypertensive drug therapy reduces the risk of ASCVD, HF, and microvascular complications. The recommended antihypertensive treatment target is an SBP/DBP <130/90 mmHg. Almost all patients with hypertension and diabetes mellitus require antihypertensive combination therapy, with many requiring three or four agents to achieve satisfactory BP control. Inclusion of an ACEI or ARB in the combination is recommended, especially in those with heavy proteinuria or kidney insufficiency. In addition, most patients require a diuretic. CCBs are commonly part of the antihypertensive drug regimen as well. In patients with diabetes mellitus and resistant hypertension, the addition of an MRA has been effective; however, serum potassium should be monitored carefully. Many drugs used to treat diabetes mellitus affect BP. Perhaps the best documented are SGLT2 inhibitors, which in meta-analyses result in an SBP/DBP reduction of ~5/2 mmHg, a modest reduction that does not meet the FDA requirement for classification as an antihypertensive agent. Given that patients with diabetes mellitus are often taking many medications, use of single-pill dual- or triple-combination therapy is especially useful.

OLDER ADULTS Vascular stiffening increases with aging, and as a result, isolated elevation of SBP and a wide pulse pressure are common

in older adults. Comorbidity is common, resulting in the potential for a compelling nonhypertensive indications for use of BP-lowering agents. Drug-drug interactions and delayed drug excretion due to kidney or liver disease are also possible. Despite these challenges, most older adults with hypertension can be treated in a manner similar to younger patients. Indeed, the RCT evidence for antihypertensive drug therapy generally comes from studies in which the average age was close to 70 years at baseline. Older adults tend to be at high risk for CVD and all-cause mortality and have a disproportionately large treatment-related reduction in the absolute CVD and all-cause mortality benefit. A natural concern in treating hypertension in older adults is the potential for excessive BP reduction resulting in syncope and resultant falls, or organ hypoperfusion with resultant infarction, especially in the distribution of the coronary arteries. Thus far, RCTs of antihypertensive drug treatment in older adults have been reassuring, resulting in substantial prevention of CVD and all-cause mortality with limited evidence of adverse events. An increased incidence of hypotension has been noted in some but not all trials of antihypertensive treatment in older adults. However, there has been no evidence of a resultant increase in syncope, falls, or infarctions in the RCTs. Nonrandomized analyses of data sets have identified a J-shaped association between BP and CVD risk. However, J-curves are common in observational epidemiology, and randomized comparisons, which are more helpful in guiding treatment decisions, have revealed prevention of CVD and all-cause mortality in those randomized to more versus less intensive antihypertensive therapy at any point in the J-curve. A reasonable approach is to initiate or enhance existing treatment using lower doses of medications than in younger patients. Because congestive heart failure becomes increasingly common at older age, use of a diuretic rather than a CCB for dual-therapy combinations with an ACEI or ARB is sensible. Many older patients require triple therapy or have comorbidities that necessitate treatment with a CCB. As is the case generally, BP lowering is more important than the treatment combination used to achieve the desired SBP goal of <130 mmHg. Recent trials have provided compelling evidence that more intensive antihypertensive treatment in older adults reduces the risk of cognitive impairment compared to less intensive treatment, and increasing evidence suggests that it reduces the risk of dementia.

RACE/ETHNICITY Non-Hispanic blacks have disproportionately high BP levels and higher prevalence of hypertension compared to whites and other major race/ethnicity groups in the United States. In addition, hypertension tends to occur earlier in life and is associated with a higher risk of CVD and kidney disease in blacks compared to whites and the other major race/ethnicity groups. Non-Hispanic blacks have the highest awareness of hypertension of any race/ethnicity group in the United States and have an antihypertensive drug treatment rate that is at least as high as that of whites. However, their rate of control to <140/90 mmHg in the 2017–2020 NHANES survey was 15% lower than in whites (37 vs 52%) and 6% lower for the 130/80 mmHg cut point (20 vs 26%). Genetic differences seem to explain a small fraction of the high prevalence of hypertension in black Americans, but most of the disparity is likely due to differences in the social determinants of health, including access to and quality of education and health care, neighborhood of residence and the related built environment factors, economic instability, and the social and community context. The BP, CVD, and kidney disease health discrepancies between black and nonblack U.S. adults are not only sizable but have also been persistent, with little improvement in recent decades. RCT experience demonstrates that the gap can be eliminated with high-quality care, but following termination of RCT care, there has been a relatively rapid reversion to previous patterns of inadequate BP control. Resolution of the situation is unlikely without structural change in the approach to provision of care and a multilevel effort that involves patient engagement, a team-based approach to care that frees up clinicians to address social determinants of health, health system policies that enhance the provision of high-quality care, and payors with a focus on quality and use of contemporary BP goals for BP control. Diuretics and CCBs are especially effective for lowering BP in U.S. blacks, but many patients require triple antihypertensive therapy, and use of BP-lowering agents for management of comorbid conditions is common.

SEX Although there are well-described differences in the underlying pathophysiology of hypertension in women and men, RCT experience indicates a similar benefit in prevention of CVD in both sexes in the landmark antihypertensive drug treatment trials. In the United States, women are more likely to be aware of hypertension, to be treated with antihypertensive medication, and to achieve the desired level of BP control compared with men, especially at younger ages. ACEIs and ARBs should not be used in pregnancy or women of child-bearing age who are contemplating pregnancy. Antihypertensive agents with a good safety record in pregnancy are highlighted in the section on hypertension in pregnancy. Observational studies and RCTs, including meta-analyses, have reported a reduced risk of fractures in women being treated with thiazide diuretics. This is postulated to result from decreased urinary calcium excretion and increased osteoblast cell formation. In contrast to thiazide diuretics, loop diuretics increase urinary calcium excretion. However, analyses of large observational studies have failed to associate loop diuretic use in postmenopausal women with fractures or a decrease in bone marrow density. Women report more cough with ACEIs and more pedal edema with CCB treatment compared with men.

Hypertensive Urgencies and Emergencies Adults presenting with a very high level of BP, usually designated as an SBP/DBP ≥180/100 mmHg, should be classified as having a hypertensive urgency if they are asymptomatic or a hypertensive emergency if there is evidence of active ongoing hypertensive end-organ damage such as hypertensive encephalopathy, often manifesting with headaches, vision defects, nausea, vomiting, seizures, acute left ventricular failure, or acute kidney failure. Hypertensive urgency is far more common than hypertensive emergency and should be treated with institution, reinstitution, or intensification of oral antihypertensive agents in an outpatient setting. In contrast, a hypertensive emergency requires immediate, carefully supervised management with intravenous antihypertensive agents in an emergency room or inpatient setting. A hypertensive emergency associated with acute aortic dissection, eclampsia or severe preeclampsia, or a pheochromocytoma in crisis signals the need for particularly rapid care. Several drug classes can be used intravenously to achieve a rapid reduction in BP. Intravenous sodium nitroprusside is a potent vasodilator with a long history of success in managing hypertensive emergencies but must be monitored carefully to avoid overshooting the goal BP and causing hypotension. The dihydropyridine CCB nicardipine, given intravenously, is perhaps the most commonly utilized agent for acute BP reduction in patients with a hypertensive emergency in the contemporary practice of medicine. No dose adjustment is required for its use in older adults, but it is contraindicated in patients with severe aortic stenosis. Intravenous administration of the beta blocker labetalol is also effective but is contraindicated in patients with obstructive airways diseases, chronic obstructive pulmonary disease, bradycardia, or second- or third-degree heart block. Whichever drug is employed, a reduction rather than immediate normalization of BP is sufficient, with subsequent management of the patient's hypertension with oral agents. Secondary causes of hypertension, especially renovascular disease, are relatively common in patients with a hypertensive emergency and should be considered after the immediate reduction in BP.

PREVALENCE, AWARENESS, TREATMENT, AND CONTROL OF HYPERTENSION

NHANES provides a way to monitor prevalence, awareness, treatment, and control of hypertension in the U.S. general population. The NHANES definition of hypertension is based on BPs measured at a single visit, which results in an overestimation of hypertension, and the HHANES definition of treatment and control do not take into account nondrug therapy of hypertension. However, the methods used in NHANES have been consistent and careful over time, providing very helpful estimates for the temporal trends in hypertension prevalence and BP control. NHANES hypertension prevalence estimates have been fairly stable at ~46 and 32% for definitions based on use of the

SBP/DBP cut points of 130/80 and 140/90 mmHg, respectively, with higher prevalence rates in older versus younger adults, non-Hispanic blacks versus all other major race/ethnicity groups, and men compared with women. Treatment (with antihypertensive agents) and hypertension control rates increased progressively until about 2009–2012, with close to 53% of U.S. adults being controlled to an SBP/DBP <140/90 mmHg (the recommended goal at the time) and ~26% for an SBP/DBP <130/90 mmHg. After that, there was a progressive decline in control rates, with ~48 and 24% having an SBP/DBP <140/90 and <130/80 mmHg, respectively, by 2017–2020. The percentage controlled was higher when the analysis was confined to adults being treated for hypertension, but the temporal trends pattern was similar. The decrement in hypertension control was especially prominent in adults ≥75 years old. There has been a persistent gap in hypertension control rates between non-Hispanic black adults and all other race/ethnicity groups in the United States, with the percentage of non-Hispanic blacks and whites controlled to an SBP/DBP <140/90 mmHg in 2017–2020 being ~37 and 52%, respectively (20 and 26% for an SBP/DBP <130/80 mmHg). Worldwide, the situation is worse, with a recent global estimate reporting control to an SBP/DBP <140/90 mmHg in <14% of adults and in <8% of adults in low- and middle-income countries, where most of the world's population resides.

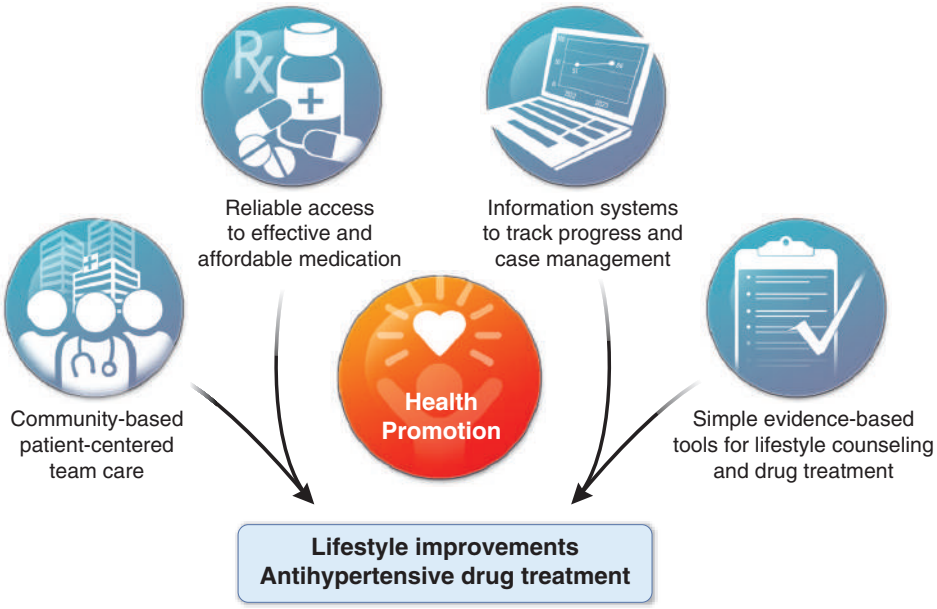

FIGURE 288-6 Best practices for control of hypertension. BP, blood pressure; HBPM, home blood pressure monitoring.

IMPROVING THE CONTROL OF HYPERTENSION

Clearly, the current hypertension control rates are unacceptable, and the traditional model of one-on-one physician-patient care for hypertension is not yielding a satisfactory outcome. Primary care physicians, who care for most patients with hypertension, are overburdened with responsibilities and have very limited time for direct provision of care in those with "routine" uncomplicated hypertension. A number of approaches have been shown to improve hypertension control rates in RCTs and clinical practice settings. Among these, team-based care has resulted in the biggest improvement in RCTs and meta-analyses. In the typical model of team-based care for hypertension management, a physician coordinates care provided by a team that may include nurses, pharmacists, community health care workers, social workers, lifestyle counselors, medical technicians, or others who have been specially trained in the provision of hypertension care. The specifics of the team composition depend on what is feasible in a practice setting and can be extended to engage front-office staff, spouses/partners, and close friends. In RCTs, team-based care has resulted in an average SBP reduction of ~7 mmHg, but in a recent high-quality, well-executed RCT, the SBP reduction exceeded 23 mmHg. It has been especially effective when trained nonphysician professionals have had the authority, usually with physician oversight, to prescribe antihypertensive medications in patients with uncomplicated hypertension. This frees up physician time to address patients with more complex care requirements. Most team-based care interventions have been multifaceted, incorporating health counseling, home BP monitoring (HBPM) and electronic support systems, and use of simple algorithms for health counseling and management of antihypertensive drug therapy. HBPM provides an excellent way to engage patients in their own care and to complement office BP management (OBPM) for monitoring long-term control of hypertension. Use of HBPM mandates advising patients on the purchase of clinically valid BP measurement devices and training in accurate measurement of BP (see BP measurement section). In U.S. adults, getting three morning (prior to taking BP medications) and three evening HBPM measurements for 3 days prior to a clinic visit is a reasonable strategy for assessing average home BP. Team-based care approaches have not only been successful in RCTs but also yielded excellent results in clinical practice settings, with Kaiser-Permanente, Northern California reporting an improvement in SBP/DBP control to <140/90 mmHg from 44% in 2001 to 90% in 2015 based on institution of a multifaceted systemwide program of health care quality improvement that incorporated many of the previously mentioned approaches. Likewise, many of these approaches have been used to good effect in the U.S. Department of Veterans Affairs Health System. An overall best practices approach is outlined in Fig. 288-6.

While it may not be possible for an individual practitioner to implement all of the suggestions in the figure, they should advocate for those that are beyond their direct control. There is great need to improve the management and control of hypertension in the United States and worldwide. Hypertension is among the most important, prevalent, modifiable, and cost-effective risk factors for CVD, kidney disease, and all-cause mortality. Its detection, treatment, and control should be a high priority for individual clinicians, systems of care, and countries worldwide.

289 Renovascular Disease

Stephen C. Textor*

The renal vasculature is unusually complex with high arteriolar flow to the cortex in excess of metabolic requirements, consistent with its primary function as a filtering organ. After delivering blood to cortical glomeruli, the postglomerular circulation supplies deeper medullary segments that support energy-dependent solute transport at multiple levels of the renal tubule. These postglomerular vessels deliver less blood and, coupled with high oxygen consumption, leave the deeper medullary regions at the margin of hypoxemia. Vascular disorders that commonly threaten the blood supply of the kidney include large-vessel atherosclerosis, fibromuscular diseases, and embolic disorders. **Microvascular injury, including inflammatory and primary hematologic disorders, is described in Chap. 329**.

MECHANISMS OF VASCULAR INJURY AND HYPERTENSION

The glomerular capillary endothelium shares susceptibility to oxidative stress, pressure injury, and inflammation with other vascular territories. Endothelial injury can be manifest by urinary albumin excretion (UAE), which is predictive of systemic atherosclerotic disease events. Increased UAE may develop years before cardiovascular events. UAE and the risk of cardiovascular events are both reduced with pharmacologic therapy such as antihypertensive drugs and statins. Experimental studies demonstrate functional changes and rarefaction of renal microvessels under conditions of accelerated atherosclerosis and/or compromise of proximal perfusion pressures with large-vessel disease **(Fig. 289-1)**.

Large-vessel renal artery occlusive disease can result from multiple conditions, including extrinsic compression of the vessel, intimal dissection, aortic stent graft placement, fibromuscular dysplasia (FMD), or, most commonly, atherosclerotic disease. Any disorder that reduces perfusion pressure to the kidney can activate mechanisms that tend to restore renal pressures at the expense of developing systemic hypertension. Because restoration of perfusion pressures can reverse these pathways, renovascular disease is considered a specifically treatable "secondary" cause of hypertension.

Renal artery stenosis is common, usually gradually progressive, and often has only minor hemodynamic effects. FMD is reported in 3–5% of normal subjects presenting as potential kidney donors without hypertension. It may present clinically with hypertension in younger individuals (between age 15 and 50), most often women. FMD does not often threaten kidney function, but sometimes produces total occlusion and can be associated with renal artery aneurysms. Atherosclerotic renal artery stenosis (ARAS) is common in the general population (6.8% of a community-based sample above age 65). The prevalence increases with age and for patients with other vascular conditions such as coronary artery disease (18–23%) and/or peripheral aortic or lower extremity disease (>30%). If untreated, ARAS progresses in nearly 50% of cases over a 5-year period, sometimes to total occlusion. Intensive treatment of arterial blood pressure and statin therapy can slow these rates and improve clinical outcomes.

Critical levels of stenosis (usually >70–80% luminal obstruction) lead to a reduction in perfusion pressure that activates the renin-angiotensin system, reduces sodium excretion, and activates sympathetic adrenergic pathways. These events lead to systemic hypertension characterized by angiotensin dependence in the early stages, widely varying pressures, loss of circadian blood pressure (BP) rhythms, and accelerated target organ injury, including left ventricular hypertrophy and renal fibrosis. Renovascular hypertension can be treated with agents that block the renin-angiotensin system and other drugs that modify these pressor pathways. It can also be treated with restoration of renal blood flow by either endovascular or surgical revascularization. Most patients require continued antihypertensive drug therapy due to preexisting hypertension and because revascularization alone rarely lowers BP to normal.

ARAS and systemic hypertension tend to affect both the poststenotic and contralateral kidneys, reducing overall glomerular filtration rate (GFR) in ARAS. When kidney function is threatened by large-vessel disease primarily, it has been labeled ischemic nephropathy. Moderately reduced blood flow that develops gradually is associated with reduced GFR and limited oxygen consumption with preserved tissue oxygenation. Hence, kidney function often remains reduced but stable during medical therapy, sometimes for years. With more advanced disease, reductions in cortical perfusion and overt tissue hypoxia develop. Unlike FMD, ARAS develops in patients with other risk factors for atherosclerosis and is commonly superimposed upon preexisting small-vessel disease in the kidney resulting from hypertension, aging, and diabetes. Nearly 85% of patients considered for renal revascularization have stage 3–5 chronic kidney disease (CKD) with estimated GFR <60 mL/min per 1.73 m^2. The presence of ARAS is a strong predictor of morbidity- and mortality-related cardiovascular events, independent of whether renal revascularization is undertaken.

DIAGNOSIS OF RENOVASCULAR DISEASE

Diagnostic approaches to renovascular disease necessarily include evaluation of the kidney vasculature and depend on the specific clinical questions to be addressed. Noninvasive characterization of the renal vasculature may be achieved by several techniques, summarized in **Table 289-1**. Although activation of the renin-angiotensin system is a key step in developing renovascular hypertension, it is transient. Levels of renin activity are therefore subject to timing, the effects of drugs, and sodium intake, and do not reliably predict the response to vascular therapy. Peak systolic renal artery velocities by Doppler ultrasound >200 cm/s generally predict lesions with more than >60% vessel lumen occlusion, although some treatment trials have required velocity >300 cm/s to avoid false positives. The renal resistive index has predictive value regarding the viability of the kidney. It remains operator- and institution-dependent, however. Contrast-enhanced computed tomography (CT) with vascular reconstruction provides excellent vascular images and functional assessment but carries a small risk of contrast toxicity. It provides a more reliable evaluation of accessory vessels and the distal vasculature than duplex or magnetic resonance imaging (MRI). Magnetic resonance angiography (MRA) is less often used than previously, as gadolinium contrast has been associated with nephrogenic systemic fibrosis particularly in patients with reduced GFR. Captopril-enhanced renography has a strong negative predictive value when entirely normal.

TREATMENT

Renal Artery Stenosis

While restoring renal blood flow and perfusion seems intuitively beneficial for high-grade occlusive lesions, revascularization procedures also pose hazards and expense. Patients with FMD are commonly younger females with otherwise normal vessels and a long

*Deceased

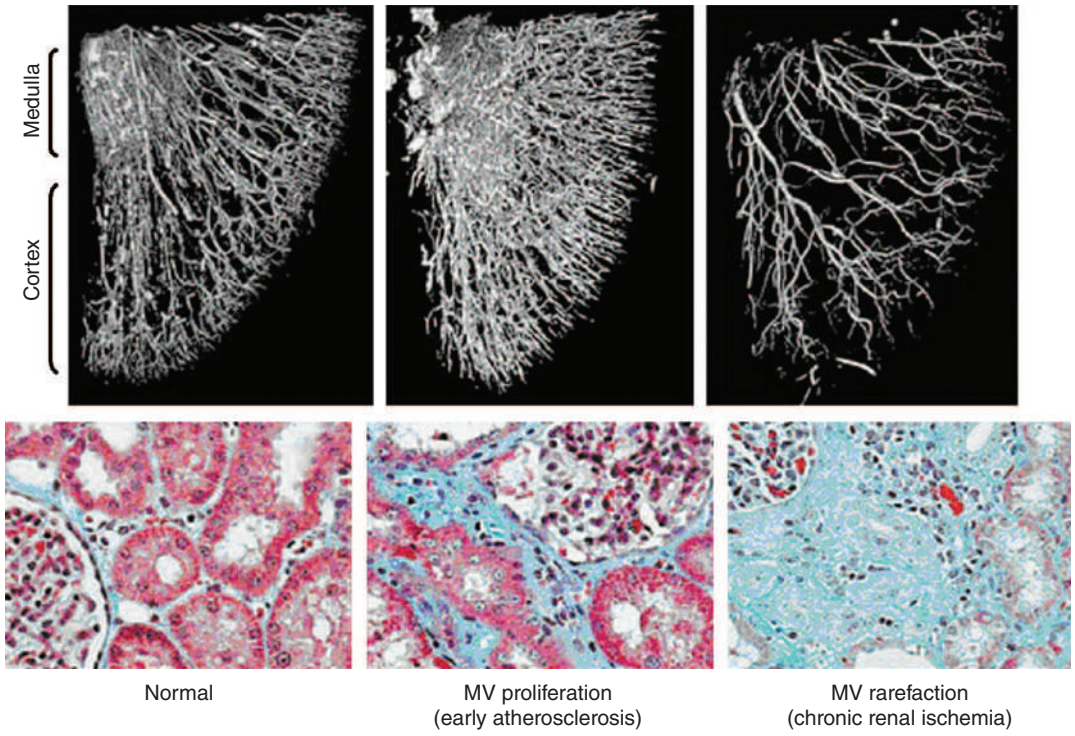

FIGURE 289-1 Examples of micro-CT images from vessels defined by radiopaque casts injected into the renal vasculature. These illustrate the complex, dense cortical capillary network supplying the kidney cortex that can either proliferate or succumb to rarefaction under the influence of atherosclerosis and/or occlusive disease. Changes in blood supply are followed by tubulointerstitial fibrosis and loss of kidney function. MV, microvascular. *(Reproduced with permission from LO Lerman, AR Chade. Angiogenesis in the kidney: A new therapeutic target? Curr Opin Nephrol Hypertens 18:160, 2009.)*

life expectancy. These patients often respond well to percutaneous renal artery angioplasty. If BP can be controlled to goal levels and kidney function remains stable in patients with ARAS, it may be argued that medical therapy with follow-up for disease progression is equally effective over periods of 3–5 years. Multiple prospective randomized controlled trials for individuals with moderate stenosis have failed to identify compelling additional benefits for interventional revascularization procedures regarding short-term results of BP and renal function. Studies of cardiovascular outcomes, including stroke, congestive heart failure, myocardial infarction, and end-stage renal failure, suggest a small mortality benefit for stented patients without proteinuria. Medical therapy should include blockade of the renin-angiotensin system, attainment of goal BPs, cessation of tobacco, statins, and aspirin. Follow-up requires surveillance for progressive occlusion manifest by worsening renal function and/or loss of BP control. Renal revascularization should be considered for patients with rapidly progressive clinical syndromes, failing medical therapy, and/or developing additional complications.

Techniques of renal revascularization are improving. With experienced operators, major complications occur in <5% of cases, including renal artery dissection, capsular perforation, hemorrhage, and occasional atheroembolic disease. Although not common, atheroembolic disease can be catastrophic and accelerate both hypertension and kidney failure, precisely the events that revascularization is intended to prevent. Although renal blood flow usually can be restored by endovascular stenting, recovery of renal function is limited to ~25% of cases, with no change in 50% and some deterioration evident in others. Patients with rapid loss of kidney function, sometimes associated with antihypertensive drug therapy, or with vascular disease affecting the entire functioning kidney mass

TABLE 289-1 Summary of Imaging Modalities for Evaluating the Kidney Vasculature

Perfusion Studies to Assess Differential Renal Blood Flow			
Captopril renography with technetium-99m mertiatide (^{99m}Tc MAG3)	Captopril-mediated fall in filtration pressure amplifies differences in renal perfusion	Normal study excludes renovascular hypertension	Multiple limitations in patients with advanced atherosclerosis or creatinine >2.0 mg/dL (177 μmol/L)
Vascular Studies to Evaluate the Renal Arteries			
Duplex ultrasonography	Shows the renal arteries and measures flow velocity as a means of assessing the severity of stenosis	Inexpensive; widely available, suitable for follow-up studies	Heavily dependent on operator's experience; less useful than invasive angiography for the diagnosis of fibromuscular dysplasia and abnormalities in accessory renal arteries
Computed tomographic angiography	Shows the renal arteries and perirenal aorta	Provides excellent images; stents do not cause artifacts	Expensive, moderate volume of contrast required
Magnetic resonance angiography	Shows the renal arteries and perirenal aorta	Not nephrotoxic, but concerns for gadolinium toxicity exclude use in GFR <30 mL/min/1.73 m^2; provides excellent images	Expensive; gadolinium excluded in renal failure, unable to visualize stented vessels
Intraarterial angiography	Shows location and severity of vascular lesion	Considered "gold standard" for diagnosis of large-vessel disease, usually performed simultaneous with planned intervention	Expensive, associated hazard of atheroemboli, contrast toxicity, procedure-related complications, e.g., dissection

Abbreviation: GFR, glomerular filtration rate.

TABLE 289-2 Clinical Factors That Determine the Role of Revascularization in Addition to Medical Therapy for Renal Artery Stenosis

Factors Favoring Medical Therapy with Revascularization for Renal Artery Stenosis
• Progressive decline in GFR during treatment of systemic hypertension
• Failure to achieve adequate blood pressure control with optimal medical therapy (medical failure)
• Rapid or recurrent decline in the GFR in association with a reduction in systemic pressure
• Decline in the GFR during therapy with ACE inhibitors or ARBs
• Recurrent congestive heart failure in a patient in whom left ventricular dysfunction does not fully explain the cause
Factors Favoring Medical Therapy and Surveillance of Renal Artery Disease
• Controlled blood pressure with stable renal function (e.g., stable renal insufficiency)
• Stable renal artery stenosis without progression on surveillance studies (e.g., serial duplex ultrasound)
• Advanced age and/or limited life expectancy
• Extensive comorbidity that make revascularization too risky
• High risk for or previous experience with atheroembolic disease
• Other concomitant renal parenchymal diseases that cause progressive renal dysfunction (e.g., interstitial nephritis, diabetic nephropathy), particularly with proteinuria

Abbreviations: ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; GFR, glomerular filtration rate.

are more likely to recover function after restoring blood flow. When hypertension is refractory to effective therapy, revascularization offers real benefits. Table 289-2 summarizes currently accepted guidelines for considering renal revascularization in addition to optimal medical therapy.

ATHEROEMBOLIC RENAL DISEASE

Emboli to the kidneys arise most frequently as a result of cholesterol crystals breaking free of atherosclerotic vascular plaque and lodging in downstream microvessels. Most clinical atheroembolic events follow angiographic procedures, often of the coronary vessels. It has been argued that nearly all arterial interventional procedures lead to plaque fracture and release of microemboli, but clinical manifestations develop only in a fraction of these. The incidence of clinical atheroemboli has been increasing with more vascular procedures and longer life spans. Atheroembolic renal disease is suspected in >3% of elderly subjects with end-stage renal disease (ESRD) and is likely underdiagnosed. It is more frequent in males with a history of diabetes, hypertension, and ischemic cardiac disease. Atheroemboli in the kidney are strongly associated with aortic aneurysmal disease and renal artery stenosis. Most clinically evident cases can be linked to precipitating events, such as angiography, vascular surgery, anticoagulation with heparin, thrombolytic therapy, or trauma. Clinical manifestations of this syndrome commonly develop between 1 and 14 days after an inciting event and may continue to develop for weeks thereafter. Systemic embolic disease manifestations, such as fever, abdominal pain, and weight loss, are present in less than half of patients, although cutaneous manifestations including livedo reticularis and localized toe gangrene may be more common. Worsening hypertension and deteriorating kidney function are common, sometimes reaching a malignant phase. Progressive renal failure can occur and require dialytic support. These cases often develop after a stuttering onset over many weeks and have an ominous prognosis. Mortality rate after 1 year exceeds 38%, and although some may eventually recover sufficiently to no longer require dialysis, many do not.

Beyond the clinical manifestations above, laboratory findings include rising creatinine, transient eosinophilia (60–80%), elevated sedimentation rate, and hypocomplementemia (15%). Establishing this diagnosis can be difficult and is often by exclusion. Definitive diagnosis depends on kidney biopsy demonstrating microvessel occlusion with cholesterol crystals that leave a "cleft" in the vessel. Biopsies obtained from patients undergoing surgical revascularization of the kidney indicate that silent cholesterol emboli are frequently present before any further manipulation is performed.

No effective therapy is available for atheroembolic disease once it has developed. Withdrawal of anticoagulation is recommended. Late recovery of kidney function after supportive measures sometimes occurs, and statin therapy may improve outcome. The role of embolic protection devices in the renal circulation during angiography is unclear, but a few prospective trials have failed to demonstrate major benefits. The effect of such devices is limited to distal protection during the endovascular procedure, and they offer no protection from embolic debris developing after removal.

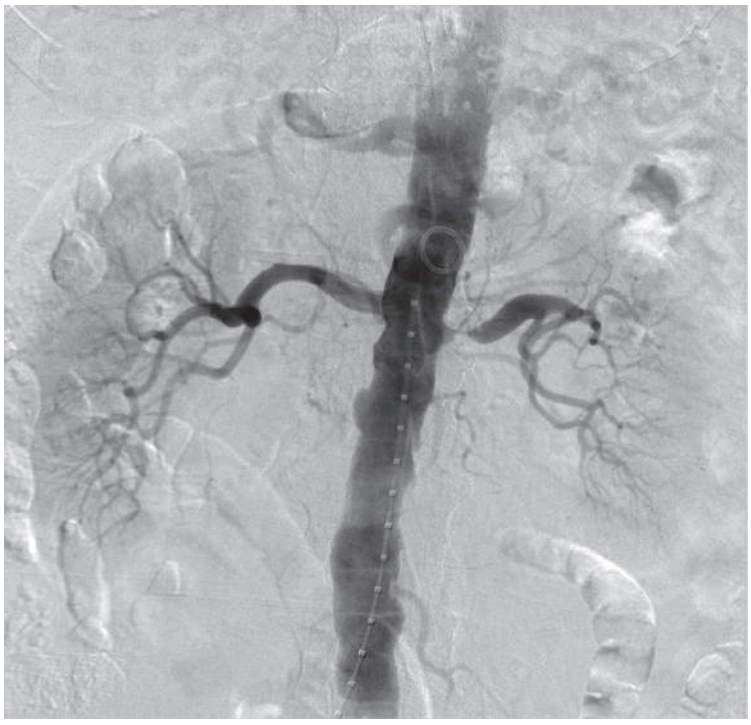
THROMBOEMBOLIC RENAL DISEASE

Thrombotic occlusion of renal vessels or branch arteries can lead to declining renal function and hypertension. It is difficult to diagnose and is often overlooked, especially in elderly patients. Thrombosis can develop as a result of local vessel abnormalities, such as local dissection, trauma, inflammatory vasculitis, or systemic infections, such as COVID-19. Local microdissections sometimes lead to patchy, transient areas of infarctions labeled "segmental arteriolar mediolysis." Although hypercoagulability conditions sometimes present as renal artery thrombosis, this is rare. It can also derive from distant embolic events, e.g., the left atrium in patients with atrial fibrillation or from fat emboli originating from traumatized tissue, most commonly large bone fractures. Cardiac sources include vegetations from subacute bacterial endocarditis. Systemic emboli to the kidneys may also arise from the venous circulation if right-to-left shunting occurs, e.g., through a patent foramen ovale.

Clinical manifestations vary depending on the rapidity of onset and extent of occlusion. Acute arterial thrombosis may produce flank pain, fever, leukocytosis, nausea, and vomiting. If kidney infarction results, enzymes such as lactate dehydrogenase (LDH) rise transiently to extreme levels. If both kidneys are affected, renal function will decline precipitously with a drop in urine output. If a single kidney is involved, renal functional changes may be minor. Hypertension related to sudden release of renin from ischemic tissue can develop rapidly, as long as some viable tissue in the "peri-infarct" border zone remains. If the infarct zone demarcates precisely, the rise in BP and renin activity may resolve. Diagnosis of renal infarction may be established by vascular imaging with CT angiography, MRI, or arteriography (Fig. 289-2).

MANAGEMENT OF ARTERIAL THROMBOSIS OF THE KIDNEY

Options for interventions of newly detected arterial occlusion include surgical reconstruction, anticoagulation, thrombolytic therapy, endovascular procedures, and supportive care, particularly antihypertensive drug therapy. Application of these methods depends on the patient's overall condition, the precipitating factors (e.g., local trauma or systemic illness), the magnitude of renal tissue and function at risk, and the likelihood of recurrent events in the future. For unilateral disease, for example, arterial dissection with thrombosis and supportive care with anticoagulation may suffice. Acute, bilateral occlusion is potentially catastrophic, producing anuric renal failure. Depending on the precipitating event, surgical or thrombolytic therapies can sometimes restore kidney viability if undertaken early in the course of the acute event.



MICROVASCULAR INJURY ASSOCIATED WITH HYPERTENSION

ARTERIOLONEPHROSCLEROSIS

"Malignant" Hypertension Although BP rises with age, it has long been recognized that some individuals develop rapidly progressive BP elevations with target organ injury including retinal hemorrhages, encephalopathy, and declining kidney function. Placebo arms during the early controlled trials of hypertension therapy identified progression to severe levels in 20% of subjects over 5 years. If untreated, patients with target organ injury including papilledema

B

FIGURE 289-2 ***A.*** CT angiogram illustrating loss of circulation to the upper pole of the right kidney in a patient with fibromuscular disease and a renal artery aneurysm. Activation of the renin-angiotensin system produced rapidly developing hypertension. ***B.*** Angiogram illustrating high-grade renal artery stenosis affecting the left kidney. This lesion is often part of widespread atherosclerosis and sometimes is an extension of aortic plaque. This lesion develops in older individuals with preexisting atherosclerotic risk factors.

and declining kidney function suffered mortality rates in excess of 50% over 6–12 months, hence the designation "malignant." Postmortem studies of such patients identified vascular lesions, designated "fibrinoid necrosis," with breakdown of the vessel wall, deposition of eosinophilic material including fibrin, and a perivascular cellular infiltrate. A separate lesion was identified in the larger interlobular arteries in many patients with hyperplastic proliferation of the vascular wall cellular elements, deposition of collagen, and separation of layers, designated the "onionskin" lesion. For many of these patients, fibrinoid necrosis led to obliteration of glomeruli and loss of tubular structures. Progressive kidney failure ensued and, without dialysis support, led to early mortality in untreated malignant-phase hypertension. These vascular changes could develop with pressure-related injury from a variety of hypertensive pathways, including but not limited to activation of the renin-angiotensin system and severe vasospasm associated with catecholamine release. Occasionally, endothelial injury is sufficient to induce microangiopathic hemolysis, as discussed below.

Antihypertensive therapy is the mainstay of therapy for malignant hypertension. With effective BP reduction, manifestations of vascular injury, including microangiopathic hemolysis and renal dysfunction, can improve over time. Whereas prior reports before the era of drug therapy suggested that 1-year mortality rates exceeded 90%, current survival over 5 years exceeds 50%.

Malignant hypertension is less common in Western countries, although it persists in parts of the world where medical care and antihypertensive drug therapy are less available. It most commonly develops in patients with treated hypertension who neglect to take medications or who may use vasospastic drugs, such as cocaine. Renal abnormalities typically include rising serum creatinine and occasionally hematuria and proteinuria. Biochemical findings may include evidence of hemolysis (anemia, schistocytes, and reticulocytosis) and changes associated with kidney failure. African-American males are more likely to develop rapidly progressive hypertension and kidney failure than are whites in the United States. Genetic polymorphisms for *APOL1* that are common in the African-American population predispose to focal sclerosing glomerular disease, with severe hypertension developing at younger ages secondary to renal disease in this instance.

"Hypertensive Nephrosclerosis" Based on experience with malignant hypertension and epidemiologic evidence linking BP with long-term risks of kidney failure, it has long been believed that lesser degrees of hypertension induce less severe, but prevalent, changes in kidney vessels and loss of kidney function. As a result, a large portion of patients reaching ESRD without a specific etiologic diagnosis are assigned the designation "hypertensive nephrosclerosis." Pathologic examination commonly identifies afferent arteriolar thickening with deposition of homogeneous eosinophilic material (hyaline arteriolosclerosis) associated with narrowing of vascular lumina. Clinical manifestations include retinal vessel changes associated with hypertension (arteriolar narrowing, arteriovenous crossing changes), left ventricular hypertrophy, and elevated BP. The role of these vascular changes in kidney function is unclear. Multiple studies of nephrectomy and biopsy samples from normotensive kidney donors demonstrate changes of nephrosclerosis associated with aging, dyslipidemia, and glucose intolerance, with only modest association with BP. Antihypertensive drug therapy does not alter the course of kidney dysfunction identified specifically as hypertensive nephrosclerosis, although BP reduction does slow progression of proteinuric kidney diseases and is warranted to reduce the excessive cardiovascular risks associated with CKD.

290 Deep-Venous Thrombosis and Pulmonary Thromboembolism

Samuel Z. Goldhaber

EPIDEMIOLOGY

Venous thromboembolism (VTE) encompasses deep-venous thrombosis (DVT) and pulmonary embolism (PE) and causes cardiovascular death, chronic disability, and emotional distress. Hospitalizations in the United States have decreased for acute myocardial infarction (MI), heart failure, and stroke among Medicare beneficiaries, but PE hospitalizations increased.

Pulmonary Embolism Mortality PE-related mortality in the United States decreased from 6 per 100,000 in 2000 and plateaued at approximately 4.5 per 100,000 in 2017. In contrast, Europe's age-standardized annual PE-related mortality rate has continued to decrease linearly since 2000. In the United States, PE-related mortality is increasing among young and middle-aged adults. Consequently, the median age at death from PE decreased from 73 years in 2000 to 68 years in 2018. During this period, the annual PE mortality was up to 50% higher in African Americans compared with Caucasians.

Socioeconomic Status To evaluate the relationship between socioeconomic status and PE, as well as other cardiovascular diseases, 10,942,483 Medicare beneficiaries were studied to determine whether they were hospitalized for PE, MI, heart failure, or stroke between 2003 and 2019. Hospitalizations for MI, heart failure, and stroke declined in socioeconomically disadvantaged and nondisadvantaged communities. In contrast, PE hospitalizations increased in both disadvantaged and nondisadvantaged communities. The heat map **(Fig. 290-1)** shows marked regional differences in the rates of PE hospitalization and degrees of social and community disadvantage throughout the United States. By 2019, 30-day mortality was similar between hospitalized beneficiaries from socioeconomically disadvantaged and nondisadvantaged communities for MI, heart failure, and ischemic stroke. In contrast, mortality among patients hospitalized with PE was consistently higher in disadvantaged areas **(Fig. 290-2)**. This finding may be due, in part, to poor outpatient follow-up and impeded access to anticoagulant medications.

Pulmonary Embolism Readmissions From 2010 to 2018, 721,710 fee-for-service Medicare beneficiaries were hospitalized with PE. The 30-day all-cause readmission rate was 11%, and the 90-day all-cause readmission rate was 15% **(Fig. 290-3)**. The most common reason for readmission was recurrent PE, accounting for about 11% of readmissions within 30 days.

COVID-19 In 2020, COVID-19 erupted and caused a global pandemic. The most notable clinical feature was a life-threatening acute respiratory syndrome requiring prolonged mechanical ventilation and resulting in a high case–fatality rate. This viral illness was associated with a high incidence of DVT and PE. At autopsy, about one-fourth of PE patients with COVID had both macrovascular and microvascular PE. Contributing etiologies included excessive inflammation with cytokine storm, platelet activation, endothelial dysfunction, and stasis **(Fig. 290-4)**.

Long-Term Sequelae of Pulmonary Embolism With respect to quality of life, about half of PE patients report persistent dyspnea, fatigue, and reduced exercise capacity, and about one-quarter have persistent right ventricular dysfunction on echocardiogram. This constellation of findings is being recognized more frequently and is called the "post-PE syndrome" **(Fig. 290-5)**. A less frequent complication of PE is the development of chronic thromboembolic pulmonary hypertension (CTEPH), which usually causes breathlessness, especially with exertion.

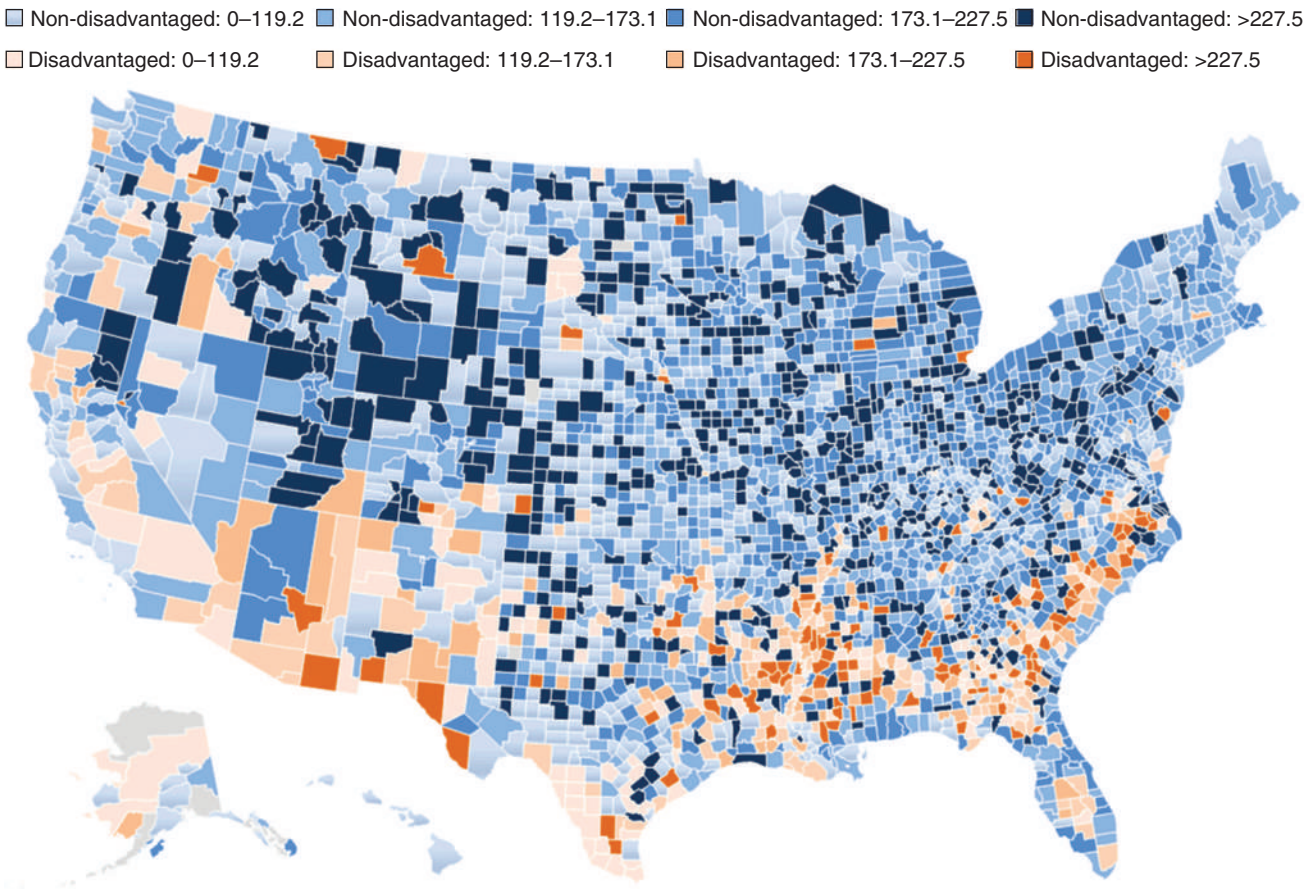

FIGURE 290-1 Observed hospitalizations for PE are shown per 100,000 Medicare beneficiaries aged 65 year or older residing in socioeconomically disadvantaged (*orange*) and nondisadvantaged (*blue*) counties of the United States in 2019. Lower hospitalization rates are represented with lighter shades of each color, and higher hospitalization rates are represented with darker shades. The range of hospitalizations per 100,000 represented by each shade of orange and each shade of blue are shown in the legend. *(Reproduced with permission from RK Wadhera et al: Circ Cardiovasc Qual Outcomes 17:e010090, 2024.)*

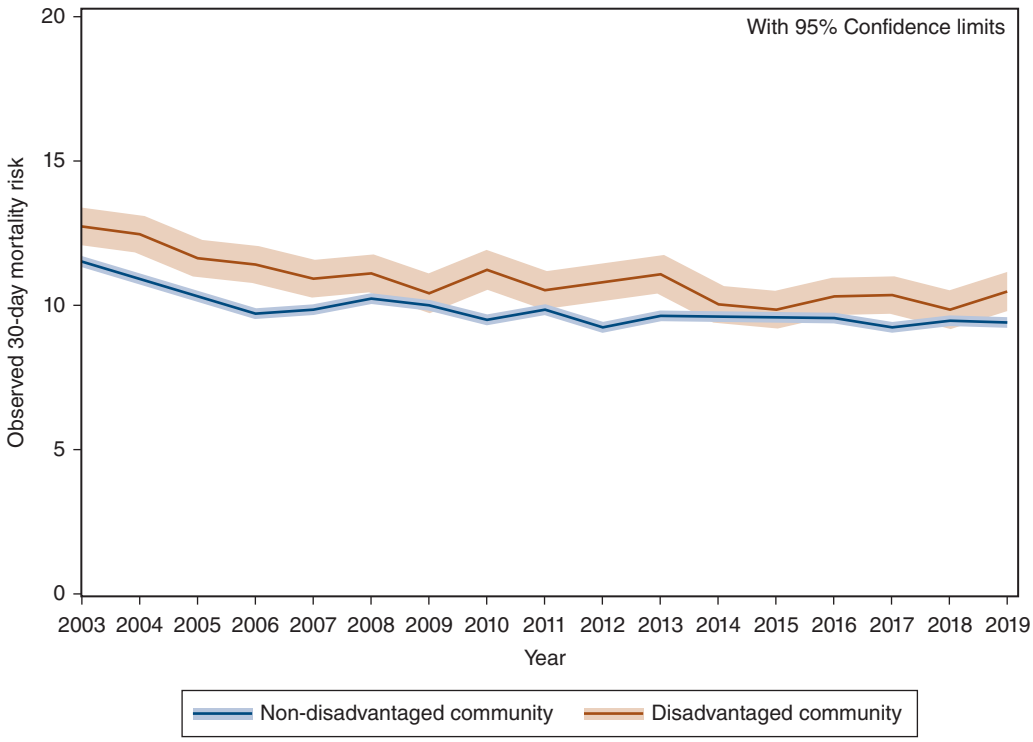

FIGURE 290-2 Trends in 30-day mortality among Medicare beneficiaries hospitalized with pulmonary embolism by community socioeconomic disadvantage from 2003 to 2019. The red lines represent beneficiaries from disadvantaged communities, and the blue line, beneficiaries from nondisadvantaged communities. The bands represent 95% confidence intervals for estimates. Trends in observed 30-day mortality among Medicare beneficiaries hospitalized with cardiovascular conditions by community socioeconomic disadvantage from 2003 to 2019. *(Reproduced with permission from RK Wadhera et al: Circ Cardiovasc Qual Outcomes 17:e010090, 2024.)*

Postthrombotic Syndrome Postthrombotic syndrome (also known as *chronic venous insufficiency*) damages the venous valves of the leg and worsens quality of life by causing ankle or calf swelling and leg aching, especially after prolonged standing. In its most severe form, postthrombotic syndrome causes deep skin ulceration **(Fig. 290-6)**.

PATHOPHYSIOLOGY

Inflammation Inflammation takes center stage as a trigger of acute PE and DVT. Inflammation-related risk factors and medical illnesses are now linked as precipitants of VTE **(Table 290-1)**.

Prothrombotic States The two most common autosomal dominant genetic mutations are (1) factor V Leiden, which causes resistance to the endogenous anticoagulant, protein C, and (2) the prothrombin gene mutation, which increases the plasma prothrombin concentration **(Chaps. 69 and 122)**. Antithrombin, protein C, and protein S are naturally occurring coagulation inhibitors. Deficiencies of these inhibitors are associated with VTE but are rare. Antiphospholipid syndrome (APS) is an acquired (not genetic) thrombophilic disorder that predisposes to both venous and arterial thrombosis. Patients with APS often warrant lifetime anticoagulation, even if the initial VTE was provoked by trauma or surgery.

Clinical Risk Factors Common comorbid VTE risk factors include cancer, obesity, cigarette smoking, systemic arterial hypertension, chronic obstructive pulmonary disease, chronic kidney disease, long-haul air travel, air pollution, estrogen-containing contraceptives, pregnancy, the first 6–12 weeks postpartum, postmenopausal hormone replacement, surgery, and trauma. A sedentary lifestyle is an increasingly prevalent risk factor. A Japanese study found that each 2 hours per day increment of television watching is associated with a 40% increased likelihood of fatal PE.

Polygenic Risk Scores Ghouse and colleagues reported a genome-wide association study of VTE that incorporated 81,190 cases and 1,419,671 controls from six cohorts. They identified 93 risk loci, 62 of which were previously unreported. Many risk loci affected the coagulation cascade or platelet function. A VTE *polygenic risk score (PRS)* enabled identification of both high- and low-risk individuals. Individuals within the top 0.1% of PRS distribution had a VTE risk similar to homozygous or compound heterozygous carriers of factor V Leiden or the prothrombin gene mutation. In contrast, in the bottom 10% of the PRS distribution, factor V Leiden and prothrombin gene mutation carriers had a VTE risk similar to that of the general population. PRS improved individual risk prediction beyond that of genetic and clinical risk factors. Some risk factors for arterial thrombosis, such as body mass index and smoking, were concordant with VTE risk, whereas others, such as blood pressure and triglyceride levels, were discordant.

Activated Platelets Virchow's triad of venous stasis, hypercoagulability, and endothelial injury, usually coupled with an inflammatory trigger, leads to recruitment of activated platelets, which release microparticles. These microparticles contain proinflammatory mediators

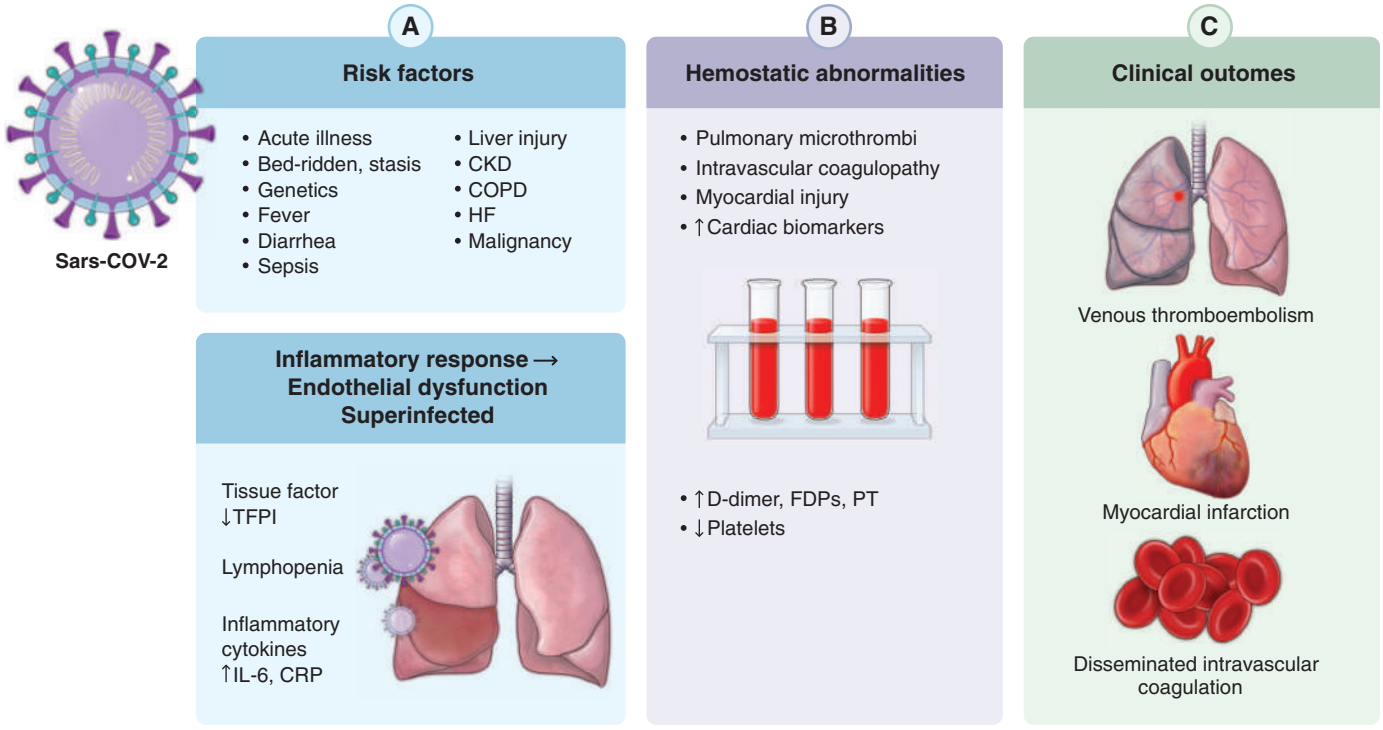

FIGURE 290-4 Postulated mechanisms of coagulopathy and pathogenesis of thrombosis in COVID-19. *A.* Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection activates an inflammatory response, leading to release of inflammatory mediators. Endothelial and hemostatic activation ensues, with decreased levels of TFPI and increased tissue factor. The inflammatory response to severe infection is marked by lymphopenia and thrombocytopenia. Liver injury may lead to decreased coagulation and antithrombin formation. ***B.*** COVID-19 may be associated with hemostatic derangement and elevated troponin. ***C.*** Increased thromboembolic state results in venous thromboembolism, myocardial infarction, or, in case of further hemostatic derangement, disseminated intravascular coagulation. PVFS scale grade		Description
0	No functional limitations	All usual duties/activities at home or at work can be carried out at the same level of intensity. Symptoms, pain and anxiety are absent.
1	Negligible functional limitations	All usual duties/activities at home or at work can be carried out at the same level of intensity, despite some symptoms, pain, or anxiety.
2	Slight functional limitations	Some usual duties/activities at home or at work are carried out at a lower level of intensity or are occasionally avoided due to symptoms, pain, or anxiety.
3	Moderate functional limitations	Usual duties/activities at home or at work have been structurally modified (reduced) due to symptoms, pain, or anxiety.
4	Severe functional limitations	Assistance needed in activities of daily living due to symptoms, pain, or anxiety: nursing care and attention are required.
D	Death	Death occurred before the scheduled assessment.

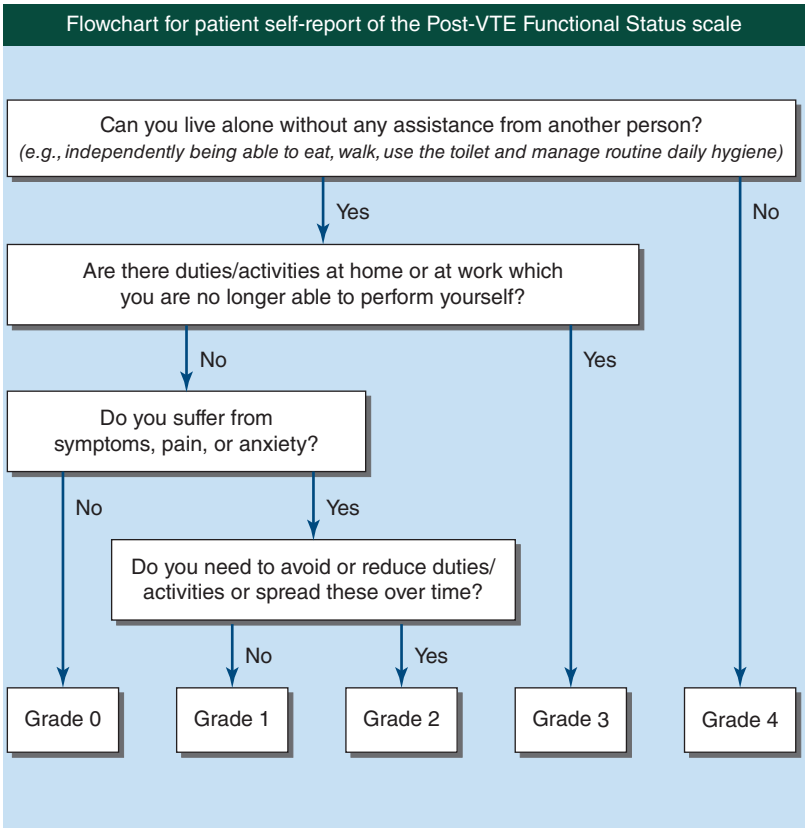

FIGURE 290-5 Flow chart for patient self-report of the Post-Venous Thromboembolism (VTE) Functional Status scale. (*Reproduced with permission from GJAM Boon et al: Thromb Res 190:45, 2020, Figure 2.)*

that bind neutrophils, stimulating them to release their nuclear material and form web-like extracellular networks called *neutrophil extracellular traps*. These prothrombotic networks contain histones that stimulate platelet aggregation and promote platelet-dependent thrombin generation. Venous thrombi form and flourish in this environment of stasis, low oxygen tension, and upregulation of proinflammatory genes.

FIGURE 290-6 Skin ulceration in the medial malleolus from postthrombotic syndrome of the leg.

Interaction Between Venous Thromboembolism and Atherothrombosis VTE (red clot) and arterial thrombotic (white clot) events were previously considered separate entities. However, the presence of carotid artery plaque is associated with double the risk of incident VTE. This observation led to the discovery of a broad interaction of VTE with acute coronary syndrome and with acute ischemic stroke (Fig. 290-7). These three vascular conditions share similar risk factors and similar pathophysiology: inflammation, hypercoagulability, and endothelial injury. Patients who suffer VTE are more than twice

TABLE 290-1 Inflammation-Linked Conditions That Can Trigger PE or DVT

Ulcerative colitis
Crohn's disease
Rheumatoid arthritis
Psoriasis
Diabetes mellitus, type 2
Obesity/metabolic syndrome
Hypercholesterolemia, especially elevated LDL cholesterol
Lipoprotein(a)
Pneumonia
Acute coronary syndrome
Acute stroke
Cigarette smoking
Sepsis/septic shock
Erythropoiesis-stimulating agents
Blood transfusion
Cancer

Abbreviations: DVT, deep-venous thrombosis; LDL, low-density lipoprotein; PE, pulmonary embolism.

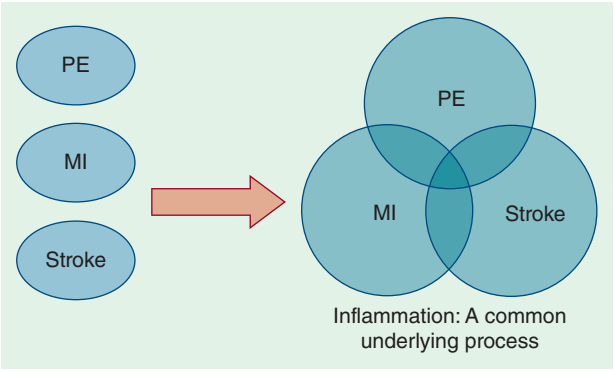

FIGURE 290-7 Broad interaction between venous thromboembolism and atherothrombosis. MI, myocardial infarction; PE, pulmonary embolism.

as likely to have a future MI or stroke. Conversely, patients with MI or stroke are more than twice as likely to suffer a future VTE.

Embolization When DVTs **(Fig. 290-8)** detach from their site of formation, they embolize to the vena cava, right atrium, and right ventricle and lodge in the pulmonary arterial circulation, thereby causing acute PE. Many patients with PE have no evidence of DVT because the leg thrombus has already embolized to the lungs. Paradoxically, these thrombi occasionally embolize to the arterial circulation through a patent foramen ovale or atrial septal defect.

Physiology The most common gas exchange abnormalities are arterial hypoxemia and an increased alveolar-arterial O_2 tension gradient, which represent the inefficiency of oxygen transfer across the lungs. Anatomic dead space increases because breathed gas does not enter gas exchange units of the lung. Physiologic dead space increases because ventilation to gas exchange units exceeds venous blood flow through the pulmonary capillaries **(Fig. 290-9)**.

Other pathophysiologic abnormalities include:

1. *Increased pulmonary vascular resistance* due to vascular obstruction or platelet secretion of vasoconstricting neurohumoral agents such as serotonin. Release of vasoactive mediators can produce ventilation-perfusion mismatching at sites remote from the embolus, thereby accounting for discordance between a small PE and a large alveolar-arterial O_2 gradient.
2. *Impaired gas exchange* due to increased alveolar dead space from vascular obstruction, hypoxemia from alveolar hypoventilation relative to perfusion in the nonobstructed lung, right-to-left shunting, or impaired carbon monoxide transfer due to loss of gas exchange surface.
3. *Alveolar hyperventilation* due to reflex stimulation of irritant receptors.

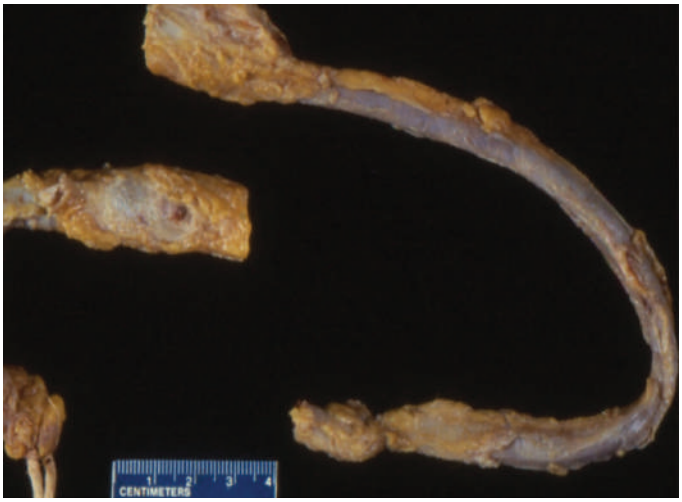

FIGURE 290-8 Deep-venous thrombosis at autopsy.

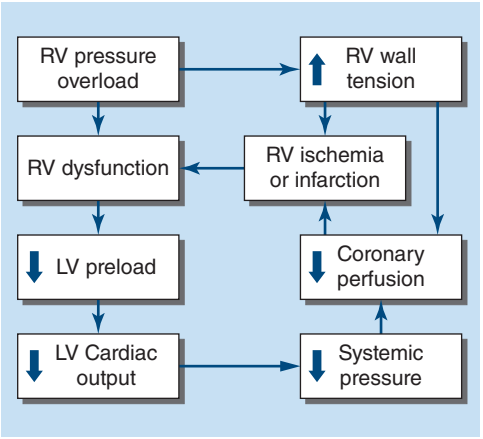

FIGURE 290-9 Pathophysiology of pulmonary embolism (PE). LV, left ventricular; RV, right ventricular.

4. *Increased airway resistance* due to constriction of airways distal to the bronchi.
5. *Decreased pulmonary compliance* due to lung edema, lung hemorrhage, or loss of surfactant.

Pulmonary Hypertension, Right Ventricular (RV) Dysfunction, and RV Microinfarction Pulmonary artery obstruction and neurohumoral mediators cause a rise in both pulmonary artery pressure and pulmonary vascular resistance. When RV wall tension rises, RV dilation, stretch, and dysfunction ensue, with release of the cardiac biomarker brain natriuretic peptide. The interventricular septum bulges into and compresses an intrinsically normal left ventricle (LV). Diastolic LV dysfunction reduces LV distensibility and impairs LV filling. Increased RV wall tension also compresses the right coronary artery, limits myocardial oxygen supply, and precipitates right coronary artery ischemia and RV microinfarction, with release of cardiac biomarkers such as troponin. Underfilling of the LV may lead to a fall in LV cardiac output and systemic arterial pressure, with consequent circulatory collapse and death (Fig. 290-9).

CLASSIFICATION OF PULMONARY EMBOLISM AND DEEP-VENOUS THROMBOSIS

Pulmonary Embolism *Massive (high-risk) PE* accounts for 5–10% of cases and is usually characterized by systemic arterial hypotension and extensive thrombosis affecting at least half of the pulmonary vasculature. Dyspnea, syncope, hypotension, and cyanosis are hallmarks of massive PE. Patients with massive PE may present in cardiogenic shock and can die from multisystem organ failure. *Submassive (intermediate-risk) PE* accounts for 20–25% of patients and is characterized by RV dysfunction despite normal systemic arterial pressure. The combination of right heart failure and release of cardiac biomarkers such as troponin indicates a high risk of clinical deterioration. *Low-risk PE* constitutes about 65–75% of cases. These patients have an excellent prognosis.

Deep-Venous Thrombosis *Lower extremity DVT* usually begins in the calf and can propagate proximally to the popliteal, femoral, and iliac veins. Leg DVT is ~10 times more common than *upper extremity DVT,* which is often precipitated by placement of pacemakers, internal cardiac defibrillators, or indwelling central venous catheters. The likelihood of upper extremity DVT increases as the catheter diameter and number of lumens increase.

Superficial venous thrombosis usually presents with erythema, tenderness, and a "palpable cord"; it is most common in the lower extremities because of varicose veins and in the upper extremities because of indwelling intravenous catheters. Superficial veins may be visible in the chest wall (*Urschel's sign*). Patients are at risk for extension of the superficial vein thrombosis to the deep-venous system.

DIAGNOSIS

Clinical Evaluation PE is known as "the great masquerader." Diagnosis is difficult because symptoms and signs are nonspecific.

The most common symptom of PE is unexplained breathlessness. When occult PE occurs concomitantly with overt congestive heart failure or pneumonia, clinical improvement often fails to ensue despite standard medical treatment of the concomitant illness. This scenario provides a clinical clue to the possible coexistence of PE.

With DVT, the most common symptom is a cramp or "charley horse" in the lower calf that persists and intensifies over several days. Wells Point Score criteria, validated in ambulatory patients but not in hospitalized patients, help estimate the clinical likelihood of DVT and PE **(Table 290-2)**. Patients with a low likelihood of DVT or a low-to-moderate likelihood of PE should undergo initial diagnostic evaluation with D-dimer testing alone (see "Blood Tests"), without obligatory imaging tests if the D-dimer test result is normal **(Fig. 290-10)**. However, patients with a high clinical likelihood of VTE should skip D-dimer testing and undergo imaging as the next step in the diagnostic algorithm.

Clinical Pearls Not all leg pain is due to DVT, and not all dyspnea is due to PE **(Table 290-3)**. Sudden, severe calf discomfort suggests a ruptured Baker's cyst. Fever and chills often herald cellulitis rather than DVT. Physical findings, if present, may consist only of mild palpation discomfort in the lower calf. However, massive DVT often presents with marked thigh swelling, tenderness, and erythema. If a leg is diffusely edematous, DVT is unlikely, except for the most serious form of DVT, *phlegmasia cerulea dolens*. Recurrent left thigh edema, especially in young women, raises the possibility of May-Thurner syndrome, with right proximal iliac artery compression of the left proximal iliac vein. This syndrome may be associated with a DVT. Upper extremity venous thrombosis may present with asymmetry in the supraclavicular fossa or in the circumference of the upper arms.

Pulmonary infarction usually indicates a small PE. This condition is exquisitely painful because the thrombus lodges peripherally, near the innervation of pleural nerves. *Nonthrombotic PE* etiologies include fat embolism after pelvic or long bone fracture, tumor embolism, bone marrow, and air embolism. Cement embolism and bony fragment embolism can occur after total hip or knee replacement. Intravenous drug users may inject themselves with a wide array of substances that can embolize, such as hair, talc, and cotton. *Amniotic fluid embolism* occurs when fetal membranes leak or tear at the placental margin.

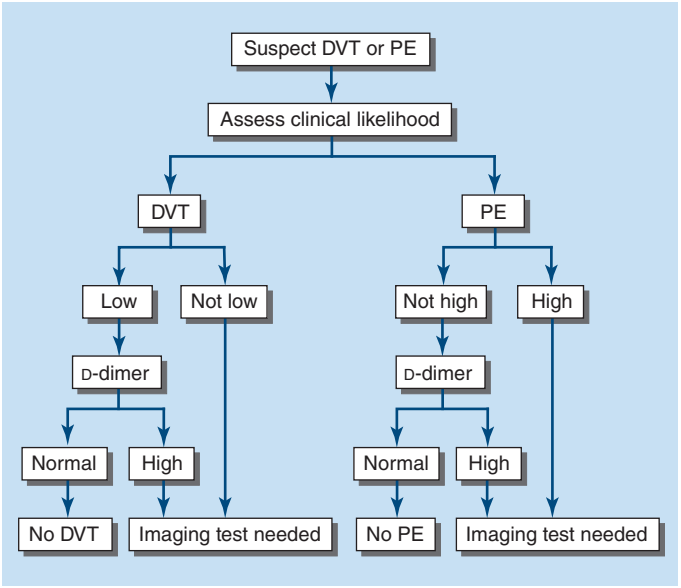

FIGURE 290-10 How to decide whether diagnostic imaging is needed. For assessment of clinical likelihood, see Table 290-2. DVT, deep-venous thrombosis; PE, pulmonary embolism.

Nonimaging Diagnostic Modalities • **BLOOD TESTS** The quantitative *plasma D-dimer enzyme-linked immunosorbent assay (ELISA)* rises in the presence of DVT or PE because of the breakdown of fibrin by plasmin. Elevation of D-dimer indicates endogenous, although often clinically ineffective, thrombolysis. The sensitivity of an abnormally elevated D-dimer is >95% for PE. A normal D-dimer is a useful "rule out" test for PE in patients with low pretest probability. However, the D-dimer assay is not specific. Levels increase in patients with MI, pneumonia, sepsis, cancer, and the postoperative state, and those in the second or third trimester of pregnancy. Therefore, D-dimer testing rarely has a useful role among hospitalized patients because levels are frequently elevated due to systemic illness.

The upper limit of normal for D-dimer was considered to be 500 ng/mL; however, guidelines now recommend use of an age-adjusted D-dimer when ruling out acute PE. The age-adjusted D-dimer applies to patients older than 50 years of age with low or intermediate clinical probability of PE. To calculate the upper limit of normal D-dimer in these patients, multiply the age by 10. For example, a 70-year-old patient suspected of PE would have 700 ng/mL as the upper limit of normal for D-dimer. Implementing routine use of the

TABLE 290-2 Clinical Decision Rules

Low Clinical Likelihood of DVT if Point Score Is Zero or Less; Moderate Likelihood if Score Is 1 to 2; High Likelihood if Score Is 3 or Greater	
CLINICAL VARIABLE	**DVT SCORE**
Active cancer	1
Paralysis, paresis, or recent cast	1
Bedridden for >3 days; major surgery <12 weeks	1
Tenderness along distribution of deep veins	1
Entire leg swelling	1
Unilateral calf swelling >3 cm	1
Pitting edema	1
Collateral superficial nonvaricose veins	1
Alternative diagnosis at least as likely as DVT	−2
High Clinical Likelihood of PE if Point Score Exceeds 4	
CLINICAL VARIABLE	**PE SCORE**
Signs and symptoms of DVT	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate >100/min	1.5
Immobilization >3 days; surgery within 4 weeks	1.5
Prior PE or DVT	1.5
Hemoptysis	1.0
Cancer	1.0

Abbreviations: DVT, deep-venous thrombosis; PE, pulmonary embolism.

TABLE 290-3 Differential Diagnosis of DVT and PE

DVT
Ruptured Baker's cyst
Muscle strain/injury
Cellulitis
Acute postthrombotic syndrome/venous insufficiency
PE
Pneumonia, asthma, chronic obstructive pulmonary disease
Congestive heart failure
Pericarditis
Pleurisy: "viral syndrome," costochondritis, musculoskeletal discomfort
Rib fracture, pneumothorax
Acute coronary syndrome
Anxiety
Vasovagal syncope

Abbreviations: DVT, deep-venous thrombosis; PE, pulmonary embolism.

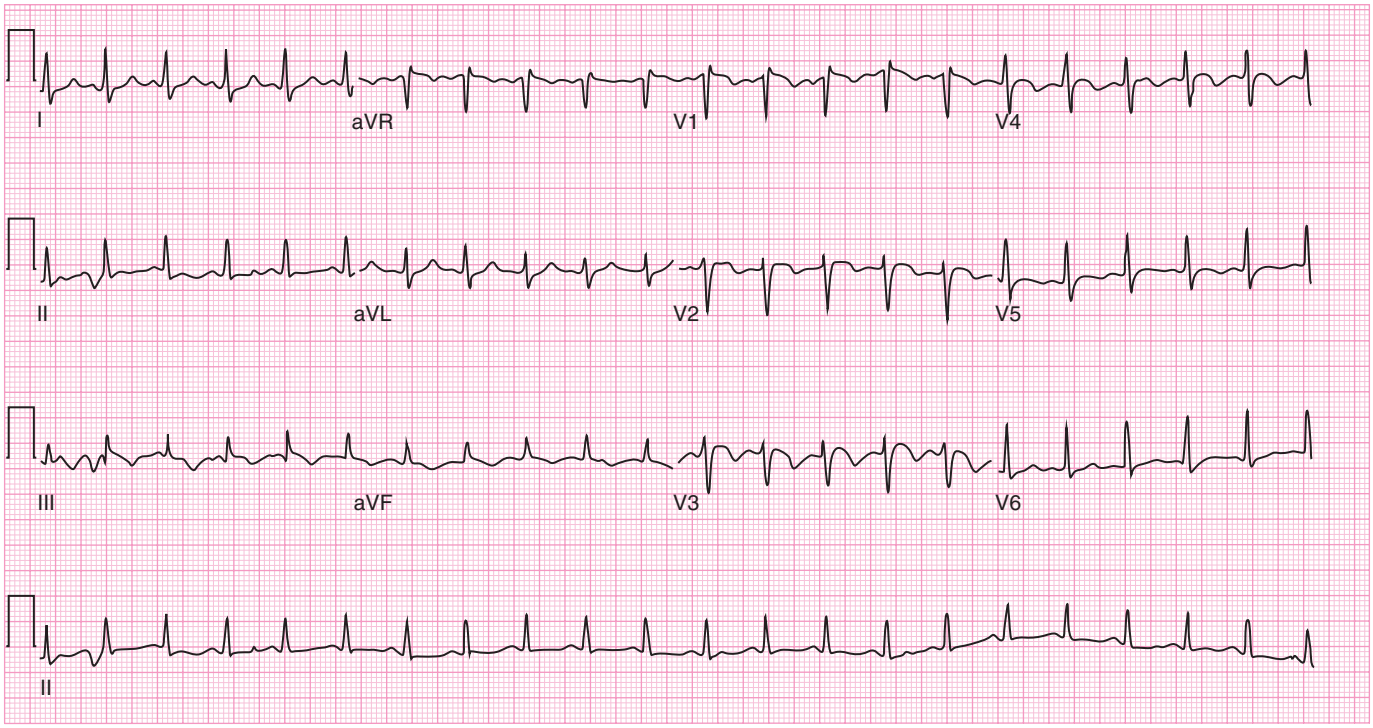

FIGURE 290-11 Electrocardiogram with both the S1Q3T3 sign and T-wave inversions in leads V_1-V_4—typical of an anatomically large pulmonary embolism. This patient's CT pulmonary angiogram is shown as **Fig. 290-13*A* and *B***.

age-adjusted D-dimer reduces the number of computed tomography (CT) pulmonary angiograms that are ordered. However, the age-adjusted D-dimer does not apply to patients suspected of acute DVT.

ELEVATED CARDIAC BIOMARKERS Serum troponin increases because of RV microinfarction. Myocardial stretch causes release of brain natriuretic peptide or NT-pro-brain natriuretic peptide.

ELECTROCARDIOGRAM The most frequently cited abnormality, in addition to sinus tachycardia, is the S1Q3T3 sign: an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III **(Chap. 247)**. This finding is relatively specific but insensitive. RV strain and ischemia cause the most common abnormality, T-wave inversion in leads V_1 to V_4 **(Fig. 290-11)**.

Noninvasive Imaging Modalities • **VENOUS ULTRASONOGRAPHY** Ultrasonography of the deep-venous system relies on loss of vein compressibility as the primary diagnostic criterion for DVT. When a normal vein is imaged in cross-section, it readily collapses with gentle manual pressure on the ultrasound transducer. This creates the illusion of a "wink." With acute DVT, the vein loses its compressibility because of passive distention by acute thrombus. The diagnosis of acute DVT is even more secure when thrombus is directly visualized; it appears homogeneous, is located in the center of the vein, and has low echogenicity **(Fig. 290-12)**. The vein itself often appears mildly dilated, and collateral channels may be absent.

Venous flow dynamics can be examined with Doppler imaging. Normally, manual calf compression causes augmentation of the Doppler flow pattern. Loss of normal respiratory variation is caused by an obstructing DVT or by any obstructive process within the pelvis. For patients with a technically poor or nondiagnostic venous ultrasound, consider alternative imaging modalities such as CT and magnetic resonance imaging.

CHEST ROENTGENOGRAPHY A normal or nearly normal chest x-ray often occurs in PE. Well-established abnormalities include focal oligemia (*Westermark's sign*), a peripheral triangular-shaped density usually located at the pleural base (*Hampton's hump*—which is usually due to pulmonary infarction), and an enlarged right descending pulmonary artery (*Palla's sign*).

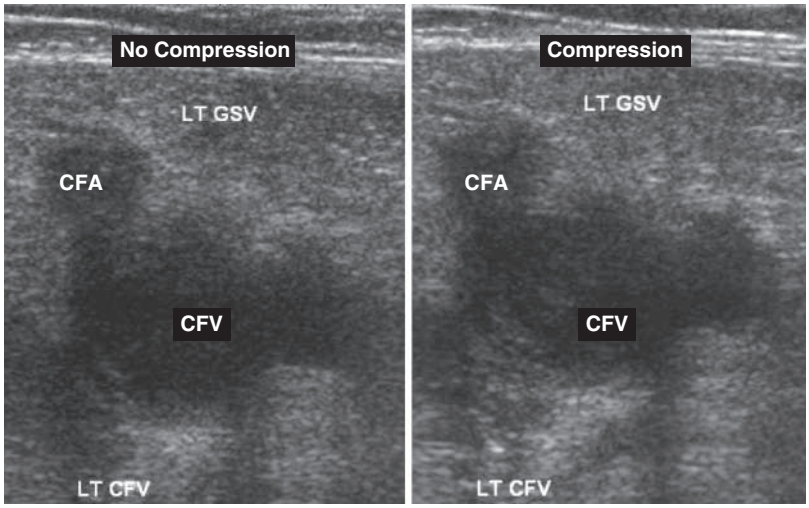

FIGURE 290-12 Venous ultrasound, with and without compression of the leg veins. CFA, common femoral artery; CFV, common femoral vein; GSV, great saphenous vein; LT, left.

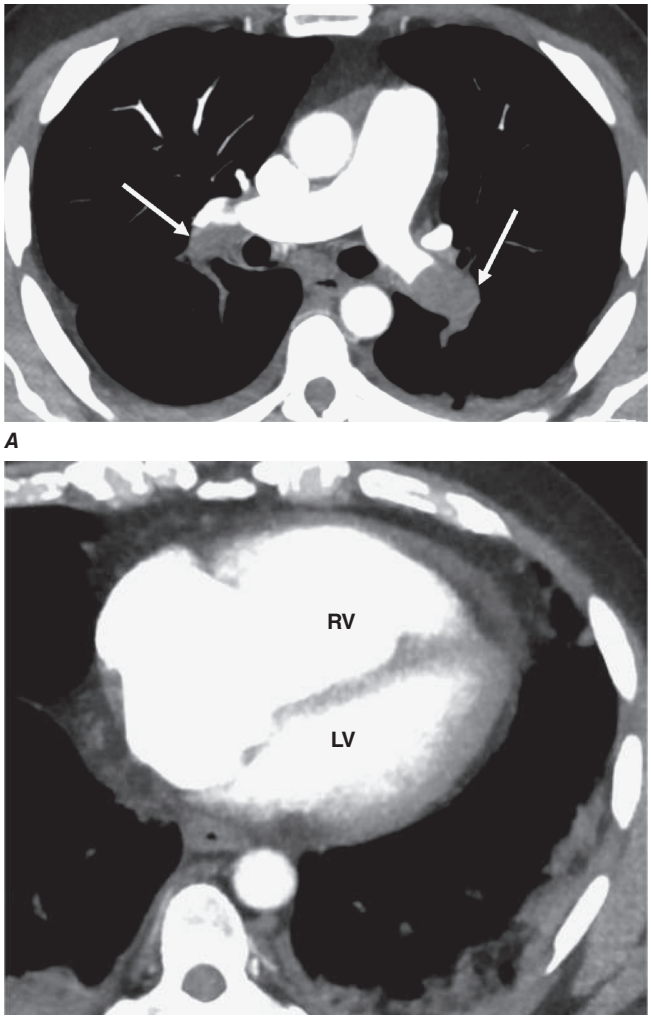

FIGURE 290-13 ***A.*** Massive bilateral proximal pulmonary embolism on an axial chest CT image in a 53-year-old man (whose electrocardiogram is shown in Fig. 290-11) with filling defects in the right and left main pulmonary arteries (*white arrows*). ***B.*** Four-chamber view in the same patient showing the right ventricle (RV) larger than the left ventricle (LV).

CHEST CT CT pulmonary angiography with intravenous contrast is the principal imaging test for the diagnosis of PE **(Fig. 290-13*A*)**. Thin-cut chest CT images can provide exquisite detail, with ≤1 mm of resolution during a short breath hold. Sixth-order branches can be visualized with resolution superior to that of conventional invasive contrast pulmonary angiography. The CT scan also provides an excellent four-chamber view of the heart **(Fig. 290-13*B*)**. RV enlargement on chest CT indicates an increased likelihood of death within the next 30 days compared with PE patients who have normal RV size (commonly defined as a right to left ventricular diameter ratio >1). In patients without PE, the lung parenchymal images may establish alternative diagnoses not apparent on chest x-ray that explain the presenting symptoms and signs, such as pneumonia, emphysema, pulmonary fibrosis, pulmonary mass, and aortic pathology.

LUNG SCANNING Ventilation/perfusion lung scanning has become a second-line diagnostic test for PE, used mostly for patients who cannot tolerate intravenous contrast. Small particulate aggregates of albumin labeled with a gamma-emitting radionuclide are injected intravenously and trapped in the pulmonary capillary bed. The perfusion scan defect indicates absent or decreased blood flow, possibly due to PE. Ventilation scans, obtained with a radiolabeled inhaled gas such as xenon or krypton, improve the specificity of the perfusion scan. Abnormal ventilation scans indicate abnormal nonventilated lung, thereby providing possible explanations for perfusion defects other than acute PE, such as asthma or chronic obstructive pulmonary disease. A high-probability scan for PE is defined as two or more segmental perfusion defects in the presence of normal ventilation. The diagnosis of PE is very unlikely in patients with normal and nearly normal scans and, in contrast, is ~90% certain in patients with high-probability scans.

MAGNETIC RESONANCE (MR) (CONTRAST-ENHANCED) IMAGING When pelvic or leg ultrasound is equivocal, MR venography with gadolinium contrast is an excellent imaging modality to diagnose DVT. MR pulmonary angiography may detect large proximal PE but is not reliable for smaller segmental and subsegmental PE.

ECHOCARDIOGRAPHY Echocardiography is *not* a reliable diagnostic imaging tool for acute PE because most patients with PE have normal echocardiograms. However, echocardiography is very useful for detecting conditions that may mimic PE, such as acute MI, pericardial tamponade, and aortic dissection. Transthoracic echocardiography rarely images thrombus directly in the main pulmonary artery or the right or left main branches. The best-known indirect sign of PE on transthoracic echocardiography is McConnell's sign: hypokinesis of the RV free wall with normal or hyperkinetic motion of the RV apex.

Invasive Diagnostic Modalities • **PULMONARY ANGIOGRAPHY** Chest CT pulmonary angiography with contrast (see above) has virtually replaced invasive pulmonary angiography as a diagnostic test. Invasive catheter-based diagnostic testing is reserved for patients with technically unsatisfactory chest CTs and for those in whom an interventional procedure such as catheter-directed thrombolysis or embolectomy is planned. A definitive diagnosis of PE requires visualization of an intraluminal filling defect in more than one projection. Secondary signs of PE include abrupt occlusion ("cut-off") of vessels, segmental oligemia, avascularity, and a prolonged arterial phase with slow filling and tortuous, tapering peripheral vessels.

CONTRAST PHLEBOGRAPHY Venous ultrasonography has virtually replaced contrast phlebography as the principal diagnostic test for suspected DVT. However, contrast phlebography is used when an interventional procedure is planned.

Integrated Diagnostic Approach An integrated diagnostic approach streamlines the workup of suspected DVT and PE **(Fig. 290-14)**.

TREATMENT

Deep-Venous Thrombosis

UPPER EXTREMITY DVT

As peripherally inserted central catheter (PICC) use has increased, so has the rate of upper extremity DVT. This rate can be decreased by more judicious selection of patients who require a PICC, use of single-lumen rather than double- or triple-lumen PICCs, and use of the smallest possible lumen size, ideally 4 French rather than 5 or 6 French.

ISOLATED CALF DVT

The GARFIELD-VTE Registry recruited 2145 patients with isolated calf DVT and 3846 patients with proximal DVT with or without calf DVT. Isolated calf DVT patients were more likely to have either undergone surgery or have experienced leg trauma, and they were less likely to have active cancer or a prior history of VTE. Almost all isolated calf DVT patients received anticoagulation, and nearly half were anticoagulated for at least 1 year.

FIBRINOLYSIS

If advanced therapy beyond anticoagulation is warranted, one can utilize clot dissolution or clot extraction therapy with catheter-directed therapy. The open vein hypothesis postulates that patients who receive primary therapy will sustain less long-term damage to venous valves, with consequent lower rates of postthrombotic syndrome. However, the ATTRACT trial randomized 692 patients with femoral or iliofemoral DVT to catheter-directed therapy plus

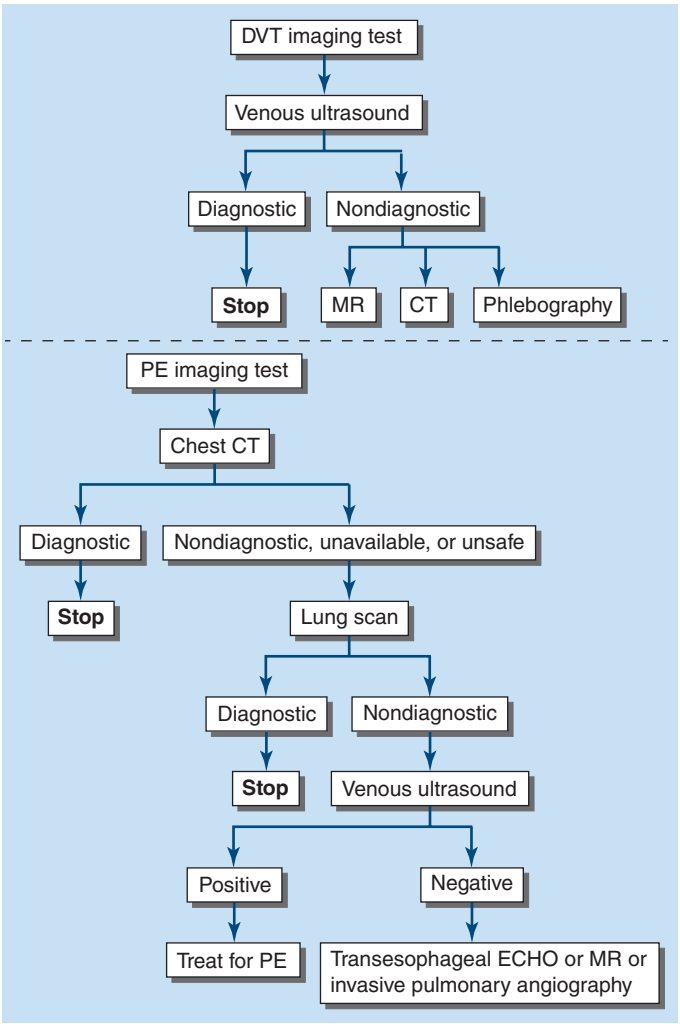

FIGURE 290-14 Integrated diagnostic approach. CT, computed tomography; DVT, deep-venous thrombosis; ECHO, echocardiography; MR, magnetic resonance; PE, pulmonary embolism.

anticoagulation versus usual care with anticoagulation alone. After 2 years of follow-up, there was no overall reduction in postthrombotic syndrome in the thrombolysis group. However, there was a trend toward less postthrombotic syndrome among patients with iliofemoral DVT (compared with only femoral DVT) who received catheter-directed thrombolysis compared with anticoagulation alone.

COMPRESSION STOCKINGS

For patients with swelling of the legs when acute DVT is diagnosed, below-knee graduated compression stockings may be prescribed, usually 30–40 mmHg or 20–30 mmHg, to lessen patient discomfort. They should be replaced every 3–6 months because they lose their elasticity. However, prescription of vascular compression stockings in asymptomatic newly diagnosed acute DVT patients does not prevent the development of postthrombotic syndrome.

TREATMENT

Pulmonary Embolism

RISK STRATIFICATION

Hemodynamic instability, RV dysfunction on echocardiography, RV enlargement on chest CT, and elevation of the troponin level due to RV microinfarction portend a high risk of adverse clinical outcomes despite anticoagulation. However, in most cases, RV function and hemodynamic function remain normal, which portend an excellent prognosis and clinical outcome **(Fig. 290-15)**.

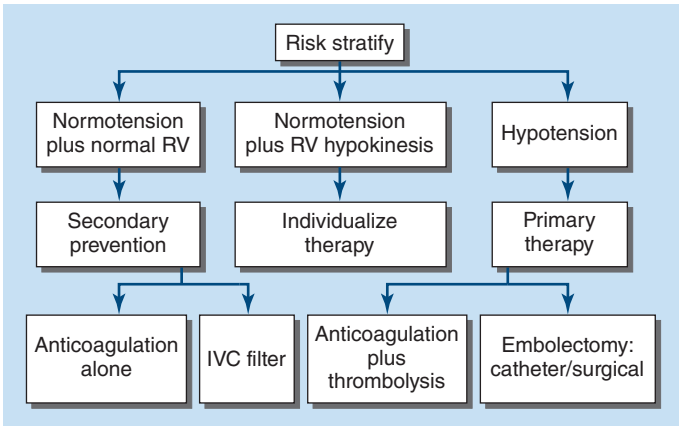

FIGURE 290-15 Acute management of pulmonary thromboembolism. IVC, inferior vena cava; PE, pulmonary embolism; RV, right ventricular.

ANTICOAGULATION

There are three major strategies for anticoagulation: (1) the well-established—but waning—strategy of parenteral anticoagulation with unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), or fondaparinux either as monotherapy or more often "bridged" to warfarin; (2) parenteral anticoagulation, switched after 5 days to dabigatran (a direct thrombin inhibitor) or edoxaban (an anti-Xa agent); or (3) oral anticoagulation monotherapy with rivaroxaban or apixaban (both anti-Xa agents) with a 3-week or 1-week loading dose, respectively. For patients with VTE in the setting of suspected or proven heparin-induced thrombocytopenia, one can choose between two intravenous direct thrombin inhibitors: argatroban (metabolized by the liver) or bivalirudin (metabolized by the kidney), or subcutaneously administered fondaparinux **(Table 290-4)**.

Unfractionated Heparin UFH binds to and accelerates the activity of antithrombin, thus preventing additional thrombus formation. Intravenous UFH is typically dosed to achieve a target activated partial thromboplastin time (aPTT) of 60–80 s, which usually corresponds to a chromogenic anti-Xa level of 0.3–0.7 U/mL. When switching from a direct oral anticoagulant (DOAC) to intravenous UFH, monitor the aPTT, not the chromogenic anti-Xa assay. However, the anti-Xa assay is more accurate than the aPTT in critically ill patients, APS, pregnancy, and suspected heparin resistance.

In patients with normal liver function, use an initial bolus of 80 U/kg as a loading dose of UFH, followed by an initial infusion rate of 18 U/kg per h in patients with normal liver function. The short half-life of UFH is especially useful in patients in whom hour-to-hour control of anticoagulation intensity is desired. Heparin also has pleiotropic effects that may decrease systemic and local inflammation.

Low-Molecular-Weight Heparins These fragments of UFH exhibit less binding to plasma proteins and endothelial cells and consequently have greater bioavailability, a more predictable dose response, and a longer half-life than UFH. No monitoring or dose adjustment is needed unless the patient is markedly obese or has chronic kidney disease.

Fondaparinux Fondaparinux, an anti-Xa pentasaccharide, is essentially an ultra-low-molecular-weight heparin. It is administered as a weight-based, once-daily subcutaneous injection in a prefilled syringe. No laboratory monitoring is required. Fondaparinux is synthesized in a laboratory and, unlike LMWH or UFH, is not derived from animal products. It does not cause heparin-induced thrombocytopenia. For patients with renal dysfunction, the fondaparinux dose must be adjusted downward.

TABLE 290-4 Anticoagulation of VTE

Non-Warfarin Anticoagulation
Unfractionated heparin, bolus and continuous infusion, to achieve aPTT 2–3 times the upper limit of the laboratory normal, *or*
Enoxaparin 1 mg/kg twice daily with normal renal function, *or*
Dalteparin 200 U/kg once daily or 100 U/kg twice daily, with normal renal function, *or*
Tinzaparin 175 U/kg once daily with normal renal function, *or*
Fondaparinux weight-based once daily; adjust for impaired renal function
Direct thrombin inhibitors: argatroban or bivalirudin (with suspected or proven heparin-induced thrombocytopenia)
Rivaroxaban 15 mg twice daily for 3 weeks, followed by 20 mg once daily with the dinner meal thereafter. For CrCl 15–50 mL/min: 10 mg twice daily.
Apixaban 10 mg twice daily for 1 week, followed by 5 mg twice daily thereafter. In patients with at least 2 of the following characteristics: age >80 years, body weight <60 kg, or serum creatinine >1.5 mg/dL, the recommended dose is 2.5 mg orally twice daily.
Dabigatran: 5 days of unfractionated heparin, LMWH, or fondaparinux followed by dabigatran 150 mg twice daily with CrCl >30 mL/min. For CrCl 15–30 mL/min: 75 mg twice daily.
Edoxaban: 5 days of unfractionated heparin, LMWH, or fondaparinux followed by edoxaban 60 mg once daily with normal renal function, weight >60 kg, in the absence of potent P-glycoprotein inhibitors. For CrCl 15–50 mL/min: 30 mg once daily.
Warfarin Anticoagulation
Requires 5–10 days of administration to achieve effectiveness as monotherapy
Use full-dose unfractionated heparin, LMWH, or fondaparinux as "bridging agents" when initiating warfarin. Continue parenteral anticoagulation for a minimum of 5 days and until two sequential INR values, at least 1 day apart, achieve the target INR range.
Usual start dose is 5 mg
Titrate to INR, target 2.0–3.0

Abbreviations: aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; INR, international normalized ratio; LMWH, low-molecular-weight heparin; VTE, venous thromboembolism.

Warfarin This vitamin K antagonist prevents carboxylation-dependent activation of coagulation factors II, VII, IX, and X (**Chap. 69**). The full effect of warfarin is attained after daily therapy for 5–7 days. Overlapping UFH, LMWH, fondaparinux, or parenteral direct thrombin inhibitors during initiation of warfarin provides therapeutic levels of anticoagulation. Parenteral anticoagulation is discontinued when warfarin has achieved a target international normalized ratio (INR) of 2.5. Warfarin can cause major hemorrhage, including intracranial hemorrhage, even when the INR remains within the desired therapeutic range. Warfarin can also cause "off-target" side effects such as alopecia or arterial vascular calcification. Centralized anticoagulation clinics have improved the efficacy and safety of warfarin dosing. Some patients can self-monitor their INR with a home point-of-care fingerstick machine, and a few can be taught to self-dose their warfarin.

Direct Oral Anticoagulants DOACs are administered in a fixed dose, establish effective anticoagulation within hours of ingestion, do not require laboratory coagulation monitoring or limitation of green leafy vegetables, and have few drug-drug interactions. DOACs should not be prescribed during pregnancy or breastfeeding. Warfarin, not DOACs, is the standard treatment for APS. The efficacy and safety of DOACs remain uncertain in patients with end-stage kidney disease or cirrhosis.

Management of Bleeding from Anticoagulants For life-threatening or intracranial hemorrhage due to heparin or LMWH, administer protamine sulfate. The dabigatran antibody, idarucizumab, is an effective, rapidly acting antidote for dabigatran. Andexanet alfa or protein complex concentrate reverses major bleeding caused by anti-Xa DOACs, but beware of rebound thrombosis. With minor bleeding, fresh-frozen plasma, vitamin K, or observation without pharmacologic intervention can be considered.

TABLE 290-5 Take-Home Points from the European Society of Cardiology 2019 Pulmonary Embolism Guidelines

1. Terminology such as "provoked" versus "unprovoked" PE/DVT is no longer supported by the guidelines, as it is potentially misleading and not helpful for decision-making regarding the duration of anticoagulation.
2. Extended oral anticoagulation without an end date should be considered for patients with a first episode of PE and:
   a. No identifiable risk factor
   b. A persistent risk factor
   c. A minor transient or reversible risk factor

Abbreviations: DVT, deep-venous thrombosis; PE, pulmonary embolism.

Cancer and Venous Thromboembolism For patients with cancer and VTE, prescribe LMWH as monotherapy or a DOAC in the absence of a gastrointestinal cancer, and continue extended-duration anticoagulation until the patient is declared cancer-free. The National Comprehensive Cancer Network guidelines endorse treatment of VTE with apixaban or edoxaban.

Duration of Anticoagulation Data-driven guidelines from the European Society of Cardiology are changing our conceptual approach to determining the optimal duration of anticoagulation (**Tables 290-5 and 290-6**). We should no longer classify VTE as "provoked" or "unprovoked," given that many types of provoked VTE have a similar recurrence rate to unprovoked VTE once anticoagulation is discontinued. Enduring risk factors such as heart failure, chronic lung disease, and inflammatory bowel diseases can heighten the risk of recurrence.

INFERIOR VENA CAVA FILTERS

The two principal indications for insertion of an inferior vena cava filter are (1) active bleeding that precludes anticoagulation and (2) recurrent venous thrombosis despite intensive anticoagulation. Prevention of PE in patients who are not candidates for anticoagulation is a much "softer" indication for filter placement. The filter itself may fail by permitting the passage of small- to medium-size clots via collateral veins that develop. Paradoxically, by providing a nidus for clot formation, filters may increase the DVT rate even though they usually prevent PE. In most situations, place a retrievable rather than a permanent filter.

MANAGEMENT OF MASSIVE PE

For patients with massive PE and hypotension, replete volume with 500 mL of normal saline. Excessive fluid administration exacerbates RV wall stress, causes more profound RV ischemia, and worsens LV compliance and filling by causing further interventricular septal shift toward the LV. Norepinephrine and dobutamine are first-line vasopressor and inotropic agents, respectively, for treatment of PE-related shock. Norepinephrine increases systemic arterial pressure. Dobutamine increases RV inotropy and lowers filling pressures. If

TABLE 290-6 Risk of Recurrent Venous Thromboembolism After Discontinuing Anticoagulation (European Society of Cardiology 2019 Pulmonary Embolism Guidelines)

RISK OF RECURRENCE	EXAMPLES
Low risk (<3% per year)	Major surgery or trauma
Intermediate risk (3–8% per year)	Minor surgery Hospitalized with acute medical illness Pregnancy/estrogens Long-haul flight Inflammatory bowel disease Autoimmune disease No identifiable risk factor (formerly called "unprovoked")
High risk (>8% per year)	Active cancer Antiphospholipid syndrome

additional hemodynamic circulatory support is required, available, and within the scope of the patient's goals of care, consider veno-arterial extracorporeal membrane oxygenation (ECMO).

FIBRINOLYSIS

Successful fibrinolytic therapy rapidly reverses right heart failure and may result in a lower rate of death and recurrent PE by (1) dissolving much of the anatomically obstructing pulmonary arterial thrombus, (2) preventing the continued release of serotonin and other neurohumoral factors that exacerbate pulmonary hypertension, and (3) lysing much of the source of the thrombus in the pelvic or deep leg veins, thereby potentially decreasing the likelihood of recurrent PE.

For massive PE, the U.S. Food and Drug Administration has approved systemically administered 100 mg of recombinant tissue plasminogen activator (tPA) (alteplase) prescribed as a continuous intravenous infusion over 2 h. The sooner thrombolysis is administered, the more effective it is. However, systemic fibrinolysis can be utilized effectively for at least 14 days after the PE has occurred. A popular but controversial off-label dosing regimen is 50 mg of tPA administered over 2 h. This lower dose appears less effective than full-dose tPA but may be associated with fewer bleeding complications.

Contraindications to fibrinolysis include intracranial disease, recent surgery, and trauma. The overall major bleeding rate is ~10%, including a 2–3% risk of intracranial hemorrhage. Careful screening of patients for contraindications to fibrinolytic therapy **(Chap. 286)** is the best way to minimize bleeding risk.

For patients with submassive PE who have preserved systolic blood pressure but moderate or severe RV dysfunction, use of fibrinolysis remains controversial. A 2019 American Heart Association Scientific Statement suggests consideration of thrombolysis or embolectomy in patients with a lack of clinical improvement, clinical deterioration, clot in transit, severe or persistent RV strain, or signs of low cardiac output.

CATHETER-DIRECTED THERAPY

There are three types of catheter-directed therapy to treat VTE: (1) pharmacologic only, (2) mechanical only, or (3) pharmacomechanical. *Pharmacologic therapy* usually utilizes a low-dose continuous infusion of tPA. *Mechanical therapy* serves as a percutaneous thrombectomy. The procedure usually employs suction, snaring, and extraction of thrombus without using thrombolytic therapy. One mechanical device is a catheter with expandable nitinol disks that traps the thrombus, which is then removed. *Pharmacomechanical therapy* is epitomized by low-energy ultrasound-facilitated low-dose thrombolysis. The low-dose thrombolysis strategy most likely explains the lower major bleeding complication rate compared with systemically administered fibrinolysis.

SURGICAL PULMONARY EMBOLECTOMY

The substantial risk of major hemorrhage with systemically administered fibrinolysis reawakened interest in alternative treatment with surgical embolectomy, an operation that had almost become extinct. More rapid referral for surgery before the onset of irreversible multisystem organ failure, improved surgical technique, and utilization of ECMO have increased the survival rate of surgical pulmonary embolectomy and have markedly improved right ventricular function.

PULMONARY THROMBOENDARTERECTOMY

CTEPH develops in about 2% of acute PE patients. Therefore, PE patients who have initial pulmonary hypertension (often detected initially during echocardiography) should be followed up at about 6 weeks and, if necessary, at 6 months, with repeat echocardiograms to determine whether pulmonary arterial pressure has worsened, plateaued, or abated. Patients impaired by dyspnea due to CTEPH should be considered for pulmonary thromboendarterectomy, which can markedly reduce, and sometimes even cure, pulmonary hypertension **(Chap. 294)**. The operation requires median sternotomy, cardiopulmonary bypass, deep hypothermia, and periods of hypothermic circulatory arrest. The mortality rate at experienced centers is 1–5%. Inoperable patients should be managed with pulmonary vasodilator therapy and balloon angioplasty of pulmonary arterial webs.

TABLE 290-7 Prevention of Venous Thromboembolism Among Hospitalized Patients

CONDITION	PROPHYLAXIS STRATEGY
High-risk nonorthopedic surgery	Unfractionated heparin 5000 units SC bid or tid Enoxaparin 40 mg daily Dalteparin 2500 or 5000 units daily
Medical oncology (ambulatory)	Apixaban or rivaroxaban for up to 6 months in high-risk patients with cancer starting a new chemotherapy regimen
Cancer surgery, including gynecologic cancer surgery	Enoxaparin 40 mg daily, consider 1 month of prophylaxis
Major orthopedic surgery	Aspirin 81 mg twice daily Rivaroxaban 10 mg daily, beginning 6–10 h postoperatively Dabigatran 110 mg first day, then 220 mg daily Apixaban 2.5 mg bid, beginning 12–24 h postoperatively Warfarin (target INR 2.0) Enoxaparin 40 mg daily Dalteparin 2500 or 5000 units daily Fondaparinux 2.5 mg daily
Medically ill patients, especially if immobilized, with a history of prior VTE, with an indwelling central venous catheter, or with cancer (but without active gastroduodenal ulcer, major bleeding within 3 months, or platelet count <50,000)	Unfractionated heparin 5000 units bid or tid Enoxaparin 40 mg daily Dalteparin 2500 or 5000 units daily Fondaparinux 2.5 mg daily
Medically ill patients about to be discharged from hospital	Rivaroxaban 10 mg daily for about 5 weeks (rarely prescribed for this indication)
Anticoagulation contraindicated	Intermittent pneumatic compression devices and/or graduated vascular below-knee compression stockings

Abbreviations: INR, international normalized ratio; VTE, venous thromboembolism.

PREVENTION OF VTE

Prevention of DVT and PE **(Table 290-7)** is of paramount importance because VTE is difficult to detect and poses a profound medical and economic burden. Low-dose UFH or LMWH is the most common form of in-hospital prophylaxis. Computerized reminder systems in ambulatory and in-hospital practices can increase the use of preventive measures and, at Brigham and Women's Hospital, have reduced the symptomatic VTE rate.

EMOTIONAL SUPPORT

Patients with VTE may feel overwhelmed when they learn that they are suffering from PE or DVT. Some have never previously encountered serious cardiovascular illness. They often assume they will have a reduced life expectancy. They worry about the health of their families and the genetic implications of their illness. At Brigham and Women's Hospital, a physician-nurse–facilitated PE support group was initiated to address these concerns and has met monthly for >30 years. The nonprofit North American Thrombosis Forum (*www.thrombosis.org*) runs monthly online support groups that garner worldwide participation.

291 Diseases of the Aorta

Mark A. Creager, Joseph Loscalzo

The aorta is the conduit through which blood ejected from the left ventricle is delivered to the systemic arterial bed. In adults, its diameter is ~3.5 cm at the origin and in the ascending portion, ~2.5 cm in the descending portion in the thorax, and 1.8–2.0 cm in the abdomen. The aortic wall consists of a thin intima composed of endothelium, subendothelial connective tissue, and an internal elastic lamina; a thick tunica media composed of smooth muscle cells, elastic fibers, collagen, and extracellular matrix; and an adventitia composed primarily of connective tissue enclosing the vasa vasorum and nervi vascularis. In addition to the conduit function of the aorta, its viscoelastic and compliant properties serve a buffering function. The aorta is distended during systole to allow a portion of the stroke volume and elastic energy to be stored, and it recoils during diastole so that blood continues to flow to the periphery. Owing to its continuous exposure to high pulsatile pressure and shear stress, the aorta is particularly prone to injury and disease resulting from mechanical trauma. The aorta is also more prone to rupture than is any other vessel, especially with the development of aneurysmal dilation, since its wall tension, as governed by Laplace's law (i.e., proportional to the product of pressure and radius), will be increased.

CONGENITAL ANOMALIES OF THE AORTA

Congenital anomalies of the aorta usually involve the aortic arch and its branches. Symptoms such as dysphagia, stridor, and cough may occur if an anomaly causes a ring around or otherwise compresses the esophagus or trachea. Anomalies associated with symptoms include double aortic arch, origin of the right subclavian artery distal to the left subclavian artery, and right-sided aortic arch with an aberrant left subclavian artery. A Kommerell diverticulum is an anatomic remnant of a right aortic arch. Most congenital anomalies of the aorta do not cause symptoms and are detected during catheter-based procedures. The diagnosis of suspected congenital anomalies of the aorta typically is confirmed by computed tomographic (CT) or magnetic resonance (MR) angiography. Surgery is used to treat symptomatic anomalies.

Coarctation of the aorta **(Chap. 280)** typically occurs near the insertion of the ligamentum arteriosum, adjacent to the left subclavian artery. It may be associated with a bicuspid aortic valve, aortic arch hypoplasia, other congenital heart defects, and intracranial aneurysms. A pulse delay or pressure differential between the upper and lower extremities should raise suspicion of aortic coarctation. Imaging modalities, including echocardiography, CT, and MR angiography are used to confirm the diagnosis. If untreated, hypertension develops in the arteries proximal to the coarctation. Treatment of hemodynamically significant aortic coarctation includes endovascular stent implantation if feasible or surgical repair.

AORTIC ANEURYSM

An *aneurysm* is defined as a pathologic dilation of a segment of a blood vessel. A *true aneurysm* involves all three layers of the vessel wall and is distinguished from a *pseudoaneurysm*, in which the intimal and medial layers are disrupted and the dilated segment of the aorta is lined by adventitia only and, at times, by perivascular clot. Aneurysms also may be classified according to their gross appearance. A *fusiform aneurysm* affects the entire circumference of a segment of the vessel, resulting in a diffusely dilated artery. In contrast, a *saccular aneurysm* involves only a portion of the circumference, resulting in an outpouching of the vessel wall. Aortic aneurysms also are classified according to location, i.e., abdominal versus thoracic. Aneurysms of the descending thoracic aorta are usually contiguous with infradiaphragmatic aneurysms and are referred to as *thoracoabdominal aortic aneurysms*.

ETIOLOGY

Aortic aneurysms result from conditions that cause degradation or abnormal production of the structural components of the aortic wall: elastin and collagen. The causes of aortic aneurysms may be broadly categorized as degenerative or sporadic, heritable, congenital, aortitis, infective, and trauma **(Table 291-1)**. Inflammation, oxidative stress, proteolysis, and biomechanical wall stress contribute to the degenerative processes that characterize most aneurysms of the abdominal and descending thoracic aorta. These are mediated by B-cell and T-cell lymphocytes, macrophages, inflammatory cytokines, and matrix metalloproteinases that degrade elastin and collagen and alter the tensile strength and ability of the aorta to accommodate pulsatile stretch. The associated histopathology demonstrates destruction of elastin and collagen, decreased vascular smooth muscle, in-growth of new blood vessels, and inflammation. Factors associated with degenerative aortic aneurysms include aging, cigarette smoking, hypercholesterolemia, hypertension, and male sex.

The most common pathologic condition associated with degenerative aortic aneurysms is *atherosclerosis*. Many patients with aortic aneurysms have coexisting risk factors for atherosclerosis, as well as atherosclerosis in other blood vessels.

The pathologic condition of aortic aneurysms associated with genetic or developmental diseases is medial degeneration, a histopathologic term used to describe the degeneration of collagen and elastic fibers in the tunica media of the aorta as well as the loss of medial cells that are replaced by multiple clefts of mucoid material, such as proteoglycans. Medial degeneration characteristically affects the proximal aorta, results in circumferential weakness and dilation, and leads to the development of fusiform aneurysms involving the ascending aorta and the sinuses of Valsalva. It is found in patients with Marfan syndrome, Loeys-Dietz syndrome, vascular Ehlers-Danlos syndrome **(Chap. 425)**, hypertension, bicuspid aortic valves, Turner syndrome, and familial thoracic aortic aneurysm syndromes. It sometimes appears as an isolated condition in patients without any other apparent disease. Thoracic and abdominal aortic aneurysms also occur in patients with fibromuscular dysplasia, although the nature of the aortic pathology is not established.

TABLE 291-1 Diseases of the Aorta: Etiology and Associated Factors

- Aortic aneurysm
  - Degenerative/sporadic
    - Aging
    - Cigarette smoking
    - Hypercholesterolemia
    - Hypertension
    - Atherosclerosis
  - Heritable
    - Marfan syndrome
    - Loeys-Dietz syndrome
    - Ehlers-Danlos syndrome type IV
    - Aneurysm-osteoarthritis syndrome
    - Smooth muscle dysfunction syndrome
    - Familial (nonsyndromic)
  - Congenital
    - Bicuspid aortic valve
    - Turner syndrome
    - Aortic coarctation
  - Fibromuscular dysplasia
  - Chronic aortic dissection
  - Aortitis (see below)
  - Infective (see below)
  - Trauma
- Acute aortic syndromes (aortic dissection, acute intramural hematoma, penetrating atherosclerotic ulcer)
  - Degenerative disorders (see above)
  - Heritable/disorders (see above)
  - Congenital disorders (see above)
  - Hypertension
  - Aortitis (see below)
  - Pregnancy
  - Trauma
- Aortic occlusion
  - Atherosclerosis
  - Thromboembolism
- Aortitis
  - Vasculitis
    - Takayasu's arteritis
    - Giant cell arteritis
    - IgG4-related aortitis
    - Isolated aortitis
  - Rheumatic
    - Rheumatoid aortitis
    - HLA-B27–associated spondyloarthropathies
    - Behçet syndrome
    - Cogan syndrome
  - Infective
    - Syphilis
    - Tuberculosis
    - Mycotic (*Salmonella*, staphylococcal, streptococcal, fungal)

Familial clusterings of aortic aneurysms occur in 20% of patients, suggesting a hereditary basis for the disease. Mutations of the gene that encodes fibrillin-1 are present in patients with Marfan syndrome. Fibrillin-1 is an important component of extracellular microfibrils, which support the architecture of elastic fibers and other connective tissue. Deficiency of fibrillin-1 in the extracellular matrix leads to excessive signaling by transforming growth factor β (TGF-β). Loeys-Dietz syndrome is caused by mutations in the genes that encode TGF-β isoforms (*TGFB2* and *TGFB3*), TGF-β receptors 1 (*TGFBR1*) and 2 (*TGFBR2*), and SMAD3, which encodes a downstream signaling protein involved with TGF binding to its receptors. Increased signaling by TGF-β and mutations of *TGFBR1*, *TGFBR2*, as well as *TGFB2* and *TGFB3*, may cause thoracic aortic aneurysms. Thoracic aortic aneurysm is associated with autosomal dominant polycystic kidney disease, which is caused by mutations in *PKD1*. Mutations of the genes encoding the smooth muscle–specific alpha-actin (*ACTA2*), smooth muscle cell–specific myosin heavy chain 11 (*MYH11*), myosin light chain kinase (*MYLK*), and type I cGMP-dependent protein kinase (*PRKG1*), as well as mutations of *TGFBR2* and *SMAD3* and several other pathogenic variants, have been reported in some patients with nonsyndromic familial thoracic aortic aneurysms. Mutations in type III procollagen (*COL3A1*) have been implicated in vascular Ehlers-Danlos syndrome.

The infectious causes of aortic aneurysms include syphilis, tuberculosis, and other bacterial infections. *Syphilis* **(Chap. 187)** is a relatively uncommon cause of aortic aneurysm. Syphilitic periaortitis and mesoaortitis damage elastic fibers, resulting in thickening and weakening of the aortic wall. Approximately 90% of syphilitic aneurysms are located in the ascending aorta or aortic arch. *Tuberculous aneurysms* **(Chap. 183)** typically affect the thoracic aorta and result from direct extension of infection from hilar lymph nodes or contiguous abscesses as well as from bacterial seeding. Loss of aortic wall elasticity results from granulomatous destruction of the medial layer. A *mycotic aneurysm* is a rare condition that develops as a result of staphylococcal, streptococcal, *Salmonella*, or other bacterial or fungal infections of the aorta, usually at an atherosclerotic plaque. These aneurysms are usually saccular. Blood cultures are often positive and reveal the nature of the infective agent.

Vasculitides associated with aortic aneurysm include Takayasu arteritis and giant cell arteritis, which may cause aneurysms of the aortic arch and descending thoracic aorta. Thoracic and abdominal aortic aneurysms also occur in patients with IgG4-related systemic disease or those with isolated aortitis. Spondyloarthropathies such as ankylosing spondylitis, rheumatoid arthritis, psoriatic arthritis, relapsing polychondritis, and reactive arthritis are associated with dilation of the ascending aorta. Aortic aneurysms also occur in patients with Behçet syndrome **(Chap. 376)** and Cogan syndrome. *Traumatic aneurysms* may occur after penetrating or nonpenetrating chest trauma and most commonly affect the descending thoracic aorta just beyond the site of insertion of the ligamentum arteriosum. Chronic aortic dissections are associated with weakening of the aortic wall that may lead to the development of aneurysmal dilatation.

THORACIC AORTIC ANEURYSMS

A contemporary definition of an aneurysm affecting the aortic root and ascending aorta is that of the diameter ≥4.5 cm, whereas a diameter of 4.0 cm to 4.4 cm is defined as aortic dilation. An aneurysm of the descending thoracic aorta and abdominal aorta is designated when their diameters are dilated 50% more than the adjacent normal diameter. The clinical manifestations and natural history of thoracic aortic aneurysms depend on their cause and location. Medial degeneration is the most common pathology associated with ascending aortic aneurysms, whereas atherosclerosis is the condition most frequently associated with aneurysms of the descending thoracic aorta. The average growth rate of thoracic aortic aneurysms is 0.1–0.2 cm per year. The risk of rupture is related to the size of the aneurysm and the presence of symptoms, ranging approximately from 2–3% per year for thoracic aortic aneurysms <4.0 cm in diameter to 7% per year for those >6 cm in diameter. Thoracic aortic aneurysms associated with Marfan syndrome may expand at a greater rate. Some patients with Loeys-Dietz syndrome, such as those with the *TGFBR1* and *TGFBR2* pathogenic variants and some with nonsyndromic familial thoracic aortic disease, are at greater risk of rupture at smaller aortic root sizes than those with Marfan syndrome. Most thoracic aortic aneurysms are asymptomatic; however, compression or erosion of adjacent tissue by aneurysms may cause symptoms such as chest pain, shortness of breath, cough, hoarseness, and dysphagia. Aneurysmal dilation of the ascending aorta may cause congestive heart failure as a consequence of aortic regurgitation,

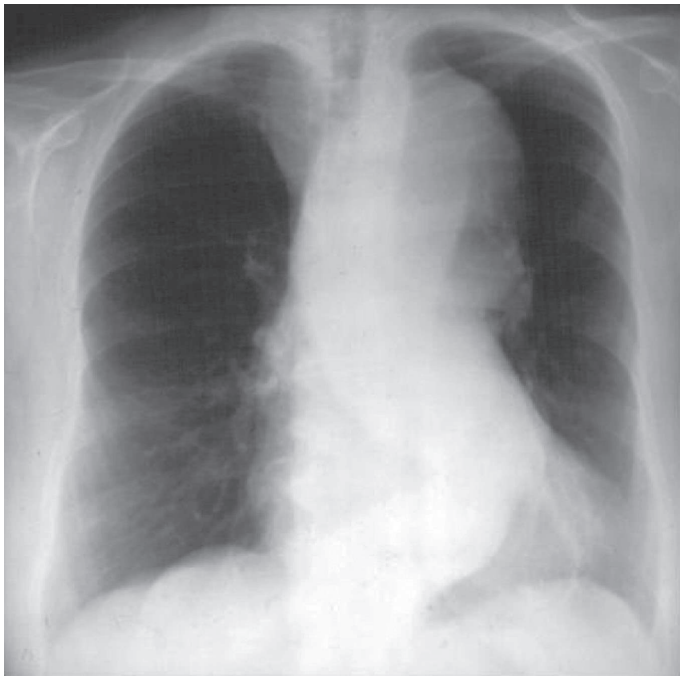

FIGURE 291-1 A chest x-ray of a patient with a thoracic aortic aneurysm.

and compression of the superior vena cava may produce congestion of the head, neck, and upper extremities.

A chest x-ray may be the first test that suggests the diagnosis of a thoracic aortic aneurysm **(Fig. 291-1)**. Findings include widening of the mediastinal shadow and displacement or compression of the trachea or left main stem bronchus. Echocardiography, particularly transesophageal echocardiography, can be used to assess the proximal ascending aorta and descending thoracic aorta. Contrast-enhanced CT, magnetic resonance imaging (MRI), and conventional invasive aortography are sensitive and specific tests for assessment of aneurysms of the thoracic aorta and involvement of branch vessels **(Fig. 291-2)**. In asymptomatic patients whose aneurysms are too small to justify surgery, noninvasive testing with either contrast-enhanced CT or MRI should be performed initially at least every 6–12 months to monitor expansion. Subsequent surveillance imaging should be performed every 6–24 months depending on the size, stability of prior measurements, and the underlying cause.

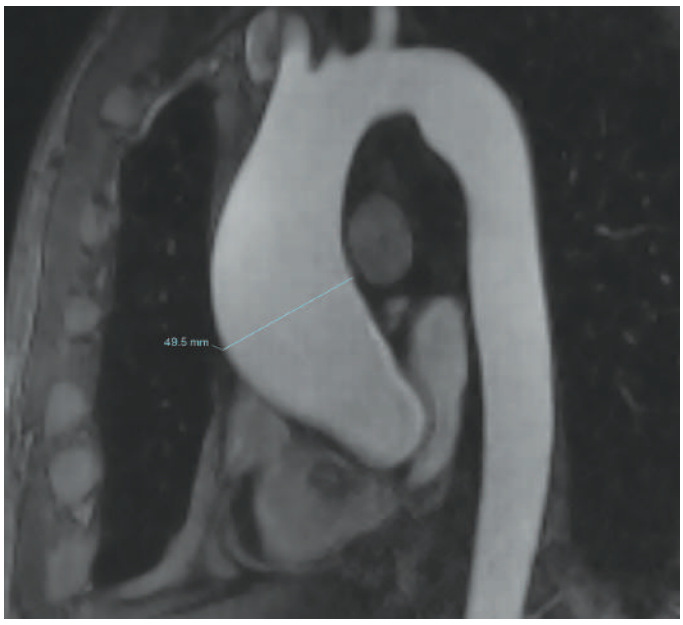

FIGURE 291-2 A magnetic resonance angiogram demonstrating a fusiform aneurysm of the ascending thoracic aorta. *(Courtesy of Dr. Michael Steigner, Brigham and Women's Hospital, Boston, MA, with permission.)*

Genetic testing is recommended in patients with ascending thoracic aortic disease who have features of Marfan syndrome, Loeys-Dietz syndrome, or vascular Ehlers-Danlos syndrome, or who present when they are <60 years of age.

TREATMENT

Thoracic Aortic Aneurysms

Many of the treatment recommendations herein are derived from the recent American Heart Association (AHA)/American College of Cardiology (ACC) Aortic Disease Clinical Practice Guidelines. Treatment with either a β-adrenergic blocker or angiotensin receptor antagonist currently is recommended for patients with thoracic aortic aneurysms associated with Marfan syndrome and Loeys-Dietz syndrome who have evidence of aortic root dilatation to reduce the rate of further expansion. Clinical outcome trials have found that the rate of aortic root enlargement in patients with Marfan syndrome was similar with a β-adrenergic blocker, such as atenolol, and an angiotensin receptor antagonist, such as losartan. These classes of drugs likely confer beneficial effects by different mechanisms. β-adrenergic blockers may decrease the rate of aortic dilation in these patients by reducing stiffness, and angiotensin receptor antagonists may reduce the rate of aortic dilation by blocking TGF-β signaling. Combination therapy with both a β-adrenergic blocker and angiotensin receptor antagonist may be considered. In patients with Ehlers-Danlos syndrome, celiprolol, a β-adrenergic blocker with vasodilator properties, has shown efficacy, but is not available in the United States. For these and other patients with thoracic aortic aneurysms, additional medical therapy should be given as necessary to control hypertension. Risk factor modification with lipid-lowering therapy, smoking cessation interventions, as well as low-dose aspirin, is advised for patients with degenerative thoracic aortic aneurysms associated with atherosclerosis. Operative repair with placement of a prosthetic graft is indicated in patients with symptomatic ascending thoracic aortic aneurysms, and for most asymptomatic aneurysms, including those associated with bicuspid aortic valves, when the aortic root or ascending aortic diameter is ≥5.0 to ≥5.5 cm. The lower threshold applies to patients with high-risk features, such as a family history of aortic dissection or an aortic growth rate ≥0.3 cm per year for 2 years or when the growth rate is >0.5 cm per year, and when performed under the direction of an experienced multidisciplinary aortic team. Replacement of the ascending aorta ≥4.5 cm is reasonable in patients with bicuspid aortic valves undergoing aortic valve replacement because of severe aortic stenosis or aortic regurgitation. In patients with Marfan syndrome, aortic root and ascending thoracic aortic aneurysms of ≥4.5 to ≥5.0 cm should be considered for surgery, with the threshold also depending on the presence of high-risk features. Due to the higher risk of dissection at smaller aortic sizes in patients with Loeys-Dietz syndrome and those with nonsyndromic familial thoracic aortic aneurysms, the aortic diameter threshold for operative repair ranges from ≥4.0 to ≥5.0 cm, depending on the genetic variant and presence of high-risk features. Repair is indicated for patients with isolated aortic arch aneurysms and descending thoracic aortic aneurysms when the diameter is ≥5.5 cm. The threshold for repair of a descending thoracic aortic aneurysm of ≥5.0 cm may be considered in patients with syndromic and nonsyndromic heritable aortopathies or when the diameter of a descending thoracic aortic aneurysm has increased >0.5 cm per year.

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms occur more frequently in males than in females, and the incidence increases with age. Cigarette smoking is a potent modifiable risk factor. Abdominal aortic aneurysms ≥4.0 cm may affect 1–2% of men aged >50 years. At least 90% of all abdominal aortic aneurysms >4.0 cm are related to atherosclerotic disease, and most of these aneurysms are below the level of the renal arteries.

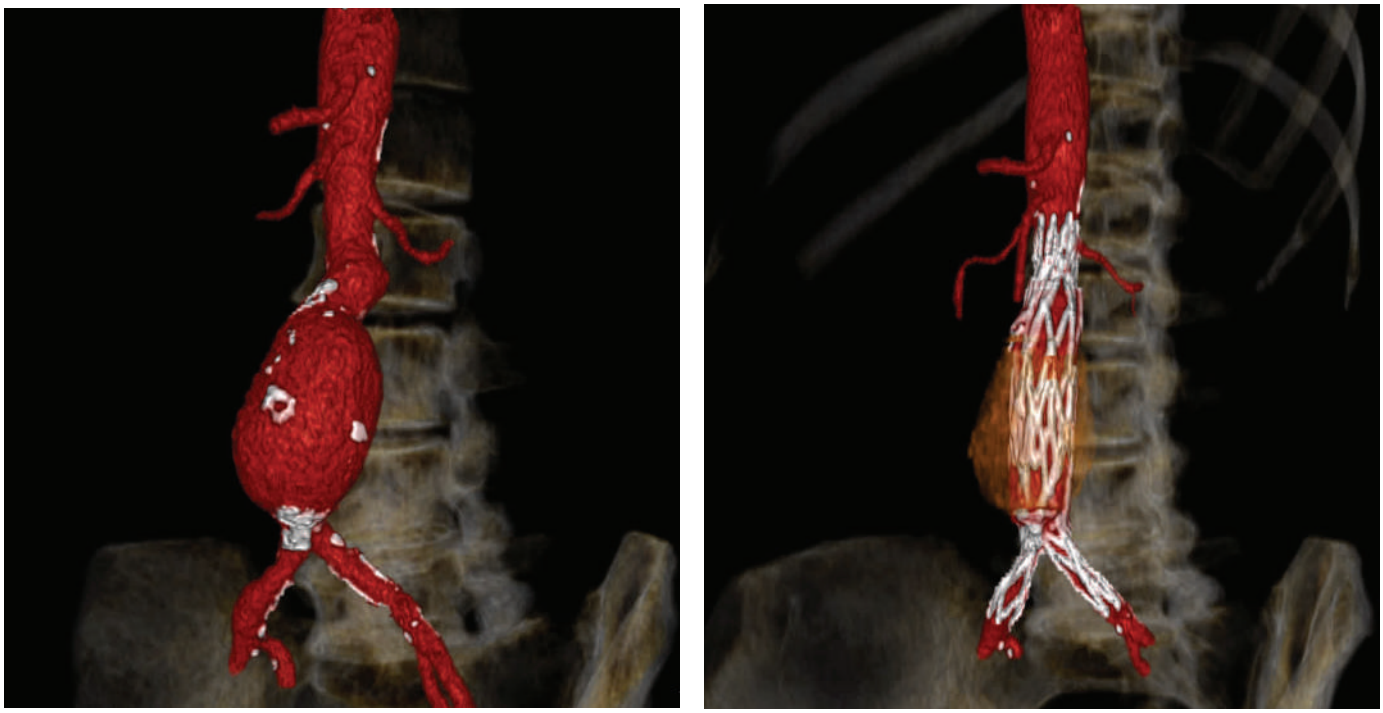

FIGURE 291-3 A computed tomographic angiogram depicting a fusiform abdominal aortic aneurysm before (***A***) and after (***B***) treatment with a bifurcated stent graft. *(Courtesy of Drs. Elizabeth George and Frank Rybicki, Brigham and Women's Hospital, Boston, MA, with permission.)*

Prognosis is related to both the size of the aneurysm and the severity of coexisting coronary artery and cerebrovascular disease. The risk of rupture increases with the size of the aneurysm: the 5-year risk for aneurysms <5 cm is 1–2%, whereas it is 20–40% for aneurysms >5 cm in diameter. The formation of mural thrombi within aneurysms may predispose to peripheral embolization.

An abdominal aortic aneurysm commonly produces no symptoms. It usually is detected on routine examination as a palpable, pulsatile, expansile, and nontender mass, or it is an incidental finding observed on an abdominal imaging study performed for other reasons. As abdominal aortic aneurysms expand, however, they may become painful. Some patients complain of strong pulsations in the abdomen; others experience pain in the chest, lower back, or scrotum. Aneurysmal pain is usually a harbinger of rupture and represents a medical emergency. More often, acute rupture occurs without any prior warning, and this complication is always life-threatening. Rarely, there is leakage of the aneurysm with severe pain and tenderness. Acute pain and hypotension occur with rupture of the aneurysm, which requires an emergency operation or endovascular repair.

Abdominal radiography may demonstrate the calcified outline of the aneurysm; however, ~25% of aneurysms are not calcified and cannot be visualized by x-ray imaging. An abdominal ultrasound can delineate the transverse and longitudinal dimensions of an abdominal aortic aneurysm and may detect mural thrombus. Abdominal ultrasound is useful for serial documentation of aneurysm size and can be used to screen patients at risk for developing an aortic aneurysm. In a large study, ultrasound screening of men aged 65–74 years was associated with a risk reduction in aneurysm-related death of 42%. In a meta-analysis of population-based randomized clinical trials, ultrasound screening of men aged 65 years or older was associated with a 35% risk reduction in aneurysm-related death over 12–15 years. According to the AHA/ACC Guidelines on Aortic Disease, screening by ultrasonography is recommended for men aged ≥65 years who have ever smoked. Although the prevalence of abdominal aortic aneurysms is less in women than in men, the risk of abdominal aortic aneurysms is still substantially increased in women who have smoked. Accordingly, it is reasonable to consider abdominal aortic aneurysm screening in women aged ≥65 years who have ever smoked. In addition, screening for abdominal aortic aneurysms is recommended for males and females ≥65 years who have siblings or offspring with abdominal aortic aneurysms. Individuals with thoracic aortic or peripheral arterial aneurysms should also undergo screening for abdominal aortic aneurysms. CT with contrast and MRI are accurate noninvasive tests to determine the location and size of abdominal aortic aneurysms and to plan endovascular or open surgical repair **(Fig. 291-3*A*)**. Contrast aortography may be used for the evaluation of patients with aneurysms, but the procedure carries a small risk of complications such as bleeding, allergic reactions, and atheroembolism. Since the presence of mural thrombi may reduce the luminal size, aortography may underestimate the diameter of an aneurysm.

TREATMENT

Abdominal Aortic Aneurysms

Many of the treatment recommendations for abdominal aortic aneurysms are derived from the AHA/ACC Aortic Disease Practice Guidelines. Statins are indicated to reduce the risk of cardiovascular events related to atherosclerosis. Medical therapies, such as β-adrenergic blockers and renin-angiotensin inhibitors, have not proven effective in reducing the rate of aneurysm growth. Nonetheless, antihypertensive therapy to lower the blood pressure to <130/<80 mmHg is recommended to reduce the risk of adverse cardiovascular events. Similarly, antiplatelet agents, such as aspirin, are recommended in patients with abdominal aortic aneurysms to reduce the risk of adverse cardiovascular outcomes, but their effects on abdominal aortic aneurysm–specific outcomes are not established. Operative repair of the aneurysm with insertion of a prosthetic graft or endovascular placement of an aortic stent graft **(Fig. 291-3*B*)** is indicated for abdominal aortic aneurysms of any size that are expanding rapidly or are associated with symptoms. For asymptomatic aneurysms, abdominal aortic aneurysm repair is indicated if the diameter is ≥5.5 cm in men and ≥5.0 cm in women. In randomized trials of patients with abdominal aortic aneurysms <5.5 cm, there was no difference in the long-term (>8-year) mortality rate between those followed with ultrasound surveillance and those undergoing elective endovascular or surgical repair. The risk of rupture, however, was higher in woman than in men at smaller diameters. Thus, serial noninvasive follow-up of smaller aneurysms

(<5.5 cm in men and <5.0 cm in women) is an alternative to immediate repair. The decision to perform an open surgical operation or endovascular repair is based in part on the vascular anatomy and comorbid conditions. Endovascular repair of abdominal aortic aneurysms has a lower short-term morbidity rate but a comparable long-term mortality rate with open surgical reconstruction. Long-term surveillance with CT or MR aortography is indicated after endovascular repair to detect leaks and possible aneurysm expansion.

In surgical candidates, careful preoperative cardiac and general medical evaluations (followed by appropriate therapy for complicating conditions) are essential. Preexisting coronary artery disease, congestive heart failure, pulmonary disease, diabetes mellitus, and advanced age add to the risk of surgery. With careful preoperative cardiac evaluation and postoperative care, the operative mortality rate approximates 1–2%. After acute rupture, the mortality rate of emergent operation is 45–50%. Endovascular repair with stent placement is an alternative approach to treat ruptured aneurysms and may be associated with a lower mortality rate.

ACUTE AORTIC SYNDROMES

The four major acute aortic syndromes are aortic rupture (discussed earlier), aortic dissection, intramural hematoma, and penetrating atherosclerotic ulcer. Aortic dissection is caused by a tear of the intima. It often occurs along the right lateral wall of the ascending aorta where the hydraulic shear stress is high. Another common site is the descending thoracic aorta just below the ligamentum arteriosum. The initiating event is either a primary intimal tear with secondary dissection into the media or a medial hemorrhage that dissects into and disrupts the intima. The pulsatile aortic flow then dissects along the elastic lamellar plates of the aorta and creates a false lumen. The dissection usually propagates distally down the descending aorta and into its major branches, but it may propagate proximally. Distal propagation may be limited by atherosclerotic plaque. In some cases, a secondary distal intimal disruption occurs, resulting in the reentry of blood from the false to the true lumen.

There are at least two important pathologic and radiologic variants of aortic dissection: intramural hematoma without an intimal flap and penetrating atherosclerotic ulcer. Acute intramural hematoma is thought to result from rupture of the vasa vasorum with hemorrhage into the wall of the aorta. Most of these hematomas occur in the descending thoracic aorta. Acute intramural hematomas may progress to dissection and rupture. Penetrating atherosclerotic ulcers are caused by erosion of a plaque into the aortic media, are usually localized, but may evolve into an intramural hematoma and also progress to dissection and rupture. They are found primarily in the middle and distal portions of the descending thoracic aorta and are associated with extensive atherosclerotic disease. The ulcer can erode beyond the internal elastic lamina, leading to medial hematoma, and may progress to false aneurysm formation or rupture.

Several classification schemes have been developed for thoracic aortic dissections. DeBakey and colleagues initially classified aortic dissections as type I, in which an intimal tear occurs in the ascending aorta but the dissection may propagate to the aortic arch, the descending thoracic aorta, and even the abdominal aorta; type II, in which the dissection is limited to the ascending aorta; and type III, in which the intimal tear is located in the descending aorta with distal propagation of the dissection **(Fig. 291-4)**. Another classification (Stanford) is that of type A, in which the dissection involves the ascending aorta (proximal dissection), and type B, in which it is limited to the arch and/or descending aorta (distal dissection). From a management standpoint, classification of aortic dissections and intramural hematomas into type A or B is more practical and useful, since DeBakey types I and II are managed in a similar manner.

The factors that predispose to aortic dissection include those associated with medial degeneration and others that increase aortic wall stress (Table 291-1). Systemic hypertension is a coexisting condition in 70% of patients. Aortic dissection is the major cause of morbidity and

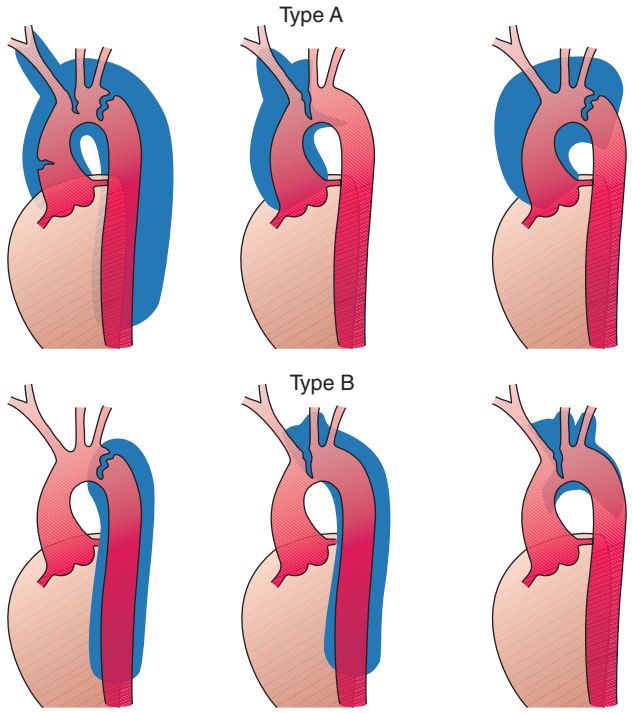

FIGURE 291-4 Classification of aortic dissections. Stanford classification: Type A dissections (*top*) involve the ascending aorta independent of site of tear and distal extension; type B dissections (*bottom*) involve transverse and/or descending aorta without involvement of the ascending aorta. DeBakey classification: Type I dissection involves ascending to descending aorta (*top left*); type II dissection is limited to ascending or transverse aorta, without descending aorta (*top center + top right*); type III dissection involves descending aorta only (*bottom left*). *(Reproduced with permission from DC Miller, in RM Doroghazi, EE Slater [eds]: Aortic Dissection. New York, McGraw-Hill, 1983.)*

mortality in patients with Marfan syndrome **(Chap. 425)** or Loeys-Dietz syndrome, and similarly may affect patients with Ehlers-Danlos syndrome. The incidence also is increased in patients with inflammatory aortitis (i.e., Takayasu's arteritis, giant cell arteritis), congenital aortic valve anomalies (e.g., bicuspid valve), coarctation of the aorta, and a history of aortic trauma. In addition, the risk of dissection is increased in otherwise normal women during the third trimester of pregnancy. Aortic dissection also may occur as a consequence of weightlifting, cocaine use, or deceleration injury.

CLINICAL MANIFESTATIONS

The peak incidence of aortic dissection is in the sixth and seventh decades. Men are more affected than women by a ratio of 2:1. The presentations of aortic dissection and its variants are the consequences of intimal tear, dissecting hematoma, occlusion of involved arteries, and compression of adjacent tissues. Acute aortic dissection presents with the sudden onset of pain **(Chap. 15)**, which often is described as very severe and tearing and is associated with diaphoresis. The pain may be localized to the front or back of the chest, often the interscapular region, and typically migrates with propagation of the dissection. Other symptoms include syncope, dyspnea, and weakness. Physical findings may include hypertension or hypotension, loss of pulses, aortic regurgitation, pulmonary edema, and neurologic findings due to carotid artery obstruction (hemiplegia, hemianesthesia) or spinal cord ischemia (paraplegia). Bowel ischemia, hematuria, and myocardial ischemia all may occur. These clinical manifestations reflect complications resulting from the dissection occluding the major arteries. Furthermore, clinical manifestations may result from the compression of adjacent structures (e.g., superior cervical ganglia, superior vena cava, bronchus, esophagus) by the expanding dissection causing aneurysmal dilation and include Horner's syndrome, superior vena cava syndrome, hoarseness, dysphagia, and airway compromise. Hemopericardium and cardiac tamponade may complicate a type A lesion with retrograde dissection. Acute aortic regurgitation is an important and common (>50%) complication of proximal dissection. It is the outcome of either

a circumferential tear that widens the aortic root or a disruption of the annulus by a dissecting hematoma that tears a leaflet(s) or displaces it inferior to the line of closure. Signs of aortic regurgitation include bounding pulses, a wide pulse pressure, a diastolic murmur often radiating along the right sternal border, and evidence of congestive heart failure. The clinical manifestations depend on the severity of the regurgitation.

In dissections involving the ascending aorta, the chest x-ray often reveals a widened superior mediastinum. A pleural effusion (usually left-sided) also may be present. This effusion is typically serosanguineous and not indicative of rupture unless accompanied by hypotension and falling hematocrit. In dissections of the descending thoracic aorta, a widened mediastinum may be observed on chest x-ray. In addition, the descending aorta may appear to be wider than the ascending portion. An electrocardiogram that shows no evidence of myocardial ischemia is helpful in distinguishing aortic dissection from myocardial infarction among patients who present with chest pain. Rarely, the dissection involves the right or, less commonly, left coronary ostium and causes acute myocardial infarction.

The diagnosis of aortic dissection can be established by noninvasive techniques such as echocardiography, CT, and MRI. Aortography is used less commonly because of the accuracy of these noninvasive techniques. Transthoracic echocardiography can be performed simply and rapidly and has an overall sensitivity of 60–85% for aortic dissection. For diagnosing proximal ascending aortic dissections, its sensitivity exceeds 80%; it is less useful for detecting dissection of the arch and descending thoracic aorta. Transesophageal echocardiography requires greater skill and patient cooperation but is very accurate in identifying dissections of the ascending and descending thoracic aorta but not the arch, achieving 98% sensitivity and ~90% specificity. Echocardiography also provides important information regarding the presence and severity of aortic regurgitation and pericardial effusion. CT and MRI are both highly accurate in identifying the intimal flap and the extent of the dissection and involvement of major arteries; each has a sensitivity and specificity >90%. They are useful in recognizing intramural hemorrhage and penetrating ulcers. The relative utility of CT, MRI, and transesophageal echocardiography depends on the availability and expertise in individual institutions, although among these, CT is the imaging method most often used due to the presence of CT scanners near emergency rooms and the rapidity of performance.

TREATMENT

Aortic Dissection

Medical therapy should be initiated as soon as the diagnosis is considered. The patient should be admitted to an intensive care unit for hemodynamic monitoring. Unless hypotension is present, therapy should be aimed at reducing cardiac contractility and systemic arterial pressure, and thus shear stress. For acute dissection, unless contraindicated, β-adrenergic blockers should be administered parenterally, using intravenous propranolol, metoprolol, or the short-acting esmolol to achieve a heart rate of 60–80 beats/min. This should be accompanied by intravenous dilators, such as sodium nitroprusside, if needed to lower systolic blood pressure to ≤120 mmHg. Labetalol **(Chap. 288)**, a drug with both β- and α-adrenergic blocking properties, also may be used as a parenteral agent in acute therapy for dissection.

The calcium channel antagonists verapamil and diltiazem may be used intravenously if nitroprusside or β-adrenergic blockers cannot be employed. The addition of a parenteral angiotensin-converting enzyme (ACE) inhibitor such as enalaprilat to a β-adrenergic blocker also may be considered. Isolated use of a direct vasodilator such as hydralazine is contraindicated because these agents can increase hydraulic shear and heart rate and may propagate the dissection.

Emergent or urgent surgical correction is the preferred treatment for acute ascending aortic dissections and intramural hematomas (type A). Surgery involves excision of the intimal flap, obliteration of the false lumen, and placement of an interposition graft. Aortic valve repair or aortic root replacement with a composite valve-graft conduit is used if the aortic valve is disrupted. The overall in-hospital mortality rate after surgical treatment of patients with aortic dissection is reported to be 15–25%. The major causes of perioperative mortality and morbidity include myocardial infarction, paraplegia, renal failure, tamponade, hemorrhage, and sepsis. Thoracic endovascular aortic repair with an endoluminal stent graft is indicated for complicated type B dissections, including those characterized by propagation, compromise of major aortic branches, impending rupture, or continued pain. Other transcatheter techniques, such as fenestration of the intimal flaps and stenting of narrowed branch vessels to increase flow to compromised organs, are used in selected patients. Surgical correction is indicated for complicated type B dissections, particularly if endovascular repair is not feasible. Hybrid procedures consisting of both surgery and endovascular repair may be used when the dissection involves both the aortic arch and the descending thoracic aorta. For uncomplicated and stable distal dissections and intramural hematomas (type B), medical therapy is the preferred treatment. The in-hospital mortality rate of medically treated patients with type B dissection is ~12%. Long-term therapy for patients with aortic dissection and intramural hematomas (with or without surgery) consists of control of hypertension and reduction of cardiac contractility with the use of β-adrenergic blockers plus other antihypertensive agents, such as ACE inhibitors or calcium antagonists. Patients with chronic type B dissection and intramural hematomas should be followed on an outpatient basis initially at 1 month, 6 months, and 12 months, and then, if stable, every 12 months with contrast-enhanced CT or MRI to detect propagation or expansion. Patients with Marfan syndrome are at high risk for postdissection complications. The long-term prognosis following hospital discharge for patients with treated dissections is generally good with careful follow-up; the 10-year survival rate is ~60%.

CHRONIC ATHEROSCLEROTIC OCCLUSIVE DISEASE

Atherosclerosis may affect the thoracic and abdominal aorta. Occlusive aortic disease caused by atherosclerosis usually is confined to the distal abdominal aorta below the renal arteries. Frequently the disease extends to the iliac arteries **(Chap. 292)**. Claudication characteristically involves the buttocks, thighs, and calves and may be associated with impotence in males (Leriche syndrome). The severity of the symptoms depends on the adequacy of collaterals. With sufficient collateral blood flow, a complete occlusion of the abdominal aorta may occur without the development of ischemic symptoms. The physical findings include the absence of femoral and other distal pulses bilaterally and the detection of an audible bruit over the abdomen (usually at or below the umbilicus) and the common femoral arteries. Atrophic skin, loss of hair, and coolness of the lower extremities usually are observed. In advanced ischemia, rubor on dependency and pallor on elevation can be seen.

The diagnosis usually is established by physical examination and noninvasive testing, including leg pressure measurements, Doppler velocity analysis, pulse volume recordings, and duplex ultrasonography. The anatomy may be defined by MRI, CT, or conventional contrast angiography, typically performed when one is considering revascularization. Catheter-based endovascular or operative treatment is indicated in patients with lifestyle-limiting or debilitating symptoms of claudication and patients with chronic limb-threatening ischemia.

ACUTE AORTIC OCCLUSION

Acute occlusion in the distal abdominal aorta constitutes a medical emergency because it threatens the viability of the lower extremities; it usually results from an occlusive (saddle) embolus that almost always originates from the heart. Rarely, acute occlusion may occur as the result of in situ thrombosis in a preexisting severely narrowed segment of the aorta.

The clinical picture is one of acute ischemia of the lower extremities. Severe rest pain, coolness, and pallor of the lower extremities and the absence of distal pulses bilaterally are the usual manifestations.

Diagnosis should be established rapidly by MRI, CT, or aortography. Emergency thrombectomy or revascularization is indicated.

AORTITIS

Aortitis, a term referring to inflammatory disease of the aorta, may be caused by large vessel vasculitides such as Takayasu arteritis, giant cell arteritis, IgG4-related systemic disease, isolated aortitis, rheumatic and HLA-B27–associated spondyloarthropathies, Behçet syndrome, antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides, Cogan syndrome, Erdheim-Chester disease, and infections such as syphilis, tuberculosis, and *Salmonella*, or it may be associated with retroperitoneal fibrosis. Aortitis may result in aneurysmal dilation and aortic regurgitation, occlusion of the aorta and its branch vessels, or acute aortic syndromes.

TAKAYASU ARTERITIS

(See also Chap. 375) This inflammatory disease often affects the ascending aorta and aortic arch, causing obstruction of the aorta and its major arteries. Takayasu arteritis is also termed *pulseless disease* because of the frequent occlusion of the large arteries originating from the aorta. It also may involve the descending thoracic and abdominal aorta and occlude large branches such as the renal arteries. Aortic aneurysms also may occur. The pathology is a panarteritis characterized by mononuclear cells and occasionally giant cells, with marked intimal hyperplasia, medial and adventitial thickening, and, in the chronic form, fibrotic occlusion. The disease is most prevalent in young females of Asian descent but does occur in women of other geographic and ethnic origins and also in young men. During the acute stage, fever, malaise, weight loss, and other systemic symptoms may be evident. Elevations of the erythrocyte sedimentation rate and C-reactive protein are common. The chronic stages of the disease, which is intermittently active, present with symptoms related to large artery occlusion, such as upper extremity claudication, cerebral ischemia, and syncope. The process is progressive, and there is no definitive therapy. Glucocorticoids are effective in most patients during the acute phase. Other immunosuppressive agents, such as methotrexate, azathioprine, leflunomide, or mycophenolate, are prescribed to some patients to lower glucocorticoid requirements and treat relapses. Biologically targeted agents, such as the tumor necrosis factor (TNF) inhibitors etanercept and infliximab, are also used, but efficacy has not been established in randomized clinical trials. Surgical bypass or endovascular intervention of a critically stenotic artery may be necessary.

GIANT CELL ARTERITIS

(See also Chap. 375) This vasculitis occurs in older individuals and affects women more often than men. Primarily large and medium-size arteries are affected. The pathology is that of focal granulomatous lesions involving the entire arterial wall; it frequently is associated with polymyalgia rheumatica. Obstruction of medium-size arteries (e.g., temporal and ophthalmic arteries) and major branches of the aorta and the development of aortitis and aortic regurgitation are important complications of the disease. High-dose glucocorticoid therapy should be administered early and then gradually tapered. Immunosuppressive therapy with methotrexate may allow reduction in steroid dosage and reduce the risk of relapse. Tocilizumab, an interleukin-6 antagonist, demonstrated efficacy in several randomized trials. Other biologically targeted therapies are under investigation.

IGG4-RELATED AORTITIS

Aortitis may occur in patients with IgG4-related disease **(Chap. 380)** and is associated with retroperitoneal fibrosis and hydronephrosis. It can affect the thoracic and abdominal aorta, as well as the iliac arteries. Serum IgG4 levels may be elevated but are not diagnostic. Histopathologic characteristics include a lymphoplasmacytic infiltrate that comprises IgG4-positive plasma cells, fibrosis, and obliterative adventitial phlebitis; it affects men more than women and typically occurs in middle age. Glucocorticoids are used for initial treatment. Case series have reported efficacy with rituximab, an anti-CD20 monoclonal antibody. Immunosuppressive agents such as azathioprine are steroid sparing and may be effective.

ISOLATED AORTITIS

Isolated abdominal aortitis is characterized by adventitial and periaortic inflammation with thickening of the aortic wall; it is associated with abdominal aortic aneurysms and idiopathic retroperitoneal fibrosis. Affected individuals may present with vague constitutional symptoms, fever, and abdominal pain. Retroperitoneal fibrosis can cause ureteral obstruction and hydronephrosis. Glucocorticoids and immunosuppressive agents may reduce the inflammation.

RHEUMATIC AORTITIS

Rheumatoid arthritis **(Chap. 370)**, ankylosing spondylitis **(Chap. 374)**, psoriatic arthritis **(Chap. 374)**, reactive arthritis (formerly known as Reiter's syndrome) **(Chap. 374)**, relapsing polychondritis, and inflammatory bowel disorders may all be associated with aortitis involving the ascending aorta. The inflammatory lesions usually involve the ascending aorta and may extend to the sinuses of Valsalva, the mitral valve leaflets, and adjacent myocardium. The clinical manifestations are aneurysm, aortic regurgitation, and involvement of the cardiac conduction system.

INFECTIVE AORTITIS

Infective aortitis may result from direct invasion of the aortic wall by bacterial pathogens such as *Staphylococcus*, *Streptococcus*, and *Salmonella* or by fungi. These bacteria cause aortitis by infecting the aorta at sites of atherosclerotic plaque. Bacterial proteases lead to degradation of collagen, and the ensuing destruction of the aortic wall leads to the formation of a saccular aneurysm referred to as a mycotic aneurysm. Mycotic aneurysms have a predilection for the suprarenal abdominal aorta. The pathologic characteristics of the aortic wall include acute and chronic inflammation, abscesses, hemorrhage, and necrosis. Mycotic aneurysms typically affect the elderly and occur in men three times more frequently than in women. Patients may present with fever, sepsis, and chest, back, or abdominal pain; there may have been a preceding diarrheal illness. Blood cultures are positive in the majority of patients. Both CT and MRI are useful to diagnose mycotic aneurysms. Treatment includes antibiotic therapy and surgical removal of the affected part of the aorta and revascularization of the lower extremities with grafts placed in uninfected tissue.

Syphilitic aortitis is a late manifestation of luetic infection **(Chap. 187)** that usually affects the proximal ascending aorta, particularly the aortic root, resulting in aortic dilation and aneurysm formation. Syphilitic aortitis occasionally may involve the aortic arch or the descending aorta. The aneurysms may be saccular or fusiform and are usually asymptomatic, but compression of and erosion into adjacent structures may result in symptoms; rupture also may occur.

The initial lesion is an obliterative endarteritis of the vasa vasorum, especially in the adventitia. This is an inflammatory response to the invasion of the adventitia by the spirochetes. Destruction of the aortic media occurs as the spirochetes spread into this layer, usually via the lymphatics accompanying the vasa vasorum. Destruction of collagen and elastic tissues leads to dilation of the aorta, scar formation, and calcification. These changes account for the characteristic radiographic appearance of linear calcification of the ascending aorta.

The disease typically presents as an incidental chest radiographic finding 15–30 years after initial infection. Symptoms may result from aortic regurgitation, narrowing of coronary ostia due to syphilitic aortitis, compression of adjacent structures (e.g., esophagus), or rupture. Diagnosis is established by a positive serologic test, such as rapid plasmin regain (RPR), Venereal Disease Research Laboratory (VDRL), or fluorescent treponemal antibody absorption (FTA-ABS). Treatment includes penicillin and surgical excision and repair.

292 Arterial Diseases of the Extremities

Mark A. Creager, Joseph Loscalzo

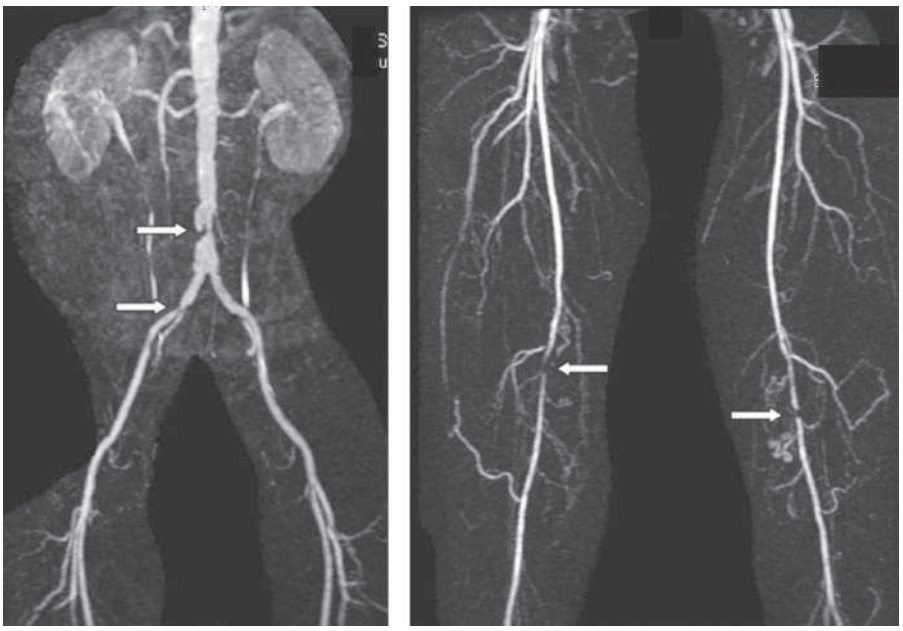
PERIPHERAL ARTERY DISEASE

Peripheral artery disease (PAD) is defined as a clinical disorder in which there is a stenosis or occlusion in the aorta or the arteries of the limbs. Atherosclerosis is the leading cause of PAD in patients >40 years old. Other causes include thrombosis, embolism, vasculitis, fibromuscular dysplasia, entrapment, cystic adventitial disease, and trauma. The highest prevalence of atherosclerotic PAD occurs in the sixth and seventh decades of life. Prevalence of PAD is similar in men and women, is greater in persons identified as black than non-Hispanic white, and is associated with lower socioeconomic status. As in patients with atherosclerosis of the coronary and cerebral vasculature, there is an increased risk of developing PAD in cigarette smokers and in persons with diabetes mellitus, hypercholesterolemia, elevated lipoprotein(a), hypertension, or renal insufficiency.

Pathology Segmental lesions that cause stenosis or occlusion are usually localized to large and medium-size vessels. The pathology of the lesions includes atherosclerotic plaques with calcium deposition, thinning of the media, patchy destruction of muscle and elastic fibers, fragmentation of the internal elastic lamina, and thrombi composed of platelets and fibrin. The primary sites of involvement are the abdominal aorta and iliac arteries (30% of symptomatic patients), the femoral and popliteal arteries (80–90% of patients), and the more distal vessels, including the tibial and peroneal arteries (40–50% of patients). Atherosclerotic lesions occur preferentially at arterial branch points, which are sites of increased turbulence, altered shear stress, and intimal injury. Involvement of the distal vasculature is most common in elderly individuals and patients with diabetes mellitus.

Clinical Evaluation Fewer than 50% of patients with PAD are symptomatic, although many have a slow or impaired gait. The most typical *symptom* is intermittent claudication, which is defined as a pain, ache, cramp, numbness, or a sense of fatigue in the muscles; it occurs during exercise and is relieved by rest. The site of claudication is distal to the location of the occlusive lesion. For example, buttock, hip, thigh, and calf discomfort occurs in patients with aortoiliac disease, whereas calf claudication develops in patients with femoral-popliteal disease. Symptoms are far more common in the lower than in the upper extremities because of the higher incidence of obstructive lesions in the former region. In patients with severe arterial occlusive disease in whom resting blood flow cannot accommodate basal nutritional needs of the tissues, chronic limb-threatening ischemia may develop. Patients complain of rest pain or a feeling of cold or numbness in the foot and toes. Frequently, these symptoms occur at night when the legs are horizontal and improve when the legs are in a dependent position. With severe ischemia, rest pain may be persistent.

A comprehensive vascular examination includes palpation of the peripheral pulses, including the femoral, popliteal, dorsalis pedis, and posterior tibial arteries; auscultation of the abdomen and groin for bruits; and inspection of the legs and feet. Important *physical findings* of PAD include decreased or absent pulses distal to the obstruction, the presence of bruits over the narrowed artery, and muscle atrophy. With more severe disease, hair loss, thickened nails, smooth and shiny skin, reduced skin temperature, and pallor or cyanosis are common physical signs. In patients with chronic limb-threatening ischemia, ulcers or gangrene may occur. Elevation of the legs and repeated flexing of the calf muscles produce pallor of the soles of the feet, whereas rubor, secondary to reactive hyperemia, may develop when the legs are dependent. The time required for rubor to develop or for the veins in the foot to fill when the patient's legs are transferred from an elevated to a dependent position is related to the severity of the ischemia and the presence of collateral vessels. Patients with severe ischemia may develop peripheral edema because they keep their legs in a dependent position much of the time. Ischemic neuropathy can result in numbness and hyporeflexia.



Noninvasive Testing The history and physical examination are often sufficient to establish the diagnosis of PAD. An objective assessment of the presence and severity of disease is obtained by noninvasive techniques. Arterial pressure can be recorded noninvasively in the legs by placement of sphygmomanometric cuffs at the ankles and the use of a Doppler device to auscultate or record blood flow from the dorsalis pedis and posterior tibial arteries. Normally, systolic blood pressure in the legs and arms is similar. Indeed, ankle pressure may be slightly higher than arm pressure due to pulse-wave amplification. In the presence of hemodynamically significant stenoses, the systolic blood pressure in the leg is decreased. Thus, the ratio of the ankle and brachial artery systolic pressures (termed the *ankle-brachial index*, or ABI) is 1.00–1.40 in normal individuals. ABI values of 0.91–0.99 are considered "borderline," and those ≤0.90 are abnormal and diagnostic of PAD. ABIs >1.40 indicate noncompressible arteries secondary to vascular calcification, as may occur in patients with diabetes mellitus or chronic kidney disease. When an ABI cannot be accurately assessed due to vascular calcification, the presence of PAD can be detected by measuring the systolic pressure of the great toe and calculating *a toe-brachial index* (TBI). A TBI of ≤0.70 is considered abnormal.

Other noninvasive tests include segmental pressure measurements, segmental pulse volume recordings, duplex ultrasonography (which combines B-mode imaging and Doppler flow velocity waveform analysis), transcutaneous oximetry, and stress testing (usually using a treadmill). Placement of pneumatic cuffs enables assessment of systolic pressure along the legs. The presence of pressure gradients between sequential cuffs provides evidence of the presence and location of hemodynamically significant stenoses. In addition, the amplitude of the pulse volume contour becomes blunted in the presence of significant PAD. Duplex ultrasonography is used to image and detect stenotic lesions in native arteries and bypass grafts.

Treadmill testing allows the physician to assess functional limitations objectively. Decline of the ABI immediately after exercise provides further support for the diagnosis of PAD in patients with equivocal symptoms and findings on examination.

Magnetic resonance angiography (MRA), computed tomographic angiography (CTA), and conventional catheter-based angiography should not be used for routine diagnostic testing, but are performed before potential revascularization **(Fig. 292-1)**. Each test is useful in defining the anatomy to assist planning for endovascular and surgical revascularization procedures.

Prognosis The natural history of patients with PAD is influenced primarily by the extent of coexisting coronary artery and cerebrovascular disease. Approximately one-third to one-half of patients with symptomatic PAD have evidence of coronary artery disease (CAD) based on clinical presentation and electrocardiogram, and over one-half have

A B

FIGURE 292-1 Magnetic resonance angiography of a patient with intermittent claudication, showing stenoses of the distal abdominal aorta and right common iliac artery (***A***) and stenoses of the right and left superficial femoral arteries (***B***). *(Courtesy of Dr. Edwin Gravereaux, with permission.)*

significant CAD by coronary angiography. Patients with PAD have a 15–25% 5-year mortality rate and a two- to fourfold increased risk of death from cardiovascular disease. Measurement of ABI is useful for detecting PAD and identifying persons at risk for adverse cardiovascular and limb events. Mortality rates are highest in those with the most severe PAD. The ABI worsens in almost 40% of patients, and symptoms progress in ~20–25% when assessed over a period of 5 years. Approximately 11% of patients with symptomatic PAD ultimately develop chronic limb-threatening ischemia, and without revascularization, approximately 25% of patients with chronic limb-threatening ischemia undergo amputation within 1 year. The prognosis is worse in patients who continue to smoke cigarettes or have diabetes mellitus.

TREATMENT

Peripheral Artery Disease

Patients with PAD should receive therapies to reduce the risk of associated cardiovascular events, such as myocardial infarction and death, and to improve limb symptoms, prevent progression to chronic limb-threatening ischemia, and preserve limb viability. Risk factor modification and antithrombotic therapy should be initiated to improve cardiovascular outcomes. The importance of discontinuing cigarette smoking cannot be overemphasized. The physician must assume a major role in this lifestyle modification. Counseling and adjunctive drug therapy with the nicotine patch, bupropion, or varenicline increase smoking cessation rates and reduce recidivism. It is important to control blood pressure in hypertensive patients. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may reduce the risk of cardiovascular events in patients with symptomatic PAD. β-Adrenergic blockers do not worsen claudication and may be used to treat hypertension, especially in patients with coexistent CAD. Treatment of hypercholesterolemia with statins and, if needed, adjunctive lipid-lowering agents such as ezetimibe or a PCSK9 inhibitor, are advocated to reduce the risk of myocardial infarction, stroke, and death. Statins and PCSK9 inhibitors also are associated with a decreased risk of adverse limb events, including amputation, in patients with PAD. The 2018 American Heart Association (AHA)/American College of Cardiology (ACC) Guideline on the Management of Blood Cholesterol recommends high-intensity statin treatment in patients with atherosclerotic disorders, including PAD, with the aim of achieving a 50% or greater reduction in low-density lipoprotein cholesterol. Intensive glucose lowering reduces the risk of amputations in patients with diabetes mellitus. Among patients with diabetes and established cardiovascular disease, including PAD, the glucagon-like protein (GLP)-1 agonists and the sodium-glucose cotransporter 2 (SGLT2) inhibitors have beneficial cardiovascular effects. GLP-1 agonists also may reduce the risk of amputation. Platelet inhibitors, including aspirin and the adenosine diphosphate (ADP) antagonist clopidogrel, reduce the risk of adverse cardiovascular events in patients with atherosclerosis and are recommended for patients with symptomatic PAD, including those with intermittent claudication or chronic limb-threatening ischemia or prior lower extremity revascularization. Outcomes with ticagrelor are similar to those with clopidogrel. The benefit of dual antiplatelet therapy with both aspirin and clopidogrel compared with aspirin alone in reducing cardiovascular morbidity and mortality rates in patients with PAD is uncertain. When added to other antiplatelet therapy, vorapaxar, a protease-activated receptor-1 antagonist that inhibits thrombin-mediated platelet activation, decreases the risk of adverse cardiovascular events in patients with atherosclerosis, including PAD. It also reduces the risk of acute limb ischemia and peripheral revascularization; however, it is associated with an increased rate of moderate bleeding. The anticoagulant warfarin is as effective as antiplatelet therapy in preventing adverse cardiovascular events but causes more major bleeding; therefore, it is not indicated to improve outcomes in patients with chronic PAD. The combination of a low dose of the oral factor Xa inhibitor rivaroxaban and aspirin improves cardiovascular and limb outcomes in patients with atherosclerosis, including those with established PAD, as well as those who have undergone peripheral revascularization, but is associated with increased risk of bleeding.

Therapies for intermittent claudication and chronic limb-threatening ischemia include supportive measures, medications, exercise training, endovascular interventions, and surgery. Supportive measures include meticulous care of the feet, which should be kept clean and protected against excessive drying with moisturizing creams. Well-fitting and protective shoes are advised to reduce trauma. Elastic support hose should be avoided, as it reduces blood flow to the skin. In patients with chronic limb-threatening ischemia, shock blocks under the head of the bed together with a canopy over the feet may improve perfusion pressure and ameliorate some of the rest pain.

Patients with claudication should be encouraged to exercise regularly and at progressively more strenuous levels. Supervised exercise

training programs for 30- to 45-min sessions, at least three times per week for 12 weeks, prolong walking distance. The beneficial effect of supervised exercise training on walking performance in patients with claudication often is similar to or greater than that realized after a revascularization procedure. Structured home and community-based exercise programs are also effective. Pharmacologic treatment of PAD has not been as successful as the medical treatment of CAD **(Chap. 284)**. In particular, vasodilators as a class have not proved to be beneficial. During exercise, peripheral vasodilation occurs distal to sites of significant arterial stenoses. As a result, perfusion pressure falls, often to levels lower than those generated in the interstitial tissue by the exercising muscle. Drugs such as α-adrenergic blocking agents, calcium channel antagonists, and other vasodilators have not been shown to be effective in patients with PAD.

Cilostazol, a phosphodiesterase-3 inhibitor with vasodilator and antiplatelet properties, increases claudication distance by 40–60% and improves measures of quality of life. The mechanism of action accounting for its beneficial effects is not known. Pentoxifylline, a substituted xanthine derivative, increases blood flow to the microcirculation and enhances tissue oxygenation. Although several placebo-controlled studies have found that pentoxifylline modestly increases the duration of exercise, its efficacy has not been confirmed in other clinical trials. Statins appeared effective for treatment of intermittent claudication in initial clinical trials, but more studies are needed to confirm the efficacy of this class of drugs.

There is no definitive medical therapy for chronic limb-threatening ischemia. Vasodilators, including prostaglandins, are not effective in relieving symptoms or preventing limb loss. Enthusiasm for therapy with angiogenic growth factors abated when clinical trials of intramuscular gene transfer of DNA encoding vascular endothelial growth factor, fibroblast growth factor, hepatocyte growth factor, or hypoxia-inducible factor 1α failed to demonstrate improvement in symptoms or outcomes in patients with intermittent claudication or critical limb ischemia. Most clinical trials of bone marrow–derived vascular progenitor cells to promote angiogenesis and preserve limb viability in patients with critical limb ischemia have failed to demonstrate benefit, although a meta-analysis of these trials suggested a modest reduction in the risk of amputation.

REVASCULARIZATION

Revascularization procedures, including catheter-based, open surgical, and hybrid interventions, are indicated for patients with chronic limb-threatening ischemia to relieve pain and prevent limb loss. These procedures are also indicated for patients with disabling, progressive, or severe symptoms of intermittent claudication despite medical therapy in order to improve walking distance and functional capacity. When revascularization is performed in conjunction with a supervised exercise program, walking distance improves more than with exercise training alone. MRA, CTA, or conventional angiography should be performed to assess vascular anatomy in patients who are being considered for revascularization.

Endovascular interventions include percutaneous transluminal balloon angioplasty (PTA) (including drug-coated balloons), stent placement (including drug-eluting stents), stent grafts, and atherectomy **(Chap. 287)**. Several operative procedures are available for treating patients with PAD. The preferred operative procedure depends on the location and extent of the obstruction(s) and the general medical condition of the patient. Operative procedures for aortoiliac disease include aortobifemoral bypass, axillofemoral bypass, femoro-femoral bypass, and aortoiliac endarterectomy. Operative therapy for femoral-popliteal and tibioperoneal artery disease includes in situ and reverse autogenous saphenous vein bypass grafts, placement of polytetrafluoroethylene (PTFE) or other synthetic grafts, and thromboendarterectomy. The decision to use an endovascular, open surgical, or a hybrid revascularization strategy depends on the vascular anatomy, including the location and extent of the arterial occlusions, the availability of suitable saphenous vein segments, comorbidities, and the skill and experience of the operator.

Preoperative cardiac risk assessment may identify individuals who are especially likely to experience an adverse cardiac event during the perioperative period. Patients with angina, prior myocardial infarction, heart failure, diabetes, or renal insufficiency are among those at increased risk. Stress testing with treadmill exercise (if feasible), radionuclide myocardial perfusion imaging, or echocardiography permits further stratification of risk in these patients, particularly those with poor or unknown functional capacity **(Chap. 287)**. Patients with abnormal test results require close supervision and adjunctive management with anti-ischemic medications. Coronary angiography and coronary artery revascularization compared with optimal medical therapy do not improve outcomes in most patients undergoing peripheral vascular surgery, but cardiac catheterization should be considered in patients with unstable angina and angina refractory to medical therapy as well as those suspected of having left main or three-vessel CAD.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a hyperplastic disorder that typically affects medium-size and small arteries, but it can also affect larger arteries. The most common histologic characteristics include medial deposition of collagen causing fibromuscular ridges alternating with areas of thinned media. FMD occurs predominantly in females and usually involves the renal and carotid/vertebral arteries but can involve coronary and mesenteric arteries, as well as extremity vessels such as the iliac and subclavian arteries. FMD may cause stenosis, dissection, aneurysm, or thrombosis in affected arteries. When limb vessels are involved, clinical manifestations are similar to those for atherosclerosis, including claudication and rest pain.

A contemporary classification based on the angiographic appearance divides FMD into two types: multifocal, identified by a "string of beads" appearance caused by the thickened fibromuscular ridges contiguous with thin, less-involved portions of the arterial wall; and focal, identified as either unifocal (<1 cm) or tubular (≥1 cm) stenoses.

Aspirin is recommended to reduce the risk of thrombosis in affected vessels. PTA and surgical reconstruction are beneficial in patients with debilitating symptoms or threatened limbs.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (Buerger's disease) is an inflammatory occlusive vascular disorder involving small and medium-size arteries and veins in the distal upper and lower extremities. Cerebral, visceral, and coronary vessels may be affected rarely. This disorder develops most frequently in men <40 years of age. The prevalence is higher in Asians and individuals of Eastern European descent. Although the cause of thromboangiitis obliterans is not known, there is a definite relationship to cigarette smoking in patients with this disorder.

In the initial stages of thromboangiitis obliterans, polymorphonuclear leukocytes infiltrate the walls of the small and medium-size arteries and veins. The internal elastic lamina is preserved, and a cellular, inflammatory thrombus develops in the vascular lumen. As the disease progresses, mononuclear cells, fibroblasts, and giant cells replace the neutrophils. Later stages are characterized by perivascular fibrosis, organized thrombus, and recanalization.

The clinical features of thromboangiitis obliterans often include a triad of claudication of the affected extremity, Raynaud phenomenon, and migratory superficial vein thrombophlebitis. Claudication usually is confined to the calves and feet or the forearms and hands because this disorder primarily affects distal vessels. In the presence of severe digital ischemia, trophic nail changes, painful ulcerations, and gangrene may develop at the tips of the fingers or toes. The physical examination shows normal brachial and popliteal pulses but reduced or absent radial, ulnar, and/or tibial pulses. MRA, CTA, and conventional arteriography are helpful in making the diagnosis. Smooth, tapering segmental lesions in the distal vessels are characteristic, as are collateral vessels at sites of vascular occlusion. Proximal atherosclerotic disease is usually absent. The diagnosis can

be confirmed by excisional biopsy and pathologic examination of an involved vessel.

There is no specific treatment except abstention from tobacco. The prognosis is worse in individuals who continue to smoke, but results are discouraging even in those who stop smoking. Arterial bypass of the larger vessels may be used in selected instances, as well as local debridement, depending on the symptoms and severity of ischemia. Antibiotics may be useful; anticoagulants and glucocorticoids are not helpful. If these measures fail, amputation may be required.

OTHER VASCULITIDES

Other vasculitides may affect the arteries that supply the upper and lower extremities. **Takayasu arteritis and giant cell (temporal) arteritis are discussed in Chap. 375.**

ACUTE LIMB ISCHEMIA

Acute limb ischemia occurs when arterial occlusion results in the sudden cessation of blood flow to an extremity. The severity of ischemia and the viability of the extremity depend on the location and extent of the occlusion and the presence and subsequent development of collateral blood vessels. Principal causes of acute arterial occlusion include embolism, thrombus in situ, arterial dissection, and trauma.

The most common sources of arterial emboli are the heart, aorta, and large arteries. Cardiac disorders that cause thromboembolism include atrial fibrillation; acute myocardial infarction; ventricular aneurysm; cardiomyopathy; infectious and marantic endocarditis; thrombi associated with prosthetic heart valves; and atrial myxoma. Emboli to the distal vessels may also originate from proximal sites of atherosclerosis and aneurysms of the aorta and large vessels. Less frequently, an arterial occlusion results paradoxically from a venous thrombus that has entered the systemic circulation via a patent foramen ovale or another septal defect. Arterial emboli tend to lodge at vessel bifurcations because the vessel caliber decreases at those sites; in the lower extremities, emboli lodge most frequently in the femoral artery, followed by the iliac artery, aorta, and popliteal and tibioperoneal arteries.

Acute arterial thrombosis in situ occurs most frequently in atherosclerotic vessels at the site of an atherosclerotic plaque or aneurysm and in arterial bypass grafts. Trauma to an artery may disrupt continuity of blood flow and cause acute limb ischemia via formation of an acute arterial thrombus or by disruption of an artery's integrity and extravasation of blood. Arterial occlusion may complicate arterial punctures and placement of catheters; it also may result from arterial dissection if the intimal flap obstructs the artery. Less common causes include thoracic outlet compression syndrome, which causes subclavian artery occlusion, and entrapment of the popliteal artery by abnormal placement of the medial head of the gastrocnemius muscle. Polycythemia and hypercoagulable disorders **(Chaps. 108 and 121)** are also associated with acute arterial thrombosis.

CLINICAL FEATURES

The symptoms of an acute arterial occlusion depend on the location, duration, and severity of the obstruction. Often severe pain, paresthesia, numbness, and coldness develop in the involved extremity within 1 h. Paralysis may occur with severe and persistent ischemia. Physical findings include loss of pulses distal to the occlusion, cyanosis or pallor, mottling, decreased skin temperature, muscle stiffening, loss of sensation, weakness, and/or absent deep tendon reflexes. If acute arterial occlusion occurs in the presence of an adequate collateral circulation, as is often the case in acute graft occlusion, the symptoms and findings may be less severe. In this situation, the patient complains about an abrupt decrease in the distance walked before claudication occurs or of modest pain and paresthesia. Pallor and coolness are evident, but sensory and motor functions generally are preserved. The clinical evaluation includes Doppler assessment of peripheral blood flow. The diagnosis of acute limb ischemia is usually apparent from the clinical presentation. In most circumstances, duplex ultrasound, MRA, CTA, or catheter-based arteriography is used to confirm the diagnosis and demonstrate the location and extent of arterial occlusion.

TREATMENT

Acute Limb Ischemia

Once the diagnosis is made, the patient should be anticoagulated with intravenous heparin to prevent propagation of the clot and recurrent embolism. In cases of severe ischemia of recent onset, particularly when limb viability is jeopardized, immediate intervention to ensure reperfusion is indicated. Catheter-directed thrombolysis/thrombectomy, surgical thromboembolectomy, and arterial bypass procedures are used to restore blood flow to the ischemic extremity promptly, particularly when a large proximal vessel is occluded.

Intraarterial thrombolytic therapy with recombinant tissue plasminogen activator, reteplase, or tenecteplase is most effective when acute arterial occlusion is recent and caused by a thrombus in an atherosclerotic vessel, arterial bypass graft, or occluded stent. Thrombolytic therapy is also indicated when the patient's overall condition contraindicates surgical intervention or when smaller distal vessels are occluded, thus preventing surgical access. Meticulous observation for hemorrhagic complications is required during intraarterial thrombolytic therapy. Ultrasound-emitting catheters may accelerate reperfusion by improving thrombus permeability to thrombolytic agents. Another endovascular approach to thrombus removal is percutaneous mechanical thrombectomy using devices that employ hydrodynamic forces or rotating baskets to fragment and remove the clot. These treatments may be used alone but usually are used in conjunction with pharmacologic thrombolysis. Surgical revascularization is preferred when restoration of blood flow must occur within 24 h to prevent limb loss. Amputation is performed when the limb is not viable, as characterized by loss of sensation, paralysis, and the absence of Doppler-detected blood flow in both arteries and veins.

Long-term anticoagulation is indicated when acute limb ischemia is caused by cardiac thromboembolism. Emboli resulting from infective endocarditis, the presence of prosthetic heart valves, or atrial myxoma often require surgical intervention to remove the cause.

ATHEROEMBOLISM

Atheroembolism is another cause of limb ischemia. In this condition, multiple small deposits of fibrin, platelets, and cholesterol debris embolize from proximal atherosclerotic lesions or aneurysmal sites. Large protruding aortic atheromas are a source of emboli that may lead to limb ischemia, as well as stroke and renal insufficiency. Atheroembolism may occur after intraarterial procedures. Since atheroemboli to limbs tend to lodge in the small vessels of the muscle and skin and may not occlude the large vessels, distal pulses usually remain palpable. Patients complain of acute pain and tenderness at the site of embolization. Digital vascular occlusion may result in ischemia and the "blue toe" syndrome; digital necrosis and gangrene may develop **(Fig. 292-2)**. Localized areas of tenderness, pallor, and livedo reticularis (see below) occur at sites of emboli. Skin or muscle biopsy may demonstrate cholesterol crystals.

Ischemia resulting from atheroemboli is notoriously difficult to treat. Local foot care and occasionally amputation may be needed to treat necrotic areas. Analgesics are indicated for pain relief. Usually neither surgical revascularization procedures nor thrombolytic therapy is helpful because of the multiplicity, composition, and distal location of the emboli. Therapy with antiplatelet drugs and statins improves cardiovascular outcome in patients with atherosclerosis, but it is not established whether either class of drugs prevents recurrent atheroembolism. Similarly, it is not known whether anticoagulant therapy is effective. Endovascular or surgical intervention to exclude or bypass the atherosclerotic vessel or aneurysm that causes the recurrent atheroemboli may be necessary.

THORACIC OUTLET COMPRESSION SYNDROME

This is a symptom complex resulting from compression of the neurovascular bundle (artery, vein, or nerves) at the thoracic outlet as it

FIGURE 292-2 Atheroembolism causing cyanotic discoloration and impending necrosis of the toes ("blue toe" syndrome).

courses through the neck and shoulder. Cervical ribs, abnormalities of the scalenus anticus muscle, proximity of the clavicle to the first rib, or abnormal insertion of the pectoralis minor muscle may compress the subclavian artery, subclavian vein, and brachial plexus as these structures pass from the thorax to the arm. Depending on the structures affected, thoracic outlet compression syndrome is divided into arterial, venous, and neurogenic forms. Patients with neurogenic thoracic outlet compression may develop shoulder and arm pain, weakness, and paresthesias. Patients with arterial compression may experience claudication, Raynaud phenomenon, and even ischemic tissue loss and gangrene. Venous compression may cause thrombosis of the subclavian and axillary veins; this is often associated with effort and is referred to as *Paget-Schroetter syndrome.*

APPROACH TO THE PATIENT

Arterial Thoracic Outlet Compression Syndrome

Examination of a patient with arterial thoracic outlet compression syndrome is often normal unless provocative maneuvers are performed. Occasionally, distal pulses are decreased or absent and digital cyanosis and ischemia may be evident.

Several maneuvers that support the diagnosis of arterial thoracic outlet compression syndrome may be used to precipitate symptoms, cause a subclavian artery bruit, and diminish arm pulses. These maneuvers include the abduction and external rotation test, in which the affected arm is abducted by 90° and the shoulder is externally rotated; the scalene maneuver (extension of the neck and rotation of the head to the side of the symptoms); the costoclavicular maneuver (posterior rotation of shoulders); and the hyperabduction maneuver (raising the arm 180°). A chest x-ray will indicate the presence of cervical ribs. Duplex ultrasonography, CTA, MRA, and contrast angiography can be performed during provocative maneuvers to demonstrate thoracic outlet compression of the subclavian artery. Neurophysiologic tests such as the electromyogram, nerve conduction studies, and somatosensory evoked potentials may be abnormal if the brachial plexus is involved, but the diagnosis of neurogenic thoracic outlet syndrome is not necessarily excluded if these tests are normal owing to their low sensitivity.

Most patients can be managed conservatively. They should be advised to avoid the positions that cause symptoms. Many patients benefit from shoulder girdle exercises. Surgical procedures such as removal of the first rib and resection of the scalenus anticus muscle are necessary occasionally for relief of symptoms or treatment of ischemia.

POPLITEAL ARTERY ENTRAPMENT

Popliteal artery entrapment typically affects young athletic men and women when the gastrocnemius or popliteus muscle compresses the popliteal artery and causes intermittent claudication. Thrombosis, embolism, or popliteal artery aneurysm may occur. The pulse examination may be normal unless provocative maneuvers such as ankle dorsiflexion and plantar flexion are performed. The diagnosis is confirmed by duplex ultrasound, CTA, MRA, or conventional angiography. Treatment involves surgical release of the popliteal artery or vascular reconstruction.

POPLITEAL ARTERY ANEURYSM

Popliteal artery aneurysms are the most common peripheral artery aneurysms. Approximately 50% are bilateral. Patients with popliteal artery aneurysms often have aneurysms of other arteries, especially the aorta. The most common clinical presentation is limb ischemia secondary to thrombosis or embolism. Rupture occurs less frequently. Other complications include compression of the adjacent popliteal vein or peroneal nerve. Popliteal artery aneurysm can be detected by palpation and confirmed by duplex ultrasonography. Repair is indicated for symptomatic aneurysms or when the diameter exceeds 2–3 cm, owing to the risk of thrombosis, embolism, or rupture.

ARTERIOVENOUS FISTULA

Abnormal communications between an artery and a vein, bypassing the capillary bed, may be congenital or acquired. Congenital arteriovenous fistulas are a result of persistent embryonic vessels that fail to differentiate into arteries and veins; they may be associated with birthmarks, can be located in almost any organ of the body, and frequently occur in the extremities. Acquired arteriovenous fistulas either are created to provide vascular access for hemodialysis or occur as a result of a penetrating injury such as a gunshot or knife wound or as complications of arterial catheterization or surgical dissection. An uncommon cause of arteriovenous fistula is rupture of an arterial aneurysm into a vein.

The clinical features depend on the location and size of the fistula. Frequently, a pulsatile mass is palpable, and a thrill and a bruit lasting throughout systole and diastole are present over the fistula. With long-standing fistulas, clinical manifestations of chronic venous insufficiency, including peripheral edema; large, tortuous varicose veins; and stasis pigmentation become apparent because of the high venous pressure. Evidence of ischemia may occur in the distal portion of the extremity. Skin temperature is higher over the arteriovenous fistula. Large arteriovenous fistulas may result in an increased cardiac output with consequent cardiomegaly and high-output heart failure **(Chap. 264)**.

The diagnosis is often evident from the physical examination. Compression of a large arteriovenous fistula may cause reflex slowing of the heart rate (Nicoladoni-Branham sign). Duplex ultrasonography may detect an arteriovenous fistula, especially one that affects the femoral artery and vein at the site of catheter access. CTA and conventional angiography can confirm the diagnosis and are useful in demonstrating the site and size of the arteriovenous fistula.

Management of arteriovenous fistulas may involve surgery, radiotherapy, or embolization. Congenital arteriovenous fistulas are often difficult to treat because the communications may be numerous and extensive, and new communications frequently develop after ligation of the most obvious ones. Many of these lesions are best treated conservatively using elastic support hose to reduce the consequences of venous hypertension. Occasionally, embolization with autologous material, such as fat or muscle, or with hemostatic agents, such as gelatin sponges or silicon spheres, is used to obliterate the fistula. Acquired arteriovenous fistulas are usually amenable to surgical treatment that involves division or excision of the fistula. Occasionally, autogenous or synthetic grafting is necessary to reestablish continuity of the artery and vein.

RAYNAUD PHENOMENON

Raynaud phenomenon is characterized by episodic digital ischemia, manifested clinically by the sequential development of digital

FIGURE 292-3 Vascular diseases associated with temperature: ***A.*** Raynaud phenomenon; ***B.*** acrocyanosis; ***C.*** livedo reticularis; ***D.*** pernio; ***E.*** erythromelalgia; and ***F.*** frostbite.

blanching, cyanosis, and rubor of the fingers or toes after cold exposure and subsequent rewarming. Emotional stress may also precipitate Raynaud phenomenon. The color changes are usually well demarcated and are confined to the fingers or toes. Typically, one or more digits will appear white when the patient is exposed to a cold environment or touches a cold object **(Fig. 292-3*A*)**. The blanching, or pallor, represents the ischemic phase of the phenomenon and results from vasospasm of digital arteries. During the ischemic phase, capillaries and venules dilate, and cyanosis results from the deoxygenated blood that is present in these vessels. A sensation of cold or numbness or paresthesia of the digits often accompanies the phases of pallor and cyanosis.

With rewarming, the digital vasospasm resolves, and blood flow into the dilated arterioles and capillaries increases dramatically. This "reactive hyperemia" imparts a bright red color to the digits. In addition to rubor and warmth, patients often experience a throbbing, painful sensation during the hyperemic phase. Although the triphasic color response is typical of Raynaud phenomenon, some patients may develop only pallor and cyanosis; others may experience only cyanosis.

Raynaud phenomenon is broadly separated into two categories: idiopathic, termed primary Raynaud phenomenon, and secondary Raynaud phenomenon, which is associated with other disease states or known causes of vasospasm **(Table 292-1)**.

Primary Raynaud Phenomenon This appellation is applied when the secondary causes of Raynaud phenomenon have been excluded. Over 50% of patients with Raynaud phenomenon have the primary form. Women are affected about five times more often than men, and the age of presentation is usually between 20 and 40 years. The fingers are involved more frequently than the toes. Initial episodes may involve only one or two fingertips, but subsequent attacks may involve the entire finger and may include all the fingers. The toes are affected in 40% of patients. Although vasospasm of the toes usually occurs in patients with symptoms in the fingers, it may happen alone. Rarely, the earlobes, the tip of the nose, tongue, nipple, or penis are involved. Raynaud phenomenon occurs frequently in patients who also have migraine headaches or variant angina from coronary vasospasm. These associations suggest that there may be a common predisposing cause for the vasospasm.

Results of physical examination are often entirely normal; the radial, ulnar, and pedal pulses are normal. The fingers and toes may be cool between attacks and may perspire excessively. Nailfold capillaroscopy reveals normal superficial capillaries, which appear as regularly spaced hairpin loops. Thickening and tightening of the digital subcutaneous tissue (*sclerodactyly*) develop in 10% of patients. Angiography of the digits for diagnostic purposes is not indicated.

TABLE 292-1 Classification of Raynaud Phenomenon

Primary or idiopathic Raynaud phenomenon
Secondary Raynaud phenomenon
Collagen vascular diseases: scleroderma, systemic lupus erythematosus, rheumatoid arthritis, dermatomyositis, polymyositis, mixed connective tissue disease, Sjögren syndrome
Arterial occlusive diseases: atherosclerosis of the extremities, thromboangiitis obliterans, acute arterial occlusion, thoracic outlet syndrome
Pulmonary hypertension
Neurologic disorders: intervertebral disk disease, syringomyelia, spinal cord tumors, stroke, poliomyelitis, carpal tunnel syndrome, complex regional pain syndrome
Blood dyscrasias: cold agglutinins, cryoglobulinemia, cryofibrinogenemia, myeloproliferative disorders, lymphoplasmacytic lymphoma
Trauma: vibration injury, hammer hand syndrome, electric shock, cold injury, typing, piano playing
Drugs and toxins: ergot derivatives, methysergide, β-adrenergic receptor blockers, bleomycin, vinblastine, cisplatin, gemcitabine, vinyl chloride

In general, patients with primary Raynaud disease have milder clinical manifestations. Fewer than 1% of these patients lose a part of a digit. After the diagnosis is made, the disease improves spontaneously in ~15% of patients and progresses in ~30%.

Secondary Causes of Raynaud Phenomenon Raynaud phenomenon occurs in 80–90% of patients with systemic sclerosis (scleroderma) and is the presenting symptom in 30% (Chap. 372). It may be the only symptom of scleroderma for many years. Abnormalities of the digital vessels may contribute to the development of Raynaud phenomenon in this disorder. Ischemic fingertip ulcers may develop and progress to gangrene and autoamputation. About 20% of patients with systemic lupus erythematosus (SLE) have Raynaud phenomenon (Chap. 368). Occasionally, persistent digital ischemia develops and may result in ulcers or gangrene. In most severe cases, the small vessels are occluded by a proliferative endarteritis. Raynaud phenomenon occurs in ~30% of patients with dermatomyositis or polymyositis (Chap. 377). It frequently develops in patients with rheumatoid arthritis and may be related to the intimal proliferation that occurs in the digital arteries.

Atherosclerosis of the extremities is a common cause of Raynaud phenomenon in men aged >50 years. Thromboangiitis obliterans is an uncommon cause of Raynaud phenomenon but should be considered in young men, particularly those who are cigarette smokers. The development of cold-induced pallor in these disorders may be confined to one or two digits of the involved extremity. Occasionally, Raynaud phenomenon may follow acute occlusion of large and medium-sized arteries by a thrombus or embolus. Embolization of atheroembolic debris may cause digital ischemia. The latter situation often involves one or two digits and should not be confused with Raynaud phenomenon. In patients with thoracic outlet compression syndrome, Raynaud phenomenon may result from diminished intravascular pressure, stimulation of sympathetic fibers in the brachial plexus, or a combination of both. Raynaud phenomenon occurs in patients with primary pulmonary hypertension (Chap. 294); this is more than coincidental and may reflect a neurohumoral abnormality that affects both the pulmonary and digital circulations.

A variety of blood dyscrasias may be associated with Raynaud phenomenon. Cold-induced precipitation of plasma proteins, hyperviscosity, and aggregation of red cells and platelets may occur in patients with cold agglutinins, cryoglobulinemia, or cryofibrinogenemia. Hyperviscosity syndromes that accompany myeloproliferative disorders and lymphoplasmacytic lymphoma (Waldenström macroglobulinemia) should also be considered in the initial evaluation of patients with Raynaud phenomenon.

Raynaud phenomenon occurs often in patients whose vocations require the use of vibrating hand tools, such as chain saws or jackhammers. The frequency of Raynaud phenomenon also seems to be increased in pianists and keyboard operators. Electric shock injury to the hands or frostbite may lead to the later development of Raynaud phenomenon.

Several drugs have been causally implicated in Raynaud phenomenon. They include ergot preparations, methysergide, β-adrenergic receptor antagonists, and the chemotherapeutic agents bleomycin, vinblastine, cisplatin, and gemcitabine.

TREATMENT

Raynaud Phenomenon

Most patients with Raynaud phenomenon experience only mild and infrequent episodes. These patients need reassurance and should be instructed to dress warmly and avoid unnecessary cold exposure. In addition to gloves and mittens, patients should protect the trunk, head, and feet with warm clothing to prevent cold-induced reflex vasoconstriction. Tobacco use is contraindicated.

Drug treatment should be reserved for severe cases. Dihydropyridine calcium channel antagonists such as nifedipine and amlodipine decrease the frequency and severity of Raynaud phenomenon. Diltiazem may be considered but is less effective. The postsynaptic α_1-adrenergic antagonist prazosin has been used with favorable responses; doxazosin and terazosin may also be effective. Phosphodiesterase type 5 inhibitors such as sildenafil, tadalafil, and vardenafil may improve symptoms in patients with secondary Raynaud phenomenon, as occurs with systemic sclerosis. There is also evidence that topical nitroglycerin preparations are effective. Digital sympathectomy is helpful in some patients who are unresponsive to medical therapy. Injection of botulinum toxin into the perivascular tissue of the wrist or palm improved ischemic manifestations of severe Raynaud phenomenon in case series, although controlled clinical trials have yielded inconsistent results.

ACROCYANOSIS

In this condition, there is arterial vasoconstriction and secondary dilation of the capillaries and venules with resulting persistent cyanosis of the hands and, less frequently, the feet. Cyanosis may be intensified by exposure to a cold environment. Acrocyanosis may be categorized as primary or secondary to an underlying condition. In primary acrocyanosis, women are affected much more frequently than men, and the age of onset is usually <30 years. Generally, patients are asymptomatic but seek medical attention because of the discoloration. The prognosis is favorable, and pain, ulcers, and gangrene do not occur. Examination reveals normal pulses, peripheral cyanosis, and moist palms (Fig. 292-3*B*). Trophic skin changes and ulcerations do *not* occur. The disorder can be distinguished from Raynaud phenomenon because it is persistent and not episodic, the discoloration extends proximally from the digits, and blanching does not occur. Ischemia secondary to arterial occlusive disease can usually be excluded by the presence of normal pulses. Central cyanosis and decreased arterial oxygen saturation are not present. Patients should be reassured and advised to dress warmly and avoid cold exposure. Pharmacologic intervention is not indicated.

Secondary acrocyanosis may result from hypoxemia, vasopressor medications, connective tissue diseases, atheroembolism, antiphospholipid antibodies, cold agglutinins, or cryoglobulins and is associated with anorexia nervosa and postural orthostatic tachycardia syndrome. Treatment should be directed at the underlying disorder.

LIVEDO RETICULARIS

In this condition, localized areas of the extremities develop a mottled or rete (netlike) appearance of reddish to blue discoloration (Fig. 293-3*C*). There are primary and secondary forms of livedo reticularis. The primary, or idiopathic, form of this disorder may be benign or associated with ulcerations. The benign form occurs more frequently in women than in men, and the most common age of onset is the third decade. The mottling typically is symmetric and uniform and may be more prominent after cold exposure and improve with warming. Patients with the benign form are usually asymptomatic and seek attention for cosmetic reasons. These patients should be reassured and advised to avoid cold environments. No drug treatment is indicated. Primary livedo reticularis with ulceration is also called *atrophie blanche en plaque*. The ulcers are painful and may take months to heal. Secondary livedo reticularis can occur with atheroembolism (see above), SLE and other vasculitides, antiphospholipid antibodies, hyperviscosity, cryoglobulinemia, and Sneddon's syndrome (ischemic stroke and livedo reticularis). Livedo racemosa is the term used to characterize secondary livedo reticularis, when the mottling is irregular and disrupted, and does not improve with warming. Rarely, skin ulcerations develop.

PERNIO (CHILBLAINS)

Pernio is a vasculitic disorder associated with exposure to cold; acute forms have been described. Raised erythematous lesions develop most commonly on the toes or fingers in cold weather (Fig. 292-3*D*). They are associated with pruritus and a burning sensation, and they may blister and ulcerate. Pathologic examination demonstrates angiitis characterized by intimal proliferation and perivascular infiltration of mononuclear and polymorphonuclear leukocytes. Giant cells may be present in the subcutaneous tissue. Patients should avoid exposure to cold, and ulcers should be kept clean and protected with sterile dressings. Sympatholytic drugs and dihydropyridine calcium channel antagonists may be effective in some patients.

ERYTHROMELALGIA

This disorder is characterized by burning pain and erythema of the extremities **(Fig. 292-3*E*)**. The feet are involved more frequently than the hands, and males are affected more frequently than females. Erythromelalgia may occur at any age but is most common in middle age. It may be primary (also termed erythermalgia) or secondary. Mutations in the *SCN9A* gene, which encodes the Nav1.7 voltage-gated sodium channel expressed in sensory and sympathetic nerves, have been described in inherited forms of erythromelalgia. The most common causes of secondary erythromelalgia are myeloproliferative disorders such as polycythemia vera and essential thrombocytosis. Less common causes include drugs, such as calcium channel blockers, bromocriptine, and pergolide; neuropathies; connective tissue diseases such as SLE; and paraneoplastic syndromes. Patients complain of burning in the extremities that is precipitated by exposure to a warm environment and aggravated by a dependent position. The symptoms are relieved by exposing the affected area to cool air or water or by elevation. Erythromelalgia can be distinguished from ischemia secondary to peripheral arterial disorders because the peripheral pulses are present. There is no specific treatment; aspirin may produce relief in patients with erythromelalgia secondary to myeloproliferative disease. Topical anesthetics, such as lidocaine, or a combination of amitriptyline and ketamine may be considered to relieve pain. Topical midodrine may also be considered. Treatment of associated disorders in secondary erythromelalgia may be helpful.

FROSTBITE

In this condition, tissue damage results from severe environmental cold exposure or from direct contact with a very cold object. Tissue injury results from both freezing and vasoconstriction. Frostbite usually affects the distal aspects of the extremities or exposed parts of the face, such as the ears, nose, chin, and cheeks. Superficial frostbite involves the skin and subcutaneous tissue. Patients experience pain or paresthesia, and the skin appears white and waxy. After rewarming, there is cyanosis and erythema, wheal-and-flare formation, edema, and superficial blisters. Deep frostbite involves muscle, nerves, and deeper blood vessels. It may result in edema of the hand or foot, vesicles and bullae, tissue necrosis, and gangrene **(Fig. 292-3*F*)**.

Initial treatment is rewarming, performed in an environment where reexposure to freezing conditions will not occur. Rewarming is accomplished by immersion of the affected part in a water bath at temperatures of 40°–44°C (104°–111°F). Massage, application of ice water, and extreme heat are contraindicated. The injured area should be cleansed with soap or antiseptic, and sterile dressings should be applied. Analgesics are often required during rewarming. Antibiotics are used if there is evidence of infection. The efficacy of sympathetic blocking drugs is not established. After recovery, the affected extremity may exhibit increased sensitivity to cold.

293 Chronic Venous Disease and Lymphedema

Mark A. Creager, Robert T. Eberhardt, Joseph Loscalzo

CHRONIC VENOUS DISEASE

Chronic venous diseases range from telangiectasias and reticular veins, to varicose veins, to chronic venous insufficiency with edema, skin changes, and ulceration. This section of the chapter will focus on identification and treatment of varicose veins and chronic venous insufficiency, since these problems are encountered frequently by the internist. The estimated prevalence of varicose veins in the United States is ~15% in men and 30% in women. Chronic venous insufficiency with edema affects ~7.5% of men and 5% of women, and the prevalence increases with age ranging from 2% among those <50 years of age to 10% of those 70 years of age. Approximately 20% of patients with chronic venous insufficiency develop venous ulcers.

VENOUS ANATOMY

Veins in the extremities can be broadly classified as either superficial or deep. The superficial veins are located between the skin and deep fascia. In the legs, these include the great and small saphenous veins and their tributaries. The great saphenous vein is the longest vein in the body. It originates on the medial side of the foot and ascends anterior to the medial malleolus and then along the medial side of the calf and thigh and drains into the common femoral vein. The small saphenous vein originates on the dorsolateral aspect of the foot, ascends posterior to the lateral malleolus and along the posterolateral aspect of the calf, and drains into the popliteal vein. The deep veins of the leg accompany the major arteries. There are usually paired peroneal, anterior tibial, and posterior tibial veins in the calf, which converge to form the popliteal vein. Soleal tributary veins drain into the posterior tibial or peroneal veins, and gastrocnemius tributary veins drain into the popliteal vein. The popliteal vein ascends in the thigh as the femoral vein. The confluence of the femoral vein and deep femoral vein form the common femoral vein, which ascends in the pelvis as the external iliac and then common iliac vein, which converges with the contralateral common iliac vein at the inferior vena cava. Perforating veins connect the superficial and deep systems in the legs at multiple locations, normally allowing blood to flow from the superficial to deep veins. In the arms, the superficial veins include the basilic, cephalic, and median cubital veins and their tributaries. The basilic and cephalic veins course along the medial and lateral aspects of the arm, respectively, and these are connected via the median cubital vein in the antecubital fossa. The deep veins of the arms accompany the major arteries and include the radial, ulnar, brachial, axillary, and subclavian veins. The subclavian vein converges with the internal jugular vein to form the brachiocephalic vein, which joins the contralateral brachiocephalic vein to form the superior vena cava. Bicuspid valves are present throughout the venous system to direct the flow of venous blood centrally.

Pathophysiology of Chronic Venous Disease *Varicose veins* are dilated, bulging, tortuous superficial veins, measuring at least 3 mm in diameter. The smaller and less tortuous reticular veins are dilated intradermal veins, which appear blue-green, measure 1–3 mm in diameter, and do not protrude from the skin surface. Telangiectasias, or spider veins, are small, dilated veins, <1 mm in diameter, located near the skin surface, and form blue, purple, or red linear, branching, or spider-web patterns.

Varicose veins can be categorized as primary or secondary. Primary varicose veins originate in the superficial system and result from defective structure and function of the valves of the saphenous veins, intrinsic weakness of the vein wall, and high intraluminal pressure. Approximately one-half of these patients have a family history of varicose veins. Other factors associated with primary varicose veins include aging, pregnancy, hormonal therapy, obesity, and prolonged standing. Secondary varicose veins result from venous hypertension, associated with deep-venous insufficiency or deep-venous obstruction, and incompetent perforating veins that cause enlargement of superficial veins. Arteriovenous fistulas also cause varicose veins in the affected limb.

Chronic venous insufficiency is a consequence of incompetent veins in which there is venous hypertension and extravasation of fluid and blood elements into the tissue of the limb. It may occur in patients with varicose veins and superficial venous disease, but more advanced manifestations are usually caused by disease in the deep veins. It also is categorized as primary or secondary. Primary venous insufficiency is a consequence of an intrinsic structural or functional abnormality in the vein wall or venous valves leading to valvular reflux. Secondary deep-venous insufficiency is caused by obstruction and/or valvular incompetence from previous deep-vein thrombosis **(Chap. 290)**. Deep-venous insufficiency occurs following deep-vein thrombosis, as the delicate valve leaflets become thickened and contracted and can no longer prevent retrograde flow of blood and the vein itself becomes rigid and thick walled. Although most veins recanalize after an episode of thrombosis, the large proximal veins may remain occluded. Secondary incompetence develops in valves distal to the obstruction because high pressures distend the vein and separate the leaflets. Other causes of secondary deep-venous insufficiency include May-Thurner syndrome, where the left iliac vein is occluded or stenosed by extrinsic compression from the overlapping right common iliac artery; extrinsic compression from tumor or retroperitoneal fibrosis; arteriovenous fistulas resulting in increased venous pressure; congenital deep-vein agenesis or hypoplasia; and venous malformations as may occur in Klippel-Trénaunay and Parkes-Weber syndromes.

Clinical Presentation Patients with venous varicosities are often asymptomatic but still concerned about the cosmetic appearance of their legs. Superficial venous thrombosis may be a recurring problem, and rarely, a varicosity ruptures and bleeds. Symptoms in patients with varicose veins or venous insufficiency, when they occur, include a dull ache, throbbing or heaviness, or pressure sensation in the legs typically after prolonged standing; these symptoms usually are relieved with leg elevation. Additional symptoms may include cramping, burning, pruritus, leg swelling, and skin ulceration.

The legs are examined in both the supine and standing positions. Visual inspection and palpation of the legs in the standing position confirm the presence of varicose veins. The location and extent of the varicose veins should be noted. Chronic venous insufficiency is characterized by the development of edema or other skin manifestations. Edema, stasis dermatitis, and skin ulceration near the ankle may be present if there is superficial venous insufficiency and venous hypertension. Findings of deep-venous insufficiency include increased leg circumference, venous varicosities, edema, and skin changes. The edema, which is usually pitting, may be confined to the ankles, extend above the ankles to the knees, or involve the thighs in severe cases. Over time, the edema may become less pitting and more indurated, particularly with the secondary development of lymphatic dysfunction. Dermatologic findings associated with venous stasis include hyperpigmentation, erythema, eczema, lipodermatosclerosis, *atrophie blanche*, and a phlebectasia corona. Lipodermatosclerosis is the combination of induration, hemosiderin deposition, and inflammation, and typically occurs in the lower part of the leg just above the ankle. Atrophie blanche is a white patch of scar tissue, often with focal telangiectasias and a hyperpigmented border; it usually develops near the medial malleolus. A phlebectasia corona is a fan-shaped pattern of intradermal veins near the ankle or on the foot. Skin ulceration may occur near the medial and lateral malleoli. A venous ulcer is often shallow and characterized by an irregular border, a base of granulation tissue, and the presence of exudate **(Fig. 293-1)**.

FIGURE 293-1 Venous insufficiency with active venous ulcer near the medial malleolus. *(Courtesy of Dr. Steven Dean, with permission.)*

Bedside maneuvers can be used to distinguish primary varicose veins from secondary varicose veins caused by deep-venous insufficiency. With the contemporary use of venous ultrasound (see below), however, these maneuvers are employed infrequently. The Brodie-Trendelenburg test is used to determine whether varicose veins are secondary to deep-venous insufficiency. As the patient is lying supine, the leg is elevated and the veins allowed to empty. Then, a tourniquet is placed on the proximal part of the thigh and the patient is asked to stand. Filling of the varicose veins within 30 s indicates that the varicose veins are caused by deep-venous insufficiency and incompetent perforating veins. Primary varicose veins with superficial venous insufficiency are the likely diagnosis if venous refilling occurs promptly after tourniquet removal. The Perthes test assesses the possibility of deep-venous obstruction. A tourniquet is placed on the midthigh after the patient has stood, and the varicose veins are filled. The patient is then instructed to walk for 5 min. A patent deep-venous system and competent perforating veins enable the superficial veins below the tourniquet to collapse. Deep-venous obstruction is likely to be present if the superficial veins distend further with walking.

Differential Diagnosis The duration of leg edema helps to distinguish chronic venous insufficiency from acute deep-vein thrombosis. Lymphedema, as discussed later in this chapter, is often confused with chronic venous insufficiency, and both may occur together when venous insufficiency impairs lymphatic function leading to phlebolymphedema. Other disorders that cause leg swelling should be considered and excluded when evaluating a patient with presumed venous insufficiency. Bilateral leg swelling occurs in patients with congestive heart failure, hypoalbuminemia secondary to nephrotic syndrome or severe hepatic disease, or myxedema caused by hypothyroidism or pretibial myxedema associated with Graves' disease, and with drugs such as dihydropyridine calcium channel blockers and thiazolidinediones. Unilateral causes of leg swelling also include ruptured leg muscles,

hematomas secondary to trauma, and popliteal cysts. Cellulitis may cause erythema and swelling of the affected limb. Leg ulcers may be caused by severe peripheral artery disease and chronic limb threatening ischemia; neuropathies, particularly those associated with diabetes; and less commonly, skin cancer, vasculitis, or rarely as a complication of hydroxyurea. The location and characteristics of venous ulcers help to differentiate these from other causes.

Classification of Chronic Venous Disease The CEAP (clinical, etiologic, anatomic, pathophysiologic) classification schema incorporates the range of symptoms and signs of chronic venous disease to characterize its severity. It also broadly categorizes the etiology as primary, secondary, or congenital; identifies the affected veins as superficial, deep, or perforating; and characterizes the pathophysiology as reflux, obstruction, both, or neither **(Table 293-1)**.

Diagnostic Testing The principal diagnostic test to evaluate patients with chronic venous disease is venous duplex ultrasonography. A venous duplex ultrasound examination uses a combination of B-mode imaging and spectral Doppler to detect the presence of venous obstruction and venous reflux in superficial and deep veins. Color-assisted Doppler ultrasound is useful to visualize venous flow patterns. Obstruction may be diagnosed by the absence of flow, the presence of an echogenic thrombus within the vein, or failure of the vein to collapse when a compression maneuver is applied by the sonographer, the last implicating the presence of an intraluminal thrombus. Venous reflux is detected by prolonged reversal of venous flow direction during a Valsalva maneuver, particularly for the common femoral vein or saphenofemoral junction, or after compression and release of a cuff placed on the limb distal to the area being interrogated.

Some vascular laboratories use air or strange gauge plethysmography to assess the severity of venous reflux and complement findings from the venous ultrasound examination. Venous volume and venous refilling time are measured when the legs are placed in a dependent position and after calf exercise to quantify the severity of venous reflux and the efficiency of the calf muscle pump to affect venous return.

Magnetic resonance, computed tomographic, and conventional venography are rarely required to determine the cause and plan treatment for chronic venous insufficiency unless there is suspicion for pathology that might warrant intervention. These modalities are used to identify obstruction or stenosis of the inferior vena cava and iliofemoral veins, as may occur in patients with previous proximal deep-vein thrombosis; occlusion of inferior vena cava filters; extrinsic compression from tumors; and May-Thurner syndrome.

TABLE 293-1 CEAP (Clinical, Etiologic, Anatomic, Pathophysiologic) Classification

Clinical Classification
C_0 No visible or palpable signs of venous disease
C_1 Telangiectasias or reticular veins
C_2 Varicose veins
C_{2r} Recurrent varicose veins
C_3 Edema
C_4 Changes in skin and subcutaneous secondary to CVD
C_{4a} Pigmentation or eczema
C_{4b} Lipodermatosclerosis or atrophie blanche
C_{4c} Corona phlebectatica
C_5 Healed venous ulcer
C_6 Active venous ulcer
C_{6r} Recurrent active venous ulcer
Etiologic Classification
E_p Primary
E_s Secondary
E_{si} Secondary – intravenous
E_{se} Secondary – extravenous
E_c Congenital
E_n No cause identified
Anatomic Classification
A_s Superficial
A_p Perforator
A_d Deep
A_n No venous anatomic location identified
Pathophysiologic Classification
P_r Reflux
P_o Obstruction
$P_{r,o}$ Reflux and obstruction
P_n No pathophysiology identified

Abbreviation: CVD, chronic venous disease.

TREATMENT

Chronic Venous Disease

SUPPORTIVE MEASURES

Varicose veins usually are treated with conservative measures. Symptoms often decrease when the legs are elevated periodically, prolonged standing is avoided, and elastic support hose are worn. External compression with elastic stockings, multilayer elastic wraps, stretch bandages, or inelastic garments provides a counterbalance to the hydrostatic pressure in the veins. Although compression garments may improve symptoms and are recommended in patients with healed or active venous ulceration, they are not curative and do not prevent progression of varicose veins. Graduated compression stockings with pressures of 20–30 mmHg are suitable for most patients with simple varicose veins, although higher pressures may be required for patients with varicose veins and manifestations of venous insufficiency such as edema and ulcers.

Patients with chronic venous insufficiency also should be advised to avoid prolonged standing or sitting; frequent leg elevation is helpful. Graded compression therapy consisting of stockings or multilayered compression bandages is the standard of care for advanced chronic venous insufficiency characterized by edema, skin changes, or venous ulcers defined as CEAP clinical class C3–C6. Graduated compression stockings of 30–40 mmHg are more effective than lesser grades for healing venous ulcers. The length of stocking depends on the distribution of edema. Calf-length stockings are tolerated better by most patients, particularly elderly patients; for patients with varicose veins or edema extending to the thigh, thigh-length stockings or panty hose should be considered. Exercise training, including leg muscle strengthening, may improve calf muscle pump function and antegrade venous flow, and reduce the severity of chronic venous insufficiency. Overweight and obese patients should be advised to lose weight via caloric restriction and exercise or consult an obesity specialist for more advanced therapies.

In addition to a compression bandage or stocking, patients with venous ulcers also may be treated with low-adherent absorbent dressings that take up exudates while maintaining a moist environment. Other types of dressings include hydrocolloid (an adhesive dressing composed of polymers such as carboxymethylcellulose that absorbs exudates by forming a gel), hydrogel (a nonabsorbent dressing comprising >80% water or glycerin that moisturizes wounds), foam (an absorbent dressing made with polymers such as polyurethane), and alginate (an absorbent, biodegradable dressing that is derived from seaweed), but there is little evidence that these are more effective than low-adherent absorbent dressings. The choice of specific dressing depends on the amount of drainage, presence of infection, and integrity of the skin surrounding the ulcer. Ulcers should be debrided of necrotic tissue. Antibiotics are not indicated unless the ulcer is infected. The multilayered compression bandage or graduated compression garment is then put over the dressing.

MEDICAL THERAPIES

There are no drugs approved by the U.S. Food and Drug Administration for the treatment of chronic venous insufficiency. Diuretics may reduce edema, but at the risk of volume depletion and compromise in renal function. Topical steroids may be used for a short period of time to treat inflammation associated with stasis dermatitis. Several herbal supplements, such as horse chestnut seed extract (aescin); ruscus extract; flavonoids, including diosmin, hesperidin, or the two combined as micronized purified flavonoid fraction; and French maritime pine bark extract, are touted to have venoconstrictive and anti-inflammatory properties. Several meta-analyses have suggested that ruscus extract and micronized purified flavonoid fraction reduce pain, leg heaviness, and/or sensation of swelling, and that micronized purified flavonoid fraction, and perhaps pentoxifylline, in conjunction with compression therapy facilitates venous ulcer healing; however, there remains insufficient evidence to recommend the general use of these substances in patients with chronic venous insufficiency.

INTERVENTIONAL AND SURGICAL THERAPIES

Ablative procedures, including endovenous thermal and nonthermal ablation, sclerotherapy, and surgery, are used to treat varicose veins in selected patients who have persistent symptoms, great saphenous vein incompetency, and complications of venous insufficiency including dermatitis, edema, and ulcers in order to treat symptoms, accelerate healing, and prevent recurrence. Ablative therapy may also be indicated for cosmetic reasons.

Endovenous thermal ablation procedures of the saphenous veins include endovenous laser and radiofrequency ablation. To ablate the great saphenous vein, a catheter is placed percutaneously and advanced from the level of the knee to just below the saphenofemoral junction via ultrasound guidance. Thermal energy is then delivered as the catheter is pulled back. The heat injures the endothelium and media and promotes thrombosis and fibrosis, resulting in venous occlusion. Average 1- and 5-year occlusion rates exceed 90% following endovenous laser therapy and are slightly less after radiofrequency ablation. Deep-vein thrombosis of the common femoral vein adjacent to the saphenofemoral junction is an uncommon but potential complication of endovenous thermal ablation. Other adverse effects of thermal ablation procedures include pain, paresthesias, bruising, hematoma, and hyperpigmentation.

Nonthermal ablation procedures of the saphenous veins include endovenous delivery of a cyanoacrylate tissue adhesive, which causes fibrosis, and mechanochemical ablation, which involves insertion of a rotating wire to injure the endothelium and infusion of a liquid sclerosant. One-year occlusion rates approximate or exceed 90%, respectively. Adverse effects of nonthermal ablation procedures include superficial thrombophlebitis, deep vein thrombosis, ecchymoses, hematomas, and hyperpigmentation.

Sclerotherapy involves the injection of a chemical into a vein to cause fibrosis and obstruction. Sclerosing agents approved by the U.S. Food and Drug Administration include sodium tetradecyl sulfate, polidocanol, sodium morrhuate, and glycerin. The sclerosing agent is administered as a liquid or mixed with air or CO_2/O_2 to create a foam. It may be used to treat the great saphenous vein, but most commonly sclerotherapy is used to treat the affected tributaries of the great saphenous vein or incompetent perforating veins either as a standalone procedure or concomitant or staged with ablative procedures of the truncal superficial veins. Following completion of the procedure, elastic bandages are applied, or 30–40 mmHg compression stockings are worn for 1–2 weeks. Average 1- and 5-year occlusion rates are 81 and 74%, respectively, following sclerotherapy. Complications are uncommon and include deep-vein thrombosis, hematomas, damage to adjacent saphenous or sural nerves, and infection. Anaphylaxis is a very rare but severe complication.

Surgical therapy usually involves ligation and stripping of the great and small saphenous veins. The procedure is performed under general anesthesia. Incisions are made at the groin and the upper calf. The great saphenous vein is ligated below the saphenofemoral junction, and a wire is inserted into the great saphenous vein and advanced distally. The proximal part of the great saphenous vein is secured to the wire and retrieved, i.e., stripped, via the calf incision. Stripping of the great saphenous vein below the knee and stripping of the small saphenous vein usually are not performed because of the respective risks of saphenous and sural nerve injury. Complications of great saphenous vein ligation and stripping include deep-vein thrombosis, bleeding, hematoma, infection, and nerve injury. Recurrent varicose veins occur in up to 50% patients by 5 years, due to technical failures, deep-venous insufficiency, and incompetent perforating veins. Endovenous ablation techniques are generally favored over ligation and stripping.

Stab phlebectomy is another surgical treatment for varicose veins. A small incision is made alongside the varicose vein, and it is avulsed by means of a forceps or hook. This procedure may be performed in conjunction with saphenous vein ligation and stripping or thermal or nonthermal ablation. Subfascial endoscopic perforator surgery (SEPS) uses endoscopy to identify and occlude incompetent perforating veins. It has largely been replaced, however, by ablative techniques applied directly to the perforating veins and performed in a staged manner for persistent or recurrent symptoms after treatment for the truncal veins.

Endovascular interventions, surgical bypass, and reconstruction of the valves of the deep veins are performed when feasible to treat patients with advanced chronic venous insufficiency who have not responded to other therapies. Catheter-based interventions, usually involving placement of endovenous stents, may be considered to treat some patients with chronic occlusion or stenosis of the iliac veins. Technical success rates exceed 85% in most series, and long-term patency is achieved in ~75% of these patients. Iliocaval bypass, femoroiliac venous bypass, and femorofemoral crossover venous bypass are procedures used occasionally to treat iliofemoral vein occlusion; saphenopopliteal vein bypass can be used to treat chronic femoropopliteal vein obstruction. Long-term patency rates for venous bypass procedures generally exceed 60% and are associated with improvement in symptoms. Surgical reconstruction of the valves of the deep veins and valve transfer procedures rarely are used to treat valvular incompetence. Valvuloplasty involves tightening the valve by commissural apposition. With valve transfer procedures, a segment of vein with a competent valve, such as a brachial or axillary vein, or adjacent saphenous or deep femoral vein, is inserted as an interposition graft in the incompetent vein. Both valvuloplasty and vein transfer operations may result in ulcer healing in the majority of patients, although they are uncommonly performed and the success rates are somewhat better with valvuloplasty.

Lymphedema Lymphedema is a chronic condition caused by impaired transport of lymph and characterized by swelling of one or more limbs and occasionally the trunk and genitalia. Fluid accumulates in interstitial tissues when there is an imbalance between lymph production and lymph absorption, a process governed in large part by Starling forces. Deficiency, reflux, or obstruction of lymph vessels perturbs the ability of the lymphatic system to reabsorb proteins that had been filtered by blood vessels, and the tissue osmotic load promotes interstitial accumulation of water. Persistent lymphedema leads to inflammatory and immune responses characterized by infiltration of mononuclear cells, fibroblasts, and adipocytes, leading to adipose and collagen deposition in the skin and subcutaneous tissues.

Lymphatic Anatomy Lymphatic capillaries are blind-ended tubes formed by a single layer of endothelial cells. The absent or widely fenestrated basement membrane of lymphatic capillaries allows access to interstitial proteins and particles. Lymphatic capillaries merge to form microlymphatic precollector vessels, which contain few smooth muscle cells. The precollector vessels drain into collecting lymphatic vessels, which comprise endothelial cells, a basement membrane, smooth muscle, and bileaflet valves. The collecting lymphatic vessels

in turn merge to form larger lymphatic conduits. Analogous to venous anatomy, there are superficial and deep lymphatic vessels in the legs, which communicate at the popliteal and inguinal lymph nodes. Pelvic lymphatic vessels drain into the thoracic duct, which ascends from the abdomen to the thorax and connects with the left brachiocephalic vein. Superficial and deep lymphatic vessels of the arm communicate with axillary lymph nodes, and the efferent lymphatic vessels join lymphatic vessels from the head to form the right and left subclavian lymphatic trunks, which ultimately enter the right brachiocephalic vein and thoracic duct, respectively. Lymph is propelled centrally by the phasic contractile activity of lymphatic smooth muscle and facilitated by the contractions of contiguous skeletal muscle. The presence of lymphatic valves ensures unidirectional flow.

Etiology Lymphedema may be categorized as primary or secondary (Table 293-2). The prevalence of primary lymphedema is ~1.15 per 100,000 persons <20 years of age. Females are affected more frequently than males. Primary lymphedema may be caused by agenesis, hypoplasia, hyperplasia, or obstruction of the lymphatic vessels. There are three clinical subtypes: congenital lymphedema, which appears shortly after birth; lymphedema praecox, which has its onset at the time of puberty; and lymphedema tarda, which usually begins after age 35. Familial forms of congenital lymphedema (Milroy's disease) and lymphedema praecox (Meige's disease) may be inherited in an autosomal dominant manner with variable penetrance; autosomal or sex-linked recessive forms are less common. At least 19 genes are associated with inherited forms of lymphedema. Mutations in the FLT4 gene expressing vascular endothelial growth factor receptor 3 (*VEGFR3*), which is a determinant of lymphangiogenesis, cause Milroy's disease; and a mutation of the gene encoding *VEGF-C*, a ligand for *VEGFR3*, may cause a Milroy's disease-like phenotype. A mutation of the *LSC1* gene is associated with the cholestasis-lymphedema syndrome. Mutations in the *FOXC2* gene, which encodes a transcription factor that interacts with a signaling pathway involved in the development of lymphatic vessels, cause the lymphedema-distichiasis syndrome, in which lymphedema praecox occurs in patients who also have a double row of eyelashes. A mutation of *SOX18*, a transcription factor upstream of lymphatic endothelial cell differentiation, has been described in patients with lymphedema, alopecia, and telangiectasias (hypotrichosis, lymphedema, telangiectasia syndrome). Mutations of the *CCBE1* gene, which enhances the lymphangiogenic effects of VEGF-C, cause Hennekam's lymphangiectasia-lymphedema syndrome, and *KIF11* gene mutations are associated with microcephaly-lymphedema syndrome. Mutations of the *GATA2* gene, which is involved in the development of lymphatic valves, cause lymphedema and a predisposition to acute myeloid leukemia. Patients with a chromosomal aneuploidy, such as Turner's syndrome, Klinefelter's syndrome, or trisomy 18, 13, or 21, may develop lymphedema. Syndromic vascular anomalies associated with lymphedema also include Klippel-Trénaunay syndrome and Parkes-Weber syndrome. Other disorders associated with lymphedema include Noonan's syndrome, yellow nail syndrome, intestinal lymphangiectasia syndrome, lymphangiomyomatosis, and neurofibromatosis type 1.

TABLE 293-2 Causes of Lymphedema

Primary
Sporadic (no identified cause)
Genetic disorders
Milroy's disease (*VEGFR3, VEGF-C*)
Meige's disease (gene mutation not established)
Lymphedema-distichiasis syndrome (*FOXC2*)
Cholestasis-lymphedema (*LSC1*)
Hennekam's lymphangiectasia-lymphedema syndrome (*LCCBE1*)
Emberger's syndrome-lymphedema and predisposition to AML (*GATA2*)
Microcephaly-lymphedema syndrome (*KIF11*)
Hypotrichosis-lymphedema-telangiectasia (*SOX18*)
Chromosomal aneuploidies
Turner's syndrome
Klinefelter's syndrome
Trisomy 13, 18, or 21
Other disorders associated with primary lymphedema
Noonan's syndrome
Klippel-Trénaunay syndrome
Parkes-Weber syndrome
Yellow nail syndrome
Intestinal lymphangiectasia syndrome
Lymphangiomyomatosis
Neurofibromatosis type 1
Secondary
Infection
Bacterial lymphangitis (*Streptococcus pyogenes, Staphylococcus aureus*)
Lymphogranuloma venereum (*Chlamydia trachomatis*)
Filariasis (*Wucheria bancrofti, Brugia malayi, B. timori*)
Tuberculosis
Neoplastic infiltration of lymph nodes
Lymphoma
Prostate
Others
Surgery or irradiation of axillary or inguinal lymph nodes for treatment of cancer Iatrogenic
Lymphatic division (during peripheral bypass surgery, varicose vein surgery, or harvesting of saphenous veins)
Miscellaneous
Chronic venous insufficiency
Contact dermatitis
Podoconiosis
Rheumatoid arthritis
Pregnancy
Factitious

Secondary lymphedema is an acquired condition that results from damage to or obstruction of previously normal lymphatic channels. Recurrent episodes of bacterial lymphangitis, usually caused by streptococci, are a very common cause of lymphedema. The most common etiology of secondary lymphedema worldwide is lymphatic filariasis, affecting >120 million children and adults and causing lymphedema and elephantiasis in 14 million of these affected individuals (Chap. 240). Recurrent bacterial lymphangitis by *Streptococcus* may result in chronic lymphedema. Other infectious causes include lymphogranuloma venereum and tuberculosis. A common acquired cause of lymphedema in tropical countries is podoconiosis, which results from barefoot exposure and absorption of silicate particles in soil derived from volcanic rock. In developed countries, the most common secondary cause of lymphedema is surgical excision or irradiation of axillary and inguinal lymph nodes for treatment of cancers, such as breast, cervical, endometrial, and prostate cancer, sarcomas, and malignant melanoma. Lymphedema of the arm occurs in 13% of breast cancer patients after axillary node dissection and in 22% after both surgery and radiotherapy. Lymphedema of the leg affects ~15% of patients with cancer after inguinal lymph node dissection. Tumors, such as prostate cancer and lymphoma, also can infiltrate and obstruct lymphatic vessels. Chronic venous insufficiency is gaining recognition as a cause of lymphedema termed phlebolymphedema. Less common causes include contact dermatitis, rheumatoid arthritis, pregnancy, and self-induced or factitious lymphedema after application of tourniquets.

Clinical Presentation Lymphedema is generally a painless condition, but patients may experience a chronic dull, heavy sensation in the leg, and most often, they are concerned about the appearance of the leg. Lymphedema of the lower extremity initially involves the foot and gradually progresses up the leg so that the entire limb becomes

A B

FIGURE 293-2 ***A.*** Lymphedema characterized by swelling of the leg, nonpitting edema, and squaring of the toes. *(Courtesy of Dr. Marie Gerhard-Herman, with permission.)* ***B.*** Advanced chronic stage of lymphedema illustrating the woody appearance of the leg with acanthosis and verrucous overgrowths. *(Courtesy of Dr. Jeffrey Olin, with permission.)*

edematous (Fig. 293-2). In the early stages, the edema is soft and pits easily with pressure. Over time, subcutaneous adipose tissue accumulates, the limb enlarges further and loses its normal contour, and the toes appear square. Thickening of the skin is detected by Stemmer's sign, which is the inability to tent the skin at the base of the toes. *Peau d'orange* is a term used to describe dimpling of the skin, resembling that of an orange peel, caused by lymphedema. In the chronic stages, the edema no longer pits and the limb acquires a woody texture as the tissues become indurated and fibrotic. The International Society of Lymphology describes four clinical stages of lymphedema (Table 293-3).

Differential Diagnosis Lymphedema should be distinguished from other disorders that cause unilateral leg swelling, such as deep-vein thrombosis and chronic venous insufficiency. In the latter condition, the edema is softer, and there is often evidence of a stasis dermatitis, hyperpigmentation, and superficial venous varicosities, as described earlier. Other causes of leg swelling that resemble lymphedema are myxedema and lipedema. Lipedema usually occurs in women and is caused by accumulation of adipose tissue in the leg from the thigh to the ankle with sparing of the feet.

TABLE 293-3 Stages of Lymphedema

Stage 0 (or Ia)
A latent or subclinical condition where swelling is not evident despite impaired lymph transport. It may exist for months or years before overt edema occurs.
Stage I
Early accumulation of fluid relatively high in protein content that subsides with limb elevation. Pitting may occur. An increase in proliferating cells may also be seen.
Stage II
Limb elevation alone rarely reduces tissue swelling, and pitting is manifest. Late in stage II, the limb may or may not pit as excess fat and fibrosis supervene.
Stage III
Lymphostatic elephantiasis where pitting can be absent and trophic skin changes such as acanthosis, further deposition of fat and fibrosis, and warty overgrowths have developed.

Diagnostic Testing Physical examination is usually sufficient to establish a diagnosis of lymphedema. The evaluation of patients with lymphedema should include diagnostic studies to clarify the cause. Abdominal and pelvic ultrasound and computed tomography (CT) can be used to detect obstructing lesions such as neoplasms. Magnetic resonance imaging (MRI) of the affected limb may reveal a honeycomb pattern characteristic of lymphedema in the epifascial compartment and identify enlarged lymphatic channels and lymph nodes. MRI also is useful to distinguish lymphedema from lipedema. Lymphoscintigraphy and lymphangiography are rarely indicated, but either can be used to confirm the diagnosis or differentiate primary from secondary lymphedema. Lymphoscintigraphy involves the injection of radioactively labeled technetium-containing colloid into the distal subcutaneous tissue of the affected extremity, which is imaged with a scintigraphic camera to visualize lymphatic vessels and lymph nodes. Findings indicative of primary lymphedema include absent or delayed filling of the lymphatic vessels or dermal back flow caused by lymphatic reflux. Findings of secondary lymphedema include dilated lymphatic vessels distal to an area of obstruction. In lymphangiography, iodinated radiocontrast material is injected into a distal lymphatic vessel that has been isolated and cannulated. In primary lymphedema, lymphatic channels are absent, hypoplastic, or ectatic. In secondary lymphedema, lymphatic channels often appear dilated beneath the level of obstruction. The complexities of lymphatic cannulation and the risk of lymphangitis associated with the contrast agent limit the utility of lymphangiography. Optical imaging with a near-infrared fluorescence dye enables quantitative imaging of peripheral superficial lymph flow and is useful in the operative setting.

TREATMENT

Lymphedema

Patients with lymphedema of the lower extremities must be instructed to take meticulous care of their feet and legs to prevent cellulitis and lymphangitis. Skin hygiene is important, and emollients can be used to prevent drying. Prophylactic antibiotics are often helpful, and fungal infection should be treated aggressively. Patients should be encouraged to participate in physical activity, as exercise may minimize symptoms and maintain functionality; frequent leg elevation can reduce the amount of edema. Psychosocial support is indicated to assist patients cope with anxiety or depression related to body image, self-esteem, functional disability, and fear of limb loss.

Physical therapy, including massage to facilitate lymphatic drainage, may be helpful. The type of massage, termed manual lymphatic drainage, is part of comprehensive decongestive physiotherapy for lymphedema and involves mild compression of the skin of the affected extremity to dilate the lymphatic channels and enhance lymphatic motility. Multilayered, compressive bandages are applied after each massage session to reduce recurrent edema. After optimal reduction in limb volume by decongestive physiotherapy, patients can be fitted with graduated compression hose or other adjustable compression garments. Sequential intermittent pneumatic compression devices can also be applied at home to facilitate reduction of the edema, improve quality of life, and reduce recurrent cellulitis. Diuretics are contraindicated and may cause depletion of intravascular volume and metabolic abnormalities. Failure to control limb edema may lead to recurrent infections, progressive trophic skin changes, and rarely a highly lethal complication of lymphangiosarcoma.

Liposuction in conjunction with decongestive physiotherapy may be considered to treat lymphedema, particularly postmastectomy

lymphedema. Other surgical interventions, including lymph node transfer, are rarely used and often not successful in ameliorating lymphedema. Microsurgical lymphaticovenous anastomotic procedures have been performed to rechannel lymph flow from obstructed lymphatic vessels into the venous system and may improve lymphatic transport and quality of life in secondary lymphedema. Limb reduction procedures to resect subcutaneous tissue and excessive skin are performed occasionally in severe cases of lymphedema to improve mobility. Modification of surgical techniques to minimize impact upon the lymphatic system or enhance drainage with prophylactic lymphatic-venous shunts are being employed during operations that require lymph node dissection to reduce the risk of lymphedema.

Therapeutic lymphangiogenesis has intriguing potential as it has been studied in animal models of lymphedema. Overexpression of VEGF-C generates new lymphatic vessels and improves lymphedema in a murine model of primary lymphedema. The administration of recombinant VEGF-C or VEGF-D stimulated lymphatic growth in preclinical models of postsurgical lymphedema. There may be additional benefits when administered in conjunction with lymph node transfer. However, clinical trials in patients with lymphedema are still required to determine efficacy of gene transfer and cell-based therapies for lymphedema.

294 Pulmonary Hypertension

Bradley A. Maron, Joseph Loscalzo

Pulmonary hypertension (PH) is a heterogeneous disease involving pathogenic remodeling of the pulmonary vasculature, which increases pulmonary artery pressure and pulmonary vascular resistance (PVR). The most common causes of PH are left heart or primary lung disease. Additionally, PH is observed in some patients as a later complication of luminal pulmonary embolism and may be observed variably in patients with various hematologic, myeloproliferative, and other systemic diseases. Pulmonary arterial hypertension (PAH) is an uncommon, but distinct, PH subtype characterized by the interplay between molecular and genetic events that cause an obliterative arteriopathy and symptoms of dyspnea, chest pain, and syncope. If left untreated, PH carries a high mortality rate, largely owing to decompensated right heart failure.

There have been significant advances in diagnosis, classification, and treatment of PH patients. For example, the mean pulmonary artery pressure (mPAP) used to diagnose PH has been lowered from ≥25 mmHg to >20 mmHg, and the PVR level used to identify patients with PAH and other forms of precapillary PH has been lowered from ≥3 to >2 Wood units (WU). These adjustments emphasize earlier disease detection, as a substantial delay in diagnosis of up to 2 years is common in PAH and has important implications for both quality of life and life span. Clinicians should be able to recognize the signs and symptoms of PH and complete a systematic evaluation in at-risk patients. In this way, prompt diagnosis, appropriate treatment, and optimized patient outcome are achievable.

PATHOBIOLOGY

Apoptosis resistance, cell proliferation, dysregulated metabolism, and increased oxidant stress involving pulmonary vascular cells, pericytes, and adventitial fibroblasts underlie the pathogenesis of PAH. These events lead to hypertrophic, fibrotic, and plexogenic remodeling of distal (small) pulmonary arterioles, which decreases vascular compliance and promotes in situ thrombosis **(Fig. 294-1)**. The remodeling pattern also includes extracellular matrix expansion, which is rich in integrins, nonfibrillar collagens, fibronectin, and other tensile proteins that stiffen affected blood vessels further. A minority of patients appear to have a vasoconstriction-dominant phenotype, which, if present, requires a unique treatment strategy discussed in greater detail below. There is now greater understanding that in PAH, right ventricular dysfunction occurs due not only to increased right ventricular afterload but also as a consequence of depressed right ventricular sarcomere function from chronic inflammation or autoimmune mechanisms.

Genetic Drivers Several germline variants in genes that regulate fundamental cellular processes such as growth, proliferation, or phenotype switching are associated with incident PAH and follow a familial pattern. A variant in the gene encoding bone morphogenetic protein receptor-2 (*BMPR2*) is the most common cause of hereditary PAH, although penetrance is variable and may be as low as 20% in some populations. Sporadic mutations involving *BMPR2* are also reported in PAH patients. BMPR2 is within the (super)family of transforming growth factor- β (TGF-β) receptors that transduce a wide range of cellular events via stimulation by activins, inhibins, and bone morphogenetic proteins **(Fig. 294-2)**. Indeed, imbalance between proliferative and antiproliferative TGF-β receptor signaling in PAH has emerged as a bona fide therapeutic target based on clinical trials testing the effect of activin signal inhibitor therapy on outcome in PAH (see section on sotatercept).

The advance of genome-wide association studies has expanded the range of genetic drivers linked to pathogenic mechanisms underlying PAH, to include *TBX4* and *SOX17*, which regulate activation of fibroblast growth factor-10 and hepatocyte growth factor, respectively. Genetic predisposition to PH in the setting of left heart disease is unresolved, although single-gene polymorphisms that target actin

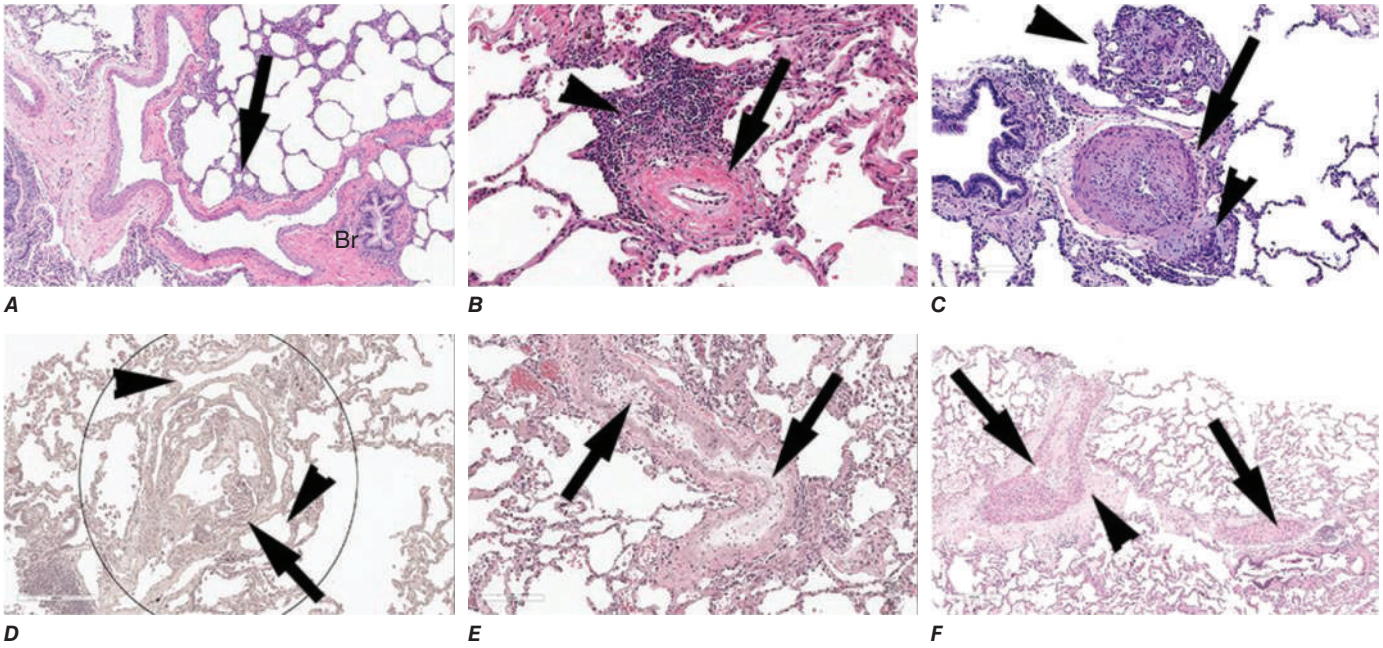

FIGURE 294-1 Panels on the left show examples of plexogenic pulmonary arteriopathy. Representative images of a normal lung (***A***) and examples of pulmonary vascular remodeling in pulmonary arterial hypertension (***B–F***), including idiopathic pulmonary arterial hypertension (***B–E***) and pulmonary venoocclusive disease (***F***), are shown. ***A.*** Normal pulmonary artery (*arrow*) adjacent to a terminal bronchiole (Br). ***B.*** Marked media and intima thickening of small vessels (*arrow*), partly surrounded by lymphoid cells, form a cluster reminiscent of a primary follicle (*arrowhead*). ***C.*** Idiopathic pulmonary hypertension lung with a markedly muscularized medium-sized pulmonary artery (*arrow*), which distally branches into a plexiform lesion (*lower arrowhead*) and an adjacent plexiform lesion (*upper arrowhead*). ***D.*** Complex vascular lesion (*circle*) with a combination of telangiectatic-like dilations of the pulmonary artery (*arrowheads*) and a plexiform lesion (*arrow*). ***E.*** Medium-sized pulmonary artery with complete lumen obliteration with a loose collagen, poorly cellular matrix (*arrows*). ***F.*** Interlobular septal, medium-sized vein (*arrowhead*) obliterated by loose connective tissue (*arrows*), likely the result of an organized thrombus, characteristic of venoocclusive disease. *(These representative images were provided courtesy of Dr. Rubin Tuder. The samples were obtained through the evaluation of lungs collected by the Pulmonary Hypertension Breakthrough Initiative, with similar pulmonary vascular pathology spectrum as reported in reference E Stacher et al: Modern age pathology of pulmonary arterial hypertension. Am J Respir Crit Care Med 186:261, 2012. Adapted with permission of the American Thoracic Society. Copyright © 2021 American Thoracic Society. All rights reserved. Reproduced with permission from BA Maron et al: Pulmonary Arterial Hypertension: Diagnosis, Treatment, and Novel Advances. Am J Respir Crit Care Med 203:1472, 2021.)*

binding, basement membrane, and major histocompatibility complex II proteins have been reported in lung tissue of affected patients. A variant in *EIF2AK4* is an established genetic risk factor for pulmonary venoocclusive disease with a recessive mode of transmission, although clinical expression among carriers is evident initially across a wide age range (10–60 years).

Epigenetics in PH The baseline DNA damage profile is increased in pulmonary artery endothelial cells and circulating blood mononuclear cells from PAH patients. This finding implicates DNA itself as a target of injury and is accompanied by epigenetic disease mechanisms involving methylation and demethylation that include translocation methylcytosine dioxygenase 2 (*TET2*) and methyltransferase 3B (*DNMT3B*). The extent to which these events are transmissible across generations remains limited to experimental disease models. Nevertheless, bromodomain-containing 4 and histone deacetylation inhibition, particularly for HDAC-1 and HDAC-5, are promising future PAH therapeutics. Long noncoding RNAs, which regulate epigenetic (among other)

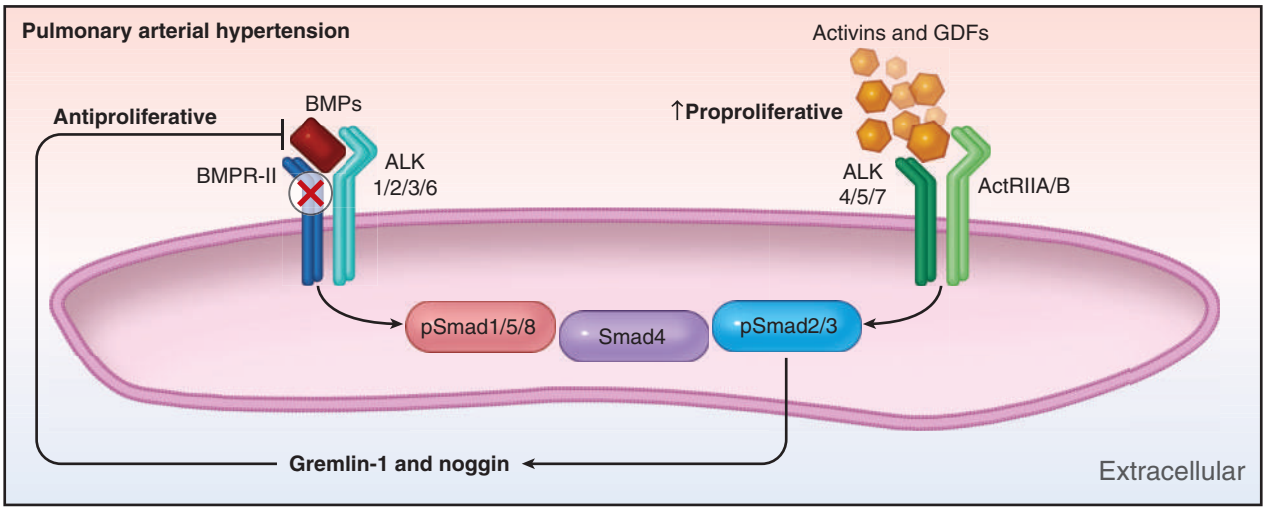

FIGURE 294-2 Pulmonary arterial hypertension is associated with dysregulation of the bone morphogenetic protein (BMP) receptor type II (BMPR-II)–Smad1/5/8 pathway in pulmonary vascular smooth muscle and endothelial cells, causing an imbalance between proproliferative and antiproliferative signaling pathways. BMPR-II–Smad1/5/8 pathway downregulation leads to increased production of activin ligands, such as activin A, growth differentiation factor 8 (GDF8), and GDF11, which contributes to activin receptor type IIA (ActRIIA)–Smad2/3 pathway upregulation. Increased phosphorylated Smad (pSmad) 2/3 activity promotes expression of the endogenous BMP antagonists gremlin-1 and noggin. Gremlin-1 and noggin further reduce BMP–Smad1/5/8 signaling. The overall result is that antiproliferative signaling is reduced, shifting the balance toward proproliferative activin–Smad2/3 signaling, which leads to pulmonary vascular remodeling. *(Adapted from M Humbert et al: N Engl J Med 384:1204, 2021.)*

processes that underpin hypertrophic vascular remodeling in PAH, include the tyrosine kinase receptor–inducing long noncoding RNA through its effects on p53/platelet-derived growth factor receptor β in lung pericytes. At present, hypoxia is the most well-studied epigenetic driver linked to PH, but a practical framework to predict disease onset through this mechanism in individual patients is unresolved.

Endothelial-Mesenchymal Transition Plexigenic and fibrotic pulmonary arterial remodeling in PAH is linked to cellular phenotype switching, particularly endothelial-mesenchymal transition (End-MT) for which specific markers are identified in ~6% of cells in explanted lungs from patients or at autopsy. Inflammation as well as hypoxia plus vascular endothelial growth factor receptor inhibition have been shown to increase End-MT, which in affected cells is characterized by migration, gain of smooth muscle actin fibers, and loss of cell-cell contacts. Interestingly, End-MT is related to a loss of BMPR2 expression, tying together a monogenic risk to a key endophenotype that drives PAH pathology.

Hypoxia, Metabolism, and Matrix Remodeling Abnormalities in multiple molecular pathways, genes, and cell types are associated with potentially modifying therapeutics, particularly those that focus on extracellular matrix remodeling **(Fig. 294-3)**. The tyrosine kinase Janus kinase 2 (JAK2) is overactivated in PAH, which is inhibited by ruxolitinib to attenuate cellular proliferation and experimental PH. Hypoxia-inducible factor (HIF) signaling is a potentially modifiable disease-causing pathway, as treatment with the novel HIF-2α inhibitor PT2567 improves hemodynamics and vascular remodeling in PAH. Pulmonary artery smooth muscle cells isolated from PAH patients preferentially synthesize lactic acid in the presence of abundant molecular oxygen (Warburg effect). This metabolic change results in a proliferative cellular phenotype and has stimulated intense interest on metabolic modulating therapies. Dichloroacetate, which inhibits pyruvate dehydrogenase kinase to normalize voltage-gated K^+ channels and promote pulmonary artery smooth muscle cell apoptosis, has been tested clinically with overall mixed results but a signal toward predicting treatment response by *SIRT3* and *UCP2* genotype. Nonetheless, numerous alternative metabolic targets show therapeutic promise, including SOD2, PPARγ, and NFAT. Finally, there is greater interest in reverse remodeling pathways in PAH. For example, matrix metalloproteinase (MMP)-8 is protective against PAH by stabilizing mechanosensitive focal adhesion kinase–yes-associated protein/transcriptional coactivator with PDZ-binding motif (FAK-YAP/TAZ). This stabilization, in turn, suppresses extracellular matrix expansion and vascular fibrosis.

PATHOPHYSIOLOGY

In PAH, plexogenic and fibrotic remodeling of pulmonary arterioles impairs pulmonary arterial compliance and results in a progressive increase in total PVR. The resting PVR increases through the temporal progression of PAH, corresponding to a rise in mPAP. To preserve cardiac output (CO) in the face of elevated right ventricular afterload, right ventricular work must increase. A sustained (or progressive) increase in right ventricular work causes a shift in the efficiency of right ventricular systolic function by which maintaining pulmonary

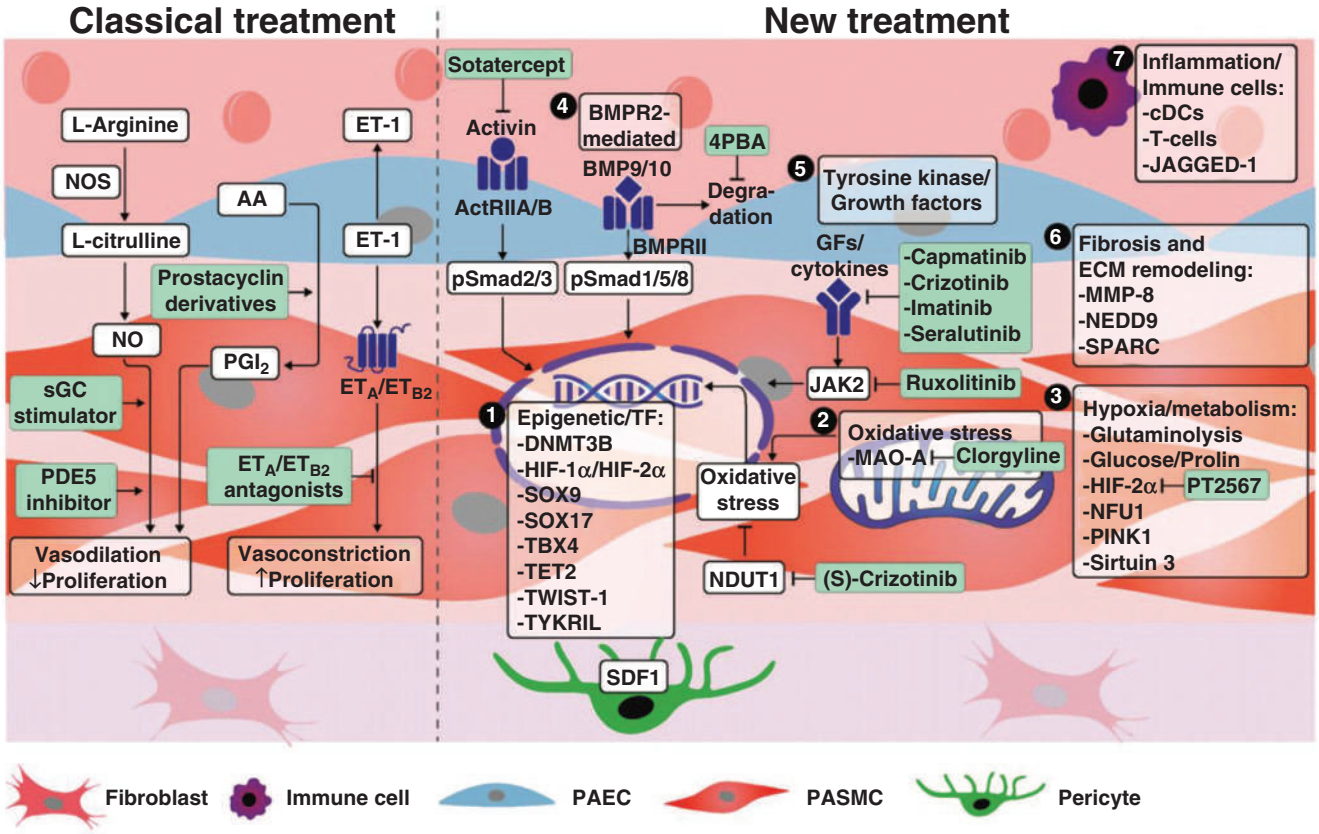

FIGURE 294-3 Modifiable pathobiological targets in pulmonary arterial hypertension. Current treatment approaches focus on endothelin, nitric oxide, and prostacyclin signaling. Novel treatment targets address (1) epigenetic mechanisms/transcriptional factors; (2) oxidative stress; (3) hypoxia and metabolic signaling; (4) BMPR2-mediated signaling; (5) tyrosine kinase and growth factor signaling; (6) fibrosis and extracellular matrix remodeling; and (7) inflammation and immune cell infiltration. 4PBA, 4-phenylbutyric acid; AA, arachidonic acid; ActRII, activin receptor type II; BMP, bone morphogenetic protein; BMPR2, bone morphogenetic protein receptor type 2; cDC, conventional dendritic cell; DNMT3B, DNA methyltransferase 3 b; ET, endothelin; GDFs, growth and differentiation factors; HIF = hypoxia-inducible factor; JAGGED-1, jagged canonical Notch ligand 1; JAK, Janus kinase; MAO-A, monoaminoxidase A; MMP, matrix metalloproteinase; NUDT1, nudix hydrolase 1; NEDD9, neural precursor cell–expressed developmentally downregulated protein 9; NFU1, NFU1 iron-sulfur cluster scaffold; NO, nitric oxide; NOS, nitric oxide synthase; PAEC, pulmonary artery endothelial cell; PASMC, pulmonary arterial smooth muscle cell; PDE5, phosphodiesterase 5; PGI2, prostacyclin; PINK1, phosphatase and tensin homolog–induced kinase 1; SDF1, stromal cell–derived factor 1; sGC, soluble guanylate cyclase; SOX9, SRY-box transcription factor 9; SOX17, SRY-box transcription factor 17; SPARC, secreted protein acidic and rich in cysteine; TBX4, T-box transcription factor 4; TET2, Tet methylcytosine dioxygenase 2; TWIST1, Twist family BHLH transcription factor 1; TYKRIL, tyrosine kinase receptor–inducing long noncoding RNA. *(Reproduced with permission from SJ Johnson et al: Am J Respir Crit Care Med 208:528, 2023.)*

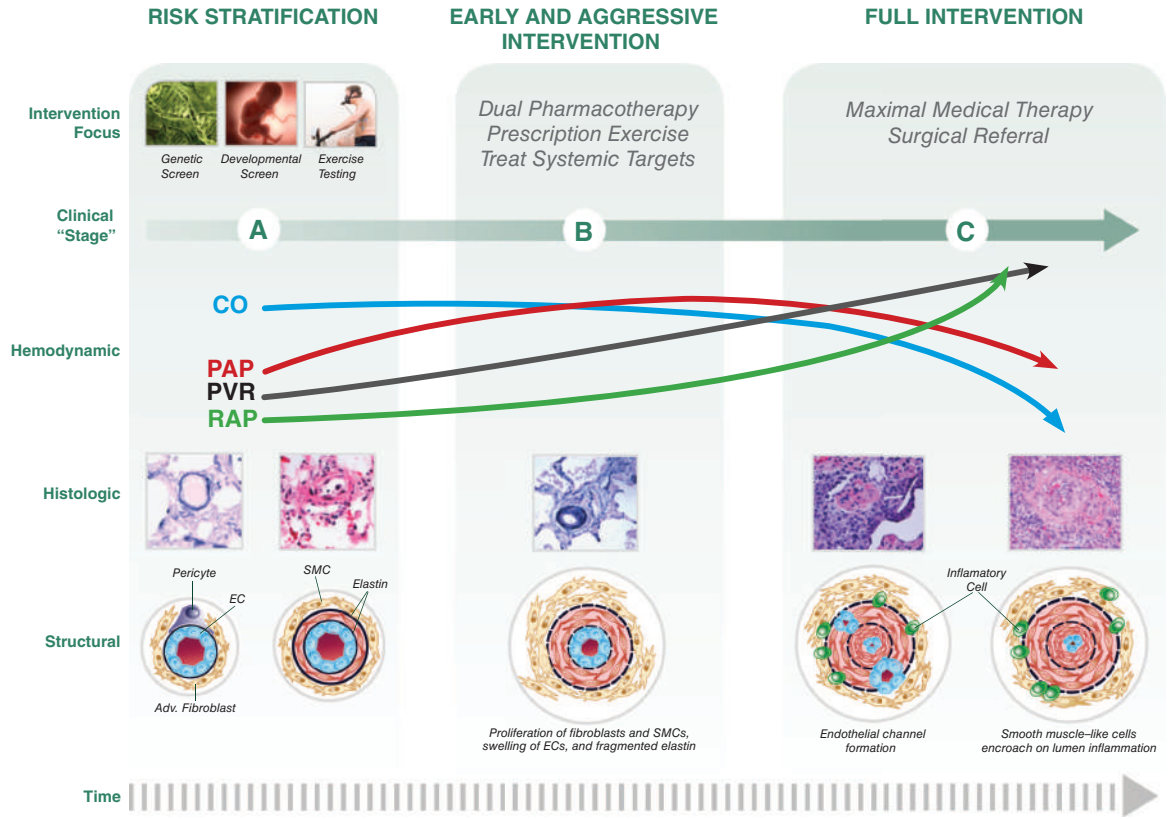

FIGURE 294-4 An integrated overview of pulmonary arterial hypertension (PAH). In PAH, initial changes in the histopathophenotype of distal pulmonary arterioles precede significant changes in hemodynamics or the development of symptoms in most patients (clinical stage A). As vascular remodeling progresses, there is an increase in pulmonary vascular resistance (PVR), pulmonary artery pressure (PAP), and right atrial pressure (RAP). In clinical stage B, symptoms are evident and, when diagnosed, prompt early, aggressive treatment. Effacement of pulmonary arterioles results in severely increased PVR that promotes right heart failure, defined by a decrease in cardiac output (CO) and PAP. Patients in clinical stage C have severe symptoms and require full therapeutic intervention. Identifying clinical stage A patients remains challenging, although genetic risk factors or symptoms with exercise may be informative. EC, endothelial cell; SMC, smooth muscle cell. *(Reproduced with permission from Maron BA, Abman SH: Focusing on Developmental Origins and Disease Inception for the Prevention of Pulmonary Hypertension. Am J Respir Crit Care Med 195:292, 2017.)*

circulatory pressure depletes myocardial energy. These changes occur at the expense of energy normally reserved to maintain optimal blood perfusion through the alveolar-capillary interface for blood oxygenation, a process termed right ventricular–pulmonary arterial uncoupling. In end-stage PAH, the CO declines, leading to a decrease in mPAP **(Fig. 294-4)**, with extrapulmonary vascular manifestations. These include overactivation of neurohumoral signaling, renal failure, abnormal episcleral vessels (seen in patients with hereditary PAH due to *BMPR2* mutation), and hyper- or hypothyroidism. Volitional muscle atrophy in PAH is associated with reduced muscle strength, type I fiber switching to fatigable type II fibers, and decreased capillary density. This myopathy affects respiratory function, as well, including impairment of maximal inspiratory and expiratory pressure. Overall, sarcopenia in PAH with right ventricular heart failure is likely multifactorial, driven by deconditioning and alternative pathophysiological mechanisms linked to impaired cardiac output (i.e., neurohumoral signaling) and possibly through the ectopic effects of molecular intermediaries such as miR-136 downregulation **(Fig. 294-5)**.

DIAGNOSIS

The diagnosis of PH can be missed without a reasonable index of suspicion. Indeed, findings from clinical registries suggest that PH is often overlooked, even among patients with numerous risk factors. This shortcoming may be because PH symptoms are nonspecific, insidious, and overlap considerably with many common conditions, such as asthma, heart failure with preserved ejection fraction, and deconditioning. Additionally, there is a misconception that in patients with comorbid cardiopulmonary conditions (e.g., interstitial lung disease, mitral valve disease), PH is merely an extension of the underlying disease rather than a specific clinical entity.

Most patients will present with dyspnea and/or fatigue, whereas edema, chest pain, presyncope, and syncope are less common and associated with more advanced disease. In early phases of PAH, the physical examination is often unrevealing. As the disease progresses, there may be evidence of right ventricular failure with elevated jugular venous pressure, lower extremity edema, and ascites. Additionally, the cardiovascular examination may reveal an accentuated P_2 component of the second heart sound, a right-sided S_3 or S_4, and a holosystolic tricuspid regurgitant murmur. It is also important to seek signs of the diseases that are commonly concurrent with PH: clubbing may be seen in some chronic lung diseases, sclerodactyly and telangiectasia may signify scleroderma (or the limited cutaneous form, CREST [calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia]), and crackles on examination of the lungs and systemic hypertension may be clues to left-sided systolic or diastolic heart failure.

Overview of the Diagnostic Clinical Evaluation Once clinical suspicion is raised, a systematic approach to diagnosis and assessment is essential. In advanced disease, electrocardiography may show right ventricular hypertrophy or strain, and enlargement of pulmonary arteries and obliteration of the retrosternal space are often observed on chest roentgenography **(Fig. 294-6)**. In turn, echocardiography with agitated saline (bubble) study is the most important initial screening test. Elevated estimated pulmonary artery systolic pressure (>35 mmHg), notched waveform on continuous wave Doppler interrogation of the right ventricular outflow tract, or a hypertrophied or dilated right ventricle supports the diagnosis of PH. Important additional information can be gleaned about specific etiologies of PH, such as valvular disease, left ventricular systolic

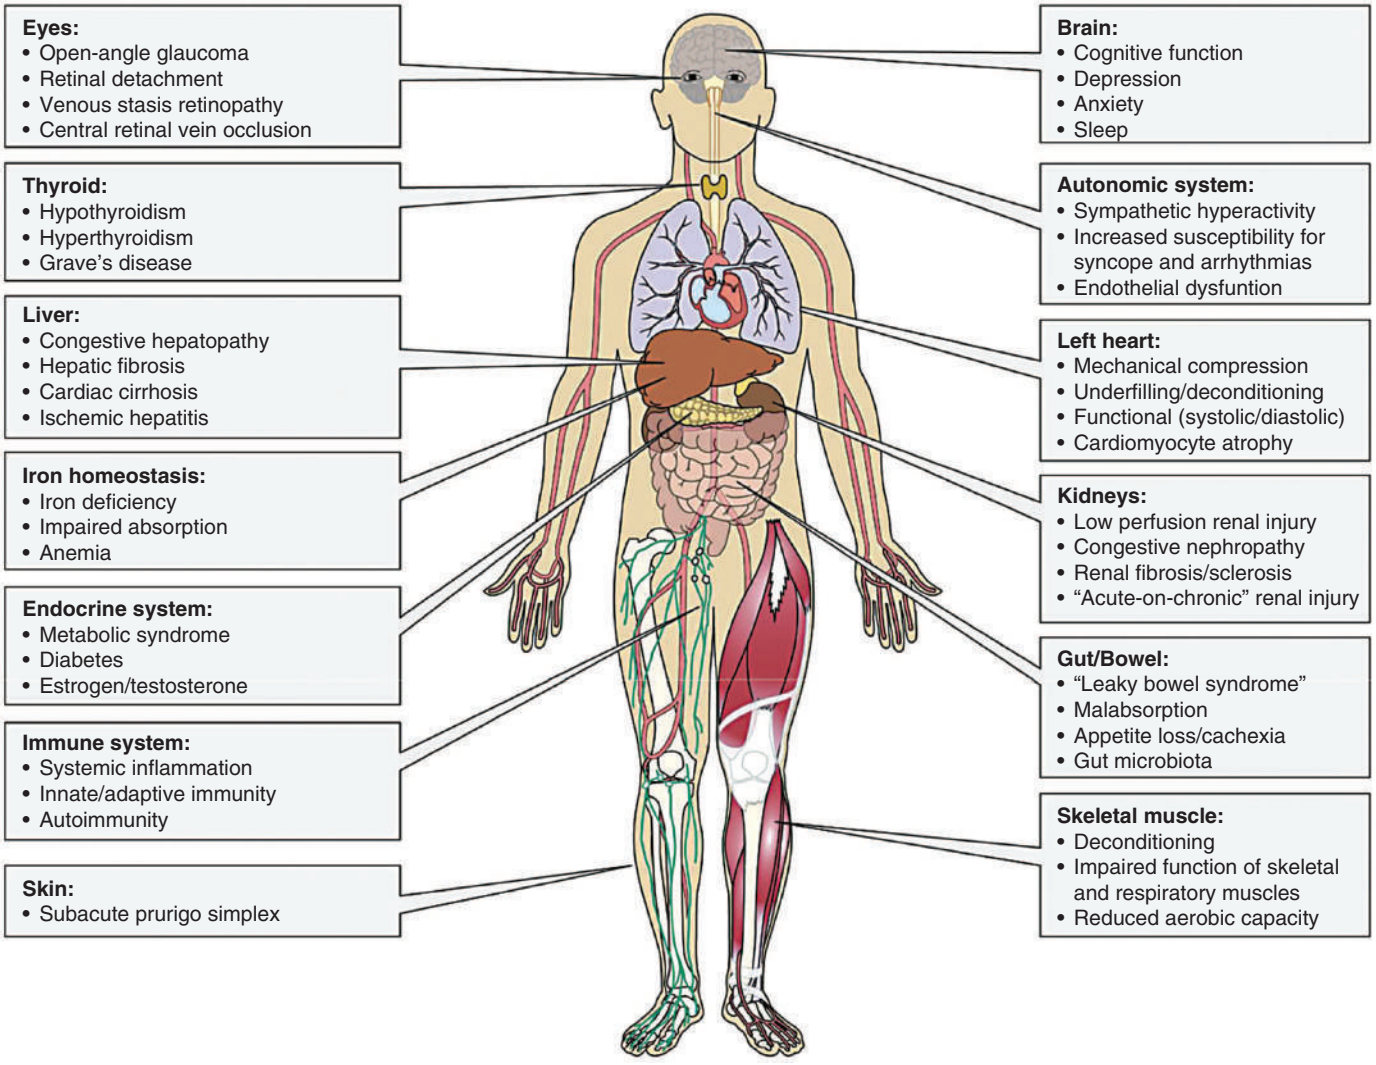

FIGURE 294-5 Systemic manifestations of right heart failure. *(Reproduced with permission from S Rosenkranz et al: Systemic consequences of pulmonary hypertension and right-sided heart failure. Circulation 141:67, 2020.)*

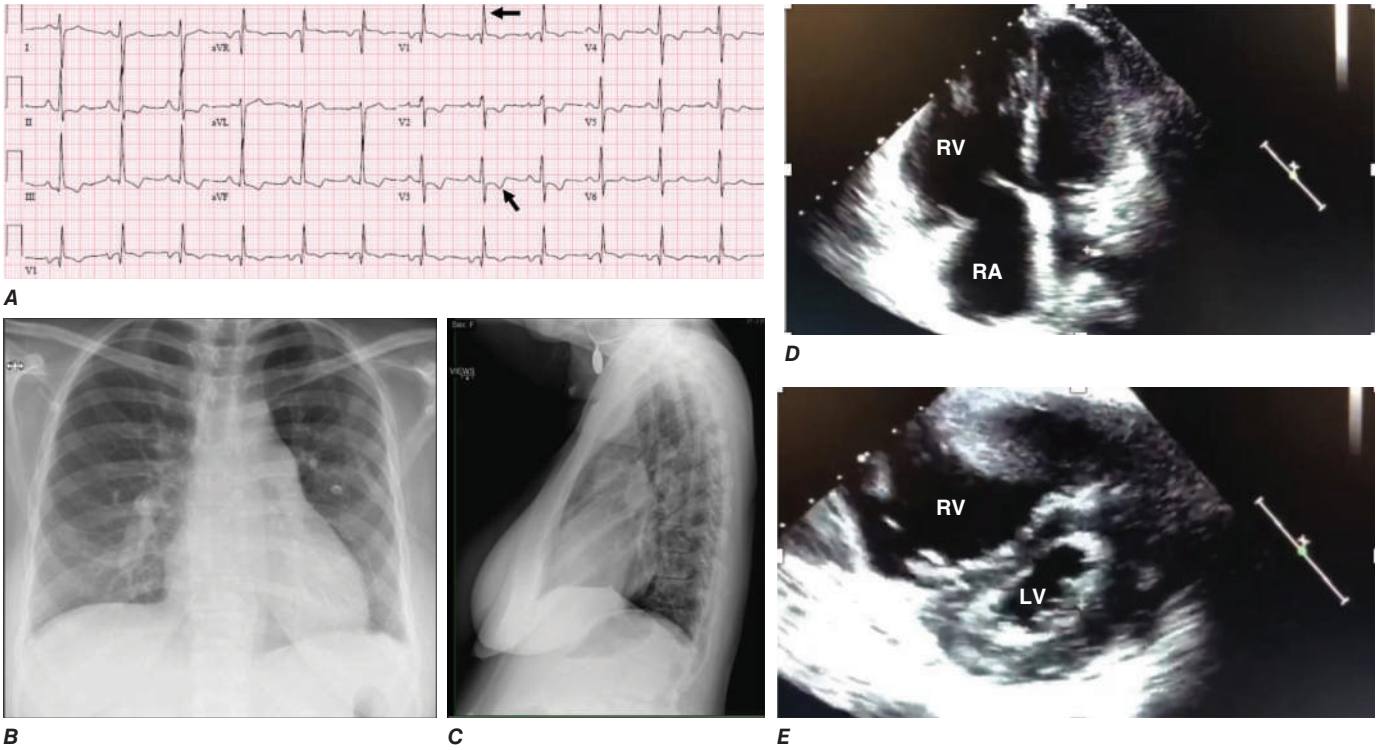
dysfunction, left atrial enlargement, and intracardiac shunt. In addition, hypertrophic cardiomyopathy (HCM), amyloid cardiomyopathy, and sarcoid cardiomyopathy, which are specific forms of left heart disease that predispose to PH, are linked to disease-specific approaches to treatment.



A high-quality echocardiogram that is absolutely normal may obviate the need for further PH evaluation. However, this is distinct from an echocardiogram in which tricuspid regurgitation is not detected. In this scenario, the information required to estimate pulmonary artery pressure is lacking, and PH is observed in one-third of such patients. Patients with evidence of PH on echocardiography or in whom unexplained dyspnea or hypoxemia is evident despite an unremarkable echocardiogram often require further assessment.

Additional tests focusing on functional capacity are useful for quantifying disease burden, such as a 6-minute walk distance (6-MWD) assessment, which also aids in assessing prognosis. Cardiopulmonary exercise testing (CPET) may differentiate between cardiac and pulmonary limitations to exercise thereby providing pathophysiologic insights on the cause of dyspnea. Peak volume of oxygen consumption (pVO_2), which is an integrated parameter of cardiopulmonary fitness, is prognostic in PH patients when <15 mL/kg/min. However, low pVO_2 is an important clinical finding across the spectrum of heart-lung disease and, thus, is not diagnostic of PH per se. In patients with a normal CPET, further invasive testing is often unnecessary. One exception to this approach is in patients with reassuring CPET results but in whom a significant decrease in exercise tolerance from baseline is nonetheless reported, often observed in elite athletes or highly conditioned individuals with early-stage PH or subacute pulmonary embolism.

Invasive hemodynamic monitoring with right heart catheterization (RHC) is the gold standard for PH diagnosis and severity assessment. Interpretation of RHC data, however, is often optimized by information from diagnostic tests that support and frame the clinical context of pulmonary vascular disease.

Stepwise Approach to Diagnosing PH One common PH diagnostic strategy is outlined in **Figure 294-7**; however, the approach should be individualized in practice according to a particular patient's clinical and risk factor profile. For example, patients with a strong history of inhaled tobacco use may benefit from prioritizing diagnostic tests assessing pulmonary function and the lung parenchyma, whereas a myocardial ischemia evaluation should be considered early in the evaluation of patients with left-sided cardiomyopathy.

PULMONARY FUNCTION AND LUNG IMAGING Pulmonary function testing results may suggest restrictive or obstructive lung diseases as the cause of dyspnea or PH. In PAH, an isolated reduction in diffusing capacity of the lungs for carbon monoxide (DL_{CO}) is a classic finding. High-resolution computed tomography (CT) provides useful information, particularly enlargement of the main pulmonary artery, right ventricle, and atria, as well as peripheral pruning of small vessels; however, high-resolution CT may also reveal signs of venous congestion, including centrilobular ground glass infiltrate and thickened septa. In the absence of left heart disease, these findings suggest pulmonary venous disease, a rare cause of PAH that can be quite challenging to diagnose. CT is also critical for distinguishing comorbid interstitial lung disease, emphysema, or overlap syndromes that include fibrosis and obstructive pulmonary disease.

FIGURE 294-6 Electrocardiography, chest roentgenography, and two-dimensional echocardiography in advanced pulmonary arterial hypertension. ***A.*** Standard 12-lead electrocardiogram shows peaked R waves in lead V_1 and ST-segment depression in leads V_2–V_3, suggestive of right ventricular hypertrophy with strain (*arrows*). ***B, C.*** Anterior-posterior and lateral chest roentgenogram demonstrating enlargement of central pulmonary arteries and obliteration of the retrosternal space, indicative of right ventricular hypertrophy. ***D, E.*** Apical four-chamber and two-chamber short axis views acquired by transthoracic echocardiography demonstrate right ventricular (RV) and right atrial (RA) enlargement, as well as interventricular septal flattening in diastole consistent with pressure overload. LV, left ventricle.

SLEEP STUDIES Nocturnal desaturation is a common finding in PH, even in the absence of sleep-disordered breathing. Thus, all patients should undergo nocturnal oximetry screening, regardless of whether classic symptoms of obstructive sleep apnea or obesity-hypoventilation syndrome are present.

ASSESSMENT OF PULMONARY ARTERIAL THROMBOSIS Patients with prior luminal pulmonary embolism are at increased risk for chronic thromboembolic pulmonary hypertension (CTEPH), which is a specific PH subtype characterized by vascular fibrosis and arterial microthrombus. Although CTEPH is curable in many patients by surgical endarterectomy, it is also widely underdiagnosed. Ventilation-perfusion ($\dot{V}/\dot{Q}$) scanning is still the primary test used to screen and diagnose CTEPH, which should be considered in any patient with PH of unclear etiology. Nonetheless, CT angiography is increasingly used in clinical

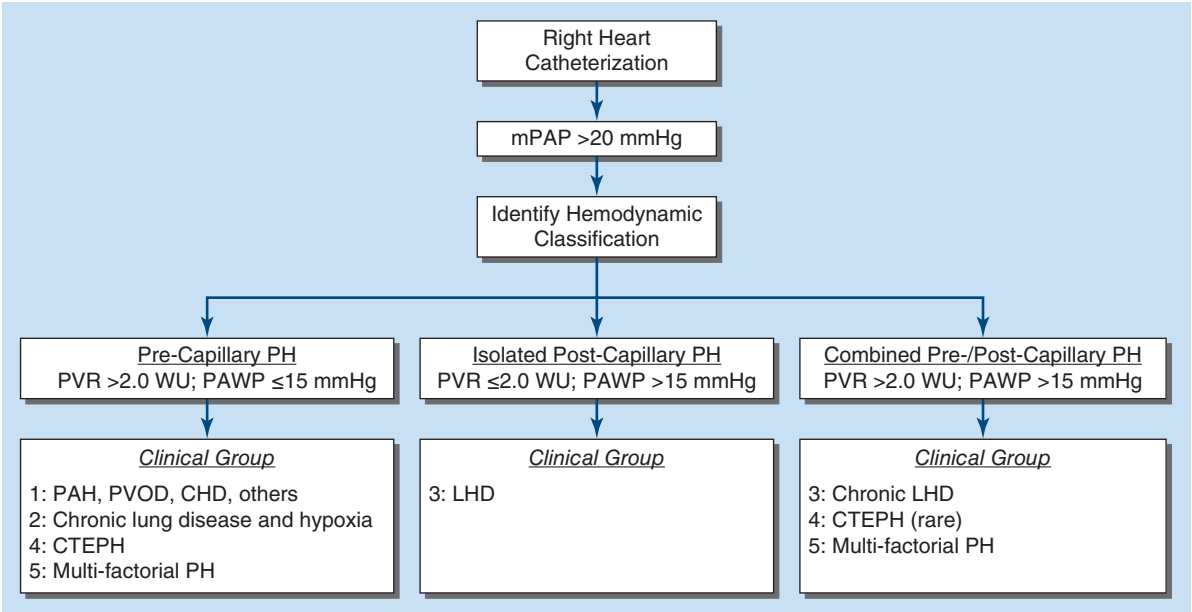

FIGURE 294-7 Integrating the cardiopulmonary hemodynamic and clinical profile of patients with pulmonary hypertension (PH). Diagnosing PH is achieved by right heart catheterization and requires a mean pulmonary artery pressure (mPAP) >20 mmHg. Patients are then classified by hemodynamic category, which together with the clinical profile and other supporting data (e.g., chest imaging, serology, genetic testing) is used to determine the PH clinical group. Certain clinical groups are incompatible with hemodynamic classifications; for example, pulmonary arterial hypertension (PAH) cannot be diagnosed in patients with isolated postcapillary or combined pre-/postcapillary PH hemodynamics. CHD, congenital heart disease; CTEPH, chronic thromboembolic PH; LHD, left heart disease; PAWP, pulmonary artery wedge pressure; PVOD, pulmonary venoocclusive disease; PVR, pulmonary vascular resistance. *(Reproduced with permission from BA Maron et al: Cardiopulmonary hemodynamics in pulmonary hypertension and heart failure: JACC Review Topic of the Week. J Am Coll Cardiol 76:2671, 2020.)*

practice to manage CTEPH especially for staging anatomic thromboembolic burden, which may be ultimately necessary to determine operative candidacy. The definitive diagnostic procedure is digital subtraction pulmonary angiography since contrast enhancement in this study provides detailed information on webbing, stricture, and vascular tapering patterns pathognomonic for CTEPH.

SEROLOGY Laboratory data that are important for screening include a human immunodeficiency virus (HIV) test when clinically indicated. In addition, all patients should have antinuclear antibodies, rheumatoid factor, and anti-Scl-70 antibodies assessed to screen for the most common rheumatologic diseases associated with PH. Liver function and hepatitis serology tests are important to screen for underlying liver disease. Methamphetamine use is recognized increasingly as a cause of PAH, and screening should be considered in patients from endemic regions or in whom the cause of PAH is not otherwise established. Finally, brain natriuretic peptide (BNP) and the N-terminus of its propeptide (NT-proBNP) correlate with right ventricular dysfunction, hemodynamic severity, and functional status in PAH. Medical therapy also lowers NT-proBNP levels in PAH, and therefore, this test may be used as a biomarker for assessing treatment response in clinical practice once a baseline level is established.

INVASIVE CARDIOPULMONARY HEMODYNAMICS The RHC remains the gold standard test to both establish the diagnosis of PH and guide selection of appropriate medical therapy. The hemodynamic criteria for diagnosing PH requires, first, an mPAP >20 mmHg. Precapillary and postcapillary PH are then distinguished by virtue of a pulmonary artery wedge pressure (PAWP) (or left ventricular end-diastolic pressure [LVEDP]) ≤15 mmHg or >15 mmHg, respectively. Isolated precapillary PH also requires a PVR >2.0 WU, whereas isolated postcapillary PH is defined by PVR ≤2.0 WU. Increasingly, combined pre- and postcapillary PH is recognized, defined by elevated mPAP >20 mmHg, PVR >2.0 WU, and PAWP >15 mmHg (Fig. 294-7).

These hemodynamic profiles inform PH clinical categorization. For example, isolated precapillary PH is most often due to primary lung disease, PAH, or CTEPH. Isolated postcapillary PH occurs in patients with mitral valvular disease, left ventricular systolic dysfunction, heart failure with preserved ejection faction, HCM, and amyloid cardiomyopathy. The same etiologies for isolated postcapillary PH also underlie combined pre- and postcapillary PH. When present, this indicates that chronic vascular congestion due to left atrial hypertension has resulted in substantial pulmonary vascular remodeling, although the precise mechanisms that transition patients from isolated postcapillary PH to combined pre-/postcapillary PH are not known. Patients with left heart disease risk factors who are diuresed aggressively prior to RHC may appear to have an isolated precapillary PH profile, tempting a diagnosis of PAH. However, these patients require specific consideration given the potential effects of diuresis on masking the true underlying PH hemodynamic classification.

Vasoreactivity testing should be reserved for patients with idiopathic or hereditary PAH. Vasodilators with a short duration of action, such as inhaled nitric oxide ($NO^{\bullet}$) or inhaled epoprostenol, are preferred for testing. A decrease in mPAP by ≥10 mmHg to an absolute level ≤40 mmHg without a decrease in CO is defined as a positive pulmonary vasodilator response, and such responders are considered for long-term treatment with calcium channel blockers. Less than 5% of patients are deemed vasoreactive, although prognosis among these patients is particularly favorable.

PULMONARY HYPERTENSION CLASSIFICATION

The current classification system, last revised in 2018 during the Sixth World Symposium on Pulmonary Hypertension (WSPH), recognizes five PH categories listed here sequentially as groups 1–5: PAH; PH due to left heart disease; PH due to chronic lung disease or sleep-disordered breathing; CTEPH; and a group of miscellaneous diseases that rarely (or inconsistently) cause PH **(Table 294-1)**.

TABLE 294-1 World Symposium on Pulmonary Hypertension Clinical Classification

GROUP 1 Pulmonary arterial hypertension (PAH)
- 1.1 Idiopathic
  - 1.1.1 Non-responders at vasoreactivity testing
  - 1.1.2 Acute responders at vasoreactivity testing
- 1.2 Heritable[a]
- 1.3 Associated with drugs and toxins[a]
- 1.4 Associated with:
  - 1.4.1 Connective tissue disease
  - 1.4.2 HIV infection
  - 1.4.3 Portal hypertension
  - 1.4.4 Congenital heart disease
  - 1.4.5 Schistosomiasis
- 1.5 PAH with features of venous/capillary (PVOD/PCH) involvement
- 1.6 Persistent PH of the newborn

GROUP 2 PH associated with left heart disease
- 2.1 Heart failure:
  - 2.1.1 with preserved ejection fraction
  - 2.1.2 with reduced or mildly reduced ejection fraction[b]
- 2.2 Valvular heart disease
- 2.3 Congenital/acquired cardiovascular conditions leading to post-capillary PH

GROUP 3 PH associated with lung diseases and/or hypoxia
- 3.1 Obstructive lung disease or emphysema
- 3.2 Restrictive lung disease
- 3.3 Lung disease with mixed restrictive/obstructive pattern
- 3.4 Hypoventilation syndromes
- 3.5 Hypoxia without lung disease (*e.g.* high altitude)
- 3.6 Developmental lung disorders

GROUP 4 PH associated with pulmonary artery obstructions
- 4.1 Chronic thrombo-embolic PH
- 4.2 Other pulmonary artery obstructions[c]

GROUP 5 PH with unclear and/or multifactorial mechanisms
- 5.1 Hematological disorders[d]
- 5.2 Systemic disorders[e]
- 5.3 Metabolic disorders[f]
- 5.4 Chronic renal failure with or without hemodialysis
- 5.5 Pulmonary tumor thrombotic microangiopathy
- 5.6 Fibrosing mediastinitis

Note: Patients with heritable PAH or PAH associated with drugs and toxins might be acute responders. Left ventricular ejection fraction for HF with reduced ejection fraction: ≤40%; for HF with mildly reduced ejection fraction: 41–49%. Other causes of pulmonary artery obstructions include: sarcomas (high or intermediate grade or angiosarcoma), other malignant tumors (e.g., renal carcinoma, uterine carcinoma, germ-cell tumors of the testis), non-malignant tumors (e.g., inherited and acquired chronic hemolytic anemia and chronic myeloproliferative disorders, sarcoidosis, pulmonary Langerhans's cell histiocytosis, and neurofibromatosis type 1, glycogen storage diseases and Gaucher disease.)

Abbreviations: HF, heart failure; HIV, human immunodeficiency virus; PAH, pulmonary arterial hypertension; PCH, pulmonary capillary hemangiomatosis; PH, pulmonary hypertension; PVOD, pulmonary veno-occlusive disease.

Source: Reproduced with permission of the © ERS 2024: Eur Resp J 61:2200879, 2023; DOI:10.1183/13993003.00879-2022.

Pulmonary Arterial Hypertension WSPH group 1 PH, or PAH, involves marked pulmonary arterial precapillary remodeling, including intimal fibrosis, increased medial thickness, pulmonary arteriolar occlusion, and classic plexiform lesions (described in detail above in the Pathobiology section). The hemodynamic criteria for PAH are sustained elevation in resting mPAP >20 mmHg, PVR >2.0 WU, and PAWP or LVEDP of ≤15 mmHg based on RHC. Idiopathic PAH (IPAH) is a progressive disease that leads to right heart failure and early mortality. From the original National Institutes of Health registry on IPAH in 1987, the average age at diagnosis was 36 years, with only 9% of patients with IPAH over the age of 60. However, contemporary data now inclusive of numerous international registries suggest a different clinical profile. The mean age of PAH patients is reported to be 54–68 years old across studies. This reflects, in part, rising awareness

of this disease in the elderly. The prevalence of IPAH favors women to men by ~3.1-fold; however, the hemodynamics at diagnosis are more severe, and the prognosis is less favorable in men compared to women. Patients with hereditary PAH from a *BMPR2* mutation tend to be younger at diagnosis with more severe cardiopulmonary hemodynamics and are associated with comparatively greater clinical risk compared to IPAH. The rate of conversion to PAH among carriers without clinical evidence of disease is ~2.3% per year.

Diseases Associated with PAH Other forms of PAH that deserve specific consideration are those associated with congenital heart disease with intracardiac shunt, connective tissue disease, portal hypertension, and HIV.

CONGENITAL HEART DISEASE PAH in the setting of congenital heart disease is important to recognize since surgical correction may be indicated and when successful is associated with favorable prognosis. This is particularly salient today, as more congenital heart disease patients live to adulthood and populate general medical practices. Still, referral to adult congenital heart disease centers should be considered for patients with suspected PAH, which in this population is subclassified into four groups: Eisenmenger's syndrome, systemic-to-pulmonary shunts, coincidental or small defects causing shunts, and postoperative/closed defects causing shunts. Surgical repair of congenital anatomic lesions may be indicated prior to elevation in PVR >3.0 WU to avoid the development of Eisenmenger's syndrome, a pathophysiologic consequence of progressive pulmonary vascular remodeling due to a large-volume left-to-right shunt that is associated with cyanosis, hyperviscosity, weakness, and shortened life span. Indeed, the effect of changing the PVR threshold to define precapillary PH from 3.0 to 2.0 WU on the timing of shunt repair is an evolving concept.

CONNECTIVE TISSUE DISEASE Patients with connective tissue disease–associated PAH are encountered relatively commonly in clinical practice. Although case series link rheumatoid arthritis and systemic lupus erythematosus with pulmonary vascular disease, the predominant clinical phenotype is systemic sclerosis-associated PAH. It is important to distinguish patients with limited cutaneous scleroderma from those with diffuse scleroderma because PH in the former is likely PAH and PH in the latter often occurs in the setting of interstitial lung disease. Although the average age of scleroderma onset is between 30 and 50 years old, patients who eventually develop scleroderma-associated PAH tend to be older at the time of scleroderma diagnosis. The development of PAH in scleroderma is particularly worrisome prognostically, although implementation of modern therapies improves outcome. Overlap between pulmonary circulatory and interstitial lung disease is encountered commonly in clinical practice. It is tempting to focus on the hemodynamic derangement of these patients as a focal point of clinical care, although the efficacy of implementing PAH-specific treatment to these overlap syndrome patients is unproven.

PORTOPULMONARY HYPERTENSION Among patients with established portal hypertension, 2–10% develop portopulmonary hypertension independent of the cause of liver disease. Furthermore, portopulmonary hypertension is observed in patients with nonhepatic etiologies of portal hypertension. A hyperdynamic circulatory state is common, as in most patients with advanced liver disease; however, the same pulmonary vascular remodeling observed in other forms of PAH is seen in the pulmonary vascular bed in portopulmonary hypertension. It is important to distinguish this process from hepatopulmonary syndrome, which can also manifest with dyspnea and hypoxemia but is pathophysiologically distinct from portopulmonary hypertension in that abnormal vasodilation of the pulmonary vasculature leads to intrapulmonary shunting. Portopulmonary hypertension is an established marker of adverse outcome in the post–liver transplant period with 100% mortality reported in one study among patients with mPAP ≥50 mmHg. The optimal preoperative PVR threshold used to predict elevated postoperative risk must also consider morbidity linked to prolonged transplant wait time. At present, PVR >3.0 WU is considered a strong predicter of unfavorable outcome after transplant, although PVR >2.0 WU also appears to capture potential risk.

HIV-PAH The true prevalence of HIV-PAH is not known; however, this PAH subtype is an important cause of mortality in the HIV-infected population, and prognosis in these patients is among the least favorable for all PH subgroups. There is no correlation between the stage of HIV infection and the development of PAH. By contrast, population data from the U.S. Veterans Administration database suggest a positive and inverse correlation, respectively, between CD4+ count and viral load with estimated pulmonary artery systolic pressure (ePASP) on echocardiography. An ePASP >40 mmHg in HIV-infected patients is associated with a 40% increase in all-cause mortality compared to uninfected counterparts. Although delineating patients with PAH from within this cohort and other unselected populations is not possible, there is a pressing need to understand further the role of HIV-PH in prognosis patients, particularly in endemic areas of the world.

Pulmonary Hypertension Associated with Left Heart Disease Patients with PH due to left ventricular systolic dysfunction, aortic and mitral valve disease, and heart failure with preserved ejection fraction (HFpEF) are classified in WSPH group 2. The hallmark of this PH phenotype is elevated left atrial pressure with resulting pulmonary venous hypertension. In left-sided systolic heart failure or HFpEF, even mildly elevated mPAP is associated with adverse clinical outcome. It should be noted that PH in the setting of mitral stenosis or regurgitation is an indication for surgical (or percutaneous) valve intervention. Recent data suggest that PH is common in obstructive HCM and associated with fibroproliferative remodeling of distal pulmonary arterials even when mPAP is only mildly elevated **(Fig. 294-8)**. In amyloid cardiomyopathy, ~75% of patients have elevated mPAP, and combined pre-/postcapillary PH is the most common hemodynamic subgroup. Regardless of the cause of elevated left atrial pressure, left atrial hypertension causes pulmonary venule sclerosis and thickening that leads to PH and, ultimately, pathogenic changes to pulmonary arterioles.

Pulmonary Hypertension Associated with Lung Disease Intrinsic lung disease is the second most common cause of PH and has been observed in both chronic obstructive pulmonary disease (COPD) and interstitial lung disease. Additionally, PH is also diagnosed in diseases of mixed obstructive/restrictive pathophysiology: bronchiectasis, cystic fibrosis, mixed obstructive-restrictive disease marked by fibrosis in the lower lung zones, and emphysema predominantly in the upper lung zones. When associated with chronic lung disease, PH is usually modest. For example, 90% of COPD patients have mPAP >20 mmHg, but an mPAP >35 mmHg is observed in only 5% of patients. Nonetheless, the subgroup of patients with primary lung disease and severe PH is challenging clinically, as extensive pulmonary arterial involvement, very low DL_{CO} on pulmonary function testing, and inhibition of normal vasoreactivity are observed and are associated with poor outcome. Sleep-disordered syndromes generally result in mild PH.

Pulmonary Hypertension Associated with Chronic Thromboembolic Disease The development of PH after chronic thromboembolic obstruction of the pulmonary arteries, termed CTEPH, is well described. The incidence of CTEPH following a single pulmonary embolic event is difficult to determine accurately, but probably is between 3 and 7% of patients. Importantly, 25% of patients with CTEPH have no history of clinical venous thromboembolism, suggesting that CTEPH may develop following a subclinical pulmonary embolism or through a diverse range of mechanisms. Obstruction of the proximal pulmonary vasculature due to webbing, stricture, or focal fibrotic occlusion signifies proximal vessel involvement. Distal pulmonary arterioles remodel by luminal narrowing or obliteration. Approximately 10–15% of patients will develop a disease very similar clinically and pathologically to PAH after resection of the proximal thrombus **(Fig. 294-9)**. Chronic thromboembolic disease refers to patients with thrombotic pulmonary arterial remodeling and diminished exercise capacity with correlative symptoms in the absence of PH. This subtype is less common than CTEPH but requires consideration in patients with prior PE and dyspnea even if echocardiography is reassuring.

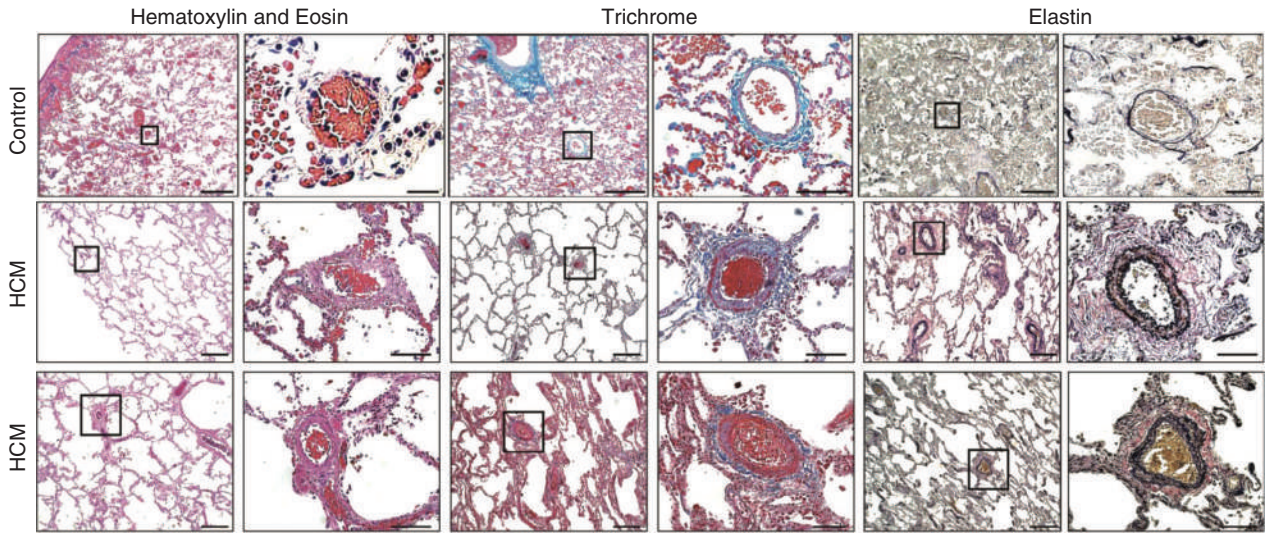

FIGURE 294-8 Pulmonary vascular remodeling in patients with obstructive hypertrophic cardiomyopathy (HCM) and mild pulmonary hypertension. Photomicrographs showing pulmonary arterial histopathophenotype of HCM. Paraffin-embedded tissue sections from control donors without lung disease and example autopsy specimens from patients with symptomatic obstructive HCM were analyzed after hematoxylin and eosin, Masson trichrome, and Verhoeff-Van Gieson staining. *(Adapted with permission from BA Maron et al: Chest 163:678, 2023.)*

OTHER DISORDERS AFFECTING THE PULMONARY VASCULATURE

Sarcoidosis Patients with sarcoidosis can develop PH as a result of lung involvement, and those who present with progressive dyspnea and PH require a thorough evaluation. In sarcoidosis, PH develops mainly due to granulomatous inflammation of the pulmonary vessels, although mechanical compression of pulmonary arteries by enlarged lymph nodes is also reported.

Sickle Cell Disease Cardiovascular system abnormalities are prominent in the clinical spectrum of sickle cell disease (and other hemoglobinopathies), including PH, which occurs in 6–10% of patients. The etiology is multifactorial, including hemolysis, hypoxemia, thromboembolism, chronically high CO, and chronic liver disease.

Schistosomiasis Schistosomiasis affects >230 million people worldwide, of whom 5% develop PAH. Thus, this infection is among the most common causes of PAH worldwide. The development of PAH occurs in the setting of hepatosplenic disease and portal hypertension. Indeed, even in the absence of schistosomiasis, splenectomy is a risk factor for PAH, presumably through impaired platelet sequestration and associated microthrombosis of pulmonary arterioles. Studies suggest that inflammation from a schistosomiasis infection induces pulmonary vascular injury through a combination of the following mechanisms: luminal obstruction by worm eggs, pulmonary artery endothelial cell inflammation, or portal hypertension that promotes a portopulmonary hypertension-PH phenotype The diagnosis is confirmed by finding the parasite ova in the urine or stool of patients with symptoms, which can be difficult. The efficacy of therapies directed toward PAH in these patients is unknown.

PHARMACOLOGIC TREATMENT OF PAH

There are 14 U.S. Food and Drug Administration (FDA)–approved medical therapies for PAH, and standardized treatment strategies have been developed that emphasize early, aggressive pharmacotherapy initiated at a specialty clinical center. Among optimally treated patients, the 1-, 3-, and 5-year survival estimates are 82, 67, and 58%, respectively, but this may overestimate risk since outcome data in the era of routine dual (and in some cases triple) therapy are lacking. All approved medical therapies target the prostacyclin, $NO^{\bullet}$, or endothelin receptor signaling pathways. Drug delivery methods now include oral, inhaled, subcutaneous (including via surgically implanted devices), and intravenous routes.

Prostanoids In PAH, endothelial dysfunction and platelet activation cause an imbalance of arachidonic acid metabolites with reduced prostacyclin levels and increased thromboxane A_2 production. Prostacyclin (PGI_2) activates cyclic adenosine monophosphate

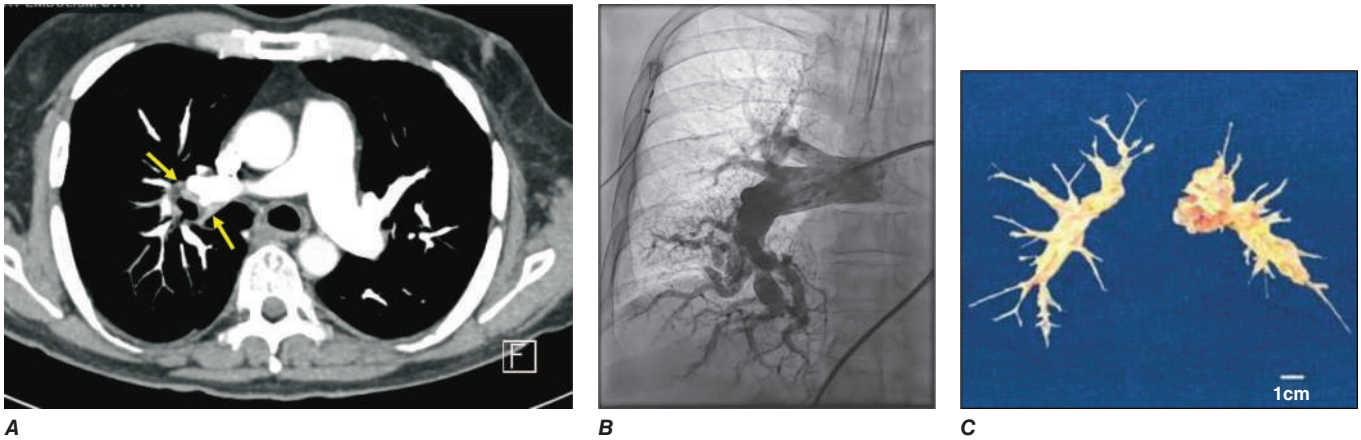

FIGURE 294-9 Chronic thromboembolic pulmonary hypertension (CTEPH) imaging findings and surgical endarterectomy specimen. *A.* Contrast-enhanced computed tomography of the chest shows an obstructive vascular pattern involving segmental pulmonary arteries (*yellow arrows*) in a 63-year-old man with exertional dyspnea and remote history of pulmonary embolism. ***B.*** Still image of a pulmonary angiography of the right lung (submaximal injection shown) shows pulmonary artery stricture, webbing, and severe dearborization that is classic for CTEPH. ***C.*** Fibrotic, chronic clot specimens resected during surgical pulmonary endarterectomy, which is curative in most CTEPH patients. *(Panel C is reproduced with permission from IM Lang, M Madani: Update on chronic thromboembolic pulmonary hypertension. Circulation 130:508, 2014.)*

(cAMP)–dependent pathways that mediate vasodilation. PGI_2 also has antiproliferative effects on vascular smooth muscle and inhibits platelet aggregation. Protein levels of prostacyclin synthase are decreased in pulmonary arteries of patients with PAH. This imbalance of mediators is offset therapeutically by the administration of either exogenous prostacyclin (and analogues, termed prostanoids) or a prostacyclin receptor agonist.

Epoprostenol was the first prostanoid available for the management of PAH. Epoprostenol delivered as a continuous intravenous infusion improves functional capacity and survival in PAH. The efficacy of epoprostenol in World Health Organization (WHO) Functional Class (FC) III and IV PAH patients was demonstrated in a clinical trial that showed improved quality of life, mPAP, PVR, 6-MWD, and mortality. Treprostinil has a longer half-life than epoprostenol (~4 h vs ~6 min), which allows for subcutaneous administration. Treprostinil has been shown to improve pulmonary hemodynamics, symptoms, exercise capacity, and survival in PAH. Inhaled prostacyclin provides the beneficial effects of infused prostacyclin therapy without the inconvenience and side effects of infusion catheters (e.g., risk of infection and infusion site reactions). Both inhaled iloprost and treprostinil have been approved for patients with PAH and severe heart failure symptoms. Oral prostacyclin is also efficacious in clinical trials, but the maximal dose is modest and, therefore, generally reserved as a second-line therapy.

Selexipag is an oral nonprostanoid diphenylpyrazine derivative that binds the prostaglandin I_2 (IP) receptor with high affinity. The active metabolite of selexipag has a prolonged half-life in comparison with prostanoid analogues and permits twice-daily dosing. The efficacy of selexipag was evaluated in patients with PAH in New York Heart Association (NYHA) FC II to III on background therapy with either an endothelin-1 (ET-1) receptor antagonist or sildenafil, or both. This trial represents the largest randomized placebo-controlled trial among patients with PAH ever completed, enrolling 1156 patients treated for a median of 1.4 years. Selexipag reduced the risk of hospitalization and the risk of disease progression by 43% ($p < .0001$) compared to those who received placebo. There were no significant differences in mortality between the two study groups, and the side effect profile was similar to that of prostacyclins.

Endothelin Receptor Antagonists Endothelin receptor antagonists (ERAs) inhibit the detrimental effects of ET-1, a potent endogenous vasoconstrictor and vascular smooth muscle mitogen. In PAH, ET-1 associates positively with PVR and mPAP and inversely with CO and 6-MWD. The ET-1 signaling axis is complex and cell type–specific: ET type A (ET_A) and type B (ET_B) receptors expressed in pulmonary artery smooth muscle cells mediate vasoconstriction, whereas human pulmonary artery endothelial cells express ET_B receptors that promote ET-1 clearance and vasodilation through endothelial nitric oxide synthase activation and prostacyclin release.

The three ERAs approved for use in the United States are the nonselective $ET_{A/B}$ receptor antagonists bosentan and macitentan and the selective ET_A antagonist ambrisentan. Studies have shown that bosentan improves hemodynamics and exercise capacity and delays clinical worsening. The randomized, placebo-controlled, phase 3 Bosentan Randomized Trial of Endothelin Antagonist Therapy (BREATHE)-1 trial comparing bosentan to placebo demonstrated improved symptoms, 6-MWD, and WHO FC in patients treated with bosentan. The Endothelin Antagonist Trial in Mildly Symptomatic Pulmonary Arterial Hypertension Patients (EARLY) study comparing bosentan to placebo demonstrated improved PVR and 6-MWD in patients with WHO FC II.

Several studies, including the phase 3, placebo-controlled Ambrisentan in Pulmonary Arterial Hypertension, (ARIES)-1 trial, have demonstrated that ambrisentan improves exercise tolerance, WHO FC, hemodynamics, and quality of life in patients with PAH. More recently, the Study with an Endothelin Receptor Antagonist in Pulmonary Arterial Hypertension to Improve Clinical Outcome (SERAPHIN) trial randomized 742 PAH patients to receive placebo or macitentan, which is an $ET_{A/B}$ antagonist with optimized receptor binding affinity. The majority of patients were on some form of background PAH therapy. Over an average treatment duration of 85 weeks, the hazard ratio for achieving the composite primary endpoint of PAH-related clinical worsening, which included death or disease progression, was decreased by 45% in the 10-mg dose arm.

Nitric Oxide Pathway Effectors The gaseous, lipophilic molecule $NO^{\bullet}$ is generated by endothelial nitric oxide synthase in endothelial cells and activates soluble guanylyl cyclase (sGC) to generate cyclic guanosine monophosphate (cGMP) in vascular smooth muscle cells and platelets. The cyclic nucleotide cGMP is a second messenger that induces vasodilation through relaxation of arterial smooth muscle cells and inhibits platelet activation. Phosphodiesterase type 5 (PDE5) enzymes are highly expressed in lung vascular tissue (and the corpus carvernosum of the penis). The PDE5 inhibitors prevent hydrolysis (inactivation) of cGMP to maximize $NO^{\bullet}$-dependent vasodilation, serving as the basis for use of this drug class in the treatment of PH (and erectile dysfunction). The two PDE5 inhibitors used for the treatment of PAH are sildenafil and tadalafil. Both agents have been shown to improve hemodynamics and 6-MWD.

Riociguat increases bioactive cGMP by (1) stabilizing the molecular interaction between $NO^{\bullet}$ and sGC, and (2) directly stimulating sGC independent of $NO^{\bullet}$ bioavailability. Riociguat significantly improved exercise capacity, pulmonary hemodynamics, WHO FC, and time to clinical worsening in patients with PAH and is the sole approved pharmacotherapy for CTEPH patients for whom surgical pulmonary endarterectomy is ineffective or contraindicated.

Activin Signal Inhibitor Therapy Motivated by basic and translational data suggesting that treatment with a TGF-β ligand trap inhibits the proproliferative activity of activin ligands in pulmonary vascular cells, sotatercept was developed as a novel fusion protein of the Fc domain of human IgG and the extracellular domain of activin receptor type II. Sotatercept blocks activin receptor II–ALK 4/5/7 signal transduction to upregulate BMPR2 bioactivity. The putative effect of this drug's reaction in PAH is rebalancing of the TGF-β–BMPR2 pathway to restore normal cellular survival and growth patterns.

The PULSAR trial was a large, phase 2, placebo-controlled trial demonstrating a dose-dependent decrease in PVR by sotatercept (0.3 and 0.7 mg/kg administered as an injection) at study week 24 compared to baseline of –1.8 WU and 3.0 WU, respectively. The STELLAR trial was a phase 3 placebo-controlled trial that studied the effect of sotatercept 0.3 mg/kg with target dose of 0.7 mg/kg on 6-MWD. The patients in the study had moderate or severe symptom burden despite ongoing pulmonary vasodilator treatment. In fact, ~60% of patients were on triple therapy, including 40% who were on treatment with intravenous prostacyclin treatment, typically reserved for high-risk or very-high-risk patients (see below). Despite this prior treatment, sotatercept therapy resulted in an average of +40 m improvement in 6-MWD compared to –1.4 m for placebo and was associated with significant improvement in nearly all secondary endpoints including WHO FC improvement, reduction in NT-proBNP level, and shorter time to death or PAH worsening. Telangiectasia development was observed in 10.4% of patients in the sotatercept group, which tracks with the angioproliferative bioactivity reported for TGF-β, although the clinical relevance of these vascular anomalies is not known. Finally, the long-term open-label study that tracked clinical progress up to 1 year in patients from PULSAR demonstrated a sustained (but not progressive) benefit in PVR reduction by sotatercept without an unexpected change in the proportion of side effects given the duration of the follow-up period.

APPROACH TO PAH TREATMENT

Treatment aims to achieve a low clinical risk profile, defined as a 1-year mortality risk of <5%. Generally, this describes a patient with minimal symptoms, WHO FC I or II, 6-WMD >440 m, and cardiac index ≥2.5 L/min per m^2. To accomplish this goal, early referral to an expert center is advised since most patients will ultimately require two or more PAH pharmacotherapies in addition to risk factor modification (such as a low-sodium diet), diuretic use to include mineralocorticoid receptor antagonists if tolerated, supplemental oxygen, and prescription (or supervised) exercise **(Fig. 294-10)**. It is clear that targeting the diverse pathobiologic and pathophysiologic events involved in vascular

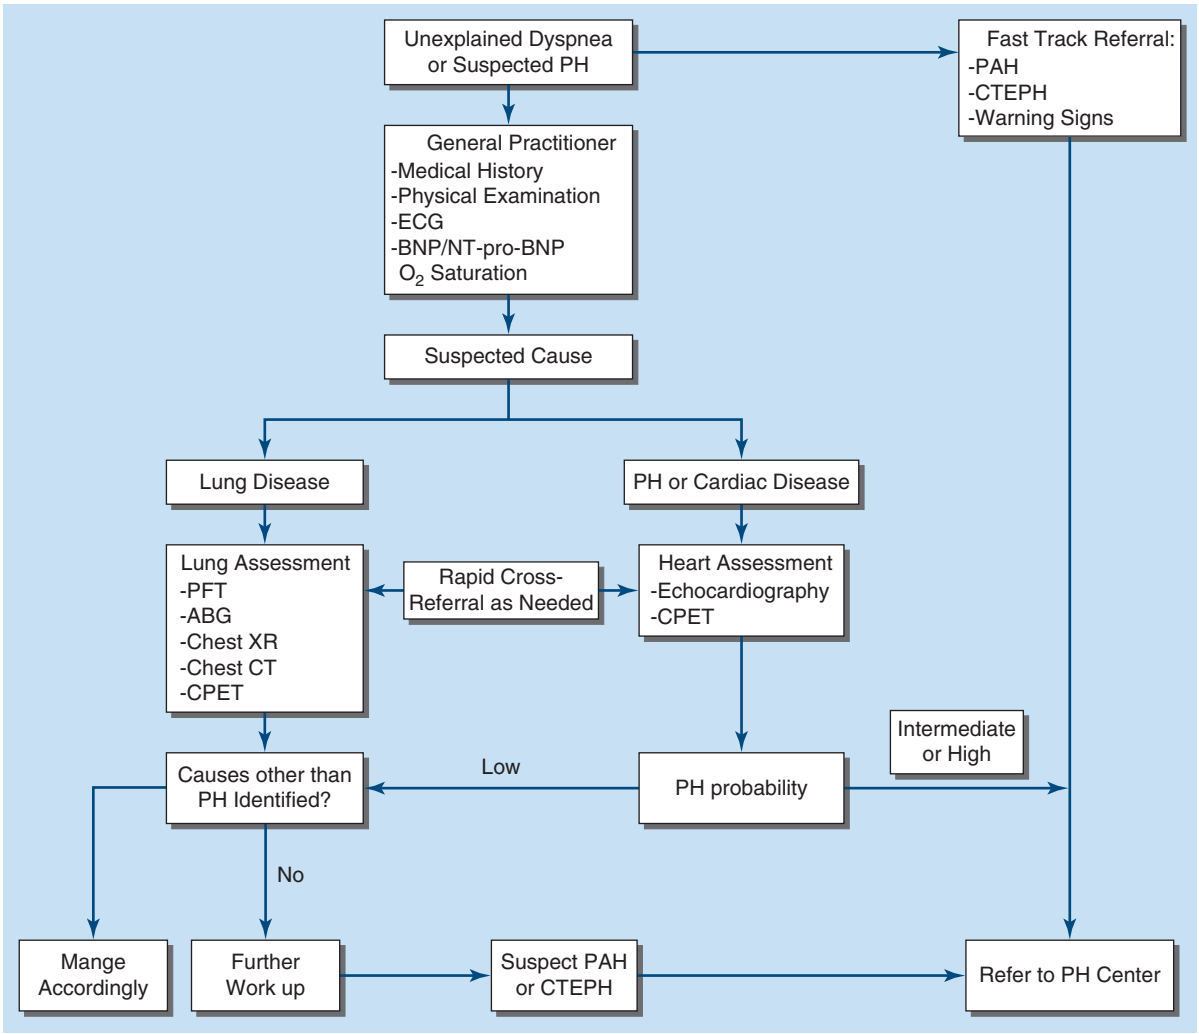

FIGURE 294-10 Strategy for diagnosing pulmonary hypertension (PH) in clinical practice. Diagnostic algorithm of patients with unexplained dyspnea and/or suspected pulmonary hypertension. ABG, arterial blood gas analysis; BNP, brain natriuretic peptide; CPET, cardiopulmonary exercise testing; CT, computed tomography; CTEPH, chronic thromboembolic pulmonary hypertension; ECG, electrocardiogram; NT-proBNP, N-terminal pro-brain natriuretic peptide; PAH, pulmonary arterial hypertension; PFT, pulmonary function tests; PH, pulmonary hypertension. Warning signs include rapid progression of symptoms, severely reduced exercise capacity, presyncope or syncope on mild exertion, and signs of right heart failure. Lung and heart assessment by specialist as per local practice. CT pulmonary angiography recommended if PH suspected. Includes connective tissue disease (especially systemic sclerosis), portal hypertension, HIV infection, and family history of PAH. *(Reproduced with permission of the © ERS 2024: Eur Resp J 61:2200879, 2023; DOI:10.1183/13993003.00879-2022.)*

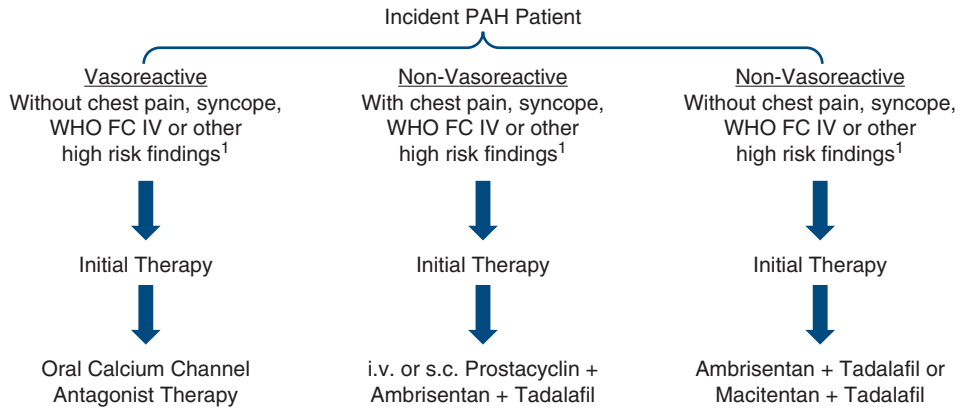

remodeling is needed to optimize treatment. The concept of combination therapy in PAH is modeled after other complex diseases in which a similar approach has been effective, including HIV, cancer, and left heart failure.

The approach to therapy in a patient with incident PAH is outlined in Fig. 294-11. The role of early, aggressive therapy with combination oral treatments was addressed in the landmark Initial Use of Ambrisentan plus Tadalafil in Pulmonary Arterial Hypertension (AMBITION) trial. Treatment-naïve, incident PAH patients (n = 500) were randomized to a combination of ambrisentan and tadalafil, ambrisentan monotherapy, or tadalafil monotherapy. Up-front combination therapy with ambrisentan and tadalafil was associated with a 50% lower risk of clinical worsening (composite of death, lung transplantation, hospitalization for PAH worsening, and worsening PAH) when compared with the monotherapy groups. This difference was driven primarily by the delay in time to first hospitalization. Importantly, initial combination therapy was not associated with an increase in adverse events. Registry data suggest that patients on dual therapy with a PDE5 inhibitor plus ERA combinations alternative to the drugs studied in AMBITION also have better outcomes compared to patients treated with monotherapy, suggesting that the attendant benefit from combination therapy may not be drug specific.

The paradigm shift toward early, aggressive pharmacotherapy in PAH is expanding to up-front triple combination therapy. Clinical studies on up-front triple therapy remain mixed, which is likely driven by challenges surrounding patient selection given the precarious balance between cumulative off-target effects occurring when multiple vasoactive drugs are initiated at the same time, frailty and limited hemodynamic reserve associated with advanced PAH, and need for aggressive treatment to mitigate severely abnormal hemodynamics or right ventricular heart failure. Generally, treatment deescalation, escalation, or class switching for patients with established PAH should be decided in partnership with a PAH clinical center of excellence.

Treatment of HFpEF Disease-specific treatments for HFpEF-PH are lacking. The focus of care should be to optimize contemporary treatment of HFpEF, including minimizing excessive salt and fluid intake while advancing SGLT-2 therapy, mineralocorticoid therapy, and diuretics, and encouraging regular exercise to promote weight loss and conditioning. Invasive PA pressure monitoring may be helpful for tracking elevation in LVEDP, detected as PH, to avert hospitalization.

Treatment of PH due to Lung Disease Inhaled iloprost improved 6-MWD on average +33 m in a placebo-controlled randomized clinical trial studying patients with interstitial lung disease and PH and moderate-to-severe exercise limitation. Although a promising future strategy for the routine management of patients, additional data are needed to confirm efficacy and clarify the criteria defining optimal patients for treatment since dosing is frequent and a substantial rate

[1]pVO_2 <11 mL/kg/min; NT-pro-BNP >1100 ng/mL; at least moderate pericardial effusion; cardiac index <2.0 L/min/m^2, PVR ≥12 WU.

FIGURE 294-11 Treatment strategy overview for patients with newly diagnosed pulmonary arterial hypertension (PAH). Newly diagnosed patients with idiopathic, hereditary, or drug-induced PAH should be considered for vasoreactivity testing in the cardiac catheterization laboratory at an expert pulmonary hypertension center. In the absence of a high-risk clinical profile, patients who demonstrate a positive vasoreactivity response, defined by decrease in mean pulmonary artery pressure ≥10 mmHg from baseline to ≤40 mmHg without a decrease in cardiac output, should be initiated on calcium channel antagonist therapy dose titrated to optimal clinical benefit/adverse effect balance. For patients with PAH without evidence of vasoreactivity but with high-risk findings, consideration of up-front therapy with the prostacyclin analogue treprostinil administered by intravenous (IV) or subcutaneous (SC) route plus the phosphodiesterase type 5 inhibitor tadalafil and endothelin receptor antagonist ambrisentan is indicated. For patients with PAH without vasoreactivity or high-risk findings, initial combination therapy with tadalafil and ambrisentan or the alternate endothelin receptor antagonist macitentan should be considered. NT-proBNP, N-terminal pro-B-type natriuretic peptide; pVO_2, peak volume of oxygen consumption; PVR, pulmonary vascular resistance; WHO-FC, World Health Organization Functional Class; WU, Wood units. *(Reproduced with permission from BA Maron: Revised definition of pulmonary hypertension and approach to management: A clinical primer. J Am Heart Assoc 12:e029024, 2023.)*

of treatment attrition is notable. It is also unclear if inhaled iloprost is generalizable to other lung-PH phenotypes, as at least one study focusing on COPD-PH was terminated early, presumably owing to a lack of benefit or adverse effects.

Treatment of CTEPH Pulmonary endarterectomy performed at a high-volume surgical referral center is the preferred therapy in patients with favorable anatomy and profile. Distal fibrothrombotic remodeling, PVR >12 WU, right heart failure, and NYHA FC IV are viewed as high-risk findings and may be prohibitive in terms of postoperative risk. Patients who are ineligible for pulmonary endarterectomy or do not experience a complete clinical result in the postoperative phase should be considered for treatment with riociguat (sGC stimulator) therapy, balloon pulmonary angioplasty (BPA), or a combination of both. Compared to riociguat, BPA modulates a decrease in mPAP of −9.3 mmHg but requires on average five procedural attempts and is associated with some important potential complications, including hemoptysis and reperfusion pulmonary edema **(Fig. 294-12)**.

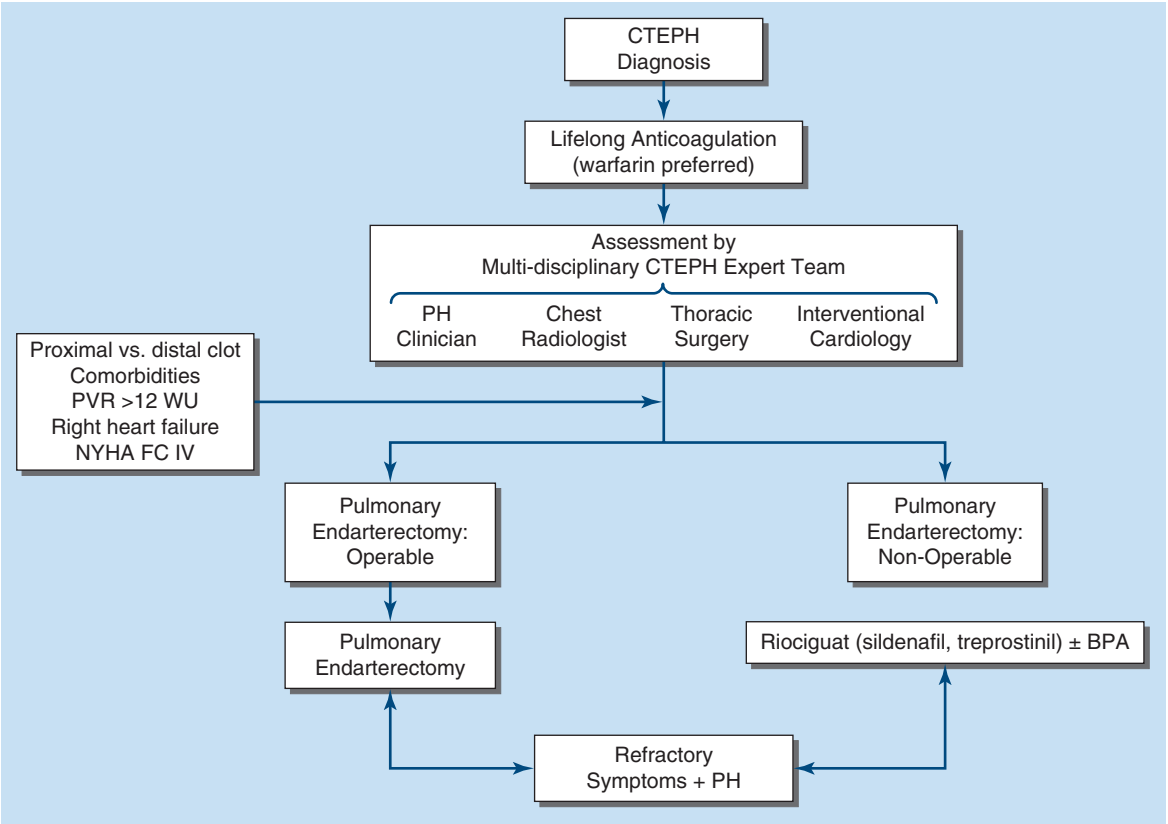

FIGURE 294-12 Algorithm for the management of chronic thromboembolic pulmonary hypertension (CTEPH). TABLE 294-2 FDA-Approved Therapies for the Treatment of Pulmonary Arterial Hypertension (PAH)

GENERIC NAME	ROUTE OF ADMINISTRATION	DRUG CLASS	INDICATION
Epoprostenol	IV	Prostacyclin derivative	Treatment of PAH to improve exercise capacity
Iloprost	Inhaled	Prostacyclin derivative	Treatment of PAH to improve a composite endpoint consisting of exercise tolerance, symptoms (NYHA class), and lack of deterioration
Treprostinil	IV or SC	Prostacyclin derivative	Treatment of PAH to diminish symptoms associated with exercise
Treprostinil	Inhaled	Prostacyclin derivative	Treatment of PAH to improve exercise ability
Treprostinil	Oral	Prostacyclin derivative	Treatment of PAH to improve exercise ability
Selexipag	Oral	Selective IP receptor agonist	Treatment of PAH to improve a composite endpoint lack of clinical deterioration
Bosentan	Oral	Endothelin receptor antagonist	Treatment of PAH to improve exercise capacity and to decrease clinical worsening
Ambrisentan	Oral	Endothelin receptor antagonist	Treatment of PAH to improve exercise capacity and delay clinical worsening
Macitentan	Oral	Endothelin receptor antagonist	Treatment of PAH to improve a composite endpoint of delay of clinical worsening
Sildenafil	Oral or IV	PDE5 inhibitor	Treatment of PAH to improve exercise capacity and delay clinical worsening
Tadalafil	Oral	PDE5 inhibitor	Treatment of PAH to improve exercise ability
Riociguat	Oral	Soluble guanylyl cyclase stimulator	Treatment of PAH to improve exercise ability

Abbreviations: FDA, U.S. Food and Drug Administration; IV, intravenous; NYHA, New York Heart Association; PAH, pulmonary arterial hypertension; PDE5, phosphodiesterase-5; SC, subcutaneous.

UNMET AND FUTURE RESEARCH NEEDS IN PULMONARY HYPERTENSION

Delayed diagnosis is a major barrier to improving outcome in PAH. Improved awareness among clinicians and patients could lead to more timely diagnosis that will affect the response to therapy and survival. At-risk patients should be referred early to a specialty center that focuses on treatment of patients with pulmonary vascular disease, which will ensure their access to state-of-the-art (multidisciplinary) care. In addition, the role of currently available drugs in early-stage disease is not known and requires further investigation **(Table 294-2)**. The anticipated approval of sotatercept is exciting and paves a path toward the availability of the first novel drug class in PAH in nearly two decades. However, clinical trial data continue to lack information from diverse patient subgroups, suggesting that health inequity in PH remains a critical opportunity for progress.

Section 1 Diagnosis of Respiratory Disorders

295 Approach to the Patient with Disease of the Respiratory System

Bruce D. Levy

The majority of diseases of the respiratory system present with cough and/or dyspnea and fall into one of three major categories: (1) obstructive; (2) restrictive; and (3) vascular diseases. Obstructive pathophysiology is most common and primarily results from airway diseases, such as asthma, chronic obstructive pulmonary disease (COPD), bronchiectasis, and bronchiolitis. Diseases resulting in restrictive pathophysiology include parenchymal lung diseases, abnormalities of the chest wall and pleura, and neuromuscular disease. Pulmonary embolism, pulmonary hypertension, and pulmonary venoocclusive disease are examples of disorders of the pulmonary vasculature. Although many specific diseases fall into these major categories, both infective and neoplastic processes can affect the respiratory system and result in myriad pathologic findings, including those listed in the three categories above (Table 295-1).

Disorders can also be grouped according to gas exchange abnormalities, including hypoxemia, hypercarbia, or combined impairment; however, many respiratory disorders do not manifest as gas exchange abnormalities.

As with the evaluation of most patients, the approach to a patient with a respiratory system disorder begins with a thorough history and a focused physical examination. Many patients will subsequently undergo pulmonary function testing, chest imaging, blood and sputum analysis, a variety of serologic or microbiologic studies, and diagnostic procedures, such as bronchoscopy. This stepwise approach is discussed in detail below.

TABLE 295-1 Categories of Respiratory Disease

CATEGORY	EXAMPLES
Obstructive pathophysiology—airway disease	Asthma Chronic obstructive pulmonary disease (COPD) Bronchiectasis Bronchiolitis
Restrictive pathophysiology—parenchymal disease	Idiopathic pulmonary fibrosis (IPF) Asbestosis Desquamative interstitial pneumonitis (DIP) Sarcoidosis
Restrictive pathophysiology—neuromuscular weakness	Amyotrophic lateral sclerosis (ALS) Guillain-Barré syndrome Myasthenia gravis
Restrictive pathophysiology—chest wall/pleural disease	Kyphoscoliosis Ankylosing spondylitis Chronic pleural effusions
Pulmonary vascular disease	Pulmonary embolism Pulmonary arterial hypertension (PAH) Pulmonary venoocclusive disease Vasculitis
Malignancy	Bronchogenic carcinoma (non-small-cell and small-cell lung cancer) Metastatic disease
Infectious diseases	Pneumonia Bronchitis Tracheitis

HISTORY

Dyspnea and Cough The cardinal symptoms of respiratory disease are dyspnea and cough (Chaps. 39 and 40). Dyspnea has many causes, some of which are not predominantly due to lung pathology. The words a patient uses to describe shortness of breath can suggest certain etiologies for dyspnea. Patients with obstructive lung disease often complain of "chest tightness" or "inability to get a deep breath," whereas patients with congestive heart failure more commonly report "air hunger" or a sense of suffocation.

The tempo of onset and the duration of a patient's dyspnea are likewise helpful in determining the etiology. Acute shortness of breath is usually associated with sudden physiologic changes, such as acute airway narrowing (e.g., laryngeal edema, bronchospasm, or mucus plugging), acute hypoxemia (e.g., pulmonary edema, pneumonia, or pulmonary embolism), or sudden changes in the work of breathing (e.g., pneumothorax). Patients with COPD and idiopathic pulmonary fibrosis (IPF) experience a gradual progression of dyspnea on exertion, punctuated by acute exacerbations of shortness of breath. In contrast, most asthmatics do not have daily symptoms, but experience intermittent episodes of dyspnea, cough, and chest tightness that are usually associated with specific triggers, such as an upper respiratory tract infection or exposure to allergens.

Specific questioning should focus on factors that incite dyspnea as well as on any intervention that helps resolve the patient's shortness of breath. Asthma is commonly exacerbated by specific triggers, although this can also be true of COPD. Many patients with lung disease report dyspnea on exertion. Determining the degree of activity that results in shortness of breath gives the clinician a gauge of the patient's degree of disability. Many patients adapt their level of activity to accommodate progressive limitation. For this reason, it is important, particularly in older patients, to delineate the activities in which they engage and how these activities have changed over time. Dyspnea on exertion is often an early symptom of underlying lung or heart disease and warrants a thorough evaluation.

For cough, the clinician should inquire about the duration of the cough, whether or not it is associated with sputum production, and any specific triggers that induce it. Acute cough productive of phlegm is often a symptom of infection of the respiratory system, including processes affecting the upper airway (e.g., sinusitis, tracheitis), the lower airways (e.g., bronchitis, bronchiectasis), and the lung parenchyma (e.g., pneumonia). Both the quantity and quality of the sputum, including whether it is blood-streaked or frankly bloody, should be determined. Hemoptysis warrants urgent evaluation as delineated in Chap. 41.

Chronic cough (defined as that persisting for >8 weeks) is commonly associated with obstructive lung diseases, particularly asthma, COPD, and chronic bronchiectasis, as well as "nonrespiratory" diseases, such as gastroesophageal reflux and postnasal drip. Diffuse parenchymal lung diseases, including IPF, frequently present as a persistent, nonproductive cough. All causes of cough are not respiratory in origin, and assessment should encompass a broad differential, including cardiac and gastrointestinal diseases as well as psychogenic causes.

Additional Symptoms Patients with respiratory disease may report wheezing, which is suggestive of airways disease, particularly asthma. Hemoptysis can be a symptom of a variety of lung diseases, including infections of the respiratory tract, bronchogenic carcinoma, and pulmonary embolism. In addition, chest pain or discomfort can be respiratory in origin. As the lung parenchyma is not innervated with pain fibers, pain in the chest from respiratory disorders usually results

from either diseases of the parietal pleura (e.g., pneumothorax) or pulmonary vascular diseases (e.g., pulmonary hypertension). As many diseases of the lung can result in strain on the right side of the heart, patients may also present with symptoms of cor pulmonale, including abdominal bloating or distention and pedal edema (Chap. 264).

Additional History A thorough social history is an essential component of the evaluation of patients with respiratory disease. All patients should be asked about current or previous cigarette smoking, as this exposure is associated with many diseases of the respiratory system, including COPD, bronchogenic lung cancer, and select parenchymal lung diseases (e.g., desquamative interstitial pneumonitis and pulmonary Langerhans cell histiocytosis). For most of these disorders, increased cigarette smoke exposure (i.e., cigarette pack-years) increases the risk of disease. E-cigarette or vaping use can lead to acute or subacute lung injury (i.e., E-cigarette or vaping use-associated lung injury [EVALI]). Secondhand smoke also increases risk for some respiratory disorders, so patients should also be asked about parents, spouses, or housemates who smoke. Possible inhalational exposures at work (e.g., asbestos, silica) or home (e.g., wood smoke, excrement from pet birds) should be explored (Chap. 300). Travel predisposes one to certain infections of the respiratory tract, most notably tuberculosis. Potential exposure to fungi is increased in specific geographic regions or climates (e.g., *Histoplasma capsulatum*), so exposures to these regions should be determined.

Associated symptoms of fever and chills should raise the suspicion of infective etiologies, both pulmonary and systemic. A comprehensive review of systems may suggest rheumatologic or autoimmune disease presenting with respiratory tract manifestations. Questions should focus on joint pain or swelling, rashes, dry eyes, dry mouth, or constitutional symptoms. In addition, carcinomas from a variety of primary sources commonly metastasize to the lung and cause respiratory symptoms. Finally, therapy for other conditions, including both irradiation and medications, can result in diseases of the chest.

Physical Examination The clinician's suspicion of respiratory disease often begins with the patient's vital signs. The respiratory rate is informative, whether elevated (tachypnea) or depressed (hypopnea). In addition, pulse oximetry should be measured, as many patients with respiratory disease have hypoxemia, either at rest or with exertion.

The first step of the physical examination is inspection. Patients with respiratory disease may be in distress and using accessory muscles of respiration to breathe. Severe kyphoscoliosis can result in restrictive pathophysiology. Inability to complete a sentence in conversation is generally a sign of severe impairment and should result in an expedited evaluation of the patient.

Percussion of the chest is used to establish diaphragm excursion and lung size. In the setting of decreased breath sounds, percussion is used to distinguish between pleural effusions (dull to percussion) and pneumothorax (hyper-resonant note).

The role of palpation is limited in the respiratory examination. Palpation can demonstrate subcutaneous air in the setting of barotrauma. It can also be used as an adjunctive assessment to determine whether an area of decreased breath sounds is due to consolidation (increased tactile fremitus) or a pleural effusion (decreased tactile fremitus). To detect unilateral disorders of ventilation, the symmetry and degree of chest wall expansion can be assessed during a deep inspiration by placing one's thumbs together at the midline over the lower posterior chest while grasping the lateral rib cage.

The majority of the manifestations of respiratory disease present as abnormalities of auscultation. Wheezes are a manifestation of airway obstruction. While most commonly a sign of asthma, peribronchial edema in the setting of congestive heart failure can also result in diffuse wheezes, as can any other process that causes narrowing of small airways. Wheezes can be polyphonic, involving multiple different size airways (e.g., asthma), or monophonic, involving one size airway (e.g., bronchogenic carcinoma). For these reasons, clinicians must take care not to attribute all wheezing to asthma.

Rhonchi are a manifestation of obstruction of medium-sized airways, most often with secretions. In the acute setting, this manifestation may be a sign of viral or bacterial bronchitis. Chronic rhonchi suggest bronchiectasis or COPD. In contrast to expiratory wheezes and rhonchi, stridor is a high-pitched, focal inspiratory wheeze, usually heard over the neck as a manifestation of upper airway obstruction.

Crackles, or rales, are commonly a sign of alveolar disease. Processes that fill the alveoli with fluid may result in crackles, including pulmonary edema and pneumonia. Crackles in pulmonary edema are generally more prominent at the bases. Interestingly, diseases that result in fibrosis of the interstitium (e.g., IPF) also result in crackles that sound like Velcro being ripped apart. Although some clinicians make a distinction between "wet" and "dry" crackles, this distinction has not been shown to be a reliable way to differentiate among etiologies of respiratory disease.

One way to help distinguish between crackles associated with alveolar fluid and those associated with interstitial fibrosis is to assess for egophony. *Egophony* is the auscultation of the sound "AH" instead of "EEE" when a patient phonates "EEE." This change in note is due to abnormal sound transmission through consolidated parenchyma and is present in pneumonia but not in IPF. Similarly, areas of alveolar filling have increased whispered *pectoriloquy* as well as transmission of larger-airway sounds (i.e., bronchial breath sounds in a lung zone where vesicular breath sounds are expected).

The lack or diminution of breath sounds can also help determine the etiology of respiratory disease. Patients with emphysema often have a quiet chest with diffusely decreased breath sounds. A pneumothorax or pleural effusion may present with an area of absent breath sounds.

Other Systems Pedal edema, if symmetric, may suggest cor pulmonale; if asymmetric, it may be due to deep venous thrombosis and associated pulmonary embolism. Jugular venous distention may also be a sign of volume overload associated with right heart failure. *Pulsus paradoxus* is an ominous sign in a patient with obstructive lung disease, as it is associated with significant negative intrathoracic (pleural) pressures required for ventilation and impending respiratory failure.

As stated earlier, rheumatologic disease may manifest primarily as lung disease. Owing to this association, particular attention should be paid to joint and skin examination. Clubbing can be found in many lung diseases, including cystic fibrosis, IPF, and lung cancer. Cyanosis is seen in hypoxemic respiratory disorders that result in >5 g of deoxygenated hemoglobin/dL.

DIAGNOSTIC EVALUATION

The sequence of studies is dictated by the clinician's differential diagnosis, as determined by the history and physical examination. Acute respiratory symptoms are often evaluated with multiple tests performed at the same time in order to diagnose any life-threatening diseases rapidly (e.g., pulmonary embolism or multilobar pneumonia). In contrast, chronic dyspnea and cough can be evaluated in a more protracted, stepwise fashion.

Pulmonary Function Testing (See also Chap. 297) The initial pulmonary function test obtained is spirometry. This study is an effort-dependent test used to assess for obstructive pathophysiology as seen in asthma, COPD, and bronchiectasis (Table 295-1). A diminished-forced expiratory volume in 1 second (FEV_1)/forced vital capacity (FVC) (often defined as <70%) is diagnostic of airflow obstruction. In addition to measuring FEV_1 and FVC, the clinician should examine the flow-volume loop (which is less effort-dependent). A plateau of the inspiratory and expiratory curves suggests large-airway obstruction in extrathoracic and intrathoracic locations, respectively.

Spirometry with symmetric decreases in FEV_1 and FVC warrants further testing, including measurement of lung volumes and the diffusion capacity of the lung for carbon monoxide (DL_{CO}). A total lung capacity <80% of the patient's predicted value defines restrictive pathophysiology. Restriction can result from parenchymal disease, neuromuscular weakness, or chest wall or pleural diseases (Table 295-1). Restriction with impaired gas exchange, as indicated by a decreased DL_{CO}, suggests parenchymal lung disease. Additional testing, such as measurements of maximal inspiratory and expiratory pressures, can help diagnose neuromuscular weakness. Normal spirometry, normal

lung volumes, and a low DL_{CO} should prompt further evaluation for pulmonary vascular disease.

Arterial blood gas testing is often helpful in assessing respiratory disease. Hypoxemia, while usually apparent with pulse oximetry, can be further evaluated with the measurement of arterial PO_2 and the calculation of an alveolar gas and arterial blood oxygen tension difference ($[A–a]DO_2$). Patients with diseases that cause ventilation-perfusion mismatch or shunt physiology have an increased $(A–a)DO_2$ at rest. Arterial blood gas testing also allows the measurement of arterial PCO_2. Hypercarbia can accompany disorders of ventilation, as seen in severe airway obstruction (e.g., COPD) or progressive restrictive physiology.

Chest Imaging **(See Chap. A12)** Most patients with disease of the respiratory system undergo imaging of the chest as part of the initial evaluation. Clinicians should generally begin with ultrasound of the chest or a plain chest radiograph, preferably posterior-anterior and lateral films. Ultrasound is often readily available and can help rapidly diagnose pneumothorax, pleural effusion, and consolidation of lung parenchyma. Chest radiographs give additional detail and can reveal findings including opacities of the parenchyma, blunting of the costophrenic angles, mass lesions, and volume loss. Of note, many diseases of the respiratory system, particularly those of the airways and pulmonary vasculature, are associated with a normal chest radiograph.

Computed tomography (CT) scan of the chest can also be useful to delineate parenchymal processes, pleural disease, masses or nodules, and large airways. If the test includes administration of intravenous contrast, the pulmonary vasculature can be assessed with particular utility for determination of pulmonary emboli. Intravenous contrast also allows lymph nodes to be examined in greater detail. When coupled with positron emission tomography (PET), lesions of the chest can be assessed for metabolic activity, helping differentiate between malignancy and scar.

FURTHER STUDIES

Depending on the clinician's suspicion, a variety of other studies may be done. Concern about large-airway lesions may warrant bronchoscopy. This procedure may also be used to sample the alveolar space with bronchoalveolar lavage or to obtain nonsurgical lung biopsies. Blood testing may include assessment for hypercoagulable states in the setting of pulmonary vascular disease, serologic testing for infectious or rheumatologic disease, or assessment of inflammatory markers or leukocyte counts (e.g., eosinophils). Genetic testing is increasingly used for heritable lung diseases such as cystic fibrosis. Sputum evaluation for malignant cells or microorganisms may be appropriate. An echocardiogram to assess right- and left-sided heart function is often obtained. Finally, at times, a surgical lung biopsy is needed to diagnose certain diseases of the respiratory system. All of these studies will be guided by the preceding history, physical examination, pulmonary function testing, and chest imaging.

296 Disturbances of Respiratory Function

George R. Washko, William M. Oldham

The primary functions of the respiratory system—to oxygenate blood and eliminate carbon dioxide—require virtual contact between blood and fresh air, which facilitates diffusion of respiratory gases between blood and gas. This process occurs in the lung alveoli, where blood flowing through alveolar wall capillaries is separated from alveolar gas by an extremely thin membrane of flattened endothelial and epithelial cells, across which respiratory gases diffuse and equilibrate. Blood flow through the lung is unidirectional via a continuous vascular path along which venous blood absorbs oxygen from and loses CO_2 to inspired gas. The path for airflow, in contrast, reaches a dead end at the alveolar walls; thus, the alveolar space must be ventilated tidally, with inflow of fresh gas and outflow of alveolar gas alternating periodically at the respiratory rate (RR). To provide an enormous alveolar surface area (typically 70 m^2) for blood-gas diffusion within the modest volume of a thoracic cavity (typically 7 L), nature has distributed both blood flow and ventilation among millions of tiny alveoli through multigenerational branching of both pulmonary arteries and bronchial airways. Ideally, for the lung to be most efficient in exchanging gas, the fresh gas ventilation of a given alveolus must be matched to its perfusion. However, as a consequence of variations in tube lengths and calibers along these pathways as well as the effects of gravity, tidal pressure fluctuations, and anatomic constraints from the chest wall, the alveoli vary in their relative ventilations and perfusions even in health.

For the respiratory system to succeed in oxygenating blood and eliminating CO_2, it must be able to ventilate the lung tidally and thus to freshen alveolar gas; it must provide for perfusion of the individual alveolus in a manner proportional to its ventilation; and it must allow adequate diffusion of respiratory gases between alveolar gas and capillary blood. Furthermore, it must accommodate several-fold increases in the demand for oxygen uptake or CO_2 elimination imposed by metabolic needs or acid-base derangement. Given these multiple requirements for normal operation, it is not surprising that many diseases disturb respiratory function. This chapter considers in some detail the physiologic determinants of lung ventilation and perfusion, elucidates how the matching distributions of these processes and rapid gas diffusion allow normal gas exchange, and discusses how common diseases derange these normal functions, thereby impairing gas exchange—or at least increase the work required by the respiratory muscles or heart to maintain adequate respiratory function.

VENTILATION

It is useful to conceptualize the respiratory system as three independently functioning components: the lung, including its airways; the neuromuscular system; and the chest wall, which includes everything that is not lung or active neuromuscular system. Accordingly, the mass of the respiratory muscles is part of the chest wall, while the force these muscles generate is part of the neuromuscular system; the abdomen (especially an obese abdomen) and the heart (especially an enlarged heart) are, for these purposes, part of the chest wall. Each of these three components has mechanical properties that relate to its enclosed volume (or—in the case of the neuromuscular system—the respiratory system volume at which it is operating) and to the rate of change of its volume (i.e., flow). The work of breathing required of the neuromuscular system is the sum of the work due to volume-related mechanical properties and the work from flow-related mechanical properties required to move air throughout the airways to create this volume change.

Volume-Related Mechanical Properties—Statics Figure 296-1 shows the volume-related properties of each component of the respiratory system. The natural tendency of the lung is to collapse because

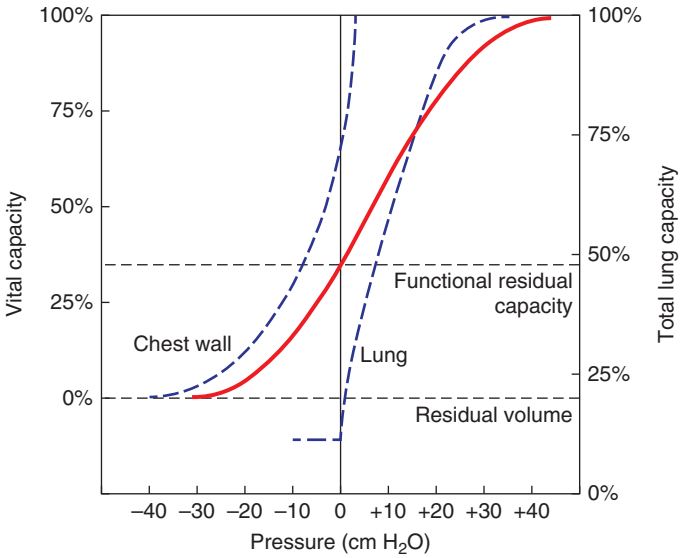

FIGURE 296-1 Pressure-volume curves of the isolated lung, isolated chest wall, combined respiratory system, inspiratory muscles, and expiratory muscles. FRC, functional residual capacity; RV, residual volume; TLC, total lung capacity.

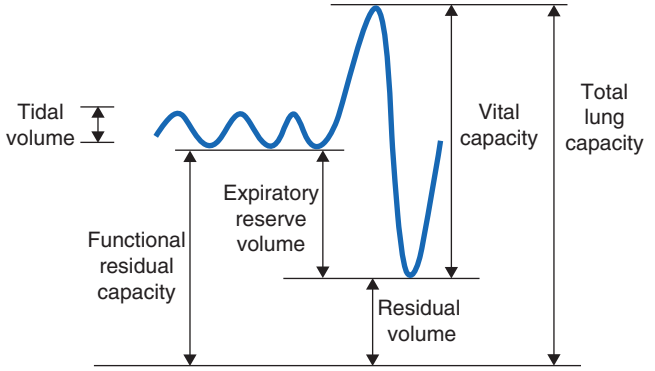

FIGURE 296-2 Spirogram demonstrating a slow vital capacity maneuver and various lung volumes.

of both surface tension at the air-liquid interface between alveolar wall lining fluid and alveolar gas and elastic recoil of the lung tissue itself. To stay inflated, the pressure within the alveolus must equal or exceed the pressure at the pleural surface. This difference in pressures ($P_{alveolus} - P_{pleura}$) is expressed as the transpulmonary pressure.

The elastic recoil of the lung is not constant, increasing with inflation. At high lung volume, the lung becomes rather stiff, so that large changes in transpulmonary pressure are required for relatively small changes in lung volume. In contrast, the lung is compliant at lower volumes, including those at which tidal breathing normally occurs. At zero inflation pressure, even normal lungs retain some air in the alveoli. Because the small peripheral airways are tethered open by outward radial pull from inflated lung parenchyma attached to adventitia, as the lung deflates during exhalation, those small airways are pulled open progressively less, and eventually close, trapping some gas in the alveoli. This effect can be exaggerated with age and especially with obstructive airway diseases, resulting in gas trapping at quite large lung volumes.

Functional residual capacity (FRC) is the passive resting point of the respiratory system attained when the outward recoil of the chest wall is balanced exactly by the inward recoil of the lung. The elastic behavior of the passive chest wall (i.e., in the absence of neuromuscular activation), differs markedly from that of the lung. While the lungs become stiff at high volumes, the chest wall stiffens at low volumes due to squeezing together of ribs and intercostal muscles, diaphragm stretch, displacement of abdominal contents, and straining of ligaments and bony articulations. The normal lung and chest wall function in mechanical series, and the pressure required to displace the passive respiratory system (lungs plus chest wall) at any volume is simply the sum of the elastic recoil pressure of the lungs and the transmural pressure across the chest wall. When plotted against respiratory system volume, this relationship assumes a sigmoid shape, exhibiting stiffness at high lung volumes (imparted by the lung), stiffness at low lung volumes (imparted by the chest wall or sometimes by airway closure), and compliance in the middle range of lung volumes where normal tidal breathing occurs. As these recoils are transmitted through the pleural fluid, the lung is pulled both outward and inward simultaneously at FRC, where the negative intrapleural pressure is exactly offset by the positive intrapulmonary pressure yielding an airway pressure of 0 mmHg.

The normal passive respiratory system would equilibrate at the FRC and remain there were it not for the actions of the respiratory muscles. Gas flows from high to low pressure and the lung inflates when pressure at the airway opening exceeds pressure in the alveoli. The lung deflates when pressure in the alveoli exceeds pressure at the airway opening. The inspiratory muscles act on the chest wall to expand the volume of the thorax, decreasing pleural pressure, lowering pressure in the alveoli below pressure at the airway opening. In contrast, the expiratory muscles raise the alveolar gas pressure above pressure at the airway opening, leading to an outflow of gas from the lung.

The maximal pressures these sets of muscles can generate vary with the lung volume at which they operate. This variation is due to length-tension relationships in striated muscle sarcomeres and to changes in mechanical advantage as the angles of insertion change with lung volume (Fig. 296-1). Nonetheless, under normal conditions, the respiratory muscles are substantially "overpowered" for their roles and generate more than adequate force to drive the respiratory system to its stiffness extremes, as determined by the lung (total lung capacity [TLC]) or by chest wall or airway closure (residual volume [RV]); the airway closure always prevents the adult lung from emptying completely under normal circumstances. The excursion between full and minimal lung inflation is called *vital capacity* (VC; **Fig. 296-2**). The VC is easy to measure (see below), but it provides little information about the intrinsic properties of the respiratory system. As will become clear, it is much more useful for the clinician to consider TLC and RV individually.

Flow-Related Mechanical Properties—Dynamics The passive chest wall and active neuromuscular system both exhibit mechanical behaviors related to the rate of change of volume, but these behaviors become quantitatively important only at markedly supraphysiologic breathing frequencies (e.g., during high-frequency mechanical ventilation), and thus will not be addressed here. In contrast, the dynamic airflow properties of the lung substantially affect its ability to ventilate and contribute importantly to the work of breathing, and these properties are often deranged by disease. Understanding dynamic airflow properties is, therefore, worthwhile.

As with the flow of any fluid (gas or liquid) in any tube, maintenance of airflow within the pulmonary airways requires a pressure gradient that falls along the direction of flow, the magnitude of which is determined by the flow rate and the frictional resistance to flow. During quiet tidal breathing, the pressure gradients driving inspiratory or expiratory flow are small owing to the very low frictional resistance of normal pulmonary airways (R_{aw}, normally <2 $cmH_2O/L/s$). However, during rapid exhalation, another phenomenon reduces flow below that which would have been expected if frictional resistance were the only impediment to flow. This phenomenon is called *dynamic airflow limitation*, and it occurs because the bronchial airways through which air is exhaled are collapsible rather than rigid **(Fig. 296-3)**. An important anatomic feature of the structure of the pulmonary airways is their tree-like branching pattern. While the individual airways in each successive generation, from most proximal (trachea) to most distal (respiratory bronchioles), are smaller than those of the parent generation, their number increases exponentially such that the summed cross-sectional area of the airways becomes very large toward the lung periphery. Because flow (volume/time) is constant along the airway tree, the velocity of airflow (flow/summed cross-sectional area)

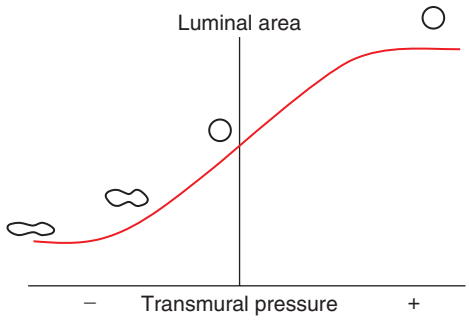

FIGURE 296-3 Luminal area versus transmural pressure relationship. Transmural pressure represents the pressure difference across the airway wall from inside to outside.

is much greater in the central airways than in the peripheral airways. During exhalation, gas leaving the alveoli must, therefore, gain velocity as it proceeds toward the mouth. This acceleration reduces intraluminal gas pressure and airway transmural pressure leading to a reduction in airway size. Referred to as the Bernoulli effect, this process may be best appreciated in the example of the airplane. As the flow of air accelerates over the curved surface of its wings, it provides lift to the plane (Fig. 296-3). If an individual attempts to exhale more forcefully, the local velocity increases further (increasing "lift") and airway size grows smaller, resulting in no net increase in flow. Under these circumstances, flow has reached its maximum possible value, or its *flow limit*.

Lungs normally exhibit such dynamic airflow limitation. This limitation can be assessed by spirometry, in which an individual inhales fully to TLC and then forcibly exhales to RV. Maximal expiratory flow at any lung volume is determined by gas density, airway cross-section and distensibility, elastic recoil pressure of the lung, and frictional pressure loss to the flow-limiting airway site. Under normal conditions, maximal expiratory flow falls with lung volume **(Fig. 296-4)**, primarily because of the dependence of lung recoil pressure on lung volume (Fig. 296-1). In pulmonary fibrosis, lung recoil pressure is increased at any lung volume, and thus the maximal expiratory flow is elevated when considered in relation to lung volume. Conversely, in emphysema, lung recoil pressure is reduced; this reduction is a principal mechanism by which maximal expiratory flows fall. Diseases that narrow the airway lumen at any transmural pressure (e.g., asthma or chronic bronchitis) or that cause excessive airway collapsibility (e.g., tracheomalacia) also reduce maximal expiratory flow.

The Bernoulli effect also applies during inspiration, but the more negative pleural pressures during inspiration lower the pressure outside of the airways, thereby increasing transmural pressure and promoting airway expansion. Thus, inspiratory airflow limitation seldom occurs due to diffuse pulmonary airway disease. Conversely, extrathoracic airway narrowing (e.g., due to a tracheal adenoma or posttracheostomy stricture) can lead to inspiratory airflow limitation (Fig. 296-4).

The Work of Breathing In health, the elastic (volume change-related) and dynamic (flow-related) loads that must be overcome to ventilate the lungs at rest are small, and the work required of the respiratory muscles is minimal. However, the work of breathing can increase considerably due to a metabolic requirement for substantially increased ventilation, an abnormally increased mechanical load, or both. As discussed below, the rate of ventilation is primarily set by the need to eliminate carbon dioxide, and thus, ventilation increases during exercise (sometimes by >20-fold) and during metabolic acidosis as a compensatory response. Naturally, the work rate required to overcome the elasticity of the respiratory system increases with both the depth and the frequency of tidal breaths, while the work required to overcome the dynamic load increases with total ventilation. A modest increase of ventilation is most efficiently achieved by increasing tidal volume but not RR, which is the normal ventilatory response to lower-level exercise. At higher levels of exercise, deep breathing persists, but RR also increases.

The work of breathing also increases when disease reduces the compliance of the respiratory system or increases the resistance to airflow. The former occurs commonly in diseases of the lung parenchyma (interstitial processes or fibrosis, alveolar filling diseases such as pulmonary edema or pneumonia, or substantial lung resection), and the latter occurs in obstructive airway diseases such as asthma, chronic bronchitis, emphysema, and cystic fibrosis. Furthermore, severe airflow obstruction can functionally reduce the compliance of the respiratory system by leading to dynamic hyperinflation. In this scenario, expiratory flows slowed by the obstructive airways disease may be

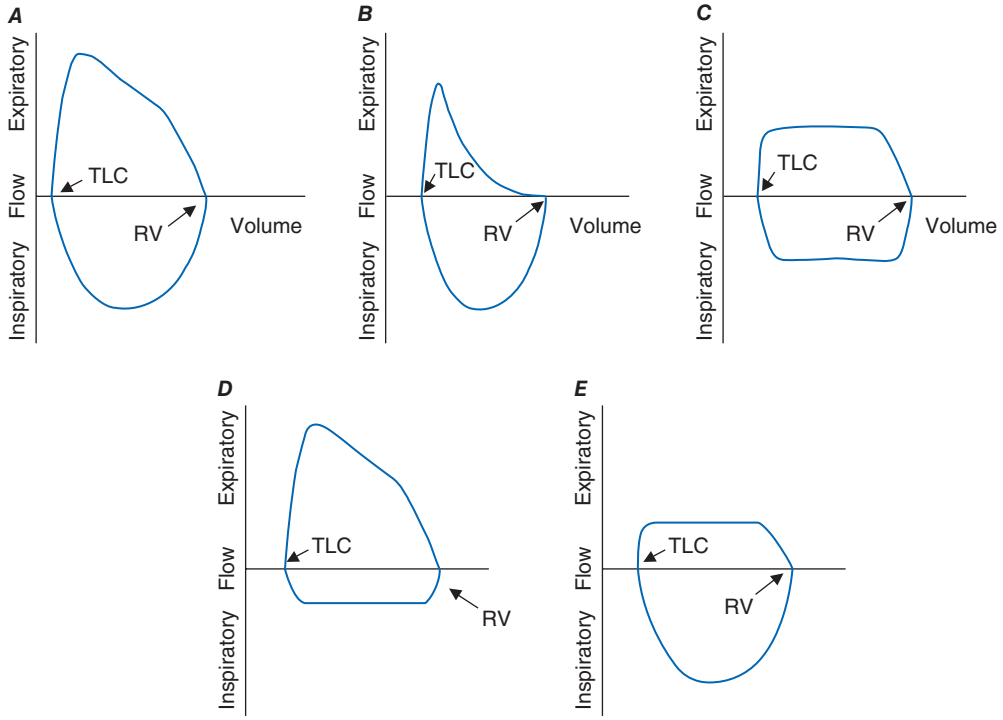

FIGURE 296-4 Flow-volume loops. ***A.*** Normal. ***B.*** Airflow obstruction. ***C.*** Fixed central airway obstruction (either above or below the thoracic inlet). ***D.*** Variable upper airway obstruction (above the thoracic inlet) ***E.*** Variable lower airway obstruction (below the thoracic inlet). RV, residual volume; TLC, total lung capacity.

insufficient to allow complete exhalation during the expiratory phase of tidal breathing; as a result, the "functional residual capacity (FRC)" from which the next breath is inhaled is greater than the static FRC. With repetition of incomplete exhalations of each tidal breath, the operating FRC becomes dynamically elevated, sometimes to a level that approaches TLC. At these high lung volumes, the respiratory system is much less compliant than at normal breathing volumes, and thus, the elastic work of each tidal breath is also increased. The dynamic pulmonary hyperinflation that accompanies severe airflow obstruction causes patients to sense difficulty in inhaling—even though the root cause of this pathophysiologic abnormality is expiratory airflow obstruction.

Adequacy of Ventilation As noted above, the respiratory control system that sets the rate of ventilation responds to chemical signals, including arterial CO_2 and oxygen tensions and blood pH, and to volitional needs, such as the need to inhale deeply before playing a long phrase on the trumpet. Disturbances in ventilation are discussed in **Chap. 307**. The focus of this chapter is on the relationship between ventilation of the lung and CO_2 elimination.

At the end of each tidal exhalation, the conducting airways are filled with alveolar gas that did not reach the mouth when expiratory flow stopped. During the ensuing inhalation, fresh gas immediately enters the airway tree at the mouth, but the gas first entering the alveoli at the start of inhalation is that same alveolar gas in the conducting airways that had just left the alveoli. Accordingly, fresh gas does not enter the alveoli until the volume of the conducting airways has been inspired. This volume is called the *anatomic dead space* (V_D). Quiet breathing with tidal volumes smaller than the anatomic dead space introduces no fresh gas into the alveoli at all; only that part of the inspired tidal volume (V_T) that is greater than the V_D introduces fresh gas into the alveoli. The dead space can be further increased functionally if some of the inspired tidal volume is delivered to a part of the lung that receives no pulmonary blood flow and thus cannot contribute to gas exchange (e.g., the portion of the lung distal to a large pulmonary embolus). In this situation, exhaled minute ventilation ($\dot{V}_E = V_T \times RR$) includes a component of dead space ventilation ($\dot{V}_D = V_D \times RR$) and a component of fresh gas alveolar ventilation ($\dot{V}_A = [V_T - V_D] \times RR$). Carbon dioxide elimination from the alveoli is equal to V_A times the difference in CO_2 fraction between inspired air (essentially zero) and alveolar gas (typically ~5.6% after correction for humidification of inspired air, corresponding to 40 mmHg).

In the steady state, the alveolar fraction of CO_2 is equal to metabolic CO_2 production divided by alveolar ventilation. Because, as discussed below, alveolar and arterial CO_2 tensions are equal, and because the respiratory controller normally strives to maintain arterial P_{CO_2} (Pa_{CO_2}) at ~40 mmHg, the adequacy of alveolar ventilation is reflected in Pa_{CO_2}. If the Pa_{CO_2} falls much below 40 mmHg, alveolar hyperventilation is present; if the Pa_{CO_2} exceeds 40 mmHg, alveolar hypoventilation is present. Ventilatory failure is characterized by extreme alveolar hypoventilation. In vivo, the production and clearance of CO_2 can be assessed through sampling of the arterial and central venous blood. CO_2 clearance can also be estimated noninvasively using capnography. Capnography enables visualization of respirophasic changes in CO_2 concentration at the airway opening, which at end of a tidal breath ($EtCO_2$) provides an estimate of ventilation.

As a consequence of oxygen uptake of alveolar gas into capillary blood, alveolar oxygen tension falls below that of inspired gas. The rate of oxygen uptake (determined by the body's metabolic oxygen consumption) is related to the average rate of metabolic CO_2 production, and their ratio—the "respiratory quotient" ($R = \dot{V}_{CO_2}/\dot{V}_{O_2}$)—depends largely on the fuel being metabolized. For a typical American diet, R is usually around 0.85. Together, these phenomena allow the estimation of alveolar oxygen tension, according to the following relationship, known as the *alveolar gas equation*:

$$Pa_{O_2} = F_{IO_2} \times (P_{bar} - P_{H_2O}) - Pa_{CO_2}/R$$

The alveolar gas equation also highlights the influences of inspired oxygen fraction F_{IO_2} barometric pressure (P_{bar}), and vapor pressure of water (P_{H_2O} = 47 mmHg at 37°C) in addition to alveolar ventilation (which sets Pa_{CO_2}) in determining Pa_{O_2}. An implication of the alveolar gas equation is that severe arterial hypoxemia rarely occurs as a pure consequence of alveolar hypoventilation at sea level while an individual is breathing air. The potential for alveolar hypoventilation to induce severe hypoxemia with otherwise normal lungs increases as P_{bar} falls with increasing altitude.

GAS EXCHANGE

Diffusion For oxygen to be delivered to the peripheral tissues, it must pass from alveolar gas into alveolar capillary blood by diffusing through alveolar membrane. The aggregate alveolar membrane is highly optimized for this process, with a very large surface area and minimal thickness. Diffusion through the alveolar membrane is so efficient in the human lung that in most circumstances hemoglobin of a red blood cell becomes fully oxygen saturated by the time the cell has traveled just one-third the length of the alveolar capillary. Thus, the uptake of alveolar oxygen is ordinarily limited by the amount of blood transiting the alveolar capillaries rather than by the rapidity with which oxygen can diffuse across the membrane; consequently, oxygen uptake from the lung is said to be "perfusion limited" rather than diffusion limited. CO_2 also equilibrates rapidly across the alveolar membrane. Therefore, the oxygen and CO_2 tensions in capillary blood leaving a normal alveolus are essentially equal to those in alveolar gas. Only in rare circumstances (e.g., at high altitude or in high-performance athletes exerting maximal effort) is oxygen uptake from normal lungs diffusion limited. Diffusion limitation can also occur in interstitial lung disease if substantially thickened alveolar walls remain perfused.

Ventilation/Perfusion Heterogeneity As noted above, for gas exchange to be most efficient, ventilation ($\dot{V}$) to each individual alveolus (among the millions of alveoli) should match perfusion ($\dot{Q}$) to its accompanying capillaries. Because of the differential effects of gravity on lung mechanics and blood flow throughout the lung and because of differences in airway and vascular architecture among various respiratory paths, there is minor ventilation/perfusion heterogeneity even in the normal lung; however, $\dot{V}/\dot{Q}$ heterogeneity can be particularly marked in disease. Two extreme examples are (1) ventilation of unperfused lung distal to a pulmonary embolus, in which ventilation of the physiologic dead space is "wasted" in the sense that it does not contribute to gas exchange; and (2) perfusion of nonventilated lung (a "shunt"), which allows venous blood to pass through the lung unaltered. When mixed with fully oxygenated blood leaving other well-ventilated lung units, shunted venous blood disproportionately lowers the mixed arterial Pa_{O_2} as a result of the nonlinear oxygen content versus P_{O_2} relationship of hemoglobin **(Fig. 296-5)**. Furthermore, the resulting arterial hypoxemia is refractory to supplemental inspired oxygen. The reason is that (1) raising the inspired F_{IO_2} has no effect on alveolar gas tensions in nonventilated alveoli and (2) while raising inspired F_{IO_2} increases Pa_{CO_2} in ventilated alveoli, the oxygen content of blood exiting ventilated units increases only slightly, as hemoglobin will already have been nearly fully saturated. Furthermore, the solubility of oxygen in plasma is quite small, and in normobaric conditions, the dissolved amount of oxygen in blood offers little additional physiologic benefit.

A more common occurrence than the two extreme examples given above is a widening of the distribution of ventilation/perfusion ratios; such $\dot{V}/\dot{Q}$ heterogeneity is a common consequence of lung disease. In this circumstance, perfusion of relatively underventilated alveoli results in the incomplete oxygenation of exiting blood. When mixed with well-oxygenated blood leaving higher $\dot{V}/\dot{Q}$ regions, this partially reoxygenated blood disproportionately lowers arterial Pa_{O_2}, although to a lesser extent than does a similar perfusion fraction of blood leaving regions of pure shunt. In addition, in contrast to shunt regions, inhalation of supplemental oxygen raises the Pa_{O_2} even in relatively underventilated low $\dot{V}/\dot{Q}$ regions, and so the arterial hypoxemia induced by $\dot{V}/\dot{Q}$ heterogeneity is typically responsive to oxygen therapy (Fig. 296-5).

In sum, arterial hypoxemia can be caused by substantial reduction of inspired oxygen tension, severe alveolar hypoventilation, perfusion of relatively underventilated (low $\dot{V}/\dot{Q}$) or completely unventilated

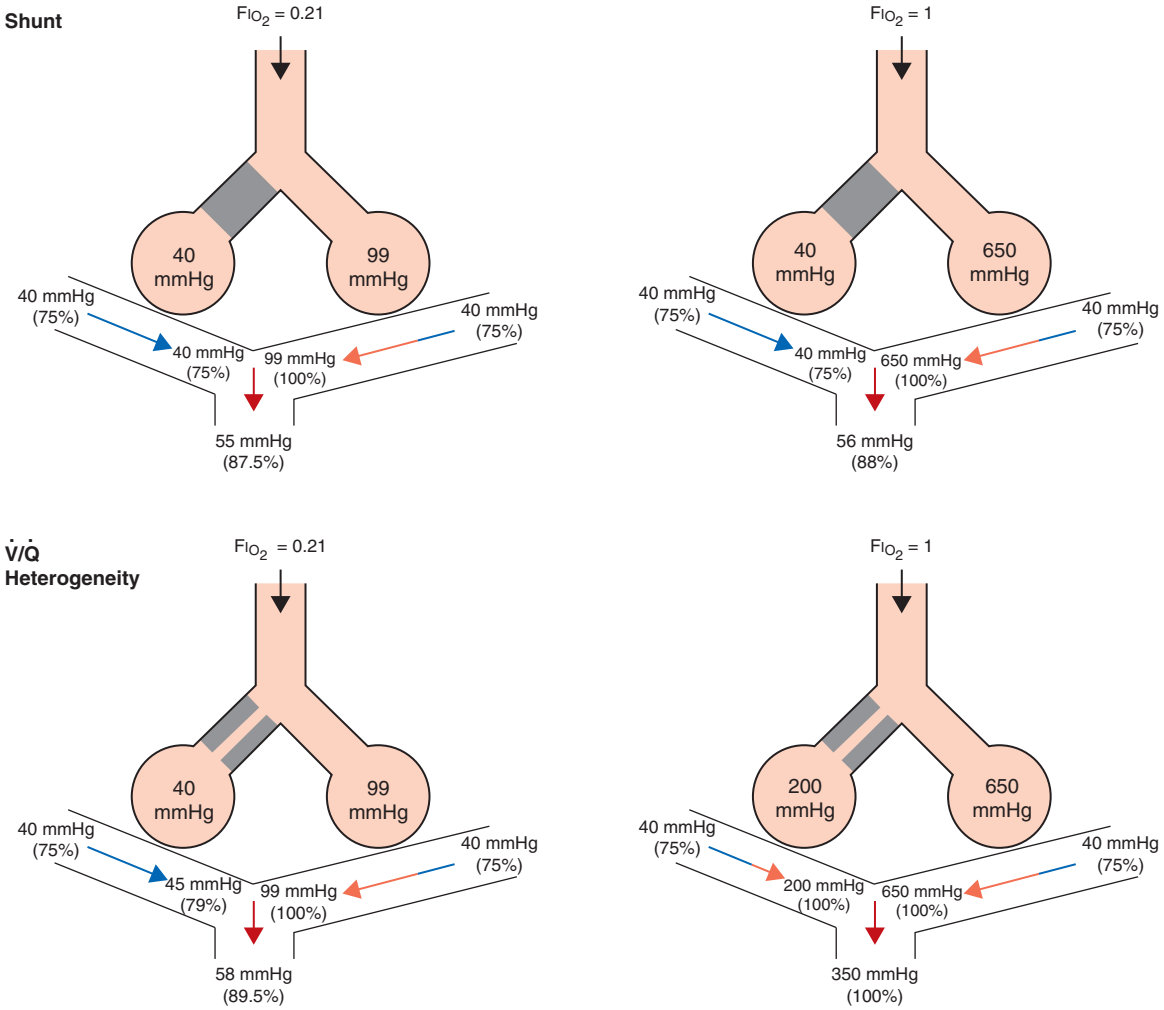

FIGURE 296-5 Influence of air versus oxygen breathing on mixed arterial oxygenation in shunt and ventilation/perfusion heterogeneity. Partial pressure of oxygen (mmHg) and oxygen saturations are shown for mixed venous blood, for end capillary blood (normal vs affected alveoli), and for mixed arterial blood. F_{IO_2} fraction of inspired oxygen; V̇/Q̇, ventilation/perfusion.

(shunt) lung regions, and, in very unusual circumstances, limitation of gas diffusion.

PATHOPHYSIOLOGY

Although many diseases injure the respiratory system, this system responds to injury in relatively few ways. For this reason, the pattern of physiologic abnormalities may or may not provide sufficient information by which to discriminate among conditions.

Figure 296-6 lists abnormalities in pulmonary function testing that are typically found in a number of common respiratory disorders and highlights the simultaneous occurrence of multiple physiologic abnormalities. The coexistence of some of these respiratory disorders results in more complex superposition of these abnormalities. Methods to measure respiratory system function clinically are described later in this chapter.

Ventilatory Restriction due to Increased Elastic Recoil—Example: Idiopathic Pulmonary Fibrosis Idiopathic pulmonary fibrosis raises lung recoil at all lung volumes, thereby lowering TLC, FRC, and RV as well as forced vital capacity (FVC). Maximal expiratory flows are also reduced from normal values but are elevated when considered in relation to lung volumes. Increased flow occurs both because the increased lung recoil drives greater maximal flow at any lung volume and because airway diameters are relatively increased due to greater radially outward traction exerted on bronchi by the stiff lung parenchyma. For the same reason, airway resistance is also normal. Destruction of the pulmonary capillaries by the fibrotic process results in a marked reduction in diffusing capacity (see below). Oxygenation is often severely reduced by persistent perfusion of alveolar units that are relatively underventilated due to fibrosis of nearby (and mechanically linked) lung due to those alveolar units already being stretched to their maximum volume with little further increase in volume with inspiration. The flow-volume loop (see below) looks like a miniature version of a normal loop but is shifted toward lower absolute lung volumes and displays maximal expiratory flows that are increased for any given volume over the normal tracing.

Ventilatory Restriction due to Chest Wall Abnormality—Example: Moderate Obesity As the size of the average American continues to increase, this pattern may become the most common of pulmonary function abnormalities. In moderate obesity, the outward recoil of the chest wall is blunted by the weight of chest wall adipose tissue and the space occupied by intraabdominal fat. In this situation, preserved inward recoil of the lung overbalances the reduced outward recoil of the chest wall, and FRC falls. Because respiratory muscle strength and lung recoil remain normal, TLC is typically unchanged (although it may fall in massive obesity) and RV is normal (but may be reduced in massive obesity). Mild hypoxemia may be present due to perfusion of alveolar units that are poorly ventilated because of airway closure in dependent portions of the lung during breathing near the reduced FRC. Flows remain normal, as does the diffusion capacity of the lung for carbon monoxide ($D_{L_{CO}}$) unless obstructive sleep apnea (which often accompanies obesity) and associated chronic intermittent hypoxemia have induced pulmonary arterial hypertension, in which case $D_{L_{CO}}$ may be low.

Ventilatory Restriction due to Reduced Muscle Strength—Example: Myasthenia Gravis In this circumstance, FRC remains

	Restriction due to increased lung elastic recoil (pulmonary fibrosis)	Restriction due to chest wall abnormality (moderate obesity)	Restriction due to respiratory muscle weakness (myasthenia gravis)	Obstruction due to airway narrowing (acute asthma)	Obstruction due to decreased elastic recoil (severe emphysema)
TLC	60%	95%	75%	100%	130%
FRC	60%	65%	100%	104%	220%
RV	60%	100%	120%	120%	310%
FVC	60%	92%	60%	90%	60%

DL_{CO}	60%	95%	80%	120%	40%

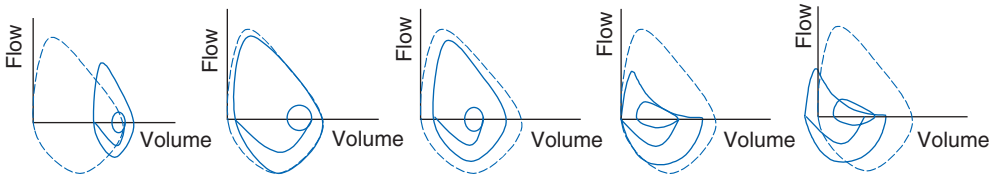

FIGURE 296-6 Common abnormalities of pulmonary function (see text). Pulmonary function values are expressed as a percentage of normal predicted values, except for R_{aw}, which is expressed as $cmH_2O/L/s$ (normal, <2 $cmH_2O/L/s$). The figures at the bottom of each column show the typical configuration of flow-volume loops in each condition, including the flow-volume relationship during tidal breathing. b.d., bronchodilator; DL_{CO} diffusion capacity of lung for carbon monoxide; FEV_1, forced expiratory volume in 1 s; FRC, functional residual capacity; FVC, forced vital capacity; R_{aw}, airways resistance; RV, residual volume; TLC, total lung capacity.

normal, as both lung recoil and passive chest wall recoil are normal. However, TLC is low and RV is elevated because respiratory muscle strength is insufficient to push the passive respiratory system fully toward either volume extreme. Caught between the low TLC and the elevated RV, FVC and forced expiratory volume in 1 s (FEV_1) are reduced as "innocent bystanders." As airway size and lung vasculature are unaffected, both R_{aw} and DL_{CO} are normal. Oxygenation is normal unless weakness becomes so severe that the patient has insufficient strength to reopen collapsed alveoli during sighs, with resulting atelectasis.

Airflow Obstruction due to Decreased Airway Diameter—Example: Acute Asthma During an episode of acute asthma, luminal narrowing due to smooth muscle constriction as well as inflammation and thickening within the small- and medium-sized bronchi raise frictional resistance and reduce airflow. "Scooping" of the flow-volume loop is caused by reduction of airflow, especially at lower lung volumes. Often, airflow obstruction can be improved through the administration of short-acting β_2-adrenergic or muscarinic agonists acutely, or by treatment with longer-acting β_2-adrenergic or muscarinic agonists, inhaled corticosteroids, and new systemically administered biologic immunotherapies chronically. TLC usually remains normal (although elevated TLC is sometimes seen in long-standing asthma), but FRC may be dynamically elevated. RV is often increased due to exaggerated airway closure at low lung volumes, and this elevation of RV reduces FVC. Because central airways are narrowed, airway resistance (R_{aw}) is usually elevated. Mild arterial hypoxemia is often present due to perfusion of relatively underventilated alveoli distal to obstructed airways (and is responsive to oxygen supplementation), but DL_{CO} is normal or mildly elevated.

Airflow Obstruction due to Decreased Elastic Recoil—Example: Severe Emphysema Loss of lung elastic recoil in severe emphysema results in pulmonary hyperinflation, of which elevated TLC is the hallmark. FRC is more severely elevated due to both loss of lung elastic recoil and dynamic hyperinflation—the same phenomenon as auto-PEEP (auto–positive end-expiratory pressure), which is the positive end-expiratory alveolar pressure that occurs when a new breath is initiated before the lung volume is allowed to return to FRC. RV is very severely elevated because of airway closure and because exhalation toward RV may take so long that RV cannot be reached before the patient must inhale again. Both FVC and FEV_1 are markedly decreased, the former because of the severe elevation of RV and the latter because loss of lung elastic recoil reduces the pressure driving maximal expiratory flow and also reduces tethering open of small intrapulmonary airways. The flow-volume loop demonstrates marked scooping, with an initial transient spike of flow attributable largely to expulsion of air from collapsing central airways at the onset of forced exhalation. Otherwise, the central airways remain relatively unaffected, so R_{aw} is normal in "pure" emphysema. Loss of alveolar surface and capillaries in the alveolar walls reduces DL_{CO}; however, because poorly ventilated emphysematous acini are also poorly perfused (due to loss of their capillaries), arterial hypoxemia usually is not seen at rest until emphysema becomes very severe. However, during exercise, Pao_2 may fall precipitously if extensive destruction of the pulmonary vasculature prevents a sufficient increase in cardiac output and mixed venous oxygen content falls substantially. Under these circumstances, any venous admixture through low $\dot{V}/\dot{Q}$ units has a particularly marked effect in lowering mixed arterial oxygen tension.

FUNCTIONAL MEASUREMENTS

Measurement of Ventilatory Function • LUNG VOLUMES Figure 296-2 demonstrates a spirometry tracing in which the volume of air entering or exiting the lung is plotted over time. In a slow vital capacity maneuver, the patient inhales from FRC, fully inflating the lungs to TLC, and then exhales slowly to RV; VC, the difference between TLC and RV, represents the maximal excursion of the respiratory system. Spirometry discloses relative volume changes during these maneuvers but cannot reveal the absolute volumes at which they occur. To determine absolute lung volumes, two approaches are commonly used: inert gas dilution and body plethysmography. In the former, a known amount of a nonabsorbable inert gas (usually helium or neon) is inhaled in a single large breath or is rebreathed from a closed circuit; the inert gas is diluted by the gas resident in the lung at the time of inhalation, and its final concentration reveals the volume of resident gas contributing to the dilution. A drawback of this method is that regions of the lung that ventilate poorly (e.g., due to airflow obstruction) may not receive much inspired inert gas and so do not contribute to its dilution. Therefore, inert gas dilution (especially in the single-breath method) often underestimates true lung volumes.

In the second approach, FRC is determined by measuring the compressibility of gas within the chest, which is proportional to the volume of gas being compressed. The patient sits in a body plethysmograph (a chamber usually made of transparent plastic to minimize claustrophobia) and, at the end of a normal tidal breath (i.e., when lung volume is at FRC), is instructed to pant against a closed shutter, thus periodically compressing air within the lung slightly. Pressure fluctuations at the mouth and volume fluctuations within the body box (equal but opposite to those in the chest) are determined, and from these measurements, the thoracic gas volume is calculated by means of Boyle's law ($P_1V_1 = P_2V_2$). Once FRC is obtained, TLC and RV are calculated by adding the value for inspiratory capacity and subtracting the value for expiratory reserve volume, respectively (both values having been obtained during spirometry) (Fig. 296-2). The most important determinants of healthy individuals' lung volumes are height, age, and sex, but there is considerable additional normal variation beyond that accounted for by these parameters. In practice, a mean "normal" value is predicted by multivariate regression equations using height, age, and sex, and the patient's value is divided by the predicted value to determine "percent predicted." For most measures of lung function, 85–115% of the predicted value can be normal; however, in health, the various lung volumes tend to scale together. For example, if one is "normal big" with a TLC 110% of the predicted value, all other lung volumes and spirometry values will also approximate 110% of their respective predicted values. This pattern is particularly helpful in evaluating airflow, as discussed below.

AIR FLOW As noted above, spirometry plays a key role in lung volume determination. Even more often, spirometry is used to measure airflow, which reflects the dynamic properties of the lung. During an FVC maneuver, the patient inhales to TLC and then exhales rapidly and forcefully to RV; this method ensures that flow limitation has been achieved, so that the precise effort made has little influence on actual flow. The total amount of air exhaled is the FVC, and the amount of air exhaled in the first second is the FEV_1; the FEV_1 is a flow rate, revealing volume change per time. Like lung volumes, an individual's maximal expiratory flows should be compared with predicted values based on height, age, and sex. While the FEV_1/FVC ratio is typically reduced in airflow obstruction, this condition can also reduce FVC by raising RV, sometimes rendering the FEV_1/FVC ratio "artifactually normal" with the erroneous implication that airflow obstruction is absent.

The relationships among volume, flow, and time during spirometry are best displayed in two plots—the spirogram (volume vs time) and the flow-volume loop (flow vs volume) (Fig. 296-4). In conditions that cause airflow obstruction, the site of obstruction is sometimes correlated with the shape of the flow-volume loop. In diseases that cause lower airway obstruction, such as asthma and emphysema, flows decrease more rapidly with declining lung volumes, leading to a characteristic scooping of the flow-volume loop. In contrast, fixed upper-airway obstruction typically leads to inspiratory and/or expiratory flow plateaus (Fig. 296-4).

RESPIRATORY MUSCLE STRENGTH To measure respiratory muscle strength, the patient is instructed to exhale or inhale with maximal effort against a closed shutter while pressure is monitored at the mouth. Pressures >±60 cmH_2O at FRC are considered adequate and make it unlikely that respiratory muscle weakness accounts for any other resting ventilatory dysfunction that is identified. A more sensitive and better tolerated approach to identify inspiratory muscle weakness is performing spirometry in the supine position. This position increases diaphragmatic work by neutralizing the assistance of gravity. FVC in normal subjects decreases approximately 3–8% from upright to supine position, and patients with diaphragmatic weakness, hemidiaphragmatic paralysis, or neuromuscular disease suffer decrements from 10 to >25%.

Measurement of Gas Exchange • **DIFFUSING CAPACITY (DL_{CO})** This test uses a small (and safe) amount of carbon monoxide (CO) to measure gas exchange across the alveolar membrane during a 10-s breath hold. CO in exhaled breath is analyzed to determine the quantity of CO crossing the alveolar membrane and combining with hemoglobin in red blood cells. This "single-breath diffusing capacity" (DL_{CO}) value increases with the surface area available for diffusion and the amount of hemoglobin within the capillaries, and it varies inversely with alveolar membrane thickness. Thus, DL_{CO} decreases in diseases that thicken or destroy alveolar membranes (e.g., pulmonary fibrosis, emphysema), curtail the pulmonary vasculature (e.g., pulmonary hypertension), or reduce alveolar capillary hemoglobin (e.g., anemia). Single-breath diffusing capacity may be elevated in asthma, polycythemia, and pulmonary hemorrhage.

Arterial Blood Gases The effectiveness of gas exchange can be assessed by measuring the partial pressures of oxygen and CO_2 in a sample of blood obtained by arterial puncture. The oxygen content of blood (CaO_2) depends on arterial saturation ($\%O_2Sat$), which is set by Pao_2, pH, and $PaCO_2$ according to the oxyhemoglobin dissociation curve. CaO_2 can also be measured by oximetry (see below):

$$CaO_2\ (mL/dL) = 1.39\ (mL/dL) \times [hemoglobin]\ (g) \times \%O_2Sat + 0.003\ (mL/dL/mmHg) \times Pao_2\ (mmHg)$$

If hemoglobin saturation alone needs to be determined, this task can be accomplished noninvasively with pulse oximetry.

297 Diagnostic Procedures in Respiratory Disease

George R. Washko, Hilary J. Goldberg, Mājid Shafiq

Diagnostic procedures in respiratory disease encompass a wide array of invasive and noninvasive modalities. Methods for acquiring diagnostic specimens are described in this chapter, as are the various imaging modalities at hand. **Pulmonary function tests and measurements of gas exchange are described in Chap. 295.**

BEDSIDE PLEURAL PROCEDURES

THORACENTESIS

Thoracentesis, also known as pleurocentesis, refers to percutaneous aspiration of fluid from the pleural space. The right and left pleural spaces do not normally communicate with each other, and either can be directly accessed between the thoracic ribs. The current standard of care entails using point-of-care ultrasonography to mark the site of needle puncture; this reduces the risks of "dry tap" as well as complications such as pneumothorax. Beside palliation of symptoms associated with pleural effusion (most commonly dyspnea), thoracentesis may be performed for diagnostic purposes. The range of hematologic, biochemical, microbiologic, and cytologic pleural fluid studies has largely remained unchanged over the past few decades, as has the widespread adoption of Light's criteria for distinguishing exudates from transudates that were described in 1972. However, newer assays such as mesothelin-1 testing for neoplastic diseases (chiefly mesothelioma) have also become available more recently. **More details on pleural fluid testing are described in Chap. 305.**

CLOSED PLEURAL BIOPSY

Closed pleural biopsy involves percutaneous sampling of the parietal pleural lining. This procedure can be performed either "blindly" (typically with an Abrams needle) or by using imaging guidance such as computed tomography (CT) or ultrasound. Closed pleural biopsy without ultrasound guidance is highly sensitive for pleural tuberculosis, owing to the diffuse pleural involvement that is typically seen in those cases.

Image-guided closed pleural biopsy is most helpful in case of focal pleural abnormalities such as pleural nodules, which are virtually pathognomonic of malignant involvement. Limited studies have shown high diagnostic yields of around 80–90% with this modality, but patient selection is key as the diagnostic performance may be considerably lower in the absence of a specific pleural abnormality that could be visualized. Between CT and ultrasound imaging, only ultrasound is typically performed in real time during the act of obtaining the biopsy.

THORACIC SURGICAL PROCEDURES

THORACOSCOPY AND THORACOTOMY

Thoracoscopy and thoracotomy encompass a spectrum of surgical procedures that involve accessing and operating within the pleural space, either via one or more small entry ports using thoracoscopic tools or via larger incisions as in thoracotomy **(Fig. 297-1)**. Thoracoscopy varies in its scope considerably. An interventional pulmonologist typically performs a pleuroscopy (also known as *medical thoracoscopy*) and accesses the pleural space through a single port for parietal pleural biopsy or for limited therapeutic purposes such as minor lysis of adhesions, thoracoscopic pleurodesis, or indwelling pleural catheter placement. This procedure can usually be performed safely under conscious sedation. On the other hand, video-assisted thoracoscopic surgery (VATS) and robotic-assisted thoracoscopic surgery (RATS) represent more invasive procedures but with more controlled environments entailing general anesthesia with single-lung ventilation, creation of multiple entry ports, and several additional diagnostic and therapeutic possibilities including, but not limited to, lung biopsy, lymph node sampling, lobectomy, decortication, and creation of a pericardial window. Open thoracotomy uses wider incisions and more conventional surgical techniques for performing all of the above as well as additional tasks such as creation of a Clagett window for chronic bronchopleural fistula with empyema.

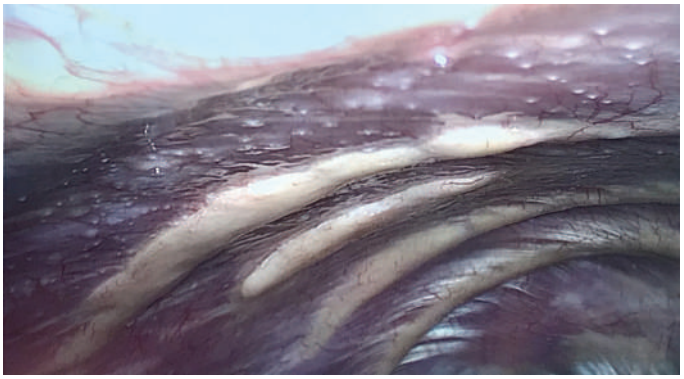

FIGURE 297-1 Thoracoscopy demonstrating numerous parietal pleural nodules in a patient with sarcoidosis-related pleural disease. Pleural biopsy revealed nonnecrotizing granulomas. *(Source: Mājid Shafiq, MD, MPH.)*

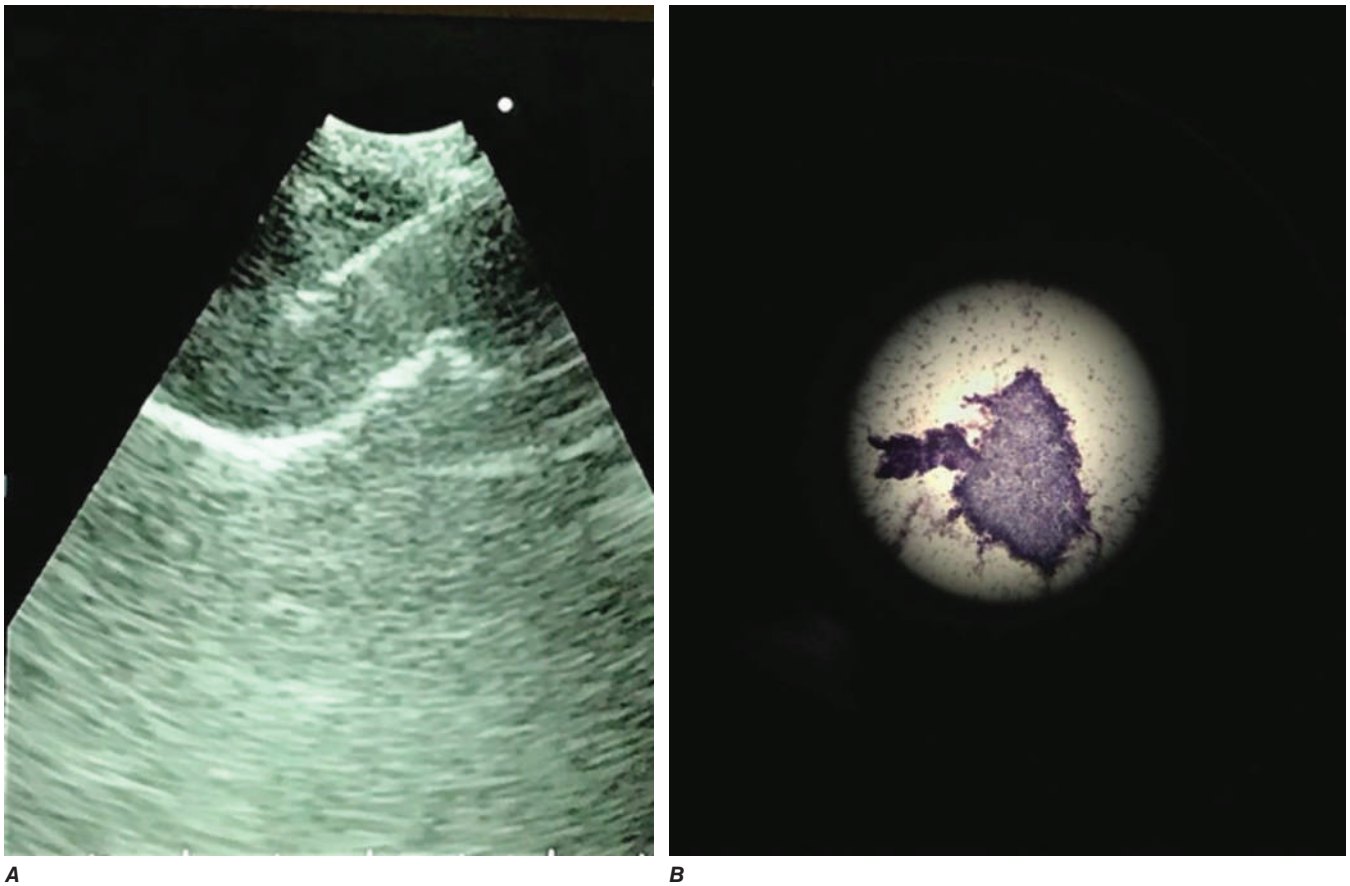
MEDIASTINOSCOPY AND MEDIASTINOTOMY

Surgical access to the mediastinum, either through a small port (mediastinoscopy) or a wider incision (mediastinotomy), enables diagnostic sampling of mediastinal structures such as mediastinal lymph nodes as part of lung cancer staging. With the advent of endoscopic needle-based techniques (see below), surgery is no longer considered the first-line option for diagnostic lymph node sampling but is recommended in cases of negative needle-based sampling where suspicion for malignant nodal involvement remains sufficiently high.

BRONCHOSCOPY

Bronchoscopy, which entails passing a tube with a lighted camera inside the lower respiratory tract, includes flexible and rigid bronchoscopy (termed after the physical properties of each bronchoscope). Flexible bronchoscopy is by far the more commonly used form and enables access to more distal parts of the respiratory tract. The rigid bronchoscope, although limited to the central airways, has the added advantage of providing a secure airway for ventilation; artificial breaths can then be administered through the scope itself as part of a closed circuit or through open jet ventilation. The rigid bronchoscope also provides a conduit for diagnostic or therapeutic instruments to be passed freely, rather than through the relatively constrained working channel of a flexible bronchoscope. When bronchoscopy is limited to diagnostic indications, the rigid bronchoscope is seldom used except on occasion as a precautionary measure for anticipated severe bleeding where having a more secure airway might be particularly advantageous (e.g., in transbronchial cryobiopsy). Different types of diagnostic bronchoscopic procedures are described below.

Bronchoalveolar Lavage Bronchoalveolar lavage (BAL) is the gold standard method for obtaining respiratory secretions for hematologic, biochemical, microbiological, and/or cytologic analyses. It avoids the risk of salivary contamination, which may be seen in a sputum specimen and is particularly useful when sputum cannot be obtained or when sampling of a specific pulmonary lobe or segment is desired. After wedging the bronchoscope in a distal airway in order to prevent fluid escape around the scope, sterile saline or distilled water is instilled through the scope's working channel (typically in one to three aliquots of ~50 mL each). Immediately thereafter, suction is applied to aspirate as much of the fluid as possible. This allows sampling of distal airways and lung parenchyma—areas not directly viewable or accessible. If there is concern for alveolar hemorrhage, serial BALs from the same site may show rising red blood cell counts and even visibly bloodier returns with subsequent lavages.



Brushing and Endobronchial Biopsy Bronchoscopic brushing is a minimally invasive sampling technique that can be used to sample the mucosal biofilm for microbiologic analyses as well as the bronchial epithelial layer for cytologic analyses. Endobronchial biopsy allows sampling of abnormal bronchial mucosa and submucosa for histopathologic analysis (as may be indicated in cases of endobronchial amyloidosis or sarcoidosis, for example). Among cigarette smokers with one or more lung nodules and a nondiagnostic bronchoscopy, bronchial brushings can be used with a commercially available classifier that estimates lung cancer probability based on a gene expression signature. Patients with intermediate pretest probability who end up with low posttest probability can more confidently opt for imaging surveillance, thus avoiding further invasive testing and related complications.

Transbronchial Biopsy Including Cryobiopsy Transbronchial biopsy involves removing a piece of alveolated lung tissue by passing a sampling tool into the alveolar space. The most commonly employed biopsy tool is flexible forceps, typically 2.0 mm or 2.8 mm in caliber. When a specific pulmonary lesion such as a lung nodule is being biopsied, various imaging and navigation tools (described below) may be used to help guide the site of forceps biopsy. When random sampling of the lung parenchyma is desired, e.g., to assess for posttransplant lung rejection, either fluoroscopic guidance or tactile feedback is commonly used to position the forceps in the subpleural lung parenchyma. Limited data point to three biopsy samples being adequate for optimizing sensitivity in case of malignant lung nodules. On the other hand, at least five distinct pieces of alveolated lung tissue are needed for formal diagnosis of acute cellular rejection among lung transplant recipients per current recommendations. An increasingly popular biopsy tool is the cryoprobe, a flexible catheter with a blunt tip that delivers liquid nitrogen or carbon dioxide over a few seconds to freeze a portion of lung parenchyma and make it adhere to the probe itself. Before the tissue can thaw and detach, the probe is pulled back (typically along with the bronchoscope itself), and a frozen piece of lung tissue is removed alongside. Cryobiopsy has a higher diagnostic yield than forceps biopsy for diffuse parenchymal illnesses such as idiopathic pulmonary fibrosis but comes with a higher risk of major bleeding and pneumothorax.

Transbronchial Needle Aspiration Transbronchial needle aspiration (TBNA) involves using a hollow-bore needle for obtaining aspirated specimens. This may be accompanied by suction or simply rely on capillary action, with data not pointing to suction impacting diagnostic sensitivity. TBNA has diagnostic sensitivity superior to that of transbronchial biopsy for malignant peripheral nodules. This makes intuitive sense given that the lesion may lie extraluminally and require traversing the airway wall, which only the needle may be able to accomplish. Furthermore, combining TBNA with conventional transbronchial biopsy appears to increase pooled diagnostic sensitivity.

Endobronchial Ultrasound-Guided Transbronchial Needle Aspiration Endobronchial ultrasound (EBUS) and EBUS-guided transbronchial needle aspiration (EBUS-TBNA) represent a major advance in diagnostic bronchoscopy over the turn of the twentieth century, largely replacing surgical methods for lymph node sampling. EBUS-TBNA involves using a specialized flexible bronchoscope that simultaneously operates a video camera and a convex ultrasound probe (which is installed at its distal end). Under real-time ultrasonographic visualization, the aspiration needle is inserted through the airway wall into the mediastinal target and the aspirate is sent for microbiologic or cytologic analyses as indicated **(Fig. 297-2)**. Newer variants of this technique involve the use of core needles or mini-forceps, providing tissue specimens rather than aspirates that can be sent for histopathologic analysis. EBUS-TBNA has a sensitivity of ~90% for epithelial malignancies and ~70% for lymphoma (higher for detecting cases of lymphoma recurrence than for de novo lymphoma). For sarcoidosis, estimates point to a sensitivity of at least 80% (higher if combined with endobronchial and transbronchial biopsies). EBUS-TBNA has been shown to provide adequate amounts of material to provide ancillary testing in cases of malignancy, such as immunostaining or genetic testing. A related needle-based technique, also using ultrasound guidance, involves sampling mediastinal structures through the esophagus, which can be a useful adjunct to EBUS-TBNA as it may provide better access to certain mediastinal lymph node stations. The combined sensitivity of these two techniques is slightly higher compared to either one alone. Esophageal sampling can be accomplished either with the standard endoscope used by gastroenterologists for endoscopic ultrasound (EUS) or by inserting the same EBUS bronchoscope through the esophagus (EUS-B).

At many centers, EBUS-TBNA is accompanied by rapid on-site cytologic evaluation (ROSE), wherein a portion of the aspirated specimen is immediately examined by a cytotechnologist or pathologist using rapid staining. This rapid assessment, while often inadequate for

A ***B***

FIGURE 297-2 ***A.*** Endobronchial ultrasound-guided transbronchial needle aspiration of a mediastinal lymph node. ***B.*** Rapid on-site evaluation (ROSE) using Diff-Quik stain indicative of noncaseating granuloma. *(Source: Mājid Shafiq, MD, MPH.)*

a definitive final diagnosis, can be helpful in establishing adequacy of sampled material by providing the bronchoscopist with real-time feedback on whether additional sampling is advisable.

The optimal way to process samples obtained via EBUS-TBNA is unknown. Some centers practice the tissue coagulum clot method, in which multiple aspirates are emptied onto a single piece of filter paper to form a clot that can help with preparation of a cell block. Other centers simply use the residue from spun specimens for this purpose. There is no conclusive evidence that one technique is superior to the other, but this question has not been well studied to date.

Guided Peripheral Bronchoscopy Including Robotic Bronchoscopy Guided peripheral bronchoscopy involves the use of advanced tools to aid with successful bronchoscopic sampling of peripherally located lesions in the lung parenchyma, such as lung nodules. Prior to 2018, this entailed the use of navigation software and/or real-time imaging while utilizing conventional flexible bronchoscopes that were already commercially available. Robotic bronchoscopic platforms, first approved for commercial use by the U.S. Food and Drug Administration (FDA) in 2018, were the first to offer additionally improved bronchoscope stability and reach within the peripheral airways compared to conventional flexible bronchoscopes (Fig. 297-3). Early data on the diagnostic performance of robotic bronchoscopy, including from small-sized multicenter prospective studies, are encouraging.

Guided peripheral bronchoscopy comprises three crucial steps:

1. Navigation: Electromagnetic navigational bronchoscopy (which involves GPS-like feedback as the bronchoscope is advanced toward the target) and virtual bronchoscopy (which overlays live endoscopic images onto a CT-derived virtual bronchoscopic map) can help with successful navigation through the airways to the appropriate lobar/segmental/subsegmental airway. Shape-sensing technology, used as part of one robotic bronchoscopy platform, also aims to achieve the same purpose.
2. Localization: The aforementioned technologies can also help localize a lesion, although they are limited by relying on previously acquired CT images that may or may not accurately represent precisely where the lesion is currently located in a three-dimensional space. Radial EBUS uses a thin ultrasound-tipped catheter that can be passed through a bronchoscope's working channel all the way to the lung periphery. This provides real-time images of structures beyond airway walls. A concentric image of the target, indicating a lesion with the airway going through its center, is associated with a high diagnostic yield. Alternatively, radiographic including fluoroscopic imaging can be used to recalibrate the precise target location on navigational bronchoscopic platforms, potentially improving localization as well. Cone-beam CT, which is a distilled version of CT imaging that has been used intraprocedurally in multiple other fields such as interventional radiology, can be used for confirmation of optimal tool-in-lesion (with the patient undergoing a breath hold) prior to sampling.
3. Sampling: The tools available for peripheral sampling include biopsy forceps, brushes, and aspiration needles, as described above, with TBNA having the highest diagnostic sensitivity for malignant lung nodules. Evidence for use of cryobiopsy for sampling discrete lesions in the lung periphery is currently limited but promising. Recent innovations also include real-time ultrasound-guided peripheral sampling (similar to EBUS-TBNA of mediastinal structures) and steerable sampling tools, which hold promise for more optimal sampling of the target lesion.

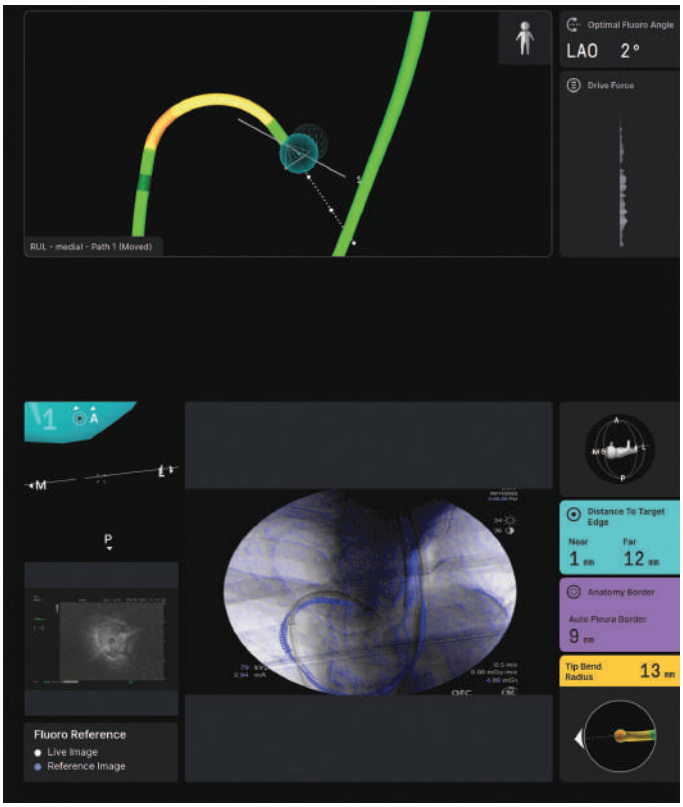


FIGURE 297-3 Use of a robotic navigational bronchoscopic platform for sampling of a 9-mm apicomedial right upper lobe nodule. The navigational software indicates that the lesion is accurately localized (*bottom right*), as does the concentric image on radial endobronchial ultrasound (*bottom left*). Biopsy showed non-small cell lung carcinoma. *(Source: Mājid Shafiq, MD, MPH.)*

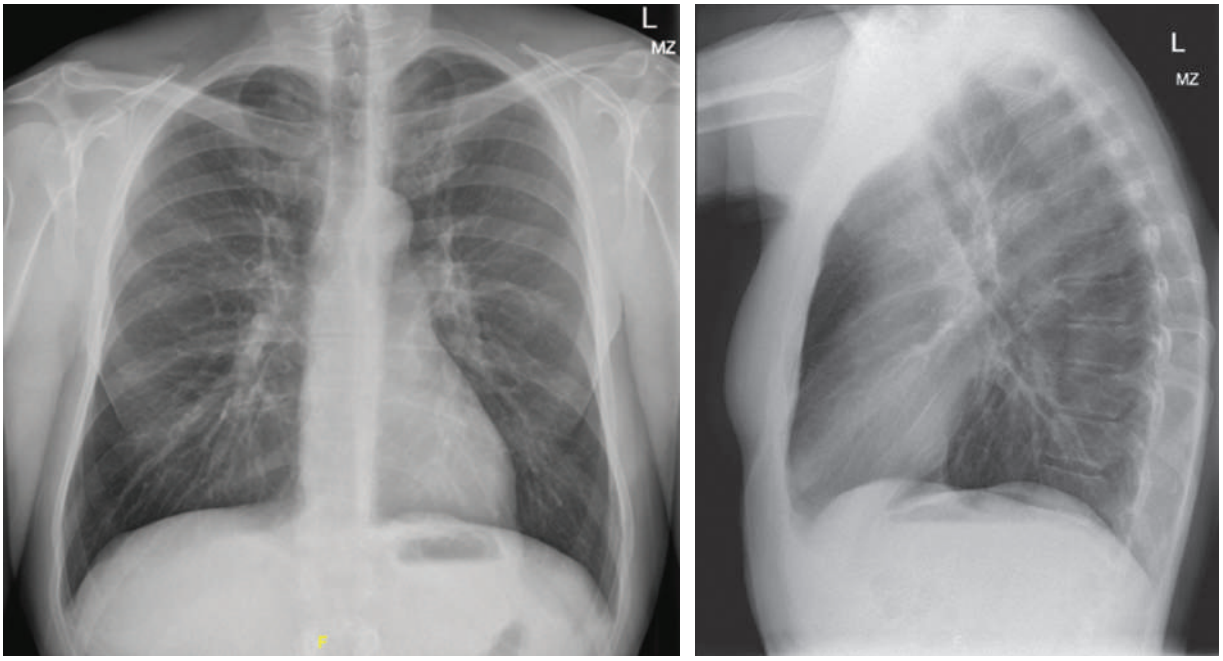
MEDICAL IMAGING



Imaging has revolutionized the practice of medicine. Technologies such as x-ray, CT, magnetic resonance imaging (MRI), and positron emission tomography (PET) can provide noninvasive assessments of alveolar perfusion, the metabolic activity of a lung nodule, the bronchovascular source of hemoptysis, or the earliest disease-related changes in parenchymal structure. Given the breadth of advances in respiratory system imaging and increasingly specialized applications across diseases, the following section is organized by technology. The final part of this section is dedicated to deep learning and the role it is increasingly playing in medical image interpretation.

CHEST X-RAY

The field of medical imaging can be traced back to work done by Wilhelm Roentgen in the 1890s. Roentgen noted that after connecting a cathode ray tube to a power supply, material in his lab would fluoresce even if the emission of visible light from the tube was blocked. He quickly deduced the presence of additional invisible "x-rays" and subsequently observed that their passage through solid material was attenuated in proportion to the material's density. Within weeks of its discovery, x-ray technology was being widely leveraged to guide surgical exploration and the extraction of foreign objects such as shrapnel from the battlefield. Chest x-ray (CXR) has since become the foundation of clinical practice for respiratory medicine and is a widely available technology even in resource-limited settings.

The most commonly used CXR images for respiratory medicine are the posteroanterior (PA) and lateral films in the outpatient setting and anteroposterior (AP) films for those studies obtained at the bedside. These are two-dimensional representations of three-dimensional structures, and the differing views can be used to examine superimposed structures (e.g., a parenchymal opacity in the retrocardiac space). The contours of the chest wall, the silhouette of the heart, great vessels, and mediastinum, as well as the appearance of the parenchyma and bronchovascular bundle are all used to detect and classify disease as well as monitor its progression or response to therapeutic intervention. An example of a normal PA and lateral CXR is provided in Fig. 297-4.

In this image of the normal lung, many of the smaller structures such as the lymphatics and distal airways are beyond the ability of conventional x-ray technology to resolve. Larger structures such as the pulmonary vasculature may also be indistinct because of body position

A *B*

FIGURE 297-4 Posteroanterior (***A***) and lateral (***B***) chest x-ray of a normal healthy subject. *(Source: George Washko.)*

and the redistribution of blood flow to more gravitationally dependent regions. Diseases involving these structures may enhance or obscure their appearance. An example of these diseases is congestive heart failure where the lymphatics become engorged (Kerley B lines), the nondependent vasculature more prominent (cephalization), and the outer boundaries of the bronchial walls blurred (bronchial cuffing). Each of these findings must be clinically contextualized, and while a thickened interstitium may be due to hydrostatic pulmonary edema, it may also be indicative of interstitial lung disease or carcinomatosis. CXR can also be used to discriminate pulmonary and extrapulmonary disease, and because of that, it is an excellent initial diagnostic for nonspecific symptoms. An elevated hemidiaphragm, fibrosis of the mediastinum, or hyperlucency of the lung parenchyma all reflect processes that cause dyspnea, but their treatment and prognosis differ markedly.

COMPUTED TOMOGRAPHY

CT was introduced to clinical care in the 1980s and quickly became one of the most heavily leveraged modalities for medical imaging. While CXR provides one or two views of the thorax from which an experienced clinician must disambiguate overlying structures, CT provides spatially resolved reconstructions of all structures in the thorax. The acquisition of a CT scan involves the same basic process as an x-ray with a patient placed between a source of photons and a detector, but the image reconstruction and advanced analytics that can be applied to those images differ markedly. The passage of photons through the body is impeded in proportion to tissue density. This absorption or attenuation of photon passage is measured in Hounsfield units (HU), and clinical CT scanners are regularly calibrated to a standard scale with water having an HU of 0 and air −1000 HU. The broad range of tissue densities (reflected as attenuation values) in the thorax and the limited human ability to visually discriminate between two structures of similar densities are addressed by modifying the image display. A window width and level (the range and center of the range of HU values to display) is selected to optimize viewing structures of interest. For example, lung windows are optimized for visual inspection of the low-density lung parenchyma and all of the surrounding higher-density structures appear white, whereas the mediastinal windows are optimized to view the higher-density structures and anything of lower tissue density such as the lung parenchyma appears black. This does not change the HU values of the voxels (three-dimensional pixels) in the image, just their presentation for visual inspection.

The visual interpretation of thoracic CT is based on the appearance of the secondary pulmonary lobule. This structure is a fundamental subunit of the lung consisting of a central airway and pulmonary artery, parenchyma, and then surrounding interstitium with the lymphatics and pulmonary veins **(Fig. 297-5)**.

Processes affecting the small airways such as respiratory bronchiolitis may appear as centrilobular nodules. Parenchymal diseases such as emphysema may begin by effacing the centroid of the lobule (centrilobular emphysema [CLE]), the periphery of the lobule (paraseptal emphysema [PSE]), or diffusely across the lobule (panlobular emphysema [PLE]). Pathology of the lymphatics or interstitium (interstitial lung disease [ILD]) results in beading and/or thickening of the interlobular septa. **Examples of many of these processes are provided in Chaps. 303 and 304.**

The diagnostic information provided by the appearance of the secondary pulmonary lobule is further augmented by the distribution of these patterns of injury across the lung. Whereas CLE tends to first appear in the upper lung zones, PLE has a predilection to be basilar predominant. Interstitial thickening in the apices is more likely to be nonspecific interstitial pneumonitis (NSIP), while a basal and dependent predominant distribution of that same process is more consistent with idiopathic pulmonary fibrosis (IPF).

Finally, morphology of the central airways and vessels can be used to diagnose disease and estimate its severity. Bronchiectatic dilation of the airways may be cylindrical and predominantly in the lower lobes, as is seen in chronic obstructive pulmonary disease (COPD), or be cystic dilation in the upper lobes (cystic fibrosis), or there may be a focal nonspecific dilation of an airway due to prior infection. Pathologic dilation of the airways may also be due to disease of the surrounding parenchyma. Because of the mechanical interdependence of the bronchial tree and parenchyma, conditions that reduce lung compliance may result in traction bronchiectasis. This may be a local process or more diffuse depending on the distribution of the underlying parenchymal disease and likely provides further insight into disease severity.

The caliber of the central pulmonary arterial (PA) trunk proximal to its first bifurcation is directly related to pulmonary arterial pressure. A measure of >3 cm is suggestive of the presence of elevated pulmonary vascular pressures, and more recent studies have demonstrated that an increased ratio of the PA diameter to the diameter of the adjacent aorta (PA/A) provides a metric of disease severity and, in the case of chronic respiratory diseases such as COPD, is prognostic for both

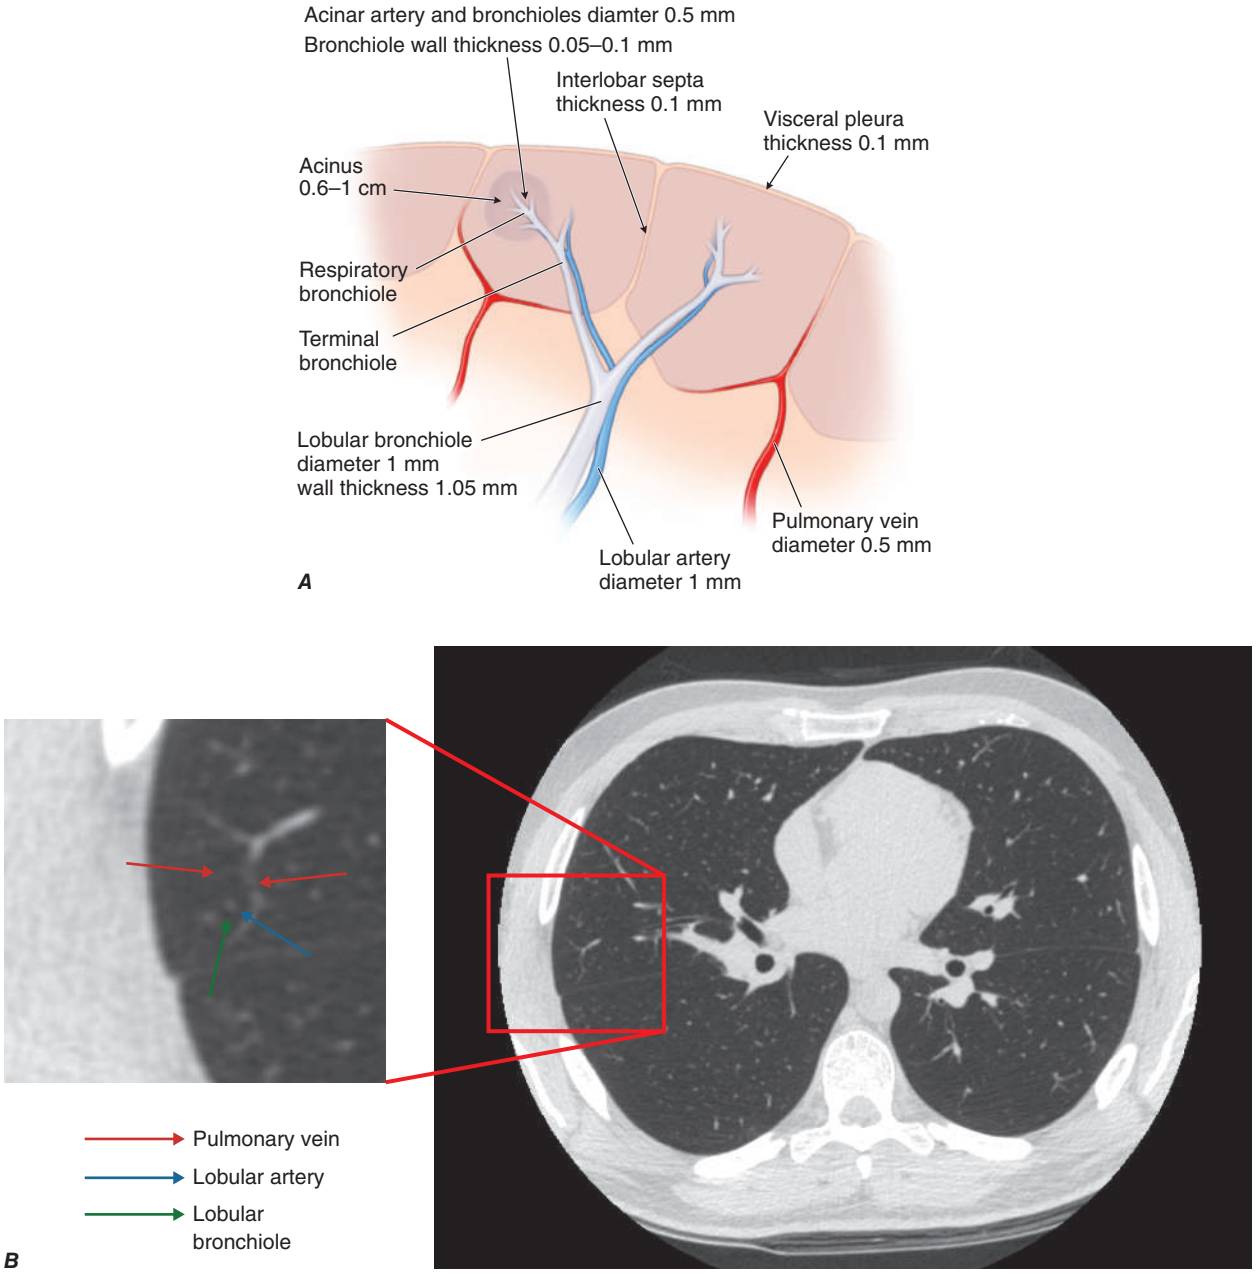


FIGURE 297-5 ***A.*** Illustration of the anatomy of the secondary pulmonary lobule. ***B.*** Computed tomography image showing the visible anatomy of the secondary pulmonary lobule. *(Panel A adapted from WR Webb: Thin-section CT of the secondary pulmonary lobule: Anatomy and the Image–The 2004 Fleischner Lecture. acute respiratory exacerbations and death. Assessment of the intraparenchymal pulmonary vasculature is typically augmented through the intravenous infusion or bolus of iodinated contrast. This bolus and subsequent image acquisition may be timed to visualize passage of contrast through the pulmonary arteries to enable detection of thromboembolic disease, which appears as dark filling voids in otherwise bright white vessels.

It must be noted that the acquisition of CXRs and thoracic CT scans involves exposing the patient to ionizing radiation. Several studies have estimated the excess numbers of cancer due to CT scanning, and extensive efforts have been made by both CT manufacturers and clinicians to reduce the radiation dose to the lowest possible amount that does not jeopardize image quality and interpretability.

MAGNETIC RESONANCE IMAGING

MRI is based on the behavior of protons in a magnetic field. A strong magnetic field is applied to align the protons, and then a pulse of radiofrequency current is applied to the subject. This perturbs the protons, and the speed at which they subsequently realign differs based on the properties of the tissues within the region of interest. While this technique provides exquisite imaging data for the chest wall or solid organs such as the brain or heart, the abundance of air in the lung creates an artifact that impairs direct assessment of the parenchyma. For this reason, MRI of the lung leverages intravenous contrast agents such as gadolinium and is increasingly exploring the use of inhaled agents such as hyperpolarized noble gas. These respective agents enable in vivo assessments of organ perfusion and detailed measures of the morphology of the distal airspaces. An example of noble gas–enhanced MRI is shown in Fig. 297-6. The inhaled agent is ^{3}He, and because it is proton rich, it can be used to examine lung ventilation visually and objectively. Regions of the lung that are poorly ventilated due to disease of the airways or distal airspaces have low concentrations of ^{3}He and appear as dark regions in an otherwise bright blue organ.

While an MRI may have a longer acquisition time than CT, and the geometry of the equipment often leads to a sense of claustrophobia, it does not involve the administration of ionizing radiation. This makes it a modality of choice in the pediatric population or clinical situations where repeated assessments are required.

POSITRON EMISSION TOMOGRAPHY

PET generates an image based on the aggregation of radiolabeled tracers. The most common agent used for these purposes is [^{18}F]-fluoro-2-deoxyglucose (FDG). This radiolabeled glucose analogue is administered intravenously and is taken up by cells in direct proportion to their metabolic activity. In the clinical setting, it is most commonly used for the discrimination of benign and malignant lung nodules, as well as lung cancer staging. Given the relatively low resolution of PET, co-registration with CT is common and the aligned imaging modalities allow the reader to determine the structural source of heightened metabolic activity.

There is increasing interest in the use of PET imaging in the biomedical community. These applications are largely still confined to research, but advances in areas such as in vivo assessments of vascular biology in acute and chronic disease have been impressive.

ARTIFICIAL INTELLIGENCE/DEEP LEARNING

The final aspect to thoracic imaging that must be discussed is the growing field of artificial intelligence and deep learning applied to image analysis. Classic machine learning approaches to medical image interpretation involve the development of advanced algorithms to detect structures of interest, segment their boundaries, and then extract metrics related to size, shape, texture, and so on. The massive increase in processing capacity afforded by graphical processing units (GPUs), the increasing availability of large amounts of data, and the wide dissemination of open-source software libraries allowing developers to create powerful work environments have led to explosive growth in the utilization of deep learning for image analytics. Some of the first medical applications of deep learning were in the field of dermatology, and more recently, this advanced form of pattern recognition has been reported to excel at the discrimination of benign and malignant lung nodules in thoracic CT scan. The breadth of application of these tools continues to expand to include image navigation and feature detection, biomarker development, and direct prediction of clinical outcomes. An example of deep learning–enabled segmentation of the heart and pulmonary vasculature from non–contrast-enhanced non–cardiac-gated CT scan is shown in **Fig. 297-7**.

TRANSTHORACIC NEEDLE ASPIRATION

Radiologically guided needle biopsy has served as a long-standing mechanism for evaluation of parenchymal lung lesions, both malignant and infectious. In the setting of published guidelines recommending low-dose screening CT scan for lung malignancy in high-risk patients, and with evolving guidelines for monitoring and assessment of incidental lung lesions arising in this setting, radiologically guided sampling of lung lesions has become an increasingly important mechanism to address parenchymal lung abnormalities concerning for cancer. Moreover, as novel immune modulators and biologic agents are increasingly utilized for the management of systemic disease and transplantation, effective interventions are becoming progressively more important in assessing for potential pulmonary infections arising as complications of immune suppression. Transthoracic needle aspiration (TTNA) remains one important arm in the assessment of these pulmonary complications.

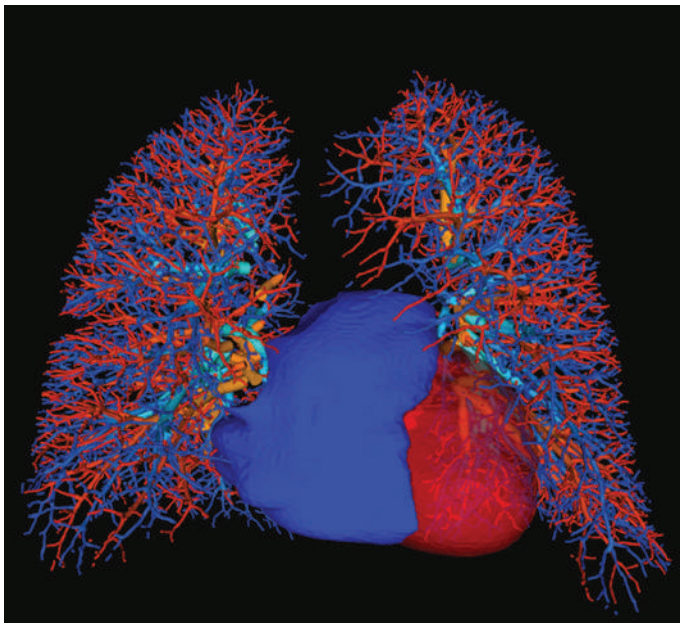

FIGURE 297-7 Arterial/venous segmentation of the pulmonary vasculature (*blue:* arteries; *red:* veins) and epicardial surface of the right (*blue*) and left ventricles (*red*). *(Image courtesy of Raul San Jose Estepar, PhD, Applied Chest Imaging Laboratory, Department of Radiology, Brigham and Women's Hospital, Boston, MA.)*

TTNA can be accomplished with a variety of complementary imaging mechanisms, including under fluoroscopic, CT, ultrasound, or MRI guidance. Overall adequacy of sampling as well as adequacy for epidermal growth factor receptor (EGFR) analysis of >90% and for cytologic analysis of >80%. CT is currently the most common imaging modality used to assess parenchymal lung lesions, with sensitivity and specificity reported to be >90%. Sensitivity of CT-guided TTNA is increased in more peripheral lesions. Transthoracic ultrasound has the advantages of a low complication rate in the setting of fine-needle aspiration (FNA) and portability, allowing for more logistical simplicity in the setting of lung lesion assessment. In a prospective study of ultrasound-guided percutaneous FNA compared with CT-guided FNA, diagnostic rates were comparable between the two groups, with shorter procedure time associated with ultrasound guidance, numerical suggestion of decreased complication rate using ultrasound guidance, and lower costs associated with ultrasound guidance. Use of elastography to better characterize lung lesions has also been proposed in the context of ultrasound, although additional diagnostic yield has not yet been proven. Color Doppler ultrasonographic imaging has been demonstrated to have a high sensitivity and specificity and a low complication rate in another study. Electromagnetic guidance, unlike CT imaging, can be used in combination with endobronchial ultrasound and/or navigational bronchoscopy in the operative setting, theoretically allowing for a multimodal approach that could increase diagnostic yield and allow for a combined staging procedure. Electromagnetic TTNA alone has demonstrated an 83% diagnostic yield in a pilot study, with an increase to 87% when combined with navigational bronchoscopy. Conflicting data are available regarding the diagnostic superiority of TTNA compared with alternative biopsy modalities such as endobronchial ultrasound for diagnosis of lung lesions, and results may depend on center experience.

Transthoracic sampling can be obtained using FNA or core needle biopsy. In one retrospective study, FNA was found to have an inferior diagnostic rate, compared with core needle sampling, as well as lower specificity. In this study, a method involving two FNA passes was compared to core needle sampling with six cores obtained from a single pass. No significant differences in complication rates were noted. In another retrospective study, in which procedure was determined by operator preferences, core needle aspirate samples were more likely to

provide sufficient material for molecular testing than FNA. A systematic review of these techniques concluded that insufficient evidence was available to support a difference between FNA and core needle biopsy in diagnostic efficiency, though core needle biopsy may be more specific in diagnosing benign lung lesions. Given the negative predictive value estimate of 70%, negative results from TTNA are less reliable than positive results and should not be considered definitive to eliminate the concern for malignancy. Further assessment is needed to directly compare imaging modalities for TTNA guidance and to compare TTNA with other diagnostic modalities to determine the optimal choice of procedure in particular settings. Choice of procedure should be considered in the context of the size and location of the lesion, the experience of the center and operator, and patient-specific factors.

In regard to the safety of TTNA, in a retrospective study from 2015, the presence of mild to moderate pulmonary hypertension in patients did not increase complication rates in the setting of TTNA. The complication rates noted in this report were substantial, however, with hemorrhage occurring in one-third to one-quarter of patients, and pneumothorax in 17–28%. The majority of pneumothoraces did not require chest tube placement. Other complications included hemoptysis and hemothorax, though these were uncommon. These complication rates are consistent with those reported in other studies. In a meta-analysis of complication rates of CT-guided TTNA, complication rates were higher with core needle aspirates than FNA (38.8% [95% confidence interval (CI) 34.3–43.5%] vs 24% [95% CI 18.2–30.8%]). The majority of these complications were minor. Risk factors for complications with FNA included smaller nodule diameter, larger needle diameter, and increased traversed lung parenchyma. No clear risk factors were noted for complications after core needle biopsies in this publication. More generally, the risks of TTNA increase for more centrally located lesions and those residing in close proximity to intrathoracic vasculature. In a study of patient claims in the Medicare and a subset of the commercial population between 2016 and 2020, the use of TTNA decreased in both groups, with the use of endobronchial ultrasound guidance for sampling increasing in the Medicare population. In this study, TTNA presented a higher risk for pneumothorax than the use of alternate modalities.

Despite the outstanding questions regarding the context and optimal approach for TTNA, this modality has been shown to be effective in cancer diagnosis in the thorax. Adenocarcinoma has become the most prevalent parenchymal lung malignancy in reported studies and also the most common malignant diagnosis found on TTNA of the lung. TTNA can also be effective in diagnosing less common tumors of the lung, both malignant and benign, including squamous and small cell carcinomas, lymphomas, and others, as well as in assessing tumors of the mediastinum. The diagnostic utility of TTNA is consistent across solid, subsolid, and partially calcified lung nodules. Immunocytochemistry markers can be utilized in TTNA samples to assist with diagnosis, prognosis, and prediction of response to therapy, and samples should be preserved whenever possible to allow for these studies, if needed. RNA extraction has also proven feasible in the setting of a single FNA sample, which could be instrumental in gene expression profiling, though this has thus far only been successfully accomplished in a research context.

The utility of TTNA in diagnosing pulmonary infections is variable in published literature. Some publications have reported that TTNA establishes a diagnosis of infection in 60–70% of cases, with a particularly high yield in the setting of *Aspergillus* infections. TTNA has also been shown to be particularly effective in the diagnosis of pulmonary tuberculosis, though a wide variety of infections have been diagnosed using this method. The presence of necrosis in lung lesions makes establishing an infectious diagnosis more likely using TTNA. Numerous staining techniques are available to assist with infectious diagnoses, and immunohistochemistry can also aid in the diagnosis of infection. Cytology should be correlated with histopathology and culture results, when available. Metagenomics using next-generation sequencing for detection of infection is evolving but requires further study. TTNA has also been useful in identifying granulomatous inflammation, which can provide supportive evidence of a granulomatous parenchymal lung disease in the appropriate clinical setting.

In summary, TTNA is an important element of diagnostic algorithms in the setting of lung nodules and masses, particularly when concern for malignancy is not high enough to warrant immediate excision, when the patient is not a surgical candidate, or the lesion or disease is not amenable to surgical resection. Further study is needed, however, to better understand the role of TTNA and other diagnostic modalities in the evaluation of parenchymal lung lesions.

MISCELLANEOUS TESTING

SPUTUM TESTING

Sputum microscopy and culture are commonly utilized to diagnose respiratory tract infections and identify the causative organisms. In patients with productive cough, the sampling is simple and noninvasive; however, it is subject to patient technique and the potential for oropharyngeal and/or upper respiratory tract contamination. In those who are not expectorating, sputum induction can be considered using provocative nebulization with saline. This technique has been demonstrated to be generally safe and well tolerated even in patients with airflow limitation. Numerous studies have attempted to define criteria for reliability and reproducibility of sputum samples. The majority include quantification of number of epithelial cells and white blood cells per low-power field, and many assess the ratio of the two for adequacy of sampling. None has been confirmed as superior in establishing the reliability of sampling to reflect lower respiratory tract growth. The quality of the sputum sample directly impacts the diagnostic reliability in the setting of bacterial pneumonia. Growth of *Mycobacterium tuberculosis, Legionella,* or pneumocystis should raise concern for infection, even in the setting of a poor sample. In a prospective study of the use of a multiplex polymerase chain reaction (PCR) assay in conjunction with sputum sampling, good-quality samples had a higher proportion of bacterial detections than low-quality samples but equivalent frequency of samples with bacterial growth in patients who received treatment. In this study, 40% of bacterial detections would have been missed if only high-quality samples were analyzed. The authors conclude that all samples submitted for PCR-based testing should be analyzed, regardless of sputum sample quality. In systematic analyses and meta-analyses, multiplex PCR assays have been shown to decrease the time to diagnosis and length of stay in the setting of viral infections and in patients with COVID-19 and bacterial co-infection. Endotracheal aspirates have not been demonstrated to be clearly superior to expectorated sputum in terms of diagnostic reliability, but such sampling may be required if spontaneous coughing is nonproductive and induced sputum is not feasible or successful. The use of multiplex fluorescence PCR may allow for assessment of multiple pathogens with a reduced time to pathogen identification.

As in the context of infection, sputum cytologic analysis has been utilized to assist in the diagnosis of malignancy, mainly because it can be obtained noninvasively. While sputum cytology demonstrating malignant cells is highly specific for a diagnosis of lung malignancy, its sensitivity has been reported at <40%. A systematic review of screening methods demonstrated no added benefit from sputum cytology when combined with CXR to screen for lung cancer. Advanced molecular techniques such as PCR, DNA methylation markers, micro-RNA assessment, and tumor-related protein analysis have been proposed in sputum assessment for diagnostic purposes and risk stratification. At present, however, sputum cytology is recommended only when more invasive techniques cannot be pursued, such as in patients with prohibitive comorbidities or in resource-limited settings.

EXHALED BREATH CONDENSATE

Exhaled breath condensate includes gaseous, liquid, and water-soluble components, with numerous biomarker types and collection system varieties developed over time. Validation standards for many components are still being determined. Exhaled nitric oxide is the most highly validated of the biomarkers identified in exhaled breath condensate. The fraction of exhaled nitric oxide (FeNO) has been demonstrated in higher concentrations in exhaled breath condensate of patients with asthma than in healthy individuals, has been shown in a systematic

review and meta-analysis to help differentiate asthma/chronic obstructive pulmonary disease overlap syndrome, and has been shown in some studies to correlate with the presence of eosinophils in the sputum and blood and with response to inhaled corticosteroids, although data are conflicting. For example, in a systematic review and meta-analysis, FeNO elevation increased the odds of having asthma in both children above the age of 5 years and adults. In another systematic review of FeNO utilization in the management of adults with asthma, the assessment was helpful in the management of severe exacerbations but had no significant impact on overall exacerbations or inhaled corticosteroid use. Moreover, evidence suggests that tailoring of asthma therapy based on sputum eosinophil levels was effective in decreasing asthma exacerbations, but tailoring of therapy based on FeNO was not beneficial in improving outcomes, and insufficient evidence was observed to advocate the use of either sputum analysis or FeNO in clinical practice. FeNO has also been shown to be influenced by ethnicity, and appropriate reference standards for different ethnic groups have yet to be established. While FeNO has been proposed as a potential clinical guide to management, its use has not been incorporated into all guideline recommendations, and it has not been formally approved for clinical use.

SWEAT TESTING

Assessment of chloride concentration in sweat using pilocarpine iontophoresis, or sweat testing, remains a key element in the diagnostic framework of cystic fibrosis (CF). This method utilizes pilocarpine to stimulate sweat production. As patients with CF suffer from alterations to the sodium chloride ion channel, measurement of electrolytes in their secretions such as sweat reveals elevated chloride concentrations, among other abnormalities. This testing has been considered the gold standard in the diagnosis of CF due to its functional nature, its relative noninvasiveness, the establishment of validated standards for its performance, and its ability to discriminate between healthy individuals and those with CF at a chloride concentration of ≥60 mmol/L. The likelihood of a diagnosis of CF at a concentration of <40 mmol/L has been observed to be low, and an indeterminate range was defined as 40–59 mmol/L, which could be consistent with the disease if genetic and clinical manifestations were supportive.

While functional testing such as sweat chloride testing remains an essential component of diagnostic algorithms in CF, the evolution of genetic analysis has led to identification of an extensive array of genetic mutations associated with varied phenotypic impacts in this disease. In this context, the indeterminate range of chloride concentrations of 40–59 mmol/L on sweat test analysis was found to inadequately identify milder or more heterogenous forms of the disease associated with newly identified genetic mutations. As a result, the Cystic Fibrosis Foundation provided updated guidance for the interpretation of sweat test results, with a decreased lower threshold to define an intermediate range of chloride concentration (changed from 40–50 mmol/L to 30–59 mmol/L), which could be consistent with the diagnosis of CF in the appropriate genetic and clinical context. In a subsequent analysis, utilization of the new guidance was found to enhance the probability of identifying patients with CF without increasing the false-positive diagnosis rate in the population. Sweat testing is a critical component of the CF diagnostic algorithm but should be interpreted in the context of clinical manifestations of disease and correlated with genetic testing in those suspected of the diagnosis.

ALLERGY TESTING

Allergy testing is often considered in the assessment of environmental exposures, including seasonal allergens, food allergens, and drug allergens. In the case of drug allergens in particular, drug reactions are often reported based on remote history and are often unconfirmed. The hesitancy to re-expose patients with an unconfirmed drug allergy can lead to limited options for treatment, to delay in treatment, and to utilization of treatments with more extended spectrum, potentially influencing the resistance patterns of these agents. Drug reactions can be mediated by IgE (immediate-type reactions, type I), IgG or IgM (type II), immune complex reactions (type III), and delayed-type hypersensitivity reactions mediated by cellular immune mechanisms (type IV).

Skin testing, including patch testing and/or delayed intradermal testing, is available to test exposure to particular allergens and determine reactivity. These tests have been shown to aid in clinical phenotyping of type I reactions and potentially in type IV reactions, though their role in type IV assessment remains more controversial. In the context of suspected type I reactions, patch testing is more cost effective and may be as effective as intradermal testing in identifying potential causative agents. The negative predictive value of intradermal skin testing in assessing for IgE-mediated drug allergies is high; however, the high sensitivity of this testing limits its specificity, and results must be interpreted in the context of the pretest probability and the clinical experience of the patient. Skin tests have also been demonstrated to assist in identifying the causative agent in type IV reactions and to assess cross-reactivity between structurally related drugs. Intradermal testing may be more sensitive than patch testing to assess for type IV drug reactions. Though some debate continues regarding a mandatory role for skin testing in the assessment of potential drug allergies, drug provocation testing or rechallenge is generally regarded as safe in low-risk individuals with history of urticaria or immediate rash, whereas skin testing has been proposed as a preliminary assessment in higher-risk individuals with a history of two or more reactions, angioedema, or anaphylaxis, prior to consideration of drug provocation testing.

Section 2 Diseases of the Respiratory System

298 Asthma

Elliot Israel

Asthma is a disease characterized by episodic airway obstruction and airway hyperresponsiveness usually accompanied by airway inflammation. In most cases, the airway obstruction is reversible, but in a subset of asthmatics, a component of the obstruction may become irreversible. In a large proportion of patients, the airway inflammation is eosinophilic, but some patients may present with differing types of airway inflammation, and in some cases, there is no obvious evidence of airway inflammation.

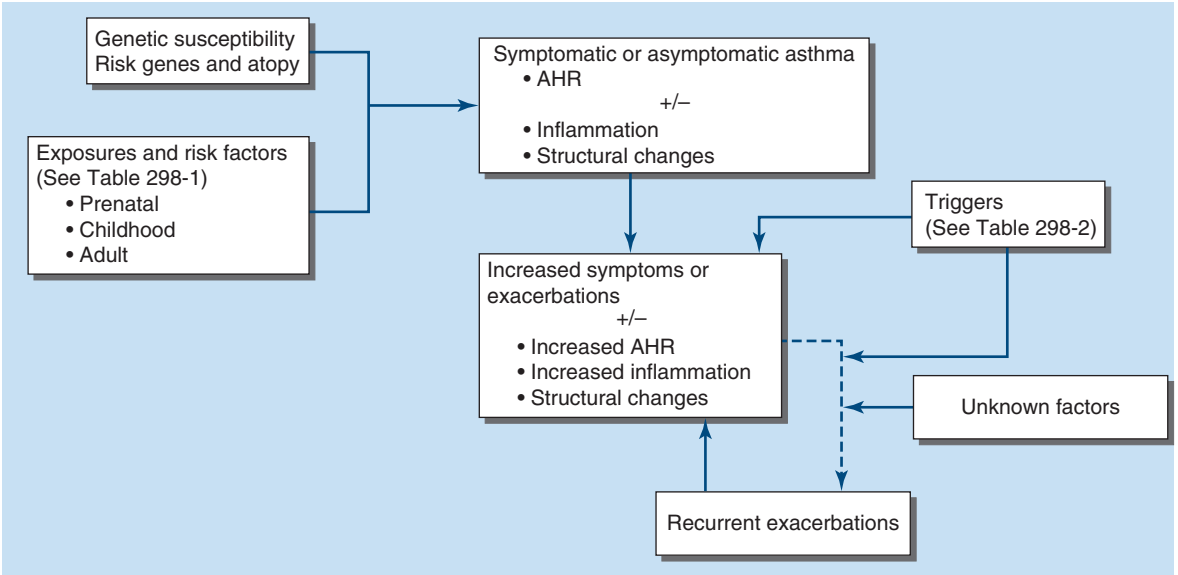

FIGURE 298-1 Asthma development pathway. Illustration of how genetic susceptibility and development and exposure during the life span interact to produce a disease that can vary in intensity and chronicity. Disease expression is characterized by airway hyperresponsiveness with varying degrees of airway inflammation and airway structural changes accompanied by varying degrees of symptoms that can be influenced by exposure to triggers that can cause acute deterioration as well as chronic symptoms. AHR, airway hyperresponsiveness.

MANIFESTATIONS

Asthma most frequently presents as episodic shortness of breath, wheezing, and cough, which can occur in relation to triggers but may also occur spontaneously. These symptoms can occur in combination or separately. Other symptoms can include chest tightness and/or mucus production. These symptoms can resolve spontaneously or with therapy. In some patients, wheezing and/or dyspnea can be persistent. Episodes of acute bronchospasm, known as exacerbations, may be severe enough to require emergency medical care or hospitalization and may result in death.

EPIDEMIOLOGY

Asthma is the most common chronic disease associated with significant morbidity and mortality, with ~262 million people affected globally. Cross-sectional studies suggest that 7.9% of the population in the United States is asthmatic as compared to ~4.3% prevalence worldwide. Prevalence continues to increase (starting at 7.3% in 2001 in the United States) and is associated with transition from rural to urban living. Asthma is more prevalent among children (8.4%) than adults (7.7%). In children, the prevalence is greatest among boys (2:1 male-to-female ratio), with a trend toward greater prevalence in women in adulthood. In some patients, asthma resolves as they enter adulthood only to "recur" later in life.

In the United States in 2016, prior to the effects of the COVID-19 pandemic, 1.8 million people visited an emergency department for asthma, and 189,000 were hospitalized. The total economic cost in the United States in 2013 was estimated at $82 billion. In the United States, asthma is more prevalent in blacks than Caucasians, and black race is associated with greater case morbidity. The ethnicity with the greatest prevalence in the United States is the Puerto Rican population.

Asthma mortality increased worldwide in the 1960s, apparently related to overuse of inhaled β_2-agonists. Reduction in mortality since then has been attributed to increased use of inhaled corticosteroids. Asthma mortality declined globally from 0.44 per 100,000 people in 1993 to 0.19 in 2006, but further reduction in mortality has not occurred since that time.

THE PATHWAY TO THE DEVELOPMENT OF ASTHMA

The pathway to development of asthma can be varied. As illustrated in Fig. 298-1, there is an interplay between genetic susceptibility (see below) and environmental exposure and endogenous developmental factors (e.g., aging and menopause [see "Etiologic Mechanisms, Risk Factors, Triggers, and Complicating Comorbidities" and Table 298-1]) that can lead to the development of asthma. Continued or additional exposures and triggers (Table 298-2) can affect the progression of disease and the degree of impairment.

PATHOPHYSIOLOGY

MECHANISMS LEADING TO ACUTE AND CHRONIC AIRWAY OBSTRUCTION

The pathobiologic processes in the airways that lead to episodic and chronic airway obstruction of asthma are discussed below. Their pathologic correlates are highlighted in Fig. 298-2, illustrating the pathologic changes that can occur in asthmatic airways. These processes can occur individually or simultaneously. There can be temporal variation of these processes in an individual based on exogenous factors, discussed later in this chapter, as well as the aging process itself. These processes can involve the entire airway (but not the parenchyma), but there can be significant spatial heterogeneity, as has now been demonstrated using hyperpolarized gas ventilation studies and high-resolution computed tomography (CT) of the thorax.

Airway Hyperresponsiveness Airway hyperresponsiveness is a hallmark of asthma. It is defined as an acute narrowing response of the airways in reaction to agents that do not elicit airway responses in nonaffected individuals or an excess narrowing response to inhaled agents as compared to that which would occur in nonaffected individuals. A component of the hyperresponsiveness occurs at the level of the airway smooth muscle itself as demonstrated by hyperresponsiveness to direct smooth-muscle–acting agents such as histamine or methacholine. In many patients, the apparent hyperresponsiveness is due

to indirect activation of airway narrowing mechanisms as a result of stimulation of inflammatory cells (which release direct bronchoconstrictors and mediators that cause airway edema and/or mucus secretion) and/or stimulation of sensory nerves that can act on the smooth muscle or inflammatory cells. Agents and physical stimuli that elicit such responses are discussed later.

The apparent increased responsiveness of the airways in asthma may also have a structural etiology. In asthma, airway wall thickness is associated with disease severity and duration. This thickening, which may result from a combination of smooth-muscle hypertrophy and hyperplasia, subepithelial collagen deposition, airway edema, and mucosal inflammation, can result in a tendency for the airway to narrow disproportionately in response to stimuli that elicit increased airway muscle tension. A major therapeutic objective in asthma is to decrease the degree of airway hyperresponsiveness.

Inflammatory Cells While airway inflammation can be precipitated by acute exposure to inhalants, most asthmatics have evidence of chronic inflammation in the airways. Most commonly, this inflammation is eosinophilic in nature. In some patients, neutrophilic inflammation may be predominant, especially in those with more severe

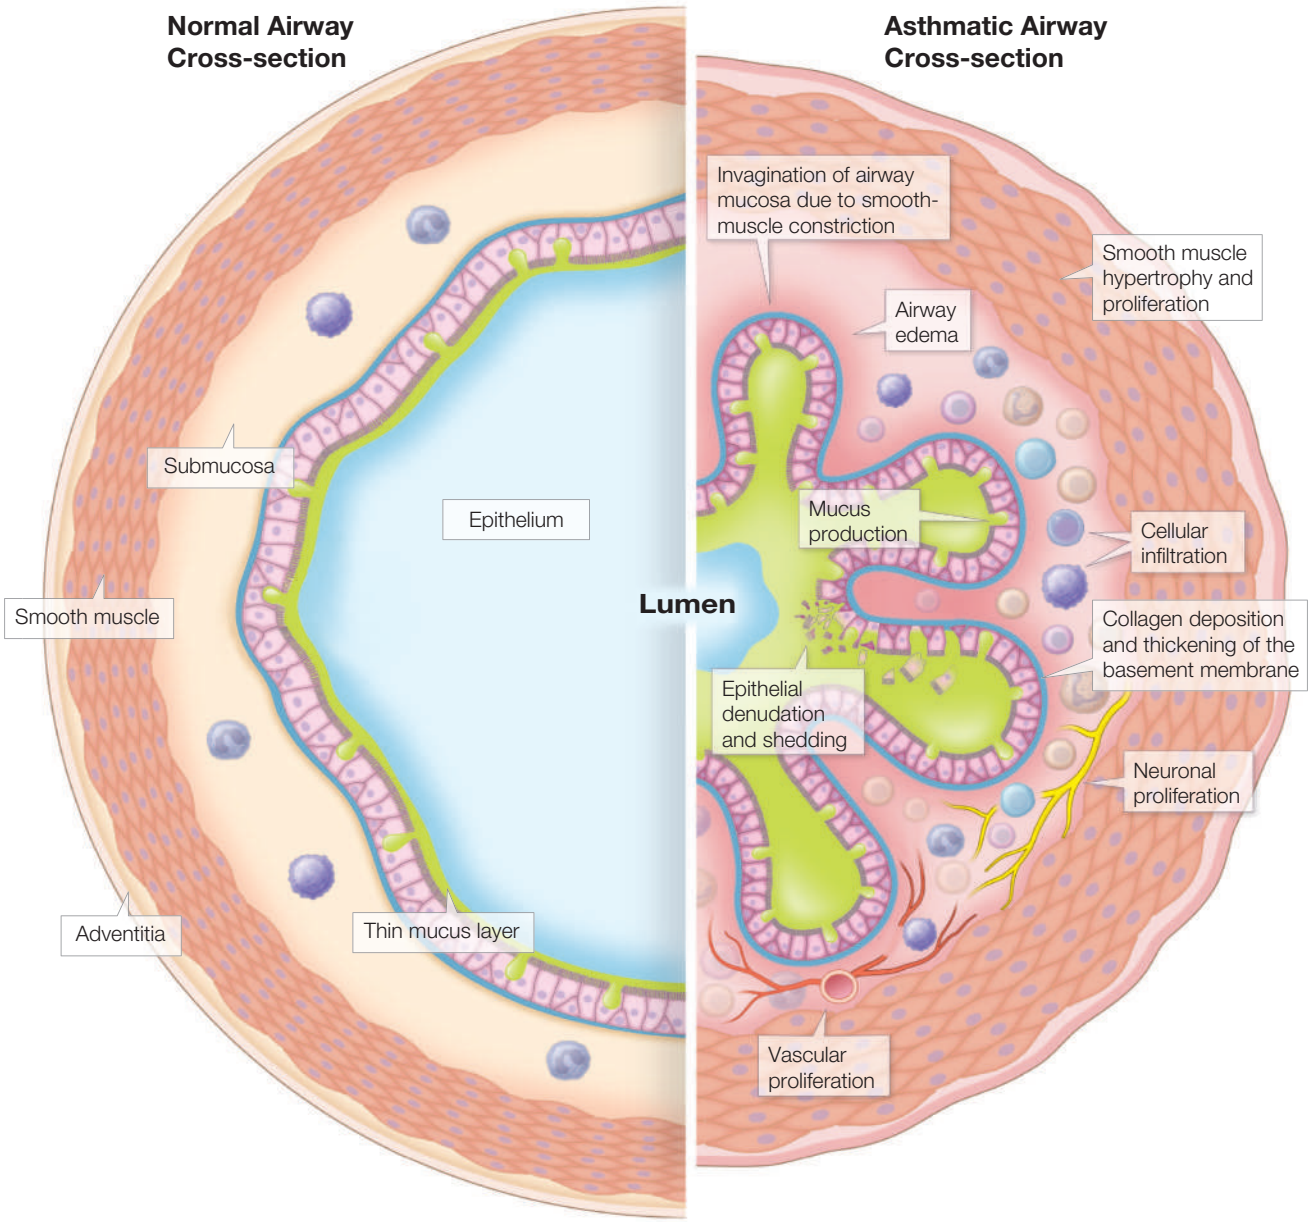

FIGURE 298-2 Pathologic changes that can be seen in asthmatic airways. Illustrated is a cross-sectional lumen of a bronchus. The left-hand side represents the normal airway, and the right represents an asthmatic airway highlighting the pathologic changes that can be seen in asthma. The asthmatic airway lumen is reduced by smooth-muscle contraction and hypertrophy, mucus in the airway lumen, and thickening of the submucosa due to edema and cellular infiltration. In addition, the ability of the lumen to increase in size with smooth-muscle relaxation may be impaired by deposition of collagen. The epithelium is disrupted, and there is evidence of vascular and neuronal proliferation. All these changes may not be present in one individual, and certain patients may have normal-appearing airways.

asthma. Patients with both eosinophilic and neutrophilic inflammation may present with the most severe phenotype. Mast cells are also more frequent. Many inflammatory cells are present in an activated state, as will be discussed in the section on inflammation.

Airway Smooth Muscle Airway smooth muscle can contribute to asthma in three ways. First, it can be hyperresponsive to stimuli, as noted above. Second, hypertrophy and hyperplasia can lead to airway wall thickening with consequences for hyperresponsiveness, as noted above. Lastly, airway smooth-muscle cells can produce chemokines and cytokines that promote airway inflammation and promote the survival of inflammatory cells, particularly mast cells.

Subepithelial Collagen Deposition and Matrix Deposition Thickening of the subepithelial basement membrane occurs as a result of deposition of repair-type collagens and tenascin, periostin, fibronectin, and osteopontin primarily from myofibroblasts under the epithelium. The deposition of collagen and matrix stiffens the airway and can result in exaggerated responses to increased circumferential tension exerted by the smooth muscle. Such deposition can also narrow the airway lumen and decrease its ability to relax and thus can contribute to chronic airway obstruction.

Airway Epithelium Airway epithelium disruption takes the form of separation of columnar cells from the basal cells. The damaged epithelium is hypothesized to form a trophic unit with the underlying mesenchyme. This unit elaborates multiple growth factors thought to contribute to airway remodeling. The airway epithelium is also a source of multiple cytokines, such as alarmins, and mediators that have been shown to promote a cascade of airway inflammation.

Vascular Proliferation In a subset of asthmatics, there is a significant degree of angiogenesis thought to be secondary to elaboration of angiogenic factors in the context of airway inflammation. Vascular leakage from postcapillary venules in response to inflammatory mediators can also contribute to the acute and chronic edema of the airways.

Airway Edema Submucosal edema can be present as an acute response in asthma and as a chronic contributor to airway wall thickening.

Epithelial Goblet Cell Metaplasia and Mucus Hypersecretion Chronic inflammation can result in the proliferation of mucus cells. Increased mucus production can reduce the effective airway luminal area. Mucus plugs can obstruct medium-size airways and can extend into the small airways. These mucus plugs can result in persistent airway obstruction.

Neuronal Proliferation Neurotrophins, which can lead to neuronal proliferation, are elaborated by smooth-muscle cells, epithelial cells, and inflammatory cells. Neuronal inputs can regulate smooth-muscle tone and mucus production, which may mediate acute bronchospasm and potentially chronically increased airway tone.

AIRWAY INFLAMMATION (TYPE 2 AND NON–TYPE 2 INFLAMMATION)

Most asthma is accompanied by airway inflammation. In the past, asthma had been divided into *atopic* and *nonatopic* (or *intrinsic*) asthma. The former was identified as relating to allergen sensitivity and exposure, with production of IgE, and occurring more commonly in children. The latter was identified as occurring in individuals with later onset asthma, with or without allergies, but frequently with eosinophilia. This paradigm is being superseded by a nosology that favors consideration of whether asthma is associated with type 2 or non–type 2 inflammation. This approach to immunologic classification is driven by a developing understanding of the underlying immune processes and by the development of therapeutic approaches that target type 2 inflammation (see later sections on asthma therapy).

Type 2 Inflammation Type 2 inflammation is an immune response involving the innate and adaptive arms of the immune system to promote barrier immunity on mucosal surfaces. It is called type 2 because it is associated with the type 2 subset of CD4+ T-helper cells, which produce the cytokines interleukin (IL) 4, IL-5, and IL-13. As shown in Fig. 298-3, these cytokines can have pleiotropic effects. IL-4 induces B-cell isotype switching to production of IgE. IgE, through its binding to basophils and mast cells, results in environmental sensitivity to allergens as a result of cross-linking of IgE on the surface of these mast cells and basophils. The products released from these cells include type 2 cytokines as well as direct activators of smooth-muscle constriction and edema. IL-5 has a critical role in regulating eosinophils. It controls formation, recruitment, and survival of these cells. IL-13 induces airway hyperresponsiveness, mucus hypersecretion, and goblet cell metaplasia. While allergen exposure in allergic individuals can elicit a cascade of activation of type 2 inflammation, it is now understood (see Fig. 298-3) that nonallergic stimuli can elicit production of type 2 cytokines, particularly due to stimulation of type 2 innate lymphoid cells (ILC2). These cells can produce IL-5 and IL-13. ILC2s can be activated by epithelial cytokines known as alarmins, which are produced in response to "nonallergic" epithelial exposures such as irritants, pollutants, oxidative agents, fungi, or viruses. Thus, these "nonallergic" stimuli can be associated with eosinophilia.

The development of anti–IL-5 drugs that dramatically reduce eosinophils has allowed us to determine that, in many asthmatics, eosinophils play a major role in asthma pathobiology. They may induce hyperresponsiveness through release of oxidative radicals and major basic protein, which can disrupt the epithelium. They produce cysteinyl-leukotrienes that directly stimulate smooth muscle contraction and resulting in airway constriction. In addition, recent CT imaging has suggested that mucus plugs, which may contain significant amounts of eosinophil aggregates, may accumulate in the airways and contribute to asthma severity.

Non–Type 2 Processes As shown in Fig. 298-2, multiple processes can contribute to airway narrowing and apparent airway hyperresponsiveness. While type 2 inflammatory processes are most common, non–type 2 processes can exist either in combination with type 2 inflammation or without type 2 inflammation. Neutrophilic inflammation, as shown in Fig. 298-3, can also occur. This type of inflammation is more commonly seen in severe asthma that has not responded to the common anti-inflammatory therapies, such as corticosteroids, that usually suppress type 2 inflammation. In some cases, it may also be associated with chronic infection, occasionally with atypical pathogens such as *Mycoplasma*, perhaps accounting for the response of some of these patients to macrolide antibiotics. It is also commonly seen in reactive airway dysfunction syndrome (see "Etiologic Mechanisms, Risk Factors, Triggers, and Complicating Comorbidities").

In a small subset of asthmatics, the pathologic changes seen in Fig. 298-2 may occur without any evidence of tissue infiltration by inflammatory cells. The etiology of such pauci-granulocytic asthma is unclear.

MEDIATORS

Many chemical substances or signaling factors can contribute to the pathobiologic picture of asthma. Some of them have been successfully targeted in developing asthma therapies.

Cytokines As illustrated in Fig. 298-3, and as discussed above, IL-4, IL-5, and IL-13 are the major cytokines associated with type 2 inflammation. They have all been targeted successfully in asthma therapies. Thymic stromal lymphopoietin (TSLP), IL-25, and IL-33 also play a role in the signaling cascade and are being actively studied as targets for treatment of asthma. IL-9 has been implicated as well. IL-6, IL-17, tumor necrosis factor α (TNF-α), IL-1β, and IL-8 have been implicated in non–type 2 inflammation.

Fatty Acid Mediators Proinflammatory mediators derived from arachidonic acid include leukotrienes and prostaglandins. The cysteinyl leukotrienes (leukotrienes C_4, D_4, and E_4) are produced by eosinophils and mast cells. They are potent smooth-muscle constrictors. They also stimulate mucus secretion, recruit allergic inflammatory cells, cause microvascular leakage, modulate cytokine production, and influence neural transmission. Cysteinyl leukotriene

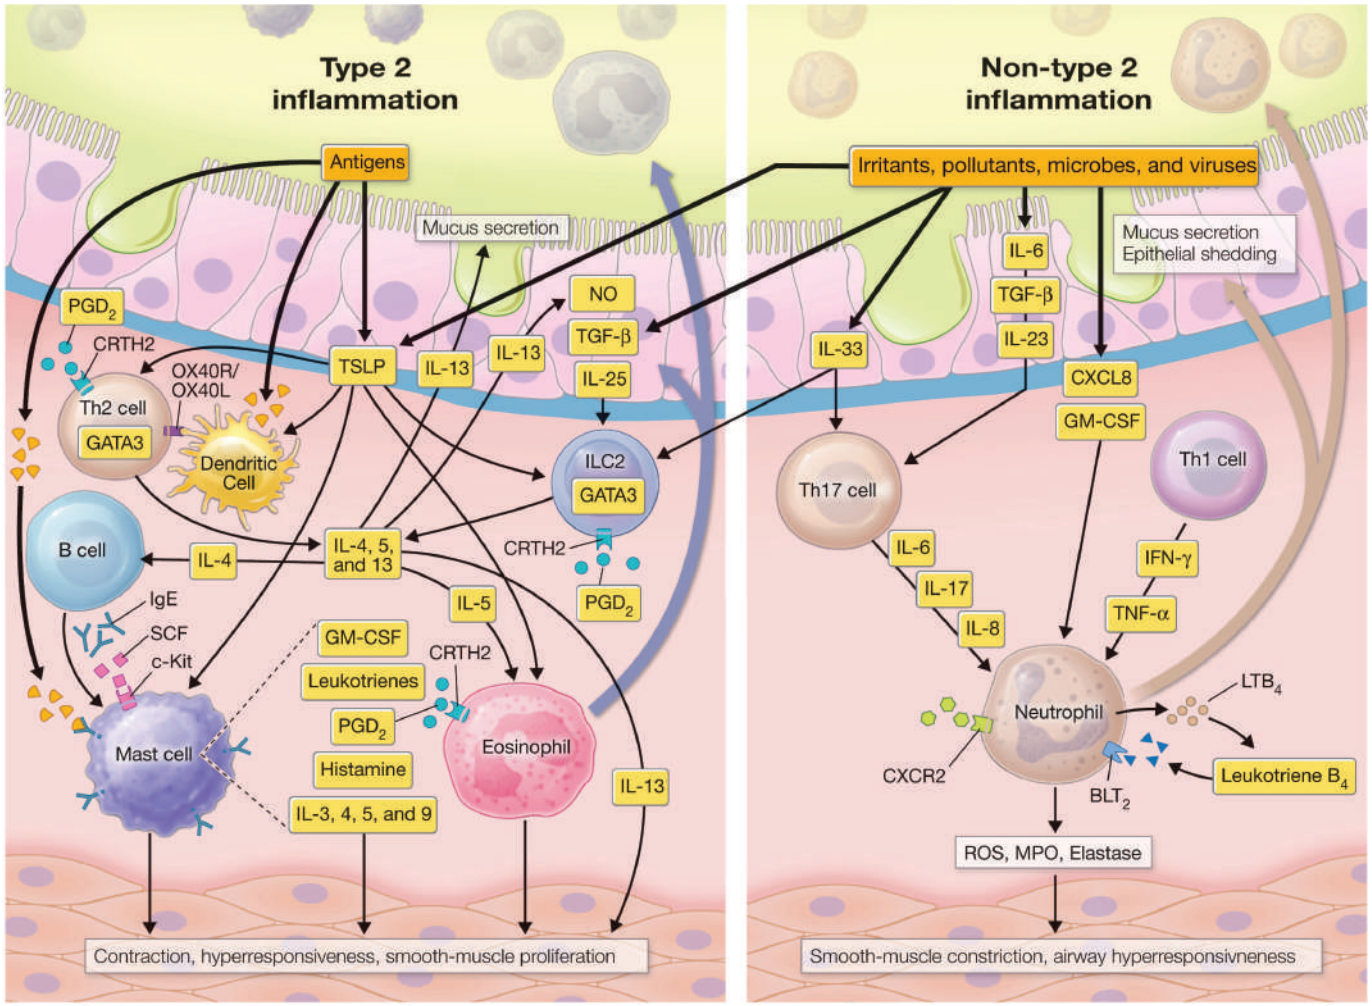

FIGURE 298-3 Inflammatory cells and mediators involved in type 2 and non–type 2 inflammation. Allergens and nonallergic stimuli can trigger activation of multiple inflammatory cells and release of mediators that are responsible for recruiting and activating these cells. The mediators can affect airway smooth-muscle proliferation and hyperresponsiveness and fibroblast proliferation and matrix deposition. BLT2, leukotriene B_4 receptor 2; CRTH2, chemoattractant receptor-homologous molecule (PGD2 receptor); CXCL8, CXC motif chemokine ligand 8; CXCR2, CXC chemokine receptor 2; GATA3, GATA binding protein 3; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN-γ, interferon gamma; IL, interleukin; ILC2, innate lymphoid type 2 cells; c-Kit, mast/stem cell growth factor receptor; LTB4, leukotriene B4; MPO, myeloperoxidase; NO, nitric oxide; OX40L/OX40R, OX40 ligand/OX40 receptor; PGD2, prostaglandin D2; ROS, reactive oxygen species; SCF, stem cell factor; TGF-β, transforming growth factor β; Th, T helper; TNF-α, tumor necrosis factor α; TSLP, thymic stromal lymphopoietin.

modifiers have shown clinical benefit in asthma. The non-cysteinyl leukotriene, LTB_4, is produced primarily from neutrophils but can also be synthesized by macrophages and epithelial cells. It is a potent neutrophil chemoattractant. Prostaglandins are for the most part proinflammatory. Prostaglandin D_2 (PGD_2) is produced by mast cells. Receptors for PGD_2 ($CRTH_2$ receptors) are present on T_H2 cells, ILC2 cells, mast cells, eosinophils, macrophages, and epithelial cells, and the activation of these receptors upregulates type 2 inflammation. However, studies with drugs blocking $CRTH_2$ have been relatively disappointing thus far.

There are several classes of fatty acid–derived mediators that are responsible for the resolution of inflammation. These include the resolvins and lipoxins. Several studies suggest that deficiencies in these moieties may be responsible for the ongoing inflammation in asthma, especially in severe asthma.

Nitric Oxide Nitric oxide is a potent vasodilator, and in vitro studies suggest that it can increase mucus production and smooth-muscle proliferation. It is produced by epithelial cells, especially in response to IL-13, and by stimulated inflammatory cells including eosinophils, mast cells, and neutrophils. Its precise role in the asthmatic diathesis is unclear. However, its production is increased in the airways in the presence of IL-13-induced inflammation, and it can be detected in exhaled breath and is reduced by interventions that interfere with IL-13 production or activity.

Reactive Oxygen Species When allergens, pollutants, bacteria, and viruses activate inflammatory cells in the airway, they induce respiratory bursts that release reactive oxygen species that result in oxidative stress in the surrounding tissue. Increases in oxidative stress have been shown to affect smooth-muscle contraction, increase mucus secretion, produce airway hyperresponsiveness, and result in epithelial shedding.

Chemokines A variety of chemokines are secreted by the epithelium (as well as other inflammatory cells) and attract inflammatory cells into the airways. Those of particular interest include eotaxin (an eosinophil chemoattractant), TARC and MDC (which attract T_H2 cells), and RANTES (which has pluripotent pro-phlogistic effects).

ETIOLOGIC MECHANISMS, RISK FACTORS, TRIGGERS, AND COMPLICATING COMORBIDITIES

As illustrated in Fig. 298-1, the development of asthma involves an interplay between risk factors and exposures (see Table 298-1) and genetic predisposition.

HERITABLE PREDISPOSITION

Asthma has a strong genetic predisposition. Family and twin studies suggest a 25–80% degree of heritability. Genetic studies suggest complex polygenic inheritance complicated by interaction with environmental exposures. Further, epigenetic modifications related

to environmental exposures may also produce heritable patterns of asthma. Many of the genes related to asthma have been associated with risk for atopy. However, there appear to be genetic modifications that predispose to asthma and its severity. Association studies have identified multiple candidate genes. In many cases, these genes vary from population to population. The most consistently identified include *ORMDL3/GSDMB* (in the 17q21 chromosomal region), *ADAM33*, *DPP-10*, *TSLP*, *IL-12*, *IL-33*, *ST2 (IL-33 receptor)*, *HLA-DQB1*, *HLA-DQB2*, *TLR1*, *IL-13,* and *IL6R*. Several of these genes have been identified in relation to the pathways involved in airway inflammation (Fig. 298-3). Regulation of ORMDL3 has been associated with altered T_H2 cytokine levels. It is important to note that there is considerable evidence of ancestry heterogeneity (difference in the strength of genetic association by ancestry) so that, for example, an association with PYHIN1 (interferon inducible protein X) is only found among people of African descent. In many cases, association studies have identified polymorphisms in noncoding regions of the genome, suggesting that the majority of the currently identified traits act as "enhancers" of biologic processes.

Genetic polymorphisms have also been associated with differential responses to asthma therapies. Variants in the β-receptor (Arg16Gly in $ADRB_2$), the glucocorticoid-induced transcript 1 gene, and genes in the leukotriene synthesis and receptor pathways have been associated with altered response to the pharmacologic agents acting at those receptors or through those pathways.

While genetic variation plays a key role in asthma susceptibility, it is important to understand that unraveling the complexities of the genetic contribution to asthma remains elusive. To wit, only 7.2% of asthma risk can be explained by the single nucleotide polymorphisms that have been associated with asthma. Recently, polygenic risk score analysis has been used as a tool to attempt to improve the prediction of asthma risk.

A significant proportion of the heritability of asthma relates to the heritability of atopy. Atopy is the genetic tendency toward specific IgE production in response to allergen exposure. Serum levels of IgE correlate closely with the development of asthma. The National Health and Nutrition Examination Survey (NHANES) III found that half of asthma in patients aged 6–59 could be attributed to atopy with evidence of allergic sensitization. The allergens most associated with risk include house dust mites, indoor fungi, cockroaches, and indoor animals.

EXPOSURES AND RISK FACTORS

Allergic Sensitization and Allergen Exposure Like asthma, the development of allergic sensitization involves an interplay between heritable susceptibility and allergen exposure. Allergen exposure during vulnerable developmental periods is believed to increase the risk of development of allergic sensitization in those with a tendency toward atopy. Allergic sensitization is increased in industrialized nations. Research comparing rural environments has suggested that early, varied microbiome exposure (exposure to bacteria and bacterial products) may reduce the development of atopy. Studies of the role of early allergen avoidance in reducing the risk of developing asthma have produced contradictory results.

Tobacco Maternal smoking and secondhand smoke exposure are associated with increased childhood asthma. Childhood secondhand smoke exposure increased asthma risk twofold. Active smoking is estimated to increase the incidence of asthma by up to fourfold in adolescents and young adults.

Air Pollution Early life exposure to pollution increases the risk of development of asthma. Proximity to major roadways increases the risk of early childhood asthma, thought to be attributed to levels of nitrogen dioxide exposure. Decreasing nitrogen dioxide exposure has been found to decrease asthma incidence in children. Studies of exposure to mixed pollutants suggest that most risk lies with carbon monoxide and nitric dioxide, with marginal effects of sulfur dioxide. Indoor air pollution from open fires and use of gas stoves has been associated with increased risk of children developing asthma symptoms. Mechanistically, pollutants are thought to cause oxidative injury to the airways, producing airway inflammation and leading to remodeling and increased risk of airway sensitization.

Infections Respiratory infections clearly can precipitate asthma deteriorations. However, the degree to which respiratory infections indicate susceptibility to asthma, represent a causal factor, or in some cases provide protection from asthma is unclear. Incidence and frequency of human rhinovirus and respiratory syncytial virus infections in children are associated with development of asthma, but whether they play a causal role is unclear. Evidence of prior *Mycoplasma pneumoniae* infection has been associated with the development of asthma in Taiwanese adults.

Occupational Exposures Occupational asthma is estimated to account for 10–25% of adult-onset asthma. The occupations associated with the most cases in European Community Health Surveys were nursing and cleaning. Two types of exposures are recognized: (1) an immunologic stimulus (further subdivided into high-molecular-weight [e.g., proteins, flour] and low-molecular-weight [e.g., formaldehyde, diisocyanate] stimuli based on whether they act as haptens or can directly stimulate a response), and (2) an irritative stimulus. The immunologic form is associated with a latency period between time of exposure and development of symptoms. The irritative form, known as reactive airway dysfunction syndrome (RADS), will be discussed below. A combination of genetic predisposition (including atopy), timing, intensity of exposure, and co-exposure (e.g., smoking) influences whether an individual will develop occupational asthma.

Diet There are suggestions that prenatal diet or vitamin deficiency may alter the risk of developing asthma. The evidence is not yet definitive, but vitamin D insufficiency may increase asthma risk in the progeny and supplementation may decrease such risk. Similarly, preliminary studies suggest that maternal supplementation with vitamins C and E and zinc may decrease asthma in children. One study suggested that maternal polyunsaturated fatty acid supplementation may decrease childhood asthma risk. Observational studies have suggested that increased maternal sugar intake may increase childhood asthma risk.

Obesity Multiple studies suggest that obesity may be a risk factor for development of childhood and adult asthma. Adipokines and IL-6 have been thought to play a pathobiologic role. Some have argued that the risk is overestimated, and a study from NHANES II found an association with dyspnea but not with airway obstruction.

Medications There are conflicting data regarding prenatal and early childhood risk for asthma posed by certain classes of medications. Use of H_2 blockers and proton pump inhibitors in pregnancy has been associated with an increased risk of asthma in children (relative risk, 1.36–1.45); however, another study found a small risk for H_2 blockers only. Conflicting data have been presented on the risk of perinatal acetaminophen and early childhood acetaminophen use. In a prospective study, the use of acetaminophen was not associated with an increased risk of exacerbations in young children with asthma, when compared to ibuprofen.

Prenatal and Perinatal Risk Factors Preeclampsia and prematurity have been associated with increased risk of asthma in the progeny. Babies born by cesarean section are at higher risk for asthma. Those with neonatal jaundice are also at increased risk. Breast-feeding reduced early wheezing but has a less clear effect on later incidence of asthma.

Endogenous Developmental Risk Factors Asthma is more prevalent among boys than girls, with the difference receding by age 20 and reversing (with increased prevalence among women) by age 40. Atopy is more prevalent among boys in childhood, and they have reduced airway size compared with girls. Both factors are thought to contribute to the sex discrepancy. A subset of women develop asthma

around menopause. Such asthma tends to involve non–type 2 mechanisms. Pregnancy may precipitate or aggravate asthma as well.

High-Concentration Irritant Exposure and RADS A solitary exposure to a high concentration of irritant agents that rapidly (usually within hours) produces bronchospasm and bronchial hyperactivity is known as RADS. Causative agents include oxidizing and reducing agents in an aerosol or high levels of particulates. The acute pathology usually involves epithelial injury with neutrophilia. There is little evidence of type 2 inflammation. This syndrome differs from occupational asthma in that these patients have not become sensitized to the provocative agent and can return to work in that environment once they have recovered. However, the course of the disease may be variable, with some series showing documented abnormalities and persistent symptoms 10 years after exposure.

Fungi and Allergic Airway Mycoses One to 2% of patients with asthma may have an IgE-mediated sensitization to colonization of the airway by fungi, with the most common fungus causing such a reaction being *Aspergillus fumigatus*. So-called allergic bronchopulmonary aspergillosis (ABPA) is characterized by a type 2 airway inflammatory response to aspergillus with IgE >1000 IU/mL, eosinophils >500/μL, positive skin test to *Aspergillus,* and specific IgE and IgG antibodies to *Aspergillus.* Patients may have intermittent mucus plugging and central bronchiectasis. Up to two-thirds of patients will grow *Aspergillus* from the sputum. Treatment involves systemic antifungal treatment with itraconazole or voriconazole and oral corticosteroids. A role for biologics has also been suggested.

Exercise-Induced Symptoms in Elite Athletes Exercise-induced airway narrowing in elite athletes undertaking extreme exercise in strenuous condition. These athletes may have little, or no, airway hyperreactivity or asthma risk factors. The condition may involve additional mechanisms including direct epithelial injury. Such a syndrome has also been reported in swimmers possibly related to pool chlorination.

TRIGGERS OF AIRWAY NARROWING

The risk factors and exposures reviewed above lead to increased airway reactivity and a propensity to react to factors that trigger airway narrowing (see Fig. 298-1). Almost all asthmatics can identify triggers that will make their asthma worse. The major triggers are listed in Table 298-2. Many of them overlap with the risk factors and etiologic factors reviewed above. In some cases, elimination of these triggers may dramatically reduce the impairment caused by asthma. In a minority, abatement can lead to "remission" so that these patients no longer require asthma medications and do not experience bronchospasm with their daily activities and routines. While acute exposures to these triggers generally cause short-lived bronchospasm, the bronchospasm may be severe enough that treatment for an exacerbation is required. Chronic exposure may lead to permanent deterioration in asthma control, although this does not appear to be true for exercise or stress. It should be noted that evidence suggests that severe asthma exacerbations (those requiring systemic corticosteroids) may, in and of themselves, accelerate lung function decline.

Allergens In patients with sensitization to particular allergens through production of allergen-specific IgE, exposure to those allergens by inhalation can result in activation of mast cells and basophils with acute production of bronchoactive mediators (see Fig. 298-3). Such exposure can produce immediate bronchospasm (early response) and a late response (2–24 h after exposure) with bronchial narrowing and inflammation. These mechanisms can account for reactions to inhalation of pollens, mold, or dust; insects (especially cockroaches); animals; occupational materials; seasonal worsening of asthma; and so-called "thunderstorm asthma." Chronic exposure may lead to persistent symptoms. While food allergies can produce bronchospasm through anaphylaxis, food allergies are generally not etiologically linked to asthma.

Irritants Many asthmatics report increased symptoms on exposure to strong odors, smoke, combustion products, cleaning fluids, or perfumes. In general, the effects are short-lived, although chronic exposure (see "Occupational Exposures" above) and large-quantity exposures (see discussion of RADS above) can lead to long-lasting or permanent symptoms.

Viral Infections Most asthmatics report that asthma exacerbations can be triggered by upper respiratory infections. The inflammation that occurs may be neutrophilic as well as eosinophilic. There is some evidence that IgE generation may reduce production of interferon, possibly predisposing to the effects of upper respiratory viruses. Increased airway reactivity after viral infections generally persists for 4–6 weeks but, in some cases, may be associated with permanent changes and impairment. The almost 50% reduction in exacerbations during the COVID-19 pandemic has been attributed to decreased viral infections.

Exercise and Cold/Dry Air Exercise may be a trigger to asthmatic bronchoconstriction in patients with asthma. Hyperventilation that occurs with exercise dries the airway lining, changing the tonicity of lining cells and causing release of bronchoconstrictive mediators. This effect is more prominent the lower the moisture content of the air, and since cold air has a lower absolute moisture content, the lower the temperature of the inspired air, the less exercise is required to induce bronchoconstriction. In addition, cold air may produce airway edema during airway wall rewarming. At routine levels of exercise, these effects are short-lived.

Air Pollution Increased rates of exacerbations have been associated with increased ambient ozone, sulfur dioxide, and nitrogen dioxide, among other air pollutants.

Drugs Beta blockers may trigger bronchospasm even when used solely in ophthalmic preparations. While the more selective beta blockers are safe for most asthmatics, beta blocker use may be a cause of difficult-to-control asthma. Aspirin may precipitate bronchospasm in those with aspirin-exacerbated respiratory disease (see "Special Considerations"). Angiotensin-converting enzyme (ACE) inhibitors (and to a lesser extent angiotensin receptor blockers) may cause cough that may be attributed to poorly controlled asthma.

Occupational Exposures In addition to RADS (see above), episodic and/or recurrent exposures to workplace irritants and/or substances to which one has become sensitized can produce symptoms. These symptoms are usually reduced when patients are away from such exposures on weekends or vacation.

Stress Asthmatics may report increased symptoms with stress. The mechanisms are poorly understood.

Hormonal Factors A small proportion of women report a regular increase in perimenstrual symptoms, and symptoms may worsen during perimenopause. This may be related to rapid fluctuations in estrogen levels. Pregnancy can precipitate worsening of asthma in approximately one-third of pregnant patients.

COMORBIDITIES

Comorbidities may make asthma difficult to manage, and the common comorbidities are listed in **Table 298-3**.

Obesity Obese adults with asthma have more severe asthma symptoms than lean adults and are two to four times more likely to be hospitalized with an asthma exacerbation. Nonrandomized studies have shown an improvement and significant reduction in exacerbations after bariatric surgery.

Gastroesophageal Reflux Disease The presence of gastroesophageal reflux disease (GERD) predicts poor quality of life and is an independent predictor of asthma exacerbations. Treatment of symptomatic reflux disease has been shown to produce modest improvements in airway function, symptoms, and exacerbation frequency. Treatment of asymptomatic patients has not shown a benefit.

TABLE 298-3 Differential Diagnosis and Comorbidities That May Make Asthma Difficult to Control

Differential Diagnosis of Diseases with Overlapping Symptoms That Can Present with Obstructive Pulmonary Function Tests
1. Heart failure
2. Chronic obstructive pulmonary disease (COPD)
3. α_1 Antitrypsin deficiency
4. Airway obstruction from mass or foreign body
5. Inducible laryngeal dysfunction (vocal cord dysfunction)
6. Bronchiolitis obliterans
7. Bronchiectasis
8. Tracheobronchomalacia
Comorbidities That Can Make Asthma Difficult to Control
1. Chronic rhinosinusitis +/– nasal polyposis
2. Obesity
3. Gastroesophageal reflux disease
4. Inducible laryngeal obstruction (vocal cord dysfunction)
5. COPD
6. Anxiety/depression
7. Obstructive sleep apnea

Rhinosinusitis and/or Nasal Polyposis Rhinosinusitis may be a manifestation of the eosinophilic inflammation in the lower airway in asthma. In addition, poorly controlled rhinosinusitis is believed to aggravate asthma by several potential mechanisms including inflammatory and irritant effects of the secretions on the lower airway, neural reflexes, and production of inflammatory mediators and cells that produce systemic inflammation. Treatment with intranasal corticosteroids has been shown to decrease airway reactivity and emergency department visits and hospitalizations. Evidence for the benefit of surgical therapy is inconclusive. There is increasing evidence that biologics targeted at type 2 inflammation may also be particularly useful for asthma associated with rhinosinusitis and polyposis in particular.

Nasal polyposis is rare in children, and its presence in adults with asthma should raise suspicions of aspirin-exacerbated respiratory disease (see "Special Considerations").

Inducible Laryngeal Obstruction Previously known as vocal cord dysfunction, this process involves inappropriate narrowing of the larynx, producing resistance to airflow; it can complicate asthma as well as mimic it, and it is more commonly seen in women and patients with anxiety and depression. Definitive diagnosis involves laryngoscopy during symptomatic episodes or during induced obstruction.

Chronic Obstructive Pulmonary Disease (COPD) See "Asthma-COPD Overlap" under "Special Considerations."

Anxiety/Depression Increased rates of asthma exacerbations occur in asthmatics with anxiety, depression, or chronic stress. Some patients may be unable to distinguish anxiety attacks from asthma.

DIAGNOSIS AND EVALUATION

APPROACH

A presumptive diagnosis of asthma can usually be made based on a compatible history of recurrent wheezing, shortness of breath, chest tightness, or cough related to common bronchoconstrictor precipitants when appropriate components of the differential diagnosis have been considered and/or eliminated. In some cases, a therapeutic trial of low-dose inhaled corticosteroid (ICS) may be considered. In all but the mildest cases, the diagnosis should be confirmed with pulmonary function testing or demonstration of airway hyperresponsiveness. Unfortunately, the diagnosis may be difficult to confirm after initiation of therapy since airway obstruction and hyperresponsiveness may be mitigated with therapy. A trial of tapering medications may be necessary. Studies have shown that more than one-third of patients with a physician diagnosis of asthma do not meet the criteria for the diagnosis.

Adjunctive evaluation, as outlined below, should be undertaken to identify precipitating factors and underlying mechanisms that may be amenable to specific therapies (e.g., allergen avoidance). Cases that require more than a daily moderate-dose ICS combined with a long-acting β_2-agonist (LABA) (together known as ICS/LABA) should undergo more formal evaluation to assess comorbidities that may make asthma difficult to control and a reassessment of any possible confounding diagnoses that may mimic asthma symptoms (see Table 298-3).

PRIMARY ASSESSMENT TOOLS FOR ESTABLISHING A DIAGNOSIS

History Patients with asthma most commonly complain of episodes of wheezing, shortness of breath, chest tightness, mucus production, or cough upon exposure to triggers listed in Table 298-2. Symptoms may be worse on arising in the morning. Some may have nocturnal symptoms alone. The latter such patients should be evaluated for postnasal drip or GERD if that is their sole presenting symptom. Patients frequently complain of symptoms with rapid changes of temperature or humidity. Exercise-induced symptoms are common and frequently reported with increased sensitivity to cold air. As compared to cardiac sources of dyspnea, exercise symptoms tend to develop more slowly after initiation of exercise and tend to resolve more slowly unless a β_2-agonist is administered after the onset of symptoms. A careful exposure history should be obtained for home (e.g., pets, molds, dust, direct or secondhand smoke), work (work environment and exposure to occupational sensitizers), and recreational (e.g., hobbies, recreational inhalants) exposures. Allergen-sensitized patients may complain of symptoms on exposure to known allergens such as animals and may complain of increased symptoms during specific pollen seasons. Up to two-thirds of patients with asthma will be atopic (as opposed to half of the U.S. population), and almost half will have a history of rhinitis, with many complaining of intermittent sinusitis. In patients with adult-onset asthma, a careful occupational history should be obtained and a history of reactions to nonsteroidal anti-inflammatory drugs (NSAIDs) or use of new medications, such as beta blockers (including ophthalmic preparations) and ACE inhibitors (due to potential cough), should be elicited.

Physical Examination In between acute attacks, physical findings may be normal. Many patients will have evidence of allergic rhinitis with pale nasal mucus membranes. Five percent or more of patients may have nasal polyps, with increased frequency in those with more severe asthma and aspirin-exacerbated respiratory disease. Some patients will have wheezing on expiration (less so on inspiration). During an acute asthma attack, patients present with tachypnea and tachycardia, and use of accessory muscles can be observed. Wheezing, with a prolonged expiratory phase, is common during attacks, but as the severity of airway obstruction progresses, the chest may become "silent" with loss of breath sounds.

Pulmonary Function Tests Effective reduction of the airway lumen in asthma produces increased resistance to airflow, which can be detected as a reduction in expiratory airflow during forced expiratory maneuvers. The peak expiratory flow rate (PEFR), forced expiratory volume in 1 s (FEV_1), and the FEV_1/forced vital capacity (FVC) ratio are reduced below the lower limit of normal. The flow-volume loop may show a characteristic scalloping (see Chap. 297). These findings may not be present during acute attacks or on therapy (especially after recent use of bronchodilators). Reversibility has been newly defined as ≥10% increase in the FEV_1 percent of predicted (e.g., 60% predicted to 70% predicted) at least 15 min after administration of a β_2-agonist or after several weeks of corticosteroid therapy. Many continue to use the prior definition of a 12% increase in the baseline FEV_1 with a minimum 200-mL change. Diurnal peak flow variability of >20% has also been proposed as an indicator of reversible airways disease, but it is less reliable due to difficulties with quality control and variability of home assessments. Lung volumes and diffusing capacity should be normal in uncomplicated asthma. In more severe asthma with severe

airway obstruction, lung volumes may indicate air trapping, and total lung capacity may be under- or overestimated depending on whether body box or gas dilution methods, respectively, are utilized. Oscillometry, which does not require forced expiratory maneuvers, is gaining increased use and can be particularly useful for diagnosing large airway and variable tracheal obstruction.

Assessment of Airway Responsiveness In cases where pulmonary function tests are nonconfirmatory and the diagnosis remains in doubt, testing to demonstrate increased reactivity to provocative stimuli in the laboratory can be undertaken. Methacholine, a cholinergic agonist, inhaled in increasing concentrations is most commonly used. A provocative dose producing a 20% drop in FEV_1 (PD_{20}) is calculated, with a cumulative value ≤400 μg indicative of airway reactivity. Mannitol is used as well, and occasionally, hypertonic saline may be used. Challenge with exercise and/or cold, dry air can be performed, with a positive response recorded if there is a ≥10% drop in FEV_1 from baseline. In the case of suspected environmental/occupational exposures, specific allergen challenges may be undertaken in specialized labs.

ADJUNCTIVE ASSESSMENT TOOLS

Eosinophil Counts A large proportion of asthma patients not treated with oral or high-dose ICSs will have eosinophil counts ≥300 cells/μL. Eosinophil counts correlate with severity of disease in population studies. Their presence in patients with severe asthma indicates a likelihood that the patient would respond to medications targeted at type 2 inflammation. Extremely elevated levels should prompt consideration of eosinophilic granulomatosis with polyangiitis or primary eosinophilic disorders.

IgE, Skin Tests, and Radioallergosorbent Tests Total serum IgE levels are useful in considering whether patients with severe asthma would be eligible for anti-IgE therapy. Levels >1000 IU/mL should prompt consideration of ABPA. Skin tests, or their in vitro counterparts that detect IgE directed at specific antigens (radioallergosorbent test [RAST]), can be useful in confirming atopy and suggesting allergic rhinitis, which can complicate asthma management. Allergy investigations may be useful, when correlated with a history of reactions, in identifying environmental exposures that may be aggravating asthma.

Exhaled Nitric Oxide Fraction of exhaled nitric oxide (FeNO) in exhaled breath is an indicator of type 2 inflammation (particularly IL-13 induced) in the airways. It is easily suppressed by ICSs and, thus, can be used to assess adherence in patients in whom it was initially elevated. Elevated levels (>35–40 ppb) in untreated patients are indicative of type 2 inflammation. Levels >20–25 ppb in patients with severe asthma on moderate- to high-dose ICS indicate either poor adherence or persistent type 2 inflammation despite therapy.

ADDITIONAL EVALUATION IN SEVERE/POORLY RESPONSIVE ASTHMA

In patients with poorly responsive asthma, additional evaluations for comorbidities (see Table 298-3) may be necessary, including sinus radiographic studies (even in those who have no symptoms of sinus disease) and esophageal studies in those who have symptoms of reflux. In patients with nonreversible disease, many obtain a serum α_1 antitrypsin level. Additionally, the following evaluations may be of utility in poorly responsive asthma.

Chest CT Chest CT can be useful to assess for the presence of bronchiectasis and other structural abnormalities that could produce airway obstruction. New image analysis tools are being used in the research setting to assess airway properties such as airway wall thickness, airway diameter, mucus plugging, and evidence of air trapping.

Sputum Induced sputum may be used in more specialized centers to help characterize type 2 and non–type 2 inflammation by detection of eosinophils and neutrophils, respectively. In severe asthma, there is some evidence that some patients may have localized persistent eosinophilic airway inflammation despite lack of peripheral eosinophils on blood analysis.

TABLE 298-4 Goals of Asthma Therapy

1. Reduction in symptom frequency to ≤2 times/week
2. Reduction of nighttime awakenings to ≤2 times/month
3. Reduction of reliever use to ≤2 times a week (except before exercise)
4. No more than 1 exacerbation/year
5. Optimization of lung function
6. Maintenance of normal daily activities
7. Satisfaction with asthma care with minimal or no side effects of treatment

TREATMENT

Asthma

GOALS OF ASTHMA THERAPY AND ASSESSMENT OF CONTROL

Goals of asthma therapy in terms of achieving control of symptoms and reducing risk (as reflected in frequency of asthma exacerbations) are listed in **Table 298-4**. The therapeutic agents used in treatment are discussed below, and an integrated approach to care is discussed subsequently.

A comprehensive treatment approach involves avoiding and reducing asthma triggers and, if necessary, the adjunctive use of medications. Asthma medications are primarily divided into those that relax smooth muscle and produce a fairly rapid relief of acute symptoms and those that target inflammation or mediator production. The former medications are commonly referred to as reliever medications, and the latter are known as controller medications.

REDUCING TRIGGERS

Mitigation As shown in Tables 298-1 and 298-2, triggers and exposures can cause asthma and make it difficult to control. In the case of those with occupational exposures, removal from the offending environment may sometimes result in complete resolution of symptoms or significant improvement. Secondhand smoke exposure and frequent exposure to combustion products of cannabis are remediable environmental exposures as well. The removal of pets that are clearly associated with symptoms can reduce symptoms. Pest control at home and in the school in those with evidence of IgE-mediated sensitivity (skin test or IgE RAST) may also be beneficial. The effect of dust or mold control in reducing asthma symptoms has been more variable. There is moderate evidence that dust control (impermeable mattress and pillowcase covers) in those patients with symptoms and sensitization may be effective in reducing symptoms *only* when conducted as part of a comprehensive allergen mitigation strategy.

Allergen Immunotherapy Allergen immunotherapy reduces IgE-mediated reactions to the allergens administered. It clearly reduces the symptoms of allergic rhinitis and thus may be helpful in reducing this comorbidity. The evidence for its effectiveness in isolated asthma in those who are sensitized and have clinical symptoms is variable. Due to the risk of anaphylaxis, guidelines generally recommend immunotherapy only in patients whose asthma is under control and who have mild to moderate asthma. The evidence base for the effectiveness of sublingual allergen immunotherapy in the treatment of asthma is not substantial.

Vaccination Respiratory infections are a major cause of asthma exacerbations. Adult patients with asthma are strongly advised to receive the currently available pneumococcal vaccines (regardless of age) and yearly influenza vaccines. COVID-19 vaccination and the respiratory syncytial virus vaccines are advised, as well.

MEDICATIONS

Bronchodilators Bronchodilators relax airway smooth muscle. There are three major classes of bronchodilators, β_2-agonists, anticholinergics, and theophylline.

β_2-Agonists Available in inhaled or oral form, these agents activate β_2-receptors present on airway smooth muscle. Such receptors

are also present on mast cells, but they contribute little to the efficacy of these agents in asthma. β_2-receptors are G protein–coupled receptors that activate adenyl cyclase to produce cyclic AMP, which results in relaxation of smooth muscle.

Use β_2-Agonists are primarily used in inhaled forms to provide relief of bronchospasm or to reduce the degree of bronchospasm anticipated in response to exercise or other provocative stimuli. Regular use has been associated with tachyphylaxis of the bronchoprotective effect and possible increased airway reactivity. This may be more common in patients with a polymorphism at the 16th amino acid position of the β_2-receptor. Frequent short-acting β_2-agonist use has been associated with increased asthma mortality, resulting in decreased enthusiasm for their use in isolation without inhaled corticosteroids.

Short-Acting β_2-Agonists (SABAs) Albuterol (also known as salbutamol) is the most commonly used agent. Bronchodilation begins within 3–5 min of inhalation, and effects generally last 4–6 h. It is most commonly administered by metered-dose inhaler. Solutions for nebulization are also used, especially for relief of bronchospasm in children. Oral forms are available but are not commonly used.

Long-Acting β_2-Agonists Salmeterol and formoterol are the two available LABAs. They have an ~12-h duration of action. Formoterol has a quick onset comparable to the SABAs. Salmeterol has a slower onset of action. These agents can be used for prophylaxis of exercise-induced bronchospasm. In contrast to their use in chronic obstructive pulmonary disease (COPD), these agents are *not* recommended for use as monotherapy in the treatment of asthma. Their use in asthma is generally restricted to use in combination with an ICS.

Ultra-Long-Acting β_2-Agonists These agents (indacaterol, olodaterol, and vilanterol) have a 24-h effect. They are only used in combination with ICSs in the treatment of asthma.

Safety β_2-Agonists are fairly specific for the β_2-receptors, but in some patients and especially at higher doses, they can produce tremor, tachycardia, palpitations, and hypertension. They promote potassium reentry into cells, and at high doses, they can produce hypokalemia. Type B (nonhypoxic) lactic acidosis can also occur and is thought to be secondary to increased glycogenolysis and glycolysis and increased lipolysis, leading to a rise in fatty acid levels, which can inhibit conversion of pyruvate to acetyl-coenzyme A.

Increased asthma mortality was associated with high-potency β_2-agonists in Australia and New Zealand. Increased use of β_2-agonists for relief of bronchospasm is a clear marker of poor asthma control and has been associated with increased mortality. Questions had been raised as to whether adding LABAs to ICS might be associated with severe adverse asthma outcomes, but several studies have not detected such outcomes in comparison to maintaining the ICS dose.

Anticholinergics Cholinergic nerve–induced smooth-muscle constriction plays a role in asthmatic bronchospasm. Anticholinergic medications can produce smooth-muscle relaxation by antagonizing this mechanism of airway narrowing. Agents that have been developed for asthma have been pharmacologically designed to be less systemically absorbed so as to minimize their systemic anticholinergic effects. The long-acting agents in this class are known as long-acting muscarinic antagonists (LAMAs).

Use The short-acting agents in this class can be used alone for acute bronchodilation. They appear to be somewhat less effective than β_2-agonists and have a slower onset of action as well.

Safety Dry mouth may occur. At higher doses and in the elderly, acute glaucoma and urinary retention have been reported. There was a numerical (but not significant) difference in mortality in African Americans treated with ICS/LAMA versus ICS/LABA for asthma.

Theophylline Theophylline, an oral compound that increases cyclic AMP levels by inhibiting phosphodiesterase, is now rarely used for asthma due to its narrow therapeutic window, drug-drug interactions, and reduced bronchodilation as compared to other agents.

Controller (Anti-Inflammatory/Antimediator) Therapies So-called "controller" therapies reduce asthma exacerbations and improve long-term control, decreasing the need for intermittent use of bronchodilator therapies. None of these therapies have yet been shown to prevent progression of airway remodeling or the more rapid decline in lung function that can occur in a subset of asthma patients.

Corticosteroids Corticosteroids are particularly effective in reducing type 2 inflammation and airway hyperresponsiveness. Corticosteroids bind to a cytoplasmic glucocorticoid receptor to form a complex that translocates to the nucleus. The complex binds to positive and negative response elements that result in inhibition of T-cell activation; eosinophil function, migration, and proliferation; and proinflammatory cytokine elaboration and activation of nuclear factor-κB. It also attaches to other transcription factors, resulting in deactivation of other proinflammatory pathways.

Use Corticosteroids reduce airway hyperresponsiveness, improve airway function, prevent asthma exacerbations, and improve asthma symptoms. Corticosteroid use by inhalation (ICSs) minimizes systemic toxicity and represents a cornerstone of asthma treatment.

ICS ICSs are the cornerstone of asthma therapy. They take advantage of the pleiotropic effects of corticosteroids to produce salutary impact at levels of systemic effect considerably lower than oral corticosteroids. Their use is associated with decreased asthma mortality. They are generally used regularly twice a day as first-line therapy for all forms of persistent asthma. Doses are increased, and they are combined with LABAs to control asthma of increasing severity (see next section "ICS/LABA and ICS/SABA"). European guidelines now recommend their intermittent use even in the mildest forms of asthma to reduce the likelihood of exacerbations. Longer-acting preparations permitting once-a-day use are available. Their effects can be noticeable in several days, but continued improvement may occur over months of therapy, with the majority of improvement evident within the first month of regular use. Adherence to regular therapy is generally poor, with as few as 25% of total annual prescriptions being refilled. Very high doses are sometimes used to reduce oral corticosteroid requirements. Not all patients respond to ICS. Increasing evidence suggests that the most responsive patients are those with significant type 2–mediated asthma.

ICS/LABA and ICS/SABA ICSs are available in combination with a LABA. The combination produces asthma control using a lower dose of ICS. Guidelines suggest that they be considered for daily maintenance therapy once more than low-dose ICS are required for control. The World Health Organization Global Initiative for Asthma (GINA) Guidelines now suggest that Anti-Inflammatory Reliever (AIR) (a combination of a quick onset LABA (formoterol only) or a short acting beta-agonist, either of these agents combined with an inhaled corticosteroid (ICS/formoterol or ICS/SABA), be used instead of albuterol alone at ALL levels of severity (see **Table 298-5** and "Approach to the Patient"). In the case of long-acting beta-agonist, ONLY formoterol can be used in this manner since it acts quickly, whereas the other LABAs have a slower onset of action and therefore have not been evaluated. Currently, ICS/SABA is only available in the United States.

Oral Corticosteroids Chronic oral corticosteroids (OCSs) at the lowest doses possible (due to side effects) are used in patients who cannot achieve acceptable asthma control without them. Alternate-day dosing may be preferred. OCSs are also used to treat asthma exacerbations, frequently starting at a dose of 40–60 mg/d of prednisone or equivalent with a rapid taper over 1–2 weeks. Since they

TABLE 298-5 Step Therapy for the Treatment of Asthma Ages 12+ (Modified from GINA and NAEPP)

	Address exposures and comorbidities (see Tables 298-2 and 298-3) Confirm inhaler technique and optimize adherence Move up or down steps based on control (see Table 298-3)				
	STEP 1	**STEP 2**	**STEP 3**	**STEP 4**	**STEP 5**
Preferred regular therapy	None	None[a] or low-dose ICS[b]	Low-dose ICS/formoterol	Medium-dose ICS/formoterol	High-dose ICS/LABA + add-on LAMA
Alternative regular therapy	None	LTRA	Medium-dose ICS	High-dose ICS	Anti-IgE or anti–IL-5 or anti–IL4-Rα or anti-TSLP
Adjunctive therapy					LTM, azithromycin, OCS[c]
As-needed (PRN) reliever therapy	ICS/formoterol (low dose) or SABA[b] or ICS/SABA[f]	ICS/formoterol (low dose)[a], or PRN concomitant ICS and SABA[a,b] or SABA[e,b] or ICS/SABA[f]	ICS/formoterol (low or medium dose)[d] or ICS/SABA[f]		

[a]If using as-needed ICS/formoterol or PRN concomitant ICS and SABA, this is an option in which no regular daily therapy is prescribed. [b]National Asthma Education and Prevention Program (NAEPP) recommendation. [c]To be avoided as much as possible. [d]PRN ICS/formoterol only suggested for steps 3 and 4 by NAEPP. [e]If using low-dose ICS as regular therapy. [f]Alternative GINA recommendation.

Abbreviations: GINA, Global Initiative for Asthma; ICS, inhaled corticosteroid; ICS/LABA, combined ICS and LABA in one device; ICS/SABA, combined ICS and SABA in one device; IL, interleukin; LABA, long-acting β-agonist; LAMA, long-acting muscarinic antagonist; LTM, leukotriene modifier; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; PRN, as needed; SABA, short-acting β-agonist.

are well absorbed, they may also be used for managing hospitalized patients.

Intravenous Corticosteroids Intravenous preparations are frequently used in hospitalized patients. Patients are rapidly transitioned to OCS once their condition has stabilized.

Intramuscular Corticosteroids In high-risk, poorly adherent patients, intramuscular triamcinolone acetonide has been used to achieve asthma control and reduce exacerbations.

Safety Chronic administration of systemic corticosteroids is associated with a plethora of side effects including diabetes, osteoporosis, cataracts and glaucoma, bruising, weight gain, truncal obesity, hypertension, ulcers, depression, and accelerated cardiac risk, among others. Appropriate monitoring and infectious (pneumocystis pneumonia prophylaxis for those treated chronically with ≥20 mg prednisone/d) and bone health prophylaxis are necessary. Intermittent "bursts" of systemic corticosteroids to treat asthma exacerbations are associated with reduced side effects, but observational studies have suggested that the cumulative dose over time is associated with deleterious side effects.

ICSs have dramatically reduced side effects as compared to OCSs. At higher doses, bruising occurs and osteoporosis can accelerate. There is a small increase in glaucoma and cataracts. Local effects include thrush, which can be reduced by use of a spacer and gargling. Hoarseness may be the result of a direct myopathic effect on the vocal cords. Rare patients exhibit side effects even at moderate doses of ICS. Children may experience growth suppression.

Leukotriene Modifiers Agents that inhibit production of leukotrienes (through inhibition of 5-lipoxygenase) or the action of leukotrienes at the $CysLT_1$ receptor are moderately effective in asthma. They are also effective in reducing symptoms of allergic rhinitis. Montelukast, a $CysLT_1$ antagonist, is frequently used in children with mild asthma due to concerns of ICS-related growth suppression.

Leukotriene modifiers are effective in preventing exercise-induced bronchoconstriction without the tachyphylactic effects that occur with regular use of LABAs. They are particularly effective in aspirin-exacerbated respiratory disease, which is characterized by significant leukotriene overproduction. They have also shown modest effect as add-on therapy in patients poorly controlled on high-dose ICS/LABA.

$CysLT_1$ Antagonists Montelukast and zafirlukast are administered orally once or twice daily, respectively. The onset of effect is rapid (hours), with the majority of chronic effectiveness seen within 1 month.

5-Lipoxygenase Inhibition Zileuton in its extended form is administered orally twice a day.

Safety Montelukast is well tolerated, but has been associated with suicidal ideation. Zileuton increases liver function tests (transaminases) in 3% of patients. It inhibits CYP1A2.

Cromolyn Sodium Cromolyn sodium is an inhaled agent believed to stabilize mast cells. It is only available by nebulization and must be administered two to four times a day. It is mildly to modestly effective and appears to be helpful for exercise-induced bronchospasm. It is used primarily in pediatrics in those concerned about ICS side effects.

Anti-IgE Omalizumab, a monoclonal antibody to the Fc portion of the IgE molecule, prevents the binding of IgE to mast cells and basophils and thus blocks antigen-related signaling, which is responsible for production or release of many of the mediators and cytokines critical to asthma pathobiology. Over time, reduction in IgE production occurs as well. Anti-IgE has been shown to increase interferon production in rhinovirus infections, decrease viral-induced asthma exacerbations, and reduce the duration and peak viral shedding, probably due to interference with IgE's ability to reduce interferon γ production in response to viral infections.

Use In asthma, anti-IgE has been tested in patients with a circulating IgE ≥30 IU/mL and a positive skin test or RAST to a perennial allergen. It is generally used in patients not responsive to moderate- to high-dose ICS/LABA. It reduces exacerbations by 25–50% and can reduce asthma symptoms, but has minimal effect on lung function. Anti-IgE is dosed based on body weight and circulating IgE and is administered subcutaneously every 2–4 weeks depending on the calculated dose. In the United States, the maximum dose is 300 mg every 2 weeks, which generally restricts the drug to those with a body weight ≤150 kg. Most effects are generally seen in 3–6 months. Retrospective studies have suggested that patients with an exhaled nitric oxide approximately ≥20 ppb or circulating eosinophils ≥260/μL have the greatest response as ascertained by reduction in exacerbations. FeNO is slightly reduced by treatment, but circulating IgE, as measured by available clinical tests, is not affected since these tests measure total circulating IgE, not free IgE. Anti-IgE has also been found to be effective in patients with chronic idiopathic urticaria and nasal polyposis.

Safety The incidence of side effects is low. Anaphylaxis has been reported in 0.2% of patients receiving the drug.

IL-5–Active Drugs Mepolizumab and reslizumab are monoclonal antibodies that bind to IL-5, and benralizumab binds to the IL-5 receptor. They rapidly (within a day) reduce circulating eosinophils.

Use In patients symptomatic on moderate- to high-dose ICS/LABA, generally with two or more exacerbations that require OCS per year and with an eosinophil count of ≥300/μL (unless they are on chronic OCS), IL-5–active drugs reduce exacerbations by about half or more. FEV_1 and symptoms improve moderately as well. In patients who are not on chronic OCSs, these drugs are less effective in those with eosinophil counts <300/μL. In patients on chronic OCS, they reduce the need for OCSs regardless of circulating eosinophil count (presumably due to the fact that many of those patients have type 2 inflammation but their circulating eosinophils have been suppressed by the systemic OCS). FeNO and IgE are relatively unaffected by these drugs. Most clinical effects are usually seen within 3–6 months. Mepolizumab has been approved for treatment of nasal polyposis.

Safety These drugs are associated with minimal side effects.

Anti–IL-4/13 The IL-4 and IL-13 receptors are heterodimers that share a common subunit, IL-4 receptor α. Dupilumab is an antibody that binds to this subunit and, thus, blocks signaling through both receptors.

Use In addition to effectiveness in the phenotype of patients who respond to anti–IL-5 therapies, poorly controlled patients on moderate- to high-dose ICS/LABA with an FeNO of 20–25 ppb also appear to respond to dupilumab even if their peripheral eosinophils are not elevated. Dupilumab reduces exacerbations by ≥50%, decreases symptoms, and may produce more of an effect on FEV_1 than anti–IL-5 drugs. It has been shown to be effective for patients requiring oral corticosteroids regardless of biomarker levels. It gradually reduces FeNO and IgE levels. Paradoxically, circulating eosinophil counts may initially temporarily increase. Most effects are seen by 3–6 months of therapy. It is also approved for nasal polyposis atopic dermatitis, eosinophilic esophagitis, and lupus pernio also approved for patients with COPD with exacerbations and elevated eosinophils.

Safety Side effects are minimal, but cases of serious systemic eosinophilia, most frequently associated with the reduction of oral corticosteroids, have been noted.

Anti-TSLP Tezepelumab binds to TSLP, a proximal alarmin in the epithelial response cascade (Fig. 298-3). As a result, it affects multiple pathways and decreases blood eosinophils, FeNO, and IgE levels.

Use In addition to effectiveness in patients who qualify for and respond to anti–IL-5 therapies and anti–IL-4/13, tezepelumab has some degree of effectiveness in patients with asthma who have recurrent exacerbations without evidence of elevated levels of FeNO or blood eosinophils. This agent reduces exacerbations by 50–70% and improves lung function and symptoms. Available studies have not been able to demonstrate effectiveness in atopic eczema or in reducing OCS dose. Most effects are seen within 3–6 months of therapy, and biomarker levels may continue to fall over time.

Safety Minimal side effects have been reported.

Bronchial Thermoplasty, Alternative Therapies, and Therapies Under Development • **Bronchial Thermoplasty** This procedure involves radiofrequency ablation of the airway smooth muscle in the major airways administered through a series of three bronchoscopies for patients with severe asthma. There is some evidence that it may reduce exacerbations in very select patients. The procedure may be accompanied by significant morbidity, and most guidelines do not recommend it other than in the context of clinical trials or registries. The manufacturer has discontinued production of the devices necessary for this procedure and it may no longer be available.

Alternative Therapies Macrolides appear to be effective in a subset of asthmatics with poor response to other therapies and are suggested as possible adjunctive therapies in step 5 asthma (Table 298-5). Alternative therapies such as acupuncture and yoga have not been shown to improve asthma in controlled trials. Studies with placebo have demonstrated that there may be a significant response to placebo.

Therapies in Development Trials are underway targeting pathways and receptors shown in Fig. 298-3. Those in more advanced stages of development include therapies targeting IL-33, OX-40, and mediators involved in mucin production. Studies targeting IL-17 and TNF-α have not shown efficacy, but it is unclear if patients with appropriate endotypes were targeted. Proof-of-concept studies targeting mast cells via inhibition of tyrosine kinase have suggested efficacy in severe asthma.

APPROACH TO THE PATIENT

Asthma

U.S. (National Asthma Education and Prevention Program [NAEPP]) and World Health Organization (Global Initiative for Asthma [GINA]) guidelines advise a symptomatic approach to asthma treatment assuming that appropriate measures have been taken to address asthma triggers, exposures, and comorbidities enumerated in Tables 298-2 and 298-3. Additionally, adherence and inhaler techniques need to be addressed. Poor adherence or poor inhaler technique has been identified as the cause of poor asthma control in up to 50% of patients referred for poorly controlled asthma.

The stepwise approach to intensifying and reducing asthma therapy is outlined in Table 298-5. It involves "stepping" therapy up or down based on assessment of whether asthma is controlled by the criteria listed in Table 298-4. Assuming comorbidities have been addressed, adherence has been evaluated, education regarding avoiding triggers has been performed, and inhaler technique is verified, the cornerstone of preferred therapy is the intensification of ICS therapy in conjunction with the use of a LABA to achieve greater control at lower ICS doses.

A major change in the stepwise approach, advocated for more than two decades, has occurred. Evidence has accumulated that as-needed ICS can be used instead of regular ICS in milder asthma and that the trigger for such use could be patient perception of the need to use a reliever inhaler. This approach is now labeled AIR for Antiinflammatory Reliever. Since formoterol is a LABA with a rapid onset, combination ICS/formoterol has been used as a single agent in multiple studies: as needed without background therapy in milder asthma, and as needed in addition to twice-daily ICS/formoterol in more severe asthma. Since asthma mortality can occur even in mild asthma (albeit at lower rates than more severe asthma), GINA, as part of a comprehensive strategy of asthma management, recommends ICS/formoterol be used as the reliever in all steps of asthma severity, including intermittent asthma (step 1). With recent introduction of a combination ICS/SABA in the United States, GINA recognizes use of this preparation as alternative antiinflammatory reliever that can be used in place of albuterol. NAEPP guidelines utilizing evidence-based studies recommend that ICS/formoterol be used as the reliever medication in patients requiring step 3 and 4 therapy (see Table 298-5) and that as-needed concomitant ICS and SABA can be used as a therapy in step 2. For the sake of simplicity, an adapted GINA approach is outlined in Table 298-5 with footnotes identifying the major differences from the NAEPP. Leukotriene receptor antagonists (LTRAs) are alternative medications in step 2, which may be used in those concerned about the minimal ICS side effects. However, recent warnings about suicidal ideation associated with montelukast may make this approach less appealing. Leukotriene modifiers and long-acting anticholinergics are possible add-on (adjunctive) therapies in those requiring step 4 and/or 5 therapies. Biologics are incredibly effective in their specific endotypes (type 2 with exacerbations and specific biomarkers, as previously described), but their high cost currently relegates them to step 5 therapy or beyond.

SPECIAL CONSIDERATIONS

ASTHMA ATTACKS

Asthma deteriorations of mild to moderate severity can be initially treated with a β_2-agonist administered up to every 1 h. Increasing the dose of ICSs by four- to fivefold may be helpful as well. If patients fail to achieve adequate control and continue to require β_2-agonists hourly for several hours, they should be referred for urgent care. In the urgent care setting, PEFR or FEV_1 should be assessed, and patients are usually treated with nebulized β_2-agonists up to every 20 min. Those with PEFR >60% of predicted will frequently respond to β_2-agonists alone. If they fail to respond in 1–2 h, intravenous corticosteroids should be administered. Supplemental oxygen is usually administered to correct hypoxemia. An LTRA and magnesium are sometimes given as well. Nebulized anticholinergics can be administered to produce additional bronchodilation. Failure to achieve PEFR >60% or persistent severe tachypnea over 4–6 h should prompt consideration of admission to the hospital. In-hospital treatment may include continuous bronchodilator nebulization. Noninvasive positive-pressure ventilation to assist with respiratory exhaustion is sometimes used to prevent a need for intubation, and helium-oxygen mixtures may be used to decrease the work of breathing. Antibiotics should be administered only if there are signs of infection.

Most patients with asthma attacks present with hypocapnia due to a high respiratory rate. Normal or near-normal P_{CO_2} in a patient with asthma in respiratory distress should raise concerns of impending respiratory failure and need for mechanical ventilation. Mechanical ventilation may be difficult in patients with status asthmaticus due to high positive pressures in the setting of high resistance to airflow due to airway obstruction. Mechanical ventilation should aim for low respiratory rates and/or low ventilation volumes to decrease peak airway pressures. This can frequently be achieved by "permissive hypercapnia"—allowing the P_{CO_2} to rise and, if necessary, temporarily correcting critical acidosis with administration of bicarbonate to increase the pH. Neuromuscular paralysis may sometimes be beneficial. Bronchoscopy to clear mucus plugs has been described but may be dangerous in the setting of difficulties with mechanical ventilation.

HIGH-RISK ASTHMA PATIENTS

Three to four thousand people die from asthma in the United States each year. Table 298-6 lists characteristics of patients at high risk for asthma death. These characteristics should be considered in evaluating and treating patients who present with asthma.

EXERCISE-INDUCED SYMPTOMS

In many cases, the degree of exercise intolerance may reflect poor asthma control. Treatment involves step therapy of asthma as outlined in Table 298-5. In other cases, however, asthma may be well controlled in all other respects, but patients may report that they cannot undertake the level of exercise they desire. Some increase in exercise capacity can be achieved by starting at lower levels of exercise (warming up) and by using a mask in colder weather to condition the air. Pretreatment with a SABA can increase the threshold of ventilation required to induce bronchoconstriction. LABAs may extend the period of protection, but their use alone in asthma is to be discouraged. For occasional exercise, ICS/LABA can be used, but regular use may expose the patient to unnecessary doses of ICS. If regular exercise is undertaken, then LTRAs may provide protection and can be used regularly. A SABA (or ICS/formoterol) should always be available for quick relief.

Exercise-induced airway narrowing in elite athletes may be related to direct epithelial injury. In addition to the above, conditioning of incoming air may be of major assistance. Ipratropium has been reported to be of utility as well.

TABLE 298-6 Patients at Greater Risk for Asthma Mortality

1. History of intensive care unit admission for asthma
2. History of intubation for asthma
3. Illicit drug use
4. Depression
5. New diagnosis within past year
6. ≥2 emergency unit visits in past 6 months
7. Severe psychosocial problems
8. Lower socioeconomic status
9. On daily prednisone prior to admission

PREGNANCY

Asthma may improve, deteriorate, or remain unchanged during pregnancy. Poor asthma control, especially exacerbations, is associated with poor fetal outcomes. The general principles of asthma management and its goals are unchanged. Avoidance of triggers, especially smoking environments, is critical in view of the risk of loss of control and, in the case of smoking, its clear effects on risk of development of asthma in the child. There is extensive experience suggesting the safety of inhaled albuterol, beclomethasone, budesonide, and fluticasone, with reassuring information on formoterol and salmeterol in pregnancy. Animal studies have not suggested toxicity for montelukast, zafirlukast, omalizumab, and ipratropium. Antibodies cross the placenta, and there are few human data on the safety of the asthma biologics. Chronic use of OCS has been associated with neonatal adrenal insufficiency, preeclampsia, low birth weight, and a slight increase in the frequency of cleft palate. However, it is clear that poorly controlled asthma during pregnancy carries greater risk to the fetus and mother than these effects. There should be no hesitancy in administering routine pharmacotherapy for acute exacerbations. Initiation of allergen immunotherapy during pregnancy is not recommended. In cases where prostaglandins are needed to manage pregnancy, PGF2-α should be avoided since it is associated with bronchoconstriction.

ASPIRIN-EXACERBATED RESPIRATORY DISEASE

A subset of patients (5–10%) present in adulthood with difficult-to-control asthma and type 2 inflammation with eosinophilia, sinusitis, nasal polyposis, and severe asthma exacerbations that are precipitated by ingesting inhibitors of cyclooxygenase, with aspirin being the most prominent of such inhibitors. Such patients, classified as having aspirin-exacerbated respiratory disease, overproduce leukotrienes in response to inhibition of cyclooxygenase-1, probably secondary to inhibition of PGE_2. These patients should avoid inhibitors of cyclooxygenase-1 (aspirin and NSAIDs) but can generally tolerate inhibitors of cyclooxygenase-2 and acetaminophen. They should be treated with leukotriene modifiers. Aspirin desensitization can be undertaken to decrease upper respiratory symptoms and to allow chronic administration of aspirin or NSAIDs for those that require it. Dupilumab and the IL-5–active biologics appear to be particularly helpful (some have been approved to treat nasal polyposis in this setting) and appear to be superseding aspirin desensitization in management except when chronic administration of aspirin or NSAIDs is required for another therapeutic indication.

SEVERE ASTHMA

Severe and difficult-to-treat asthma, which composes ~5–10% of asthma, is defined as asthma that, having undergone appropriate evaluation for comorbidities and mimics, education, and trigger mitigation, remains uncontrolled on step 5 therapy or requires step 5 therapy for its control. Severe asthma can account for almost 50% of the cost of asthma care in the United States. A significant proportion of these patients have trouble with adherence and/or inhaler technique, and these factors need to be investigated vigorously. More than half of these patients have evidence of persistent eosinophilic inflammation as evidenced by peripheral blood eosinophils and/or induced sputum. Those with recurrent exacerbations have a substantially increased likelihood of responding to the type 2 targeted biologics. Tezepelumab has been shown to have some degree of effectiveness in those without elevated type 2 biomarkers. Treatment for those with mixed inflammation, isolated neutrophilic inflammation, or pauci-granulocytic inflammation remains to be determined. Some data suggest that many of these patients may have aberrations in the pathways responsible for resolution of inflammation. A rare patient may have biochemical

abnormalities that interfere with steroid response pathways. Macrolides are of use in a subset. Studies targeting mast cells, IL-6, IL-33, and other pathways illustrated in Fig. 298-3 are underway. Therapies aimed at improving pro-resolving pathways may also be promising.

ELDERLY PATIENTS WITH ASTHMA

Asthma may present at or persist into older age. The mortality of asthma in those >65 years old is five times greater than that of younger cohorts even when adjusting for comorbidities. Many of these patients had asthma as children, some with quiescent periods as they entered adulthood. Of those with new-onset asthma, almost half were smokers or are currently smoking. One-quarter of adult-onset asthma is believed to be due to occupational exposure. Patients presenting with eosinophilic inflammation appear to have more severe asthma. Besides investigations of comorbidities, these patients may require adjustment to step therapy based on intolerance of β_2-agonist therapy due to arrhythmia or tremulousness. The coexistence of COPD needs to be carefully considered (see below).

ASTHMA-COPD OVERLAP

Most clinicians agree that asthma-COPD overlap is not a syndrome, but rather recognize that it may be useful to identify patients who present with symptoms related to airway dysfunction that may be due to simultaneous coexistence of both asthma and COPD. From an asthma perspective, recognition that COPD and smoking can alter the response to asthma therapies may be important. Smoking can blunt the response to ICS. Dupilumab has been shown to be effective in patients with COPD with recurrent exacerbations and elevated eosinophils and has been approved for such use. Additionally, in patients with both diseases, earlier initiation of anticholinergics may be considered.

299 Hypersensitivity Pneumonitis and Pulmonary Infiltrates with Eosinophilia

Praveen Akuthota, Michael E. Wechsler

HYPERSENSITIVITY PNEUMONITIS

INTRODUCTION AND DEFINITION

Hypersensitivity pneumonitis (HP), also referred to as extrinsic allergic alveolitis, is a pulmonary disease that occurs due to inhalational exposure to a variety of antigens leading to an inflammatory response of the alveoli and small airways. Systemic manifestations such as fever and fatigue can accompany respiratory symptoms. Although sensitization to an inhaled antigen as manifested by specific circulating IgG antibodies is necessary for the development of HP, sensitization alone is not sufficient as a defining characteristic, because many sensitized individuals do not develop HP. The incidence and prevalence of HP are variable, depending on geography, occupation, avocation, and environment of the cohort being studied. As yet unexplained is the decreased risk of developing HP in smokers.

OFFENDING ANTIGENS

HP can be caused by any of a large list of potential offending inhaled antigens (Table 299-1). The various antigens and environmental

TABLE 299-1 Examples of Hypersensitivity Pneumonitis

DISEASE	ANTIGEN	SOURCE
Farming/Food Processing		
Farmer's lung	Thermophilic actinomycetes (e.g., *Saccharopolyspora rectivirgula*); fungus	Grain, moldy hay, silage
Bagassosis	Thermophilic actinomycetes	Sugarcane
Cheese washer's lung	*Penicillium casei; Aspergillus clavatus*	Cheese
Coffee worker's lung	Coffee bean dust	Coffee beans
Malt worker's lung	*Aspergillus* species	Barley
Miller's lung	*Sitophilus granarius* (wheat weevil)	Wheat flour
Mushroom worker's lung	Thermophilic actinomycetes; mushroom spores	Mushrooms
Potato riddler's lung	Thermophilic actinomycetes; *Aspergillus* species	Moldy hay around potatoes
Tobacco grower's lung	*Aspergillus* species	Tobacco
Wine maker's lung	*Botrytis cinerea*	Grapes
Birds and Other Animals		
Bird fancier's lung (also named by specific bird exposures)	Proteins derived by parakeets, pigeons, budgerigars	Bird feathers, droppings, serum proteins
Duck fever	Duck feathers, serum proteins	Ducks
Fish meal worker's lung	Fish meal dust	Fish meal
Furrier's lung	Dust from animal furs	Animal furs
Laboratory worker's lung	Rat urine, serum, fur	Laboratory rats
Pituitary snuff taker's lung	Animal proteins	Pituitary snuff from bovine and porcine sources
Poultry worker's lung	Chicken serum proteins	Chickens
Turkey handling disease	Turkey serum proteins	Turkeys
Other Occupational and Environmental Exposures		
Chemical worker's lung	Isocyanates	Polyurethane foam, varnish, lacquer
Detergent worker's lung	*Bacillus subtilis* enzymes	Detergent
Hot tub lung	*Cladosporium* species; *Mycobacterium avium* complex	Contaminated water, mold on ceiling
Humidifier fever (and air conditioner lung)	Several microorganisms including: *Aureobasidium pullulans*; *Candida albicans*; thermophilic actinomycetes; *Mycobacterium* species; *Klebsiella oxytoca*; *Naegleria gruberi*	Humidifiers and air conditioners (contaminated water)
Machine operator's lung	*Pseudomonas* species; *Mycobacteria* species	Metal working fluid
Sauna taker's lung	*Aureobasidium* species; other antigens	Sauna water
Suberosis	*Penicillium glabrum*; *Chrysonilia sitophila*	Cork dust
Summer-type pneumonitis	*Trichosporon cutaneum*	House dust mites, bird droppings
Woodworker's lung	*Alternaria* species; *Bacillus subtilis*	Oak, cedar, pine, mahogany dusts

conditions described to be associated with HP give rise to an expansive list of monikers given to specific forms of HP. Antigens derived from fungal, bacterial, mycobacterial, bird-derived, and chemical sources have all been implicated in causing HP.

Categories of individuals at particular risk in the United States include farmers, bird owners, industrial workers, and hot tub users. Farmer's lung occurs as a result of exposure to one of several possible sources of bacterial or fungal antigens such as grain, moldy hay, or silage. Potential offending antigens include thermophilic actinomycetes or *Aspergillus* species. Bird fancier's lung (also referred to by names corresponding to specific birds) must be considered in patients who give a history of keeping birds in their home and is precipitated by exposure to antigens derived from feathers, droppings, and serum proteins. Occupational exposure to birds may also cause HP, as is seen in poultry worker's lung. Chemical worker's lung is provoked by exposure to occupational chemical antigens such as diphenylmethane diisocyanate and toluene diisocyanate. Mycobacteria may cause HP rather than frank infection, a phenomenon observed in hot tub lung and in HP due to metalworking fluid.

PATHOPHYSIOLOGY

While much remains to be learned regarding the pathophysiology of HP, it has been established that HP is an immune-mediated condition that occurs in response to inhaled antigens that are small enough to deposit in distal airways and alveoli. From an immunologic perspective, HP is characterized by dysregulated T_H1 and T_H17 immune responses. Although the presence of precipitating IgG antibodies against specific antigens in HP suggests a prominent role for adaptive immunity in the pathophysiology of HP, innate immune mechanisms likely also make an important contribution. This is highlighted by the observation that Toll-like receptors and downstream signaling proteins such as MyD88 are activated in HP, leading to neutrophil recruitment. Although no clear genetic basis for HP has been established, in specific cohorts, polymorphisms in genes involved in antigen processing and presentation, including TAP1 and major histocompatibility complex type II, have been observed. In chronic HP, bone marrow–derived fibrocytes may contribute to lung inflammation and fibrosis. Chronic HP shares some genetic overlap with idiopathic pulmonary fibrosis (IPF), with a polymorphism in the mucin gene *MUC5B* that is associated with IPF also associated with chronic HP.

CLINICAL PRESENTATION

Given the heterogeneity among patients, variability in offending antigens, and differences in the intensity and duration of exposure to antigen, the presentation of HP is accordingly variable. Although these categories are not fully satisfactory in capturing this variability, HP has been traditionally categorized as having *acute, subacute*, and *chronic* forms. However, recent professional society guidelines advocate abandoning this terminology in favor of categorizing HP as either *nonfibrotic* or *fibrotic*. The HP Study Group found by cluster analysis that a cohort of HP patients is best described in bipartite fashion, with one group featuring recurrent systemic signs and symptoms and the other featuring more severe respiratory findings.

Symptoms of HP may be acute and can be intense in nature, although HP can also present in a more insidious and slowly progressive manner. Systemic symptoms, including fevers, chills, and malaise, can occur and are accompanied by dyspnea and cough. Acute symptoms may resolve within hours to days if no further exposure to the offending antigen occurs but may be recurrent and episodic depending on exposure patterns. A similar presentation may occur as a culmination of intermittent episodes of acute HP. Although respiratory impairment may be quite severe, antigen avoidance generally results in resolution of the symptoms, but with a slower time course, on the order of weeks to months, than that seen with acute HP. Chronic HP can present with an even more gradual onset of symptoms than subacute HP, with progressive dyspnea, cough, fatigue, weight loss, and clubbing of the digits. The insidious onset of symptoms and frequent lack of an anteceding episode of acute HP make diagnosing chronic HP a challenge. Unlike with the other forms of HP, there can be an irreversible component to the respiratory impairment that is not responsive to removal of the responsible antigen from the patient's environment. The disease progression of chronic HP to lung fibrosis with honeycombing on chest imaging and hypoxemic respiratory failure can mirror that seen in IPF, with a similar prognosis. Diagnostic uncertainty between these two entities is not uncommon. Fibrotic lung disease is a potential feature of chronic HP due to exposure to bird antigens, whereas an emphysematous phenotype may be seen in farmer's lung.

Concordant with the variability in the presentation of HP is the observed variability in outcome. HP that has not progressed to chronic lung disease has a more favorable outcome with likely resolution if antigen avoidance can be achieved. However, chronic HP resulting in lung fibrosis has a poorer prognosis, with patients with chronic pigeon breeder's lung having demonstrated a similar mortality as seen in IPF.

DIAGNOSIS

Although there is no set of universally accepted criteria for arriving at a diagnosis of HP, diagnosis depends foremost on establishing a history of exposure to an offending antigen that correlates with respiratory and systemic symptoms. A careful occupational and home exposure history should be taken and may be supplemented if necessary by a clinician visit to the work or home environment. Specific inquiries will be influenced by geography and the occupation of the patient. Questionnaires designed to identify inciting agents are under development but require further validation. When HP is suspected by history, the additional workup is aimed at establishing an immunologic and physiologic response to inhalational antigen exposure with chest imaging, pulmonary function testing (PFT), serologic studies, bronchoscopy, and, on occasion, lung biopsy. Reexposure to the offending environment may be performed to aid in confirming the diagnosis of HP.

Chest Imaging Chest x-ray findings in HP are nonspecific and can even lack any discernible abnormalities. In cases of nonfibrotic HP, findings may be transient and can include ill-defined micronodular opacities or hazy ground-glass airspace opacities. Findings on chest x-ray will often resolve with removal from the offending antigen, although the time course of resolution may vary. With fibrotic HP, the abnormalities seen on the chest radiograph are fibrotic in nature and may be difficult to distinguish from IPF.

High-resolution computed tomography (HRCT) is a common component in the diagnostic workup for HP. Although the HRCT may be normal in nonfibrotic forms of HP, this may be due to lack of temporal correlation between exposure to the offending antigen and obtaining the imaging. Additionally, because of the transient nature of acute symptoms, HRCT is not always performed. When HRCT changes are seen in nonfibrotic HP, ground-glass airspace opacities are characteristic, as is the presence of centrilobular nodules. Expiratory images may show areas of air trapping that are likely caused by involvement of the small airways **(Fig. 299-1)**. Reticular changes and traction bronchiectasis can be observed in fibrotic HP. Subpleural honeycombing similar to that seen in IPF may be present in advanced cases, although unlike in IPF, the lung bases are frequently spared.

Pulmonary Function Testing Either restrictive or obstructive PFTs can be present in HP, so the pattern of PFT change is not useful in establishing the diagnosis of HP. However, obtaining PFTs is of use in characterizing the physiologic impairment of an individual patient and in gauging the response to antigen avoidance and/or corticosteroid therapy. Diffusion capacity for carbon monoxide may be significantly impaired, particularly in cases of fibrotic HP with pulmonary parenchymal changes.

Serum Precipitins Assaying for IgG antibodies against specific antigens, either through precipitin testing or direct serum measurement, can be a useful adjunct in the diagnosis of HP. However, the presence of an immunologic response alone is not sufficient for establishing the diagnosis, because many asymptomatic individuals with high levels of exposure to antigen may display specific IgG, as has been observed in farmers and in pigeon breeders. It should also be noted that panels that test for several specific antigens often provide false-negative results, because they represent an extremely limited proportion of the universe of potential offending environmental antigens.

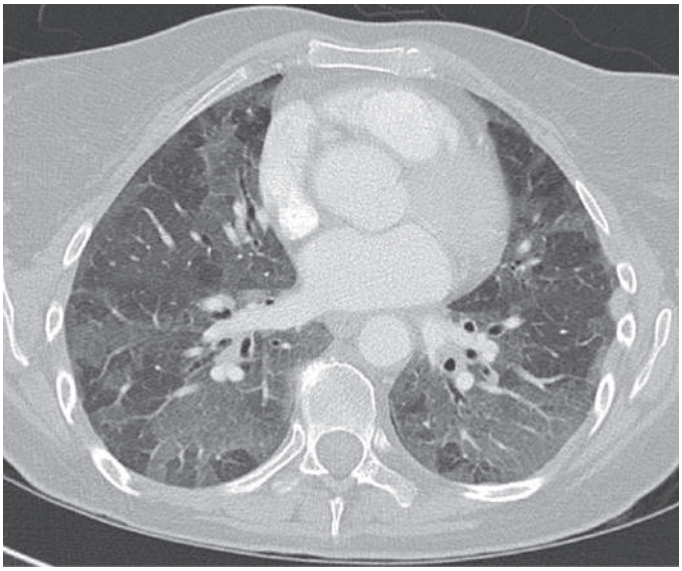

FIGURE 299-1 Chest computed tomography scan of a patient with subacute hypersensitivity pneumonitis in which scattered regions of ground-glass infiltrates in a mosaic pattern consistent with air trapping are seen bilaterally. This patient had bird fancier's lung. *(Courtesy of TJ Gross; with permission.)*

Bronchoscopy Bronchoscopy with bronchoalveolar lavage (BAL) may be used in the evaluation of HP. Although not a specific finding, BAL lymphocytosis is characteristic of HP. However, in active smokers, a lower threshold should be used to establish BAL lymphocytosis, because smoking will result in lower lymphocyte percentages. Most cases of HP have a CD4+/CD8+ lymphocyte ratio of <1, but again, this is not a specific finding and has limited utility in the diagnosis of HP.

Lung Biopsy Tissue samples may be obtained by a bronchoscopic approach using transbronchial biopsy, or more architecturally preserved specimens may be obtained by transbronchial cryobiopsy or by a surgical approach (video-assisted thoracoscopy or open approach). As is the case with BAL, histologic specimens are not absolutely necessary to establish the diagnosis of HP, but they can be useful in the correct clinical context. A common histologic feature in HP is the presence of noncaseating granulomas in the vicinity of small airways **(Fig. 299-2)**. As opposed to pulmonary sarcoidosis, in which noncaseating granulomas are well defined, the granulomas seen in HP are loose and poorly defined in nature. Within the alveolar spaces and in the interstitium, a mixed cellular infiltrate with a lymphocytic predominance is observed that is frequently patchy in distribution. Bronchiolitis with the presence of organizing exudate is also often observed. Fibrosis may be present as well, particularly in fibrotic HP. Fibrotic changes may be focal but can be diffuse and severe with honeycombing in advanced cases, similar to findings in IPF.

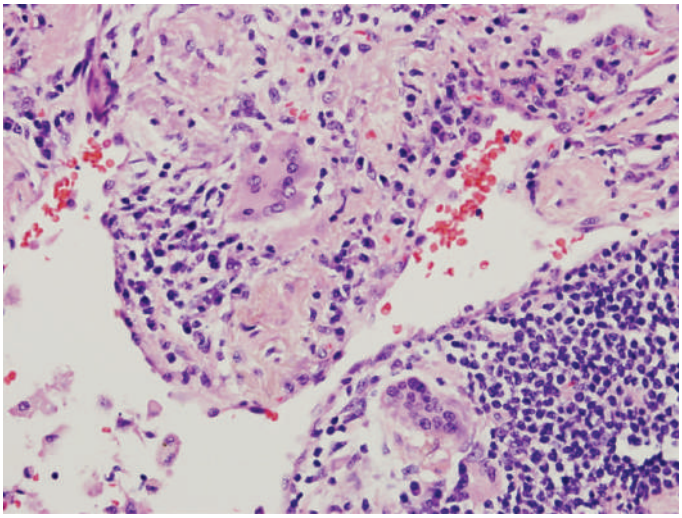

FIGURE 299-2 Open-lung biopsy from a patient with subacute hypersensitivity pneumonitis demonstrating a loose, nonnecrotizing granuloma made up of histiocytes and multinucleated giant cells. Peribronchial inflammatory infiltrate made up of lymphocytes and plasma cells is also seen. *(Courtesy of TJ Gross; with permission.)*

Clinical Prediction Rule Although not meant as a set of validated diagnostic criteria, a clinical prediction rule for predicting the presence of HP has been published by the HP Study Group. They identified six statistically significant predictors for HP, the strongest of which was exposure to an antigen known to cause HP. Other predictive criteria were the presence of serum precipitins, recurrent symptoms, symptoms occurring 4–8 h after antigen exposure, crackles on inspiration, and weight loss.

DIFFERENTIAL DIAGNOSIS

Differentiating HP from other conditions that cause a similar constellation of respiratory and systemic symptoms requires an increased index of suspicion based on obtaining a history of possible exposure to an offending antigen. Presentations of nonfibrotic HP can be mistaken for respiratory infection. In cases of fibrotic disease, HP must be differentiated from interstitial lung disease, such as IPF or nonspecific interstitial pneumonitis (NSIP); this can be a difficult task even with lung biopsy. Given the presence of pulmonary infiltrates and noncaseating granulomas on biopsy, sarcoidosis is also a consideration in the differential diagnosis of HP. Unlike in HP, however, hilar adenopathy may be prominent on chest x-ray, organs other than the lung may be involved, and noncaseating granulomas in pathologic specimens tend to be well formed. Other inhalational syndromes, such as organic toxic dust syndrome (OTDS), can be misdiagnosed as HP. OTDS occurs with exposure to organic dusts, including those produced by grains or mold silage, but neither requires prior antigen sensitization nor is characterized by positive specific IgG antibodies.

TREATMENT

Hypersensitivity Pneumonitis

The mainstay of treatment for HP is antigen avoidance, if possible. A careful exposure history must be obtained to attempt to identify the potential offending antigen and to identify the location where a patient is exposed. Once a potential antigen and location are identified, efforts should be made to modify the environment to minimize patient exposure. This may be accomplished with measures such as removal of birds, removal of molds, and improved ventilation. Personal protective equipment including respirators and ventilated helmets can be used but may not provide adequate protection for sensitized individuals. In some cases, fully avoiding specific environments may be necessary, although such a recommendation must be balanced against the effects to an individual's lifestyle or occupation. It is not uncommon for patients with HP due to exposure to household birds to be unwilling to remove them from the home.

Because nonfibrotic HP can be a self-limited disease after a discrete exposure to an offending antigen, pharmacologic therapy is often not necessary. However, in more severe nonfibrotic and fibrotic forms of the disease, there is a role for glucocorticoid therapy. In patients with particularly severe symptoms as a result of nonfibrotic HP, antigen avoidance may be insufficient after establishing the diagnosis. Although glucocorticoids do not change the long-term outcome in these patients, they can accelerate the resolution of symptoms. While there is significant variability in the approach to glucocorticoid therapy by individual clinicians, prednisone therapy can be initiated at 0.5–1 mg/kg of ideal body weight per day (not to exceed 60 mg/d or alternative glucocorticoid equivalent) over a duration of 1–2 weeks, followed by a taper over the next 2–6 weeks. In fibrotic HP, a similar trial of corticosteroids may be used, although a variable component of fibrotic disease may be irreversible. In cases with progressive lung fibrosis, antifibrotic agents such as nintedanib or pirfenidone may be considered, and in advanced cases, lung transplantation may be necessary.

GLOBAL CONSIDERATIONS

As the ever-expanding list of antigens and exposures associated with the development of HP suggests, populations at risk for HP will vary globally based on specifics of local occupational, avocational, and environmental factors. Specific examples of geographically limited HP include summer-type pneumonitis seen in Japan and suberosis seen in cork workers in Portugal and Spain.

PULMONARY INFILTRATES WITH EOSINOPHILIA

Although eosinophils are normal constituents of the lungs, there are several pulmonary eosinophilic syndromes that are characterized by pulmonary infiltrates on imaging along with an increased number of eosinophils in lung tissue, in sputum, and/or in BAL fluid, with resultant increased respiratory symptoms and the potential for systemic manifestations. Because the eosinophil plays such an important role in each of these syndromes, it is often difficult to distinguish between them, but there are important clinical and pathologic differences as well as differences in prognosis and treatment paradigms.

CLASSIFYING PULMONARY INFILTRATES WITH EOSINOPHILIA AND GENERAL APPROACH

Because there are so many different diagnoses associated with pulmonary infiltrates with eosinophilia, the first step in classifying pulmonary eosinophilic syndromes is distinguishing between primary pulmonary eosinophilic lung disorders and those with eosinophilia that are secondary to a specific cause such as a drug reaction, an infection, a malignancy, or another pulmonary condition such as asthma. Table 299-2 lists primary and secondary pulmonary eosinophilic disorders.

For each patient, a detailed history is of utmost importance and can help elucidate what the underlying disease is. Details regarding onset, timing, and precipitants of specific symptoms can help discern one diagnosis from another. History regarding pharmacologic, occupational, and environmental exposures is instructive, and family and travel history are crucial. In addition to details about the sinuses and lungs, it is important to inquire about systemic manifestations and assess for physical findings of cardiac, gastrointestinal (GI), neurologic, dermatologic, and genitourinary involvement, all of which may give clues to specific diagnoses. Once the details from history and physical are teased out, laboratory testing (including measurements of blood eosinophils, cultures, and markers of inflammation), spirometry, and radiographic imaging can help distinguish between different diseases. Often, however, BAL, transbronchial, or open lung biopsies are required. In many cases, biopsies or noninvasive diagnostic studies of other organs (e.g., echocardiogram, electromyogram, or bone marrow biopsy) can be helpful.

TABLE 299-2 Pulmonary Infiltrates with Eosinophilia

Primary Pulmonary Eosinophilic Disorders
Acute eosinophilic pneumonia
Chronic eosinophilic pneumonia
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Hypereosinophilic syndrome
Pulmonary Disorders of Known Cause Associated with Eosinophilia
Asthma and eosinophilic bronchitis
Allergic bronchopulmonary aspergillosis
Bronchocentric granulomatosis
Drug/toxin reaction
Infection (Table 299-4)
Parasitic/helminthic disease
Nonparasitic infection
Lung Diseases Associated with Eosinophilia
Cryptogenic organizing pneumonia
Hypersensitivity pneumonitis
Idiopathic pulmonary fibrosis
Pulmonary Langerhans cell granulomatosis
Malignant Neoplasms Associated with Eosinophilia
Leukemia
Lymphoma
Lung cancer
Adenocarcinoma of various organs
Squamous cell carcinoma of various organs
Systemic Disease Associated with Eosinophilia
Postradiation pneumonitis
Rheumatoid arthritis
Sarcoidosis
Sjögren's syndrome

PATHOPHYSIOLOGY

Pathologically, the pulmonary eosinophilic syndromes are characterized by tissue infiltration by eosinophils (Fig. 299-2). In eosinophilic granulomatosis with polyangiitis (EGPA), extravascular granulomas and necrotizing vasculitis may occur in the lungs, as well as in the heart, skin, muscle, liver, spleen, and kidneys, and may be associated with fibrinoid necrosis and thrombosis.

The exact etiology of the various pulmonary eosinophilic syndromes is unknown; however, it is felt that these syndromes result from dysregulated eosinophilopoiesis or an autoimmune process because of the prominence of allergic features and the presence of immune complexes, heightened T-cell immunity, and altered humoral immunity as evidenced by elevated IgE, IgG4, and rheumatoid factor. Because of its integral involvement in eosinophilopoiesis, interleukin 5 (IL-5) has been hypothesized to play an etiologic role. Monoclonal antibodies against IL-5 are now in clinical use for the treatment of eosinophilic asthma, eosinophilic granulomatosis with polyangiitis, and hypereosinophilic syndromes. Antineutrophil cytoplasmic antibodies (ANCAs) are present in about one-third to two-thirds of patients with EGPA; binding of ANCAs to vascular walls likely contributes to vascular inflammation and injury as well as chemotaxis of inflammatory cells.

ACUTE EOSINOPHILIC PNEUMONIA

Acute eosinophilic pneumonia is a syndrome characterized by fevers, acute respiratory failure that often requires mechanical ventilation, diffuse pulmonary infiltrates, and pulmonary eosinophilia in a previously healthy individual (Table 299-3).

Clinical Features and Etiology At presentation, acute eosinophilic pneumonia is often mistaken for acute lung injury or acute respiratory distress syndrome (ARDS), until a BAL is performed and reveals >25% eosinophils. Although the predominant symptoms of acute eosinophilic pneumonia are cough, dyspnea, malaise, myalgias, night sweats, and pleuritic chest pain, physical examination findings include high fevers, basilar rales, and rhonchi on forced expiration. Acute eosinophilic pneumonia most often affects males between age 20 and 40 with no history of asthma. Although no clear etiology has been identified, several case reports have linked acute eosinophilic pneumonia to recent initiation of tobacco smoking or even electronic cigarette inhalation (vaping), or exposure to other environmental stimuli including dust from indoor renovations.

TABLE 299-3 Diagnostic Criteria of Acute Eosinophilic Pneumonia

Acute febrile illness with respiratory manifestations of <1 month in duration
Hypoxemic respiratory failure
Diffuse pulmonary infiltrates on chest x-ray
Bronchoalveolar lavage eosinophilia >25%
Absence of parasitic, fungal, or other infection
Absence of drugs known to cause pulmonary eosinophilia
Quick clinical response to corticosteroids
Failure to relapse after discontinuation of corticosteroids

In addition to a suggestive history, the key to establishing a diagnosis of acute eosinophilic pneumonia is the presence of >25% eosinophilia on BAL fluid. While lung biopsies show eosinophilic infiltration with acute and organizing diffuse alveolar damage, it is generally not necessary to proceed to biopsy to establish a diagnosis. Although patients present with an elevated white blood cell count, in contrast to other pulmonary eosinophilic syndromes, acute eosinophilic pneumonia is often not associated with peripheral eosinophilia upon presentation. However, between 7 and 30 days of disease onset, peripheral eosinophilia often occurs with mean eosinophil counts of 1700. Erythrocyte sedimentation rate (ESR), C-reactive protein, and IgE levels are high but nonspecific, whereas HRCT is always abnormal with bilateral random patchy ground-glass or reticular opacities and small pleural effusions in as many as two-thirds of patients. Pleural fluid is characterized by a high pH with marked eosinophilia.

Clinical Course and Response to Therapy Although some patients improve spontaneously, most patients require admission to an intensive care unit and respiratory support with either invasive (intubation) or noninvasive mechanical ventilation. However, what distinguishes acute eosinophilic pneumonia from both other cases of acute lung injury as well as some of the other pulmonary eosinophilic syndromes is the absence of organ dysfunction or multisystem organ failure other than respiratory failure. One of the characteristic features of acute eosinophilic pneumonia is the high degree of corticosteroid responsiveness and the excellent prognosis. Another distinguishing feature of acute eosinophilic pneumonia is that complete clinical and radiographic recovery without recurrence or residual sequelae occurs in almost all patients within several weeks of initiation of therapy.

CHRONIC EOSINOPHILIC PNEUMONIA

In contrast to acute eosinophilic pneumonia, chronic eosinophilic pneumonia is a more indolent syndrome that is characterized by pulmonary infiltrates and eosinophilia in both the tissue and blood. Most patients are female nonsmokers with a mean age of 45, and patients do not usually develop the acute respiratory failure and significant hypoxemia appreciated in acute eosinophilic pneumonia. Similar to EGPA, a majority have asthma, with many having a history of allergies.

Patients present with a subacute illness over weeks to months, with cough, low-grade fevers, progressive dyspnea, weight loss, wheezing, malaise, and night sweats, and a chest x-ray with migratory bilateral peripheral or pleural-based opacities. Although this "photographic negative pulmonary edema" appearance on chest x-ray and chest CT is pathognomonic of chronic eosinophilic pneumonia, <25% of patients present with this finding. Other radiographic findings include atelectasis, pleural effusions, lymphadenopathy, and septal line thickening.

Almost 90% of patients have peripheral eosinophilia, with mean eosinophil counts of over 30% of total white blood cell count. BAL eosinophilia is also an important distinguishing feature with mean BAL eosinophil counts of ~60%. Both peripheral and BAL eosinophilia are very responsive to treatment with corticosteroids. Other laboratory features of chronic eosinophilic pneumonia include increased ESR, C-reactive protein, platelets, and IgE. Lung biopsy is also often not required to establish a diagnosis but may show accumulation of eosinophils and histiocytes in the lung parenchyma and interstitium, as well as cryptogenic organizing pneumonia, but with minimal fibrosis. Nonrespiratory manifestations are uncommon, but arthralgias, neuropathy, and skin and GI symptoms have all been reported; their presence may suggest EGPA or a hypereosinophilic syndrome. Another similarity is the rapid response to corticosteroids with quick resolution of peripheral and BAL eosinophilia and improvement in symptoms. In contrast to acute eosinophilic pneumonia, though, >50% of patients relapse, and many require prolonged courses of corticosteroids for months to years.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (EGPA)

Previously known as allergic angiitis granulomatosis or Churg-Strauss syndrome, this complex syndrome is characterized by eosinophilic vasculitis that may involve multiple organ systems including the lungs, heart, skin, GI tract, and nervous system. Although EGPA is characterized by peripheral and pulmonary eosinophilia with infiltrates on chest x-ray, the primary features that distinguish EGPA from other pulmonary eosinophilic syndromes are the presence of eosinophilic vasculitis in the setting of asthma and involvement of multiple end organs (a feature it shares with hypereosinophilic syndrome). Although perceived to be quite rare, in the last few years, there has appeared to be an increased incidence of this disease, particularly in association with various asthma therapies, including leukotriene modifiers and anti-IGE therapy with omalizumab, possibly due to concurrent systemic corticosteroid withdrawal (*forme fruste* EGPA), as well as with the anti-IL-4R therapy dupilumab.

The primary features of EGPA include asthma, peripheral eosinophilia, neuropathy, pulmonary infiltrates, paranasal sinus abnormality, and presence of eosinophilic vasculitis. The mean age at diagnosis is 48 years, with a range of 14–74 years; the average length of time between diagnosis of asthma and vasculitis is 9 years. EGPA typically occurs in several phases. The prodromal phase is characterized by asthma and allergic rhinitis, and usually begins when the individual is in their twenties or thirties, typically persisting for many years. The eosinophilic infiltrative phase is characterized by peripheral eosinophilia and eosinophilic tissue infiltration of various organs including the lungs and GI tract. The third phase is the vasculitic phase and may be associated with constitutional signs and symptoms including fever, weight loss, malaise, and fatigue. This phasic progression supports the hypothesis that there is a pathophysiologic continuum between eosinophilic asthma, chronic eosinophilic asthma, and EGPA.

Similar to other pulmonary eosinophilic syndromes, constitutional symptoms are very common in EGPA and include weight loss of 10–20 lb, fevers, and diffuse myalgias and migratory polyarthralgias. Myositis may be present with evidence of vasculitis on muscle biopsies. In contrast to the eosinophilic pneumonias, EGPA involves many organ systems including the lungs, skin, nerves, heart, GI tract, and kidneys.

Symptoms and Clinical Manifestations • **RESPIRATORY** Most EGPA patients have asthma that arises later in life and in individuals who have no family history of atopy. The asthma can often be severe, and oral corticosteroids are often required to control symptoms but may lead to suppression of vasculitic symptoms. In addition to the more common symptoms of cough, dyspnea, sinusitis, and allergic rhinitis, alveolar hemorrhage and hemoptysis may also occur.

NEUROLOGIC Over three-fourths of EGPA patients have neurologic manifestations. Mononeuritis multiplex most commonly involves the peroneal nerve, but also involves the ulnar, radial, internal popliteal, and occasionally, cranial nerves. Cerebral hemorrhage and infarction may also occur and are important causes of death. Despite treatment, neurologic sequelae often do not completely resolve.

DERMATOLOGIC Approximately half of EGPA patients develop dermatologic manifestations. These include palpable purpura, skin nodules, urticarial rashes, and livedo.

CARDIOVASCULAR Granulomas, vasculitis, and widespread myocardial damage may be found on biopsy or at autopsy, and cardiomyopathy and heart failure may be seen in up to half of all patients but are often at least partially reversible. Acute pericarditis, constrictive pericarditis, myocardial infarction, and other electrocardiographic changes all may occur. The heart is a primary target organ in EGPA, and cardiac involvement often portends a worse prognosis.

GI GI symptoms are common in EGPA and likely represent an eosinophilic gastroenteritis characterized by abdominal pain, diarrhea, GI bleeding, and colitis. Ischemic bowel, pancreatitis, and cholecystitis have also been reported in association with EGPA and usually portend a worse prognosis.

RENAL Renal involvement is more common than once thought, and ~25% of patients have some degree of renal involvement. This may include proteinuria, glomerulonephritis, renal insufficiency, and rarely, renal infarct.

Lab Abnormalities Systemic eosinophilia is the hallmark laboratory finding in patients with EGPA and reflects the likely pathogenic role that the eosinophil plays in this disease. Eosinophilia >1000 cells/μL (or >10% of peripheral white blood cell [WBC] count) is one of the defining features of this illness and may be as high as 75% of the total WBC count. It is present at the time of diagnosis in >80% of patients but may respond quickly (often within 24 h) to initiation of systemic corticosteroid therapy. Even in the absence of systemic eosinophilia, tissue eosinophilia may be present.

Although not specific to EGPA, ANCAs are present in approximately one-third of patients, mostly in a perinuclear staining pattern, with specific antibodies against myeloperoxidase detected. Nonspecific lab abnormalities that may be present in patients with EGPA include a marked elevation in ESR, a normochromic normocytic anemia, an elevated IgE, hypergammaglobulinemia, and positive rheumatoid factor and antinuclear antibodies (ANA). Although BAL often reveals significant eosinophilia, this may be seen in other eosinophilic lung diseases. Similarly, PFT often reveals an obstructive defect similar to asthma.

Radiographic Features Chest x-ray abnormalities are extremely common in EGPA and consist of bilateral, nonsegmental, patchy infiltrates that often migrate and may be interstitial or alveolar in appearance. Reticulonodular and nodular disease without cavitation can be seen, as can pleural effusions and hilar adenopathy. The most common CT findings include bilateral ground-glass opacity and airspace consolidation that is predominantly subpleural. Other CT findings include bronchial wall thickening, hyperinflation, interlobular septal thickening, lymph node enlargement, and pericardial and pleural effusions. Angiography may be used diagnostically and may show signs of vasculitis in the coronary, central nervous system, and peripheral vasculature.

Treatment and Prognosis of EGPA Most patients diagnosed with EGPA have previously been diagnosed with asthma, rhinitis, and sinusitis, and have received treatment with inhaled or systemic corticosteroids. Because these agents are also the initial treatment of choice for EGPA patients, institution of these therapies in patients with EGPA who are perceived to have severe asthma may delay the diagnosis of EGPA because signs of systemic eosinophilia and vasculitis may be masked. Corticosteroids dramatically alter the course of EGPA: up to 50% of those who are untreated die within 3 months of diagnosis, whereas treated patients have a 6-year survival of >70%. Common causes of death include heart failure, cerebral hemorrhage, renal failure, and GI bleeding. Recent data suggest that clinical remission may be obtained in >90% of patients treated; ~25% of those patients may relapse, often due to corticosteroid tapering, with a rising eosinophil count heralding the relapse. Myocardial, GI, and renal involvement most often portend a poor prognosis. In such cases, induction treatment with higher doses of corticosteroids or the addition of cytotoxic agents such as cyclophosphamide or anti-CD20 therapy with rituximab is often warranted. Although survival does not differ between those treated or untreated with cyclophosphamide, cyclophosphamide is associated with a reduced incidence of relapse and an improved clinical response to treatment. Recent studies examining the efficacy of anti-IL-5 (mepolizumab) or anti-IL-5 receptor therapy (benralizumab) have shown promise, indicating that these therapies are safe and effective corticosteroid-sparing agents that can reduce relapses and induce remission. Other therapies that have been used successfully in the management of EGPA include azathioprine, methotrexate, rituximab, omalizumab, intravenous gamma globulin, and interferon α. Plasma exchange has not been shown to provide any additional benefit.

HYPEREOSINOPHILIC SYNDROMES

Hypereosinophilic syndromes (HES) constitute a heterogeneous group of disease entities manifest by persistent eosinophilia >1500 eosinophils/μL in association with end organ damage or dysfunction, in the absence of secondary causes of eosinophilia. In addition to familial, undefined, and overlap syndromes with incomplete criteria, the predominant HES subtypes are the myeloproliferative and lymphocytic variants. The myeloproliferative variants may have acquired genetic abnormalities, including of platelet-derived growth factor receptor α (PDGFRα), attributed to a constitutively activated tyrosine kinase fusion protein (Fip1L1-PDGFRα) due to a chromosomal deletion on 4q12; this variant is often responsive to imatinib. Myeloproliferative HES may also be associated with mutations involving platelet-derived growth factor β (PDGFRβ), Janus kinase 2 (JAK2), and fibroblast growth factor receptor 1 (FGFR1). Chronic eosinophilic leukemia with demonstrable cytogenetic abnormalities and/or blasts on peripheral smear is often categorized with the myeloproliferative HES. Clinical and laboratory findings in myeloproliferative HES may include dysplastic peripheral eosinophils, increased serum vitamin B_{12}, increased tryptase, anemia, thrombocytopenia, splenomegaly, bone marrow cellularity >80%, spindle-shaped mast cells, and myelofibrosis. The evaluation for lymphocytic HES includes searching for abnormal T-cell clonal populations.

Extrapulmonary Manifestations of HES More common in men than in women, HES occurs between the ages of 20 and 50 and is characterized by significant extrapulmonary involvement, including infiltration of the heart, GI tract, kidney, liver, joints, and skin. Cardiac involvement includes myocarditis and/or endomyocardial fibrosis, as well as a restrictive cardiomyopathy.

Pulmonary Manifestations of HES Similar to the other pulmonary eosinophilic syndromes, these HES are manifested by high levels of blood, BAL, and tissue eosinophilia. Lung involvement occurs in 40% of these patients and is characterized by cough and dyspnea, as well as pulmonary infiltrates. Although it is often difficult to discern the pulmonary infiltrates and effusions seen on chest x-ray from pulmonary edema resulting from cardiac involvement, computed tomography (CT) scan findings include interstitial infiltrates, ground-glass opacities, and small nodules. HES are typically not associated with ANCA. IgE may be elevated in lymphocytic HES variants.

Course and Response to Therapy Unlike the other pulmonary eosinophilic syndromes, less than half of patients with these HES respond to corticosteroids as first-line therapy. Although other treatment options include hydroxyurea, cyclosporine, and interferon, the tyrosine kinase inhibitor imatinib has emerged as an important therapeutic option for patients with the myeloproliferative variant, particularly in individuals with the *Fip1L1-PDGFRA* gene fusion. Anti-IL-5 therapy with mepolizumab has demonstrated efficacy for HES, while benralizumab also holds promise for these patients and is currently being investigated.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis (ABPA) is an eosinophilic pulmonary disorder that occurs in response to allergic sensitization to antigens from *Aspergillus* species fungi. The predominant clinical presentation of ABPA is an asthmatic phenotype, often accompanied by cough with production of brownish plugs of mucus. ABPA has also been well described as a complication of cystic fibrosis. A workup for ABPA may be beneficial in patients who carry a diagnosis of asthma but have proven refractory to usual therapy. ABPA is a distinct diagnosis from simple asthma, characterized by prominent peripheral eosinophilia and elevated circulating levels of IgE (>500 IU/mL, but often >1000 IU/mL). Establishing a diagnosis of ABPA also requires establishing sensitivity to *Aspergillus* antigens by skin test reactivity and/or direct measurement of circulating specific IgE to *Aspergillus*. Positive serum precipitins for *Aspergillus* or direct measurement of circulating specific IgG to *Aspergillus* can be used as an adjunct diagnostic criterion. Central bronchiectasis is described as a classic finding on chest imaging in ABPA but is not necessary for making a diagnosis. Other possible findings on chest imaging include patchy infiltrates and evidence of mucus impaction.

Systemic glucocorticoids may be used in the treatment of ABPA that is persistently symptomatic despite the use of inhaled therapies for asthma. Courses of glucocorticoids should be tapered over 3–6 months, and their use must be balanced against the risks of prolonged steroid therapy. Antifungal agents such as itraconazole and voriconazole given

over a 4-month course reduce the antigenic stimulus in ABPA and may therefore modulate disease activity in selected patients. Newer azole agents may be used as well. The use of monoclonal antibody against IgE (omalizumab) has been described in treating severe ABPA, particularly in individuals with ABPA as a complication of cystic fibrosis. Other monoclonal antibodies used in severe eosinophilic asthma, such as those targeting IL-5 (or its receptor) or targeting IL-4-receptor-alpha have also demonstrated efficacy in small case series.

ABPA-like syndromes have been reported as a result of sensitization to several non-*Aspergillus* species fungi. However, these conditions are substantially rarer than ABPA, which may be present in a significant proportion of patients with refractory asthma.

INFECTIOUS PROCESSES

Infectious etiologies of pulmonary eosinophilia are largely due to helminths and are of particular importance in the evaluation of pulmonary eosinophilia in tropical environments and in the developing world (Table 299-4). These infectious conditions may also be considered in recent travelers to endemic regions. Loffler syndrome refers to transient pulmonary infiltrates with eosinophilia that occurs in response to passage of helminthic larvae through the lungs, most commonly larvae of *Ascaris* species (roundworm). Symptoms are generally self-limited and may include dyspnea, cough, wheeze, and hemoptysis. Loffler syndrome may also occur in response to hookworm infection with *Ancylostoma duodenale* or *Necator americanus*. Chronic *Strongyloides stercoralis* infection can lead to recurrent respiratory symptoms with peripheral eosinophilia between flares. In immunocompromised hosts, including patients on glucocorticoids, a severe, potentially fatal, hyperinfection syndrome can result from *Strongyloides* infection. Paragonimiasis, filariasis, and visceral larval migrans can all cause pulmonary eosinophilia as well.

DRUGS AND TOXINS

A host of medications are associated with the development of pulmonary infiltrates with peripheral eosinophilia. Therefore, drug reaction must always be included in the differential diagnosis of pulmonary eosinophilia. Although the list of medications associated with pulmonary eosinophilia is ever expanding, common culprits include nonsteroidal anti-inflammatory medications and systemic antibiotics. Additionally, various and diverse environmental exposures such as particulate metals, scorpion stings, and inhalational drugs of abuse may also cause pulmonary eosinophilia. Radiation therapy for breast cancer has been linked with eosinophilic pulmonary infiltration as well. The mainstay of treatment is removal of the offending exposure, although glucocorticoids may be necessary if respiratory symptoms are severe.

GLOBAL CONSIDERATIONS

In the United States, drug-induced eosinophilic pneumonias are the most common cause of eosinophilic pulmonary infiltrates. A travel history or evidence of recent immigration should prompt the consideration of parasite-associated disorders. Tropical eosinophilia is usually caused by filarial infection; however, eosinophilic pneumonias also occur with other parasites such as *Ascaris* spp., *Ancylostoma* spp., *Toxocara* spp., and *Strongyloides stercoralis*. Tropical eosinophilia due to *Wuchereria bancrofti* or *Wuchereria malayi* occurs most commonly in southern Asia, Africa, and South America and is treated successfully with diethylcarbamazine. In the United States, *Strongyloides* is endemic to the southeastern and Appalachian regions.

300 Occupational and Environmental Lung Disease

John R. Balmes, Mehrdad Arjomandi

Occupational and environmental lung diseases are difficult to distinguish from those of nonenvironmental origin. Virtually all major categories of pulmonary disease can be caused by environmental agents, and environmentally related disease usually presents clinically in a manner indistinguishable from that of disease not caused by such agents. In addition, the etiology of many diseases may be multifactorial; occupational and environmental factors may interact with other factors (such as smoking and genetic risk). It is often only after a careful exposure history is taken that the underlying workplace or general environmental exposure is uncovered.

Why is knowledge of occupational or environmental etiology so important? Patient management and prognosis are affected significantly by such knowledge. For example, patients with occupational asthma or hypersensitivity pneumonitis often cannot be managed adequately without cessation of exposure to the offending agent. Establishment of cause may have significant legal and financial implications for a patient who no longer can work in their usual job. Other exposed people may be identified as having the disease or prevented from getting it. In addition, new associations between exposure and disease may be identified (e.g., nylon flock worker's lung disease, diacetyl-induced bronchiolitis obliterans, military burn pit-related constrictive bronchiolitis).

Although the exact proportion of lung disease due to occupational and environmental factors is unknown, a large number of individuals are at risk. For example, 15–20% of the burden of adult asthma and

chronic obstructive pulmonary disease (COPD) has been estimated to be due to occupational factors.

HISTORY AND EXPOSURE ASSESSMENT

The patient's history is of paramount importance in assessing any potential occupational or environmental exposure. Inquiry into specific work practices should include questions about the specific contaminants involved, the presence of visible dust, chemical odors, the size and ventilation of workspaces, the use of respiratory protective equipment, and whether coworkers have similar complaints. The temporal association of exposure at work and symptoms may provide clues to occupation-related disease. In addition, the patient must be questioned about alternative sources of exposure to potentially toxic agents, including hobbies, home characteristics, exposure to secondhand tobacco smoke, and proximity to traffic or industrial facilities. Short-term and long-term exposures to potential toxic agents in the distant past also must be considered.

In the United States, workers have the right to know about potential hazards in their workplaces under federal Occupational Safety and Health Administration (OSHA) regulations. Employers must provide specific information about potential hazardous agents in products being used through Safety Data Sheets as well as training in personal protective equipment and environmental control procedures. However, the introduction of new processes and/or new chemical compounds may change exposure significantly, and often only the employee on the production line is aware of the change. For the physician caring for a patient with a suspected work-related illness, a visit to the work site can be very instructive. Alternatively, an affected worker can request an inspection by OSHA. If reliable environmental sampling data are available, that information should be used in assessing a patient's exposure. Because chronic diseases may result from exposure over many years, current environmental measurements should be combined with work histories to arrive at estimates of past exposure.

LABORATORY TESTS

Exposures to inorganic and organic dust can cause interstitial lung disease that presents with a restrictive pattern and a decreased diffusing capacity **(Chap. 296)**. Similarly, exposure to various dusts or chemical agents may result in occupational asthma or COPD that is characterized by airway obstruction. Measurement of change in forced expiratory volume in 1 second (FEV_1) before and after a working shift can be used to detect an acute bronchoconstrictive response.

The chest radiograph is useful in detecting and monitoring the pulmonary response to mineral dusts, certain metals, and organic dusts capable of inducing hypersensitivity pneumonitis. The International Labour Organisation (ILO) International Classification of Radiographs of Pneumoconioses classifies chest radiographs by the nature and size of opacities seen and the extent of involvement of the parenchyma. In general, small, rounded opacities are seen in silicosis or coal worker's pneumoconiosis, and small linear opacities are seen in asbestosis. Although useful for epidemiologic studies and screening large numbers of workers, the ILO system can be problematic when applied to an individual worker's chest radiograph. With dust causing rounded opacities, the degree of involvement on the chest radiograph may be extensive, whereas pulmonary function may be only minimally impaired. In contrast, in pneumoconiosis causing linear, irregular opacities like those seen in asbestosis, the radiograph may lead to underestimation of the severity of the impairment until relatively late in the disease. For patients with a history of dust exposure, conventional computed tomography (CT) is more sensitive for the detection of lung opacities and pleural thickening, and high-resolution CT (HRCT) improves the detection of interstitial changes.

Other procedures that may be of use in identifying the role of environmental exposures in causing lung disease include skin prick testing or specific immunoglobulin type E (IgE) antibody titers for evidence of immediate hypersensitivity to agents capable of inducing occupational asthma (e.g., flour antigens in bakers), specific immunoglobulin type G (IgG) precipitating antibody titers for agents capable of causing hypersensitivity pneumonitis (e.g., pigeon antigen in bird handlers), and assays for specific cell-mediated immune responses (e.g., beryllium lymphocyte proliferation testing in nuclear workers). Sometimes a bronchoscopy to obtain transbronchial biopsies of lung tissue may be required for histologic diagnosis (chronic beryllium disease [CBD]). Rarely, video-assisted thoracoscopic surgery to obtain a larger sample of lung tissue may be required to determine the specific diagnosis of environmentally induced lung disease (hypersensitivity pneumonitis, constrictive bronchiolitis, or giant cell interstitial pneumonitis due to cobalt exposure).

DETERMINANTS OF INHALATIONAL EXPOSURE

The chemical and physical characteristics of inhaled agents affect both the dose and the site of deposition in the respiratory tract. Water-soluble gases such as ammonia and sulfur dioxide are absorbed in the lining fluid of the upper and proximal airways and thus tend to produce irritative and bronchoconstrictive responses. In contrast, nitrogen dioxide and phosgene, which are less soluble, may penetrate to the bronchioles and alveoli in sufficient quantities to produce acute chemical pneumonitis.

Particle size of air contaminants must also be considered. Because of their settling velocities in air, particles >10–15 μm in diameter do not penetrate beyond the nose and throat. Particles <10 μm in size are deposited below the larynx. These particles are divided into three size fractions on the basis of their size characteristics and sources. Particles ~2.5–10 μm (coarse-mode fraction) contain crustal elements such as silica, aluminum, and iron. These particles mostly deposit relatively high in the tracheobronchial tree. Although the total mass of an ambient sample is dominated by these larger respirable particles, the number of particles, and therefore the surface area on which potential toxic agents can deposit and be carried to the lower airways, is dominated by particles <2.5 μm (fine-mode fraction). These fine particles are created primarily by the burning of fossil fuels or high-temperature industrial processes resulting in condensation products from gases, fumes, or vapors. The smallest particles, those <0.1 μm in size, represent the ultrafine fraction and make up the largest number of particles; they tend to remain in the airstream and deposit in the lung only on a random basis as they come into contact with the alveolar walls. If they do deposit, however, particles of this size range may penetrate into the circulation and be carried to extrapulmonary sites. New technologies create particles of this size ("nanoparticles") for use in many commercial applications. Besides the size characteristics of particles and the solubility of gases, the actual chemical composition, mechanical properties, and immunogenicity or infectivity of inhaled material determine in large part the nature of the diseases found among exposed persons.

OCCUPATIONAL EXPOSURES AND PULMONARY DISEASE

Table 300-1 provides broad categories of exposure in the workplace and diseases associated with chronic exposure in those industries.

ASBESTOS-RELATED DISEASES

Asbestos is a generic term for several different mineral silicates, including chrysolite, amosite, anthophyllite, and crocidolite. In addition to workers involved in the production of asbestos products (mining, milling, and manufacturing), many workers in the shipbuilding and construction trades, including pipe fitters and boilermakers, were occupationally exposed because asbestos was widely used during the twentieth century for its thermal and electrical insulation properties. Asbestos also was used in the manufacture of fire-resistant textiles, in cement and floor tiles, and in friction materials such as brake and clutch linings.

Exposure to asbestos is not limited to persons who directly handle the material. Cases of asbestos-related diseases have been encountered in individuals with only bystander exposure, such as painters and electricians who worked alongside insulation workers in a shipyard. Community exposure resulted from the use of asbestos-containing mine and mill tailings as landfill, road surface, and playground material (e.g., Libby, Montana, the site of a vermiculite mine in which the

TABLE 300-1 Categories of Occupational Exposure and Associated Respiratory Conditions

OCCUPATIONAL EXPOSURES	NATURE OF RESPIRATORY RESPONSES	COMMENT
Inorganic Dusts		
Asbestos: mining, processing, construction, ship repair	Fibrosis (asbestosis), pleural disease, cancer, mesothelioma	Virtually all new mining and construction with asbestos done in developing countries
Silica: mining, stone cutting, sandblasting, quarrying, artificial stone manufacture and installation	Fibrosis (silicosis), progressive massive fibrosis (PMF), cancer, tuberculosis, chronic obstructive pulmonary disease (COPD)	Improved protection in United States; persistent risk in developing countries
Coal dust: mining	Fibrosis (coal worker's pneumoconiosis), PMF, COPD	Risk persists in certain areas of United States, increasing in countries where new mines open
Beryllium: processing alloys for nuclear power and weapons, aerospace, and electronics	Acute pneumonitis (rare), chronic granulomatous disease, lung cancer (highly suspect)	Risk in high-tech industries persists
Other metals: aluminum, chromium, cobalt, nickel, titanium, tungsten carbide, or "hard metal" (contains cobalt)	Wide variety of conditions from acute pneumonitis to lung cancer and asthma	New diseases appear with new process development
Organic Dusts		
Cotton dust: milling, processing	Byssinosis (an asthma-like syndrome), chronic bronchitis, COPD	Increasing risk in developing countries with drop in United States as jobs shift overseas
Grain dust: elevator agents, dock workers, milling, bakers	Asthma, chronic bronchitis, COPD	Risk shifting more to migrant labor pool
Other agricultural dusts: fungal spores, vegetable products, insect fragments, animal dander, bird and rodent feces, endotoxins, microorganisms, pollens	Hypersensitivity pneumonitis (farmer's lung), asthma, chronic bronchitis	Important in migrant labor pool but also resulting from in-home exposures
Toxic chemicals: wide variety of industries; see Table 300-2	Asthma, chronic bronchitis, COPD, hypersensitivity pneumonitis, pneumoconiosis, and cancer	Reduced risk with recognized hazards; increasing risk for developing countries where controlled labor practices are less stringent
Other Environmental Agents		
Uranium and radon daughters, secondhand tobacco smoke, polycyclic aromatic hydrocarbons (PAHs), biomass smoke, diesel exhaust, welding fumes, wood finishing	Occupational exposures estimated to contribute to up to 10% of all lung cancers; chronic bronchitis, COPD, and fibrosis	In-home exposures important; in developing countries, biomass smoke is a major risk factor for COPD among women in these countries

ore was contaminated with asbestos). Finally, exposure can occur from the disturbance of naturally occurring asbestos (e.g., from increasing residential development in the foothills of the Sierra Mountains in California).

Asbestos has largely been replaced in the developed world with synthetic mineral fibers such as fiberglass and refractory ceramic fibers, but it continues to be used in the developing world. The major health effects from exposure to asbestos are pleural and pulmonary fibrosis, cancers of the respiratory tract, and pleural and peritoneal mesothelioma.

Asbestosis is a diffuse interstitial fibrosing disease of the lung that is directly related to the intensity and duration of exposure. The disease resembles other forms of diffuse interstitial fibrosis **(Chap. 304)**. Usually, exposure has taken place for at least 10 years before the disease becomes manifest. The mechanisms by which asbestos fibers induce lung fibrosis are not completely understood but are known to involve oxidative injury due to the generation of reactive oxygen species by the transition metals on the surface of the fibers as well as from cells engaged in phagocytosis.

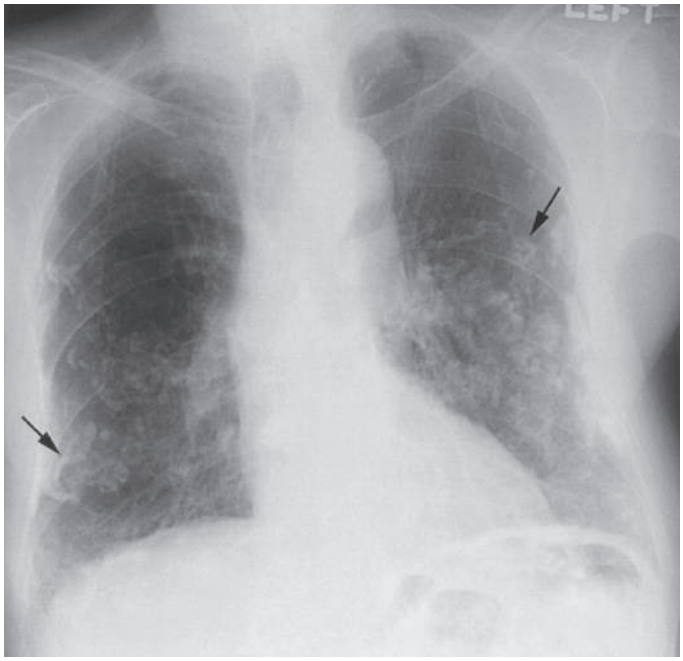
Past exposure to asbestos is specifically indicated by pleural plaques on chest radiographs, which are characterized by either thickening or calcification along the parietal pleura, particularly along the lower lung fields, the diaphragm, and the cardiac border. Without additional manifestations, pleural plaques imply only exposure, not pulmonary impairment. Benign pleural effusions also may occur.

Irregular or linear opacities that usually are first noted in the lower lung fields are the chest radiographic hallmark of asbestosis. An indistinct heart border or a "ground-glass" appearance in the lung fields may be seen. HRCT may show distinct changes of subpleural curvilinear lines 5–10 mm in length that appear to be parallel to the pleural surface **(Fig. 300-1)**.

Pulmonary function testing in asbestosis reveals a restrictive pattern with a decrease in both lung volumes and diffusing capacity. There may also be evidence of mild airflow obstruction (due to peribronchiolar fibrosis).

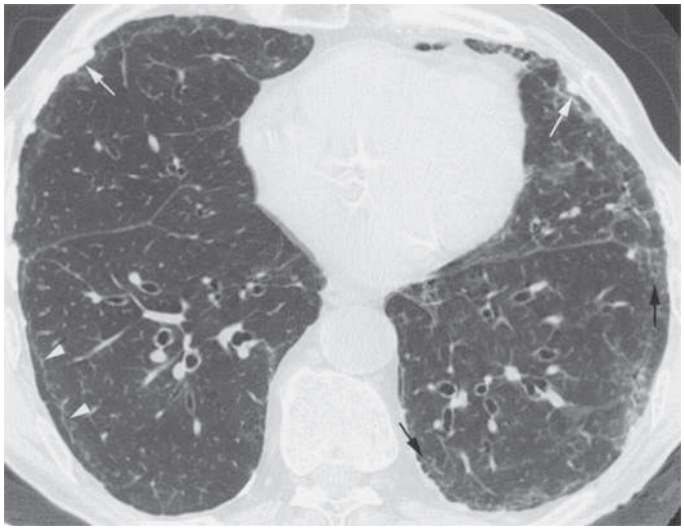
Because no specific therapy is available for asbestosis, supportive care is the same as that given to any patient with diffuse interstitial fibrosis of any cause. In general, newly diagnosed cases will have resulted from exposures that occurred many years before.

Lung cancer **(Chap. 83)** is the most common cancer associated with asbestos exposure. The excess frequency of lung cancer (all histologic types) in asbestos workers is associated with a minimum latency of 15–19 years between first exposure and development of the disease. Persons with more exposure are at greater risk of disease. In addition, there is a significant interactive effect of smoking and asbestos exposure that results in greater risk than what would be expected from the additive effect of each factor.



Mesotheliomas **(Chap. 305)**, both pleural and peritoneal, are also associated with asbestos exposure. In contrast to lung cancers, these tumors do not appear to be associated with smoking. Relatively short-term asbestos exposures of ≤1–2 years, occurring up to 40 years in the past, have been associated with the development of mesotheliomas (an observation that emphasizes the importance of obtaining a complete environmental exposure history). Although the risk of mesothelioma is much less than that of lung cancer among asbestos-exposed workers, ~3000 cases per year are diagnosed in the United States.

Because epidemiologic studies have shown that >80% of mesotheliomas may be associated with asbestos exposure, documented mesothelioma in a patient with occupational or environmental exposure to asbestos may be compensable.



SILICOSIS

Despite being one of the oldest known occupational pulmonary hazards, *free silica* (SiO_2), or crystalline quartz, is still a major cause of disease. The major occupational exposures include mining; stonecutting; sand blasting; glass and cement manufacturing; foundry work; packing of silica flour; and quarrying, particularly of granite. Most often, pulmonary fibrosis due to silica exposure (silicosis) occurs in a dose-response fashion after many years of exposure. Two recent outbreaks of silicosis have involved sandblasting of denim jeans to make them look "used" and manufacture and installation of artificial stone ("faux granite") kitchen countertops.

Workers heavily exposed through sandblasting in confined spaces, tunneling through rock with a high quartz content (15–25%), or the

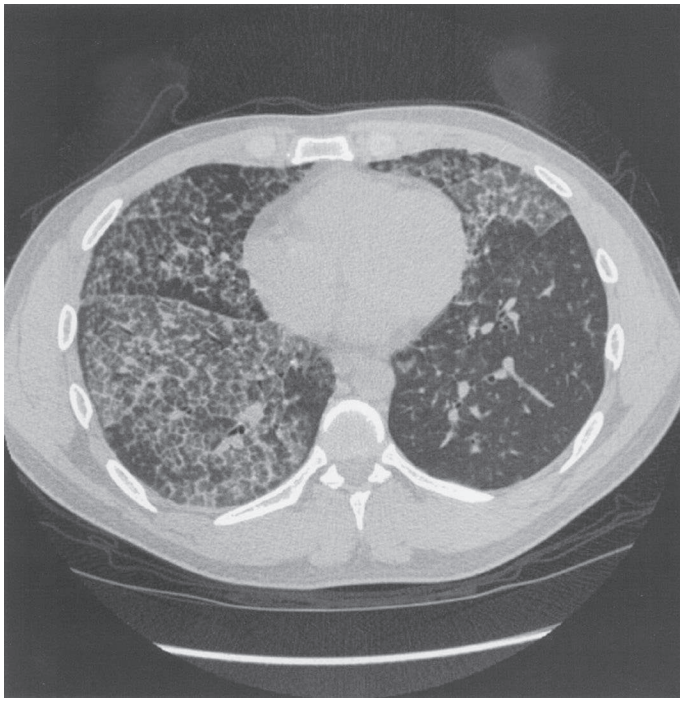
A

B

FIGURE 300-1 Asbestosis. ***A.*** Frontal chest radiograph shows bilateral calcified pleural plaques consistent with asbestos-related pleural disease. Poorly defined linear and reticular abnormalities are seen in the lower lobes bilaterally. ***B.*** Axial high-resolution computed tomography of the thorax obtained through the lung bases shows bilateral, subpleural reticulation (*black arrows*), representing fibrotic lung disease due to asbestosis. Subpleural lines are also present (*arrowheads*), characteristic of, though not specific for, asbestosis. Calcified pleural plaques representing asbestos-related pleural disease (*white arrows*) are also evident.

manufacture of artificial stone countertops may develop acute silicosis with only months of exposure. The clinical and pathologic features of acute silicosis are similar to those of pulmonary alveolar proteinosis (Chap. 304). The chest radiograph may show profuse miliary infiltration or consolidation, and a characteristic HRCT pattern known as "crazy paving" could be present (Fig. 300-2). The disease may be quite severe and progressive despite the discontinuation of exposure. Whole-lung lavage may provide symptomatic relief and slow the progression.

With long-term, less intense exposure, small rounded opacities in the upper lobes may appear on the chest radiograph after 15–20 years of exposure, usually without associated impairment of lung function (*simple silicosis*). Calcification of hilar nodes may occur in as many as 20% of cases and produces a characteristic "eggshell" pattern. Silicotic nodules may be identified more readily by HRCT (Fig. 300-3). The nodular fibrosis may be progressive in the absence of further exposure, with coalescence and formation of nonsegmental conglomerates



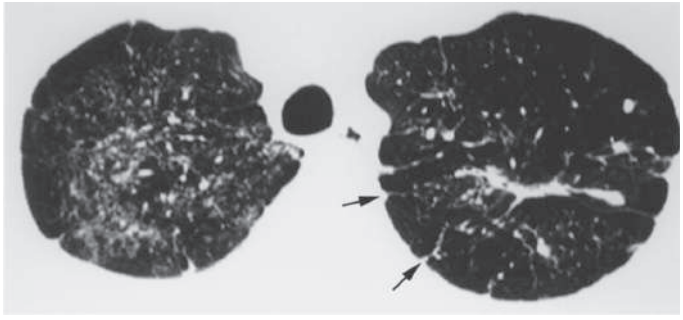


FIGURE 300-2 Acute silicosis. This high-resolution computed tomography scan shows multiple small nodules consistent with silicosis but also diffuse ground-glass densities with thickened intralobular and interlobular septa producing polygonal shapes. This has been referred to as "crazy paving."

A

B

FIGURE 300-3 Chronic silicosis. ***A.*** Frontal chest radiograph in a patient with silicosis shows variably sized, poorly defined nodules (*arrows*) predominating in the upper lobes. ***B.*** Axial thoracic computed tomography image through the lung apices shows numerous small nodules, more pronounced in the right upper lobe. A number of the nodules are subpleural in location (*arrows*).

of irregular masses >1 cm in diameter (*complicated silicosis*). These masses can become quite large, and when this occurs, the term *progressive massive fibrosis* (PMF) is applied. Significant functional impairment with both restrictive and obstructive components may be associated with PMF.

Because silica causes alveolar macrophage dysfunction, patients with silicosis are at greater risk of acquiring lung infections that involve these cells as a primary defense (*Mycobacterium tuberculosis*, atypical mycobacteria, and fungi). Because of the increased risk of active tuberculosis, the recommended treatment of latent tuberculosis in these patients is longer. Silica has immunoadjuvant properties, and another potential clinical complication of silicosis is autoimmune connective tissue disorders such as rheumatoid arthritis and scleroderma. In addition, there are sufficient epidemiologic data that the International Agency for Research on Cancer lists silica as a probable lung carcinogen.

Other, less hazardous silicates include fuller's earth, kaolin, mica, diatomaceous earths, silica gel, soapstone, carbonate dusts, and cement dusts. The production of fibrosis in workers exposed to these agents is believed to be related either to the free silica content of these dusts or, for substances that contain no free silica, to the potentially large dust loads to which these workers may be exposed. Some silicates, including *talc* and *vermiculite*, may be contaminated with asbestos. Fibrosis of lung or pleura, lung cancer, and mesothelioma have been associated with chronic exposure to talc and vermiculite dusts.

COAL WORKER'S PNEUMOCONIOSIS (CWP)

Occupational exposure to *coal dust* can lead to CWP, which has enormous social, economic, and medical significance in every nation in which coal mining is an important industry. Simple radiographically identified CWP is seen in ~10% of all coal miners and in as many as 50% of anthracite miners with >20 years of work on the coal face. The prevalence of disease is lower in workers in bituminous coal mines.

With prolonged exposure to coal dust (i.e., 15–20 years), small, rounded opacities similar to those of silicosis may develop. As in silicosis, the presence of these nodules (*simple CWP*) usually is not associated with pulmonary impairment. In addition to CWP, coal dust can cause chronic bronchitis and COPD **(Chap. 303)**. The effects of coal dust are additive to those of cigarette smoking.

Complicated CWP is manifested by the appearance on the chest radiograph of nodules ≥1 cm in diameter generally confined to the upper half of the lungs. As in silicosis, this condition can progress to PMF that is accompanied by severe lung function deficits and associated with premature mortality. Silica is often present in anthracitic coal dust, and its presence may contribute to risk of PMF. Due to increased mechanization and narrower veins of coal with more silica contamination of mine dust, cases of PMF are occurring in the Appalachian coal belt at an alarming rate.

Caplan syndrome **(Chap. 370)**, first described in coal miners but subsequently in patients with silicosis, is the combination of pneumoconiotic nodules and seropositive rheumatoid arthritis.

CHRONIC BERYLLIUM DISEASE

Beryllium is a lightweight metal with tensile strength, good electrical conductivity, and value in the control of nuclear reactions through its ability to quench neutrons. Although beryllium may produce an acute pneumonitis, it is far more commonly associated with a chronic granulomatous inflammatory disease that is similar to sarcoidosis **(Chap. 379)**. Unless one inquires specifically about occupational exposures to beryllium in the manufacture of alloys, ceramics, or high-technology electronics in a patient with sarcoidosis, one may miss entirely the etiologic relationship to the occupational exposure. Combat-related embedded metal fragments (shrapnel) in military veterans may also contain beryllium and thus be a source of exposure to the metal. What distinguishes chronic beryllium disease (CBD) from sarcoidosis is evidence of a specific cell-mediated immune response (i.e., delayed hypersensitivity) to beryllium.

The test that usually provides this evidence is the beryllium lymphocyte proliferation test (BeLPT). The BeLPT compares the in vitro proliferation of lymphocytes from blood or bronchoalveolar lavage in the presence of beryllium salts with that of unstimulated cells. Proliferation is usually measured by lymphocyte uptake of radiolabeled thymidine.

Chest imaging findings are similar to those of sarcoidosis (nodules along septal lines) except that hilar adenopathy is somewhat less common. As with sarcoidosis, pulmonary function test results may show restrictive and/or obstructive ventilatory deficits and decreased diffusing capacity. With early disease, both chest imaging studies and pulmonary function tests may be normal. Fiberoptic bronchoscopy with transbronchial lung biopsy usually is required to make the diagnosis of CBD. In a beryllium-sensitized individual, the presence of noncaseating granulomas or monocytic infiltration in lung tissue establishes the diagnosis. Accumulation of beryllium-specific CD4+ T cells occurs in the granulomatous inflammation seen on lung biopsy. Susceptibility to CBD is highly associated with human leukocyte antigen DP (HLA-DP) alleles that have a glutamic acid in position 69 of the β chain.

OTHER METALS

Aluminum and titanium dioxide have been rarely associated with a sarcoid-like reaction in lung tissue. Exposure to dust containing tungsten carbide, also known as "hard metal," may produce giant cell interstitial pneumonitis. Cobalt is a constituent of tungsten carbide and is the likely etiologic agent of both the interstitial pneumonitis and the occupational asthma that may occur. The most common exposures to tungsten carbide occur in tool and dye, saw blade, and drill bit manufacture. Diamond polishing may also involve exposure to cobalt dust. In patients with interstitial lung disease, one should always inquire about exposure to metal fumes and/or dusts. Especially when sarcoidosis appears to be the diagnosis, one should always consider possible CBD.

OTHER INORGANIC DUSTS

Most of the inorganic dusts discussed thus far are associated with the production of either dust macules or interstitial fibrotic changes in the lung. Other inorganic and organic dusts (see categories in Table 300-1), along with some of the dusts previously discussed, are associated with chronic mucus hypersecretion (chronic bronchitis), with or without reduction of expiratory flow rates. Cigarette smoking is the major cause of these conditions, and any effort to attribute some component of the disease to occupational and environmental exposures must take cigarette smoking into account. Most studies suggest an additive effect of dust exposure and smoking. The pattern of the irritant dust effect is similar to that of cigarette smoking, suggesting that small airway inflammation may be the initial site of pathologic response in those cases and continued exposure may lead to chronic bronchitis and COPD.

ORGANIC DUSTS

Some of the specific diseases associated with organic dusts are discussed in detail in the chapters on asthma **(Chap. 298)** and hypersensitivity pneumonitis **(Chap. 299)**. Many of these diseases are named for the specific setting in which they are found, e.g., farmer's lung, malt worker's disease, and mushroom worker's disease. Often the temporal relation of symptoms to exposure furnishes the best evidence for the diagnosis. Three occupational exposures are singled out for discussion here because they affect the largest proportions of workers.

Cotton Dust (Byssinosis) Workers occupationally exposed to cotton dust (but also to flax, hemp, or jute dust) in the production of yarns for textiles and rope making are at risk for an asthma-like syndrome known as byssinosis. The risk of byssinosis is associated with both cotton dust and endotoxin levels in the workplace environment.

Byssinosis is characterized clinically as occasional (early-stage) and then regular (late-stage) chest tightness toward the end of the first day of the workweek ("Monday chest tightness"). Exposed workers may show a significant drop in FEV_1 over the course of a Monday work shift. Initially the symptoms do not recur on subsequent days of the week, but in a subset of workers, chest tightness may recur or persist throughout the workweek. After >10 years of exposure, workers with

recurrent symptoms are more likely to have an obstructive pattern on pulmonary function testing.

Dust exposure can be reduced by the use of exhaust hoods, general increases in ventilation, and wetting procedures, but respiratory protective equipment may be required during certain operations. Regular surveillance of pulmonary function in cotton dust–exposed workers using spirometry before and after the work shift is required by OSHA. All workers with persistent symptoms or significantly reduced levels of pulmonary function should be moved to areas of lower risk of exposure.

Grain Dust Worldwide, many farmers and workers in grain storage facilities are exposed to grain dust. The presentation of obstructive airway disease in grain dust–exposed workers is virtually identical to the characteristic findings in cigarette smokers, i.e., persistent cough, mucus hypersecretion, wheeze and dyspnea on exertion, and reduced FEV_1 and FEV_1/FVC (forced vital capacity) ratio **(Chap. 296)**.

Dust concentrations in grain elevators vary greatly but can be >10,000 μg/m^3 with many particles in the respirable size range. The effect of grain dust exposure is additive to that of cigarette smoking, with ~50% of workers who smoke having symptoms. Smoking grain dust–exposed workers are more likely to have obstructive ventilatory deficits on pulmonary function testing. As in byssinosis, endotoxin may play a role in grain dust–induced chronic bronchitis and COPD.

Farmer's Lung This condition results from exposure to moldy hay containing spores of thermophilic actinomycetes that produce a hypersensitivity pneumonitis **(Chap. 299)**. A patient with acute farmer's lung presents 4–8 h after exposure with fever, chills, malaise, cough, and dyspnea without wheezing. The history of exposure is obviously essential to distinguish this disease from influenza or pneumonia with similar symptoms. In the chronic form of the disease, the history of repeated attacks after similar exposure is important in differentiating this syndrome from other causes of patchy fibrosis (e.g., sarcoidosis).

A wide variety of other organic dusts are associated with the occurrence of hypersensitivity pneumonitis **(Chap. 299)**. For patients who present with hypersensitivity pneumonitis, specific and careful inquiry about occupations, hobbies, and other home environmental exposures is necessary to uncover the source of the etiologic agent.

TOXIC CHEMICALS

Exposure to toxic chemicals affecting the lung generally involves gases and vapors. A common accident is one in which the victim is trapped in a confined space where the chemicals have accumulated to harmful levels. In addition to the specific toxic effects of the chemical, the victim often sustains considerable anoxia, which can play a dominant role in determining whether the individual survives.

Table 300-2 lists a variety of toxic agents that can produce acute and sometimes life-threatening reactions in the lung. All these agents in sufficient concentrations have been demonstrated, at least in animal studies, to affect the lower airways and disrupt alveolar architecture, either acutely or as a result of chronic exposure.

Firefighters and fire victims are at risk of *smoke inhalation*, an important cause of acute cardiorespiratory failure. Smoke inhalation kills more fire victims than does thermal injury. Carbon monoxide poisoning with resulting significant hypoxemia can be life-threatening **(Chap. 470)**.

TABLE 300-2 Selected Common Toxic Chemical Agents That Affect the Lung

AGENT(S)	SELECTED EXPOSURES	ACUTE EFFECTS FROM HIGH OR ACCIDENTAL EXPOSURE	CHRONIC EFFECTS FROM RELATIVELY LOW EXPOSURE
Acid anhydrides	Manufacture of resin esters, polyester resins, thermoactivated adhesives	Nasal irritation, cough	Asthma, chronic bronchitis, hypersensitivity pneumonitis
Acid fumes: H_2SO_4, HNO_3	Manufacture of fertilizers, chlorinated organic compounds, dyes, explosives, rubber products, metal etching, plastics	Mucous membrane irritation, followed by chemical pneumonitis 2–3 days later	Bronchitis and suggestion of mildly reduced pulmonary function in children with lifelong residential exposure to high levels
Acrolein and other aldehydes	By-product of burning plastics, woods, tobacco smoke	Mucous membrane irritant, decrease in lung function	Upper respiratory tract irritation
Ammonia	Refrigeration; petroleum refining; manufacture of fertilizers, explosives, plastics, and other chemicals	Same as for acid fumes, but bronchiectasis also has been reported	Upper respiratory tract irritation, chronic bronchitis
Cadmium fumes	Smelting, soldering, battery production	Mucous membrane irritant, acute respiratory distress syndrome (ARDS)	Chronic obstructive pulmonary disease (COPD)
Formaldehyde	Manufacture of resins, leathers, rubber, metals, and woods; laboratory workers, embalmers; emission from urethane foam insulation	Same as for acid fumes	Nasopharyngeal cancer
Halides and acid salts (Cl, Br, F)	Bleaching in pulp, paper, textile industry; manufacture of chemical compounds; synthetic rubber, plastics, disinfectant, rocket fuel, gasoline	Mucous membrane irritation, pulmonary edema; possible reduced forced vital capacity (FVC) 1–2 years after exposure	Upper respiratory tract irritation, epistaxis, tracheobronchitis
Hydrogen sulfide	By-product of many industrial processes, oil, other petroleum processes and storage	Increase in respiratory rate followed by respiratory arrest, lactic acidosis, pulmonary edema, death	Conjunctival irritation, chronic bronchitis, recurrent pneumonitis
Isocyanates (TDI, HDI, MDI)	Production of polyurethane foams, plastics, adhesives, surface coatings	Mucous membrane irritation, dyspnea, cough, wheeze, pulmonary edema	Upper respiratory tract irritation, cough, asthma, hypersensitivity pneumonitis, reduced lung function
Nitrogen dioxide	Silage, metal etching, explosives, rocket fuels, welding, by-product of burning fossil fuels	Cough, dyspnea, pulmonary edema may be delayed 4–12 h; possible result from acute exposure: bronchiolitis obliterans in 2–6 weeks	Emphysema in animals, chronic bronchitis, associated with reduced lung function growth in children with lifelong residential exposure
Ozone	Arc welding, flour bleaching, deodorizing, emissions from copying equipment, photochemical air pollutant	Mucous membrane irritant, reduced pulmonary function transiently in children and adults, asthma exacerbation	Excess cardiopulmonary mortality rates, increased risk for new-onset asthma in children
Phosgene	Organic compound, metallurgy, volatilization of chlorine-containing compounds	Delayed onset of bronchiolitis and pulmonary edema	Chronic bronchitis
Sulfur dioxide	Manufacture of sulfuric acid, bleaches, coating of nonferrous metals, food processing, refrigerant, burning of fossil fuels, wood pulp industry	Mucous membrane irritant, epistaxis, bronchospasm (especially in people with asthma)	Chronic bronchitis

Abbreviations: HDI, hexamethylene diisocyanate; MDI, methylene diphenyl diisocyanate; TDI, toluene diisocyanate.

Synthetic materials (plastic, polyurethanes), when burned, may release a variety of other toxic agents (such as cyanide and hydrochloric acid), and this must be considered in evaluating smoke inhalation victims. Exposed victims may have some degree of lower respiratory tract inflammation and/or pulmonary edema.

Exposure to certain highly reactive, low-molecular-weight agents used in the manufacture of synthetic polymers, paints, and coatings (*diisocyanates* in polyurethanes, *aromatic amines* and *acid anhydrides* in epoxies) is associated with a high risk of occupational asthma. Although this occupational asthma manifests clinically as if sensitization has occurred, an IgE antibody–mediated mechanism is not necessarily involved. Hypersensitivity pneumonitis–like reactions also have been described in diisocyanate and acid anhydride–exposed workers.

Fluoropolymers such as Teflon, which at normal temperatures produce no reaction, become volatilized upon high-temperature heating. The inhaled agents cause a characteristic syndrome of fever, chills, malaise, and occasionally mild wheezing, leading to the diagnosis of *polymer fume fever*. A similar self-limited, influenza-like syndrome—*metal fume fever*—results from acute exposure to fumes containing zinc oxide, typically from welding of galvanized steel. These inhalational fever syndromes may begin several hours after work and resolve within 24 h, only to return on repeated exposure.

Two other agents have been associated with potentially severe lung disease. Occupational exposure to nylon flock has been shown to induce a lymphocytic bronchiolitis, and workers exposed to diacetyl, which is used to provide "butter" flavor in the manufacture of microwave popcorn and other foods, have developed bronchiolitis obliterans **(Chap. 304)**.

World Trade Center Disaster A consequence of the attack on the World Trade Center (WTC) in New York City on September 11, 2001, was relatively heavy exposure of a large number of firefighters and other rescue workers to the dust generated by the collapse of the buildings. Environmental monitoring and chemical characterization of WTC dust have revealed a wide variety of potentially toxic constituents, although much of the dust was pulverized cement. Possibly because of the high alkalinity of WTC dust, significant cough, wheeze, and phlegm production occurred among firefighters and cleanup crews. New cough and wheeze syndromes also occurred among local residents. Heavier exposure to WTC dust among New York City firefighters was associated with accelerated decline of lung function over the first year after the disaster. More recently, concerns have been raised about risk of interstitial lung disease, especially of a granulomatous nature.

Burn Pit Emissions The U.S. military used open pits to burn waste of all types—so-called burn pits—during conflicts in the Middle Eastern and Southwest Asian theaters of operations. After deployment to these theaters, a considerable number of veterans complained of symptoms, primarily but not exclusively respiratory, that seem to have been chronologically attributable to exposure to burn pit emissions. A myriad of materials were burned using jet fuel, including plastics, metals, and human waste, generating multiple toxic agents in both particulate and gaseous form. While understanding the health effects of such exposures is an active area of ongoing research, the U.S. Congress recently passed legislation that provides disability compensation to military veterans for multiple burn pit and other toxic exposure presumptive conditions, including allergic rhinitis, asthma, COPD, vocal cord dysfunction, constrictive or obliterative bronchiolitis, and several interstitial lung diseases.

OCCUPATIONAL RESPIRATORY CARCINOGENS

Exposures at work have been estimated to contribute to 10% of all lung cancer cases. In addition to asbestos, other agents either proven or suspected to be respiratory carcinogens include acrylonitrile, arsenic compounds, beryllium, bis(chloromethyl) ether, chromium (hexavalent), formaldehyde (nasal), isopropanol (nasal sinuses), mustard gas, nickel carbonyl (nickel smelting), polycyclic aromatic hydrocarbons (coke oven emissions and diesel exhaust), secondhand tobacco smoke, silica (both mining and processing), talc (possible asbestos contamination in both mining and milling), vinyl chloride (sarcomas), wood (nasal), and uranium. Workers at risk of radiation-related lung cancer include not only those involved in mining or processing uranium but also those exposed in underground mining operations of other ores where radon daughters may be emitted from rock formations.

ASSESSMENT OF DISABILITY

Disability is the term used to describe the decreased ability to work due to the effects of a medical condition. Physicians are generally able to assess physiologic dysfunction, or *impairment*, but the rating of disability for compensation of loss of income also involves nonmedical factors such as the education and employability of the individual. The disability rating scheme differs with the compensation-granting agency. For example, the U.S. Social Security Administration requires that an individual be unable to do any work (i.e., *total* disability) before they will receive income replacement payments. Many state workers' compensation systems allow for payments for *partial* disability. In the Social Security scheme, no determination of cause is done, whereas work-relatedness must be established in workers' compensation systems.

For respiratory impairment rating, resting pulmonary function tests (spirometry and diffusing capacity) are used as the initial assessment tool, with cardiopulmonary exercise testing (to assess maximal oxygen consumption) used if the results of the resting tests do not correlate with the patient's symptoms. Methacholine challenge (to assess airway reactivity) can also be useful in patients with asthma who have normal spirometry when evaluated. Some compensation agencies (e.g., Social Security) have proscribed disability classification schemes based on pulmonary function test results. When no specific scheme is proscribed, the *Guidelines of the American Medical Association* should be used.

GENERAL ENVIRONMENTAL EXPOSURES

OUTDOOR AIR POLLUTION

Primary standards regulated by the U.S. Environmental Protection Agency (EPA) designed to protect the public health with an adequate margin of safety exist for sulfur dioxide, particulate matter (PM), nitrogen dioxide, ozone, lead, and carbon monoxide. Standards for each of these pollutants are updated regularly through an extensive review process conducted by the EPA. (For details on current standards, go to *https://www.epa.gov/criteria-air-pollutants/naaqs-table*.)

Pollutants are generated from both stationary sources (power plants and industrial facilities) and mobile sources (motor vehicles), and none of the regulated pollutants occurs in isolation. Furthermore, pollutants may be changed by chemical reactions after being emitted. For example, sulfur dioxide and PM emissions from a coal-fired power plant may react in air to produce acid sulfate aerosols, which can be transported long distances in the atmosphere. Oxides of nitrogen and volatile organic compounds from automobile exhaust react with sunlight to produce ozone. Although originally recognized in Los Angeles, photochemically derived pollution ("smog") is now known to be a problem throughout the United States and in many other countries. Both acute and chronic effects of pollutant exposures have been documented in large population studies.

The symptoms and diseases associated with air pollution are the same as conditions commonly associated with cigarette smoking. In addition, decreased growth of lung function and asthma have been associated with chronic exposure to only modestly elevated levels of traffic-related air pollution. Multiple population-based time-series studies within cities have demonstrated excess health care utilization for asthma and other cardiopulmonary conditions as well as increased mortality rates. Cohort studies comparing cities that have relatively high levels of particulate exposures with less polluted communities suggest excess morbidity and mortality rates from cardiopulmonary conditions in long-term residents of the former. The strong epidemiologic evidence that fine PM is a risk factor for cardiovascular morbidity and mortality has prompted toxicologic investigations into the underlying mechanisms. The inhalation of

fine particles from combustion sources generates oxidative stress followed by local injury and inflammation in the lungs that in turn lead to autonomic and systemic inflammatory responses. Recent research findings on the health effects of air pollutants have led to stricter U.S. ambient air quality standards for ozone, oxides of nitrogen, and PM as well as greater emphasis on publicizing pollution alerts to encourage individuals with cardiovascular and respiratory disorders to stay indoors during high-pollution episodes (e.g., from wildfires). In addition to staying indoors during episodes of poor air quality due to wildfires, creating clean air spaces in homes and buildings with central ventilation filtration and/or the use of portable HEPA air cleaners can reduce exposure to wildfire PM.

INDOOR EXPOSURES

Secondhand tobacco smoke **(Chap. 465)**, radon gas, wood smoke, and other biologic agents generated indoors must be considered. Several studies have shown that the respirable particulate load in any household is directly proportional to the number of cigarette smokers living in that home. Increases in prevalence of respiratory illnesses, especially asthma, and reduced levels of pulmonary function have been found in the children of smoking parents in a number of studies. Recent meta-analyses for lung cancer and cardiopulmonary diseases, combining data from multiple secondhand tobacco smoke epidemiologic studies, suggest an ~25% increase in relative risk for each condition, even after adjustment for major potential confounders.

Exposure to *radon gas* in homes is a risk factor for lung cancer. The main radon product (radon-222) is a gas that results from the decay series of uranium-238, with the immediate precursor being radium-226. The amount of radium in earth materials determines how much radon gas will be emitted. Levels associated with excess lung cancer risk may be present in as many as 10% of the houses in the United States. When smokers reside in the home, the problem is potentially greater, because the molecular size of radon particles allows them to attach readily to smoke particles that are inhaled. Fortunately, technology is available for assessing and reducing the level of exposure.

Other indoor exposures of concern are bioaerosols that contain antigenic material (fungi, cockroaches, dust mites, and pet danders) associated with an increased risk of atopy and asthma. Indoor chemical agents that have been associated with respiratory symptoms include strong cleaning agents (bleach, ammonia), formaldehyde, perfumes, and pesticides, Exposure to oxides of nitrogen from gas appliances, especially stoves has been associated with increased risk of asthma. Nonspecific responses associated with "tight-building syndrome," perhaps better termed "building-associated illness," in which no particular agent has been implicated, have included a wide variety of complaints, among them respiratory symptoms that are relieved only by avoiding exposure in the building in question. Indoor exposure to *household air pollution* from cooking or heating with solid fuels (wood, dung, crop residues, charcoal, coal) is estimated to be responsible for 4% of deaths worldwide, due to pneumonia in children, COPD and lung cancer in women, and cardiovascular disease among men. This burden of disease places exposure to household air pollution as one of the leading environmental hazards for poor health on a global scale.

Forty percent of the world's population uses solid fuel for cooking, heating, or baking. Kerosene (similar to diesel fuel) is often used for lighting and sometimes cooking. This occurs predominantly in the rural areas of developing countries. Because many families burn coal or biomass fuels in open stoves, which are highly inefficient, and inside homes with poor ventilation, women and young children are exposed on a daily basis to high levels of smoke. In these homes, 24-h mean levels of fine PM have been reported to be 2–30 times higher than the National Ambient Air Quality Standard set by the U.S. EPA.

Epidemiologic studies have consistently shown associations between exposure to biomass smoke and both chronic bronchitis and COPD. Because of increased migration to the United States from developing countries, clinicians need to be aware of the chronic respiratory effects of exposure to biomass smoke, which can include interstitial lung disease **(Fig. 300-4)**.

Household air pollution (HAP) from domestic use of solid fuels also contributes substantially to outdoor air pollution. Contributions from HAP, coal-fired power plants without emission scrubbers, and increased traffic congestion involving motor vehicles without pollution controls can lead to high concentrations of outdoor air pollution, especially fine PM, in mega-cities in developing countries (e.g., Delhi).

301 Bronchiectasis

Rebecca M. Baron, Beverly W. Baron, Miriam Baron Barshak

Bronchiectasis refers to an irreversible airway dilation that involves the lung in either a focal or a diffuse manner and that classically has been categorized as cylindrical or tubular (the most common form), varicose, or cystic. This chapter will focus largely on non–cystic fibrosis (CF) bronchiectasis. **The reader is referred to Chapter 302 for a more focused discussion on CF bronchiectasis.**

ETIOLOGY

Bronchiectasis can arise from infectious or noninfectious causes (Table 301-1). Clues to the underlying etiology often are provided by the pattern of lung involvement. *Focal bronchiectasis* refers to bronchiectatic changes in a localized area of the lung and can be a consequence of obstruction of the airway—either extrinsic (e.g., due to compression by adjacent lymphadenopathy or parenchymal tumor mass) or intrinsic (e.g., due to an airway tumor or aspirated foreign body, a scarred/stenotic airway, or bronchial atresia from congenital underdevelopment of the airway). *Diffuse bronchiectasis* is characterized by widespread bronchiectatic changes throughout the lung and often arises from an underlying systemic or infectious disease process.

More pronounced involvement of the upper lung fields is most common in CF and also is observed in postradiation fibrosis, corresponding to the lung region encompassed by the radiation port. Bronchiectasis with predominant involvement of the lower lung fields usually has its source in chronic recurrent aspiration (e.g., due to esophageal motility disorders like those in scleroderma), end-stage fibrotic lung disease (e.g., traction bronchiectasis from idiopathic pulmonary fibrosis), or recurrent immunodeficiency-associated infections (e.g., hypogammaglobulinemia). Bronchiectasis resulting from infection by nontuberculous mycobacteria (NTM), most commonly the *Mycobacterium avium-intracellulare* complex (MAC), often preferentially affects the midlung fields. Congenital causes of bronchiectasis with predominant midlung field involvement include the dyskinetic/immotile cilia syndrome. Finally, predominant involvement of the central airways is reported in association with allergic bronchopulmonary aspergillosis (ABPA), in which an immune-mediated reaction to *Aspergillus* damages the bronchial wall. Congenital causes of central airway–predominant bronchiectasis resulting from cartilage deficiency include tracheobronchomegaly (Mounier-Kuhn syndrome) and Williams-Campbell syndrome.

In many cases, the etiology of bronchiectasis is not determined. In case series, as many as 25–50% of patients referred for bronchiectasis have idiopathic disease. There is increasing appreciation for the need to define disease subphenotypes in this heterogeneous group of underlying causes of bronchiectasis, which might permit better targeting of clinical trials and treatment strategies.

TABLE 301-1 Major Etiologies of Bronchiectasis and Proposed Workup

PATTERN OF LUNG INVOLVEMENT	ETIOLOGY BY CATEGORY (EXAMPLES)	WORKUP
Focal	Obstruction (e.g., aspirated foreign body, tumor mass)	Chest imaging (chest x-ray and/or chest CT) [a]; bronchoscopy
Diffuse	Infection (e.g., bacterial, nontuberculous mycobacterial)	Sputum Gram's stain/culture; stains/cultures for acid-fast bacilli and fungi. If no pathogen is identified, consider bronchoscopy with bronchoalveolar lavage.
	Immunodeficiency (e.g., hypogammaglobulinemia, HIV infection, bronchiolitis obliterans after lung transplantation)	Complete blood count with differential; immunoglobulin measurement; HIV testing
	Genetic causes (e.g., cystic fibrosis, Kartagener's syndrome, α_1 antitrypsin deficiency)	Measurement of chloride levels in sweat (for cystic fibrosis), α_1 antitrypsin levels; nasal or respiratory tract brush/biopsy (for dyskinetic/immotile cilia syndrome); genetic testing
	Autoimmune or rheumatologic causes (e.g., rheumatoid arthritis, Sjögren's syndrome, inflammatory bowel disease); immune-mediated disease (e.g., allergic bronchopulmonary aspergillosis)	Clinical examination with careful joint exam, serologic testing (e.g., for rheumatoid factor). Consider workup for allergic bronchopulmonary aspergillosis, especially in patients with refractory asthma.[b]
	Recurrent aspiration	Test of swallowing function and general neuromuscular strength
	Miscellaneous (e.g., yellow nail syndrome, traction bronchiectasis from postradiation fibrosis or idiopathic pulmonary fibrosis)	Guided by clinical condition
	Idiopathic	Exclusion of other causes

[a]Chest imaging is included in the general workup for all etiologies of bronchiectasis as described in the text. [b]Skin testing for *Aspergillus* reactivity; measurement of serum precipitins for *Aspergillus*, serum IgE levels, serum eosinophils, etc.

EPIDEMIOLOGY

The overall reported prevalence of bronchiectasis in the United States has recently increased, but the epidemiology of bronchiectasis varies greatly with the underlying etiology. For example, patients with CF often develop significant clinical bronchiectasis in late adolescence or early adulthood, although atypical presentations of CF in adults in their thirties and forties also are possible. In contrast, bronchiectasis resulting from MAC infection classically affects nonsmoking women >50 years of age. In general, the incidence of bronchiectasis increases with age. Bronchiectasis is more common among women than among men. Bronchiectasis may also frequently be co-diagnosed with chronic obstructive pulmonary disease (COPD) or asthma.

In areas where tuberculosis is prevalent, bronchiectasis more frequently occurs as a sequela of granulomatous infection. Focal bronchiectasis can arise from extrinsic compression of the airway by enlarged granulomatous lymph nodes and/or from development of intrinsic obstruction as a result of erosion of a calcified lymph node through the airway wall (e.g., broncholithiasis). Especially in reactivated tuberculosis, parenchymal destruction from infection can result in areas of more diffuse bronchiectasis. Apart from cases associated with tuberculosis, an increased incidence of non-CF bronchiectasis with an unclear underlying mechanism has been reported as a significant problem in developing nations. It has been suggested that the high incidence of malnutrition in certain areas may predispose to immune dysfunction and development of bronchiectasis.

PATHOGENESIS AND PATHOLOGY

The most widely cited mechanism of infectious bronchiectasis is the "vicious cycle hypothesis," in which susceptibility to infection and poor mucociliary clearance result in microbial colonization of the bronchial tree. Some organisms, such as *Pseudomonas aeruginosa*, exhibit a particular propensity for colonizing damaged airways and evading host defense mechanisms. Impaired mucociliary clearance can result from inherited conditions such as CF or dyskinetic cilia syndrome, and it has been proposed that a single severe infection (e.g., pneumonia caused by *Bordetella pertussis* or *Mycoplasma pneumoniae*) can result in significant airway damage and poor secretion clearance. The presence of the microbes incites continued chronic

inflammation, with consequent damage to the airway wall, continued impairment of secretions and microbial clearance, and ongoing propagation of the infectious/inflammatory cycle. Moreover, it has been proposed that mediators released directly from bacteria can interfere with mucociliary clearance. A recent study suggested that there exist molecular endotypes of bronchiectasis with differential inflammatory markers and microbiome signatures that correlate with risk of exacerbations. Classic studies of the pathology of bronchiectasis from the 1950s demonstrated significant small-airway wall inflammation and larger-airway wall destruction as well as dilation, with loss of elastin, smooth muscle, and cartilage. It has been proposed that inflammatory cells in the small airways release proteases and other mediators, such as reactive oxygen species and proinflammatory cytokines, that damage the larger airway walls. Furthermore, the ongoing inflammatory process in the smaller airways results in airflow obstruction. It is thought that antiproteases, such as α_1 antitrypsin, play an important role in neutralizing the damaging effects of neutrophil elastase and in enhancing bacterial killing. Bronchiectasis and emphysema have been observed in patients with α_1 antitrypsin deficiency. Interestingly, a recent phase 2 study demonstrated improved bronchiectasis outcomes with an oral inhibitor of neutrophil serine protease activity.

Proposed mechanisms for noninfectious bronchiectasis include immune-mediated reactions that damage the bronchial wall (e.g., those associated with systemic autoimmune conditions such as Sjögren's syndrome and rheumatoid arthritis). Recent studies suggest that there might exist a new bronchiectasis endophenotype of patients with sensitization to multiple environmental allergens. *Traction bronchiectasis* refers to dilated airways arising from parenchymal distortion as a result of lung fibrosis (e.g., postradiation fibrosis or idiopathic pulmonary fibrosis).

CLINICAL MANIFESTATIONS

The most common clinical presentation is a persistent productive cough with ongoing production of thick, tenacious sputum. Physical findings frequently include crackles and wheezing on lung auscultation, and some patients with bronchiectasis exhibit clubbing of the digits. Mild to moderate airflow obstruction often is detected on pulmonary function tests, overlapping with that seen at presentation with other conditions, such as COPD. Acute exacerbations of bronchiectasis usually are characterized by changes in the nature of sputum production, with increased volume and purulence. However, typical signs and symptoms of lung infection, such as fever and new infiltrates, may not be present.

DIAGNOSIS

The diagnosis usually is based on presentation with a persistent chronic cough and sputum production accompanied by consistent radiographic features. Although chest radiographs lack sensitivity, the presence of "tram tracks" indicating dilated airways is consistent with bronchiectasis. Chest CT is more specific for bronchiectasis and is the imaging modality of choice for confirming the diagnosis. CT findings include airway dilation (detected as parallel "tram tracks" or as the "signet-ring sign"—a cross-sectional area of the airway with a diameter at least 1.5 times that of the adjacent vessel), lack of bronchial tapering (including the presence of tubular structures within 1 cm from the pleural surface), bronchial wall thickening in dilated airways, inspissated secretions (e.g., the "tree-in-bud" pattern), or cysts emanating from the bronchial wall (especially pronounced in cystic bronchiectasis) **(Fig. 301-1)**. Recently, a group of international experts put forth consensus guidelines for clinical and radiologic diagnosis of bronchiectasis, proposing that a diagnosis of bronchiectasis should require radiologic criteria (at least one of the following on chest CT: [1] inner- or [2] outer-airway-artery diameter ratio ≥1.5; [3] lack of airway tapering; and, [4] visibility of airways in the periphery) along with the clinical syndrome (at least two of the following: [1] cough most days of the week; [2] sputum production most days of the week; and [3] history of exacerbations).

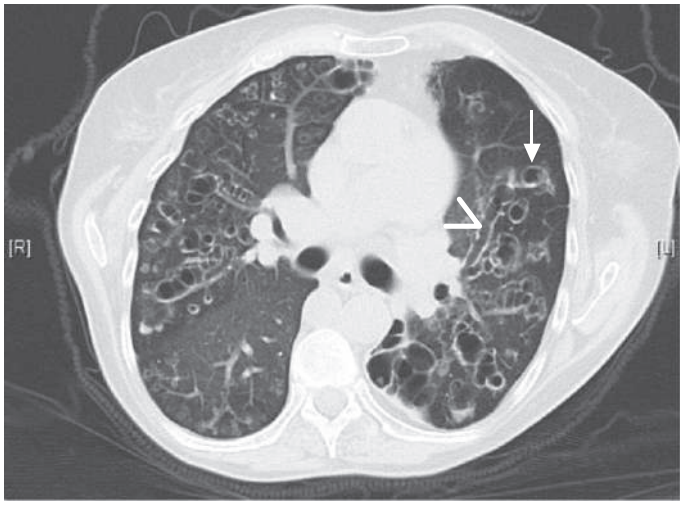

FIGURE 301-1 Representative chest CT image of severe bronchiectasis. This patient's CT demonstrates many severely dilated airways, seen both longitudinally (*arrowhead*) and in cross-section (*arrow*).

APPROACH TO THE PATIENT

Bronchiectasis

The evaluation of a patient with bronchiectasis entails elicitation of a clinical history, chest imaging, and a workup to determine the underlying etiology. Evaluation of focal bronchiectasis almost always requires bronchoscopy to exclude airway obstruction by an underlying mass or foreign body. A workup for diffuse bronchiectasis includes analysis for the major etiologies (Table 301-1), with an initial focus on excluding CF. Pulmonary function testing is an important component of a functional assessment of the patient.

TREATMENT

Bronchiectasis

Treatment of infectious bronchiectasis is directed at the control of active infection and improvements in secretion clearance and bronchial hygiene so as to decrease the microbial load within the airways and minimize the risk of repeated infections.

ANTIBIOTIC TREATMENT

Antibiotics targeting the causative or presumptive pathogen (with *Haemophilus influenzae* and *P. aeruginosa* isolated commonly) should be administered in acute exacerbations, usually for a minimum of 7–10 days and perhaps for as long as 14 days. Decisions about treatment of NTM infection can be difficult, given that these organisms can be colonizers as well as pathogens, and the prolonged treatment course often is not well tolerated. Consensus guidelines have advised that diagnostic criteria for true clinical infection with NTM should be considered in patients with symptoms and radiographic findings of lung disease who have at least two sputum samples positive on culture; at least one bronchoalveolar lavage (BAL) fluid sample positive on culture; a biopsy sample displaying histopathologic features of NTM infection (e.g., granuloma or a positive stain for acid-fast bacilli) along with one positive sputum culture; or a pleural fluid sample (or a sample from another sterile extrapulmonary site) positive on culture. MAC strains are the most common NTM pathogens, and the recommended regimen for HIV-negative patients infected with macrolide-sensitive MAC includes a macrolide combined with rifampin and ethambutol. Consensus guidelines recommend macrolide susceptibility testing for clinically significant MAC isolates.

BRONCHIAL HYGIENE

The numerous approaches used to enhance secretion clearance in bronchiectasis include hydration and mucolytic administration, aerosolization of bronchodilators and hyperosmolar agents (e.g., hypertonic saline), and chest physiotherapy (e.g., postural drainage, traditional mechanical chest percussion via hand clapping to the chest, or use of devices such as an oscillatory positive expiratory pressure flutter valve or a high-frequency chest wall oscillation vest). Pulmonary rehabilitation and a regular exercise program may assist with secretion clearance as well as with other aspects of bronchiectasis, including improved exercise capacity and quality of life. The mucolytic dornase (DNase) is recommended routinely in CF-related bronchiectasis but not in non-CF bronchiectasis, given concerns about lack of efficacy and potential harm in the non-CF population.

ANTI-INFLAMMATORY THERAPY

It has been proposed that control of the inflammatory response may be of benefit in bronchiectasis, and relatively small-scale trials have yielded evidence of alleviated dyspnea, decreased need for inhaled β-agonists, and reduced sputum production with inhaled glucocorticoids. However, no significant differences in lung function or bronchiectasis exacerbation rates have been observed. Risks of immunosuppression and adrenal suppression must be carefully considered with use of anti-inflammatory therapy in infectious bronchiectasis. Nevertheless, administration of oral/systemic glucocorticoids may be important in treatment of bronchiectasis due to certain etiologies, such as ABPA, or of noninfectious bronchiectasis due to underlying conditions, especially that in which an autoimmune condition is believed to be active (e.g., rheumatoid arthritis or Sjögren's syndrome). Patients with ABPA also may benefit from a prolonged course of treatment with an oral antifungal agent such as itraconazole.

REFRACTORY CASES

In select cases, surgery can be considered, with resection of a focal area of suppuration. In advanced cases, lung transplantation can be considered.

COMPLICATIONS

In more severe cases of infectious bronchiectasis, recurrent infections and repeated courses of antibiotics can lead to microbial resistance to antibiotics. In certain cases, combinations of antibiotics that have independent toxicity profiles may be necessary to treat resistant organisms.

Recurrent infections can result in injury to superficial mucosal vessels, with bleeding and, in severe cases, life-threatening hemoptysis. Management of massive hemoptysis usually requires intubation to stabilize the patient, identification of the source of bleeding, and protection of the nonbleeding lung. Control of bleeding often necessitates bronchial artery embolization and, in severe cases, surgery.

PROGNOSIS

Outcomes of bronchiectasis can vary widely with the underlying etiology and comorbid conditions and may also be influenced by the frequency of exacerbations and (in infectious cases) the specific pathogens involved (with worse outcomes associated with *P. aeruginosa* colonization). Increasing attention is being given to defining clinical subphenotypes of bronchiectasis in light of heterogeneous clinical, radiographic, and microbial features and to developing screening tools for the assessment of quality of life and disease severity. In one study, the decline of lung function in patients with non-CF bronchiectasis was similar to that in patients with COPD, with the forced expiratory volume in 1 s (FEV_1) declining by 50–55 mL per year as opposed to 20–30 mL per year for healthy controls.

PREVENTION

Reversal of an underlying immunodeficient state (e.g., by administration of gamma globulin for immunoglobulin-deficient patients) and vaccination of patients with chronic respiratory conditions (e.g., influenza, pneumococcal, COVID, and RSV vaccines) can decrease the risk of recurrent infections. Patients who smoke should be counseled about smoking cessation.

After resolution of an acute infection in patients with recurrences (e.g., ≥3 episodes per year), the use of suppressive antibiotics to minimize the microbial load and reduce the frequency of exacerbations has been proposed. Although there is less consensus about this approach in non-CF-associated bronchiectasis than in CF-related bronchiectasis, small studies have supported benefits of selected therapies, though with concerns for development of antibiotic resistance over time. Possible suppressive treatments include (1) administration of an oral antibiotic (e.g., ciprofloxacin) daily for 1–2 weeks per month; (2) use of a rotating schedule of oral antibiotics (to minimize the risk of development of drug resistance); (3) administration of a macrolide antibiotic (see below) daily or three times per week (with mechanisms of possible benefit related to non-antimicrobial properties, such as anti-inflammatory effects and reduction of gram-negative bacillary biofilms); (4) inhalation of aerosolized antibiotics (e.g., tobramycin inhalation solution) for select patients on a rotating schedule (e.g., 30 days on, 30 days off), with the goal of decreasing the microbial load without eliciting the side effects of systemic drug administration; other studies examining inhaled aztreonam and inhaled ciprofloxacin formulations have shown conflicting results, suggesting there might be subpopulations of patients with bronchiectasis who might benefit from specific therapies; and (5) intermittent administration of IV antibiotics (e.g., "clean-outs") for patients with more severe bronchiectasis and/or resistant pathogens. In relation to macrolide therapy (point 3 above), a number of double-blind, placebo-controlled, randomized trials have been published in non-CF bronchiectasis and support a benefit of long-term macrolides (6–12 months of azithromycin or erythromycin) in decreasing rates of bronchiectasis exacerbation, mucus production, and decline in lung function. However, two of these studies and a meta-analysis also reported increased macrolide resistance in commensal pathogens, dampening enthusiasm for universal use of macrolides in this setting and raising the question of whether there might be select non-CF bronchiectasis patients with higher morbidity for whom benefits of long-term macrolides might outweigh the risks of emergence of antibiotic resistance. In particular, development of macrolide-resistant NTM is a potential concern, making treatment of those pathogens much more difficult. Furthermore, patients with different patterns of microbial colonization may not all experience similar benefits with macrolide therapy. Therefore, before chronic macrolide therapy is considered, it is advisable to rule out NTM infection and carefully consider each patient's scenario closely, obtaining an electrocardiogram to rule out a prolonged QT interval that might place the patient at increased risk of arrhythmias.

In addition, ongoing consistent attention to bronchial hygiene can promote secretion clearance and decrease the microbial load in the airways.

CLINICAL FEATURES

Cystic fibrosis (CF) is an autosomal recessive exocrinopathy affecting multiple epithelial tissues. The gene product responsible for CF (the cystic fibrosis transmembrane conductance regulator [CFTR]) serves as an anion channel in the apical (luminal) plasma membranes of epithelial cells and regulates volume and composition of exocrine secretion. A highly sophisticated understanding of CFTR molecular genetics and membrane protein biochemistry has enabled recent and transformative drug discovery for patients with this disease.

Respiratory Manifestations The major morbidity and mortality associated with CF is attributable to pulmonary compromise, characterized by copious hyperviscous and adherent secretions that obstruct small and medium-sized airways. CF respiratory secretions are exceedingly difficult to clear, and a complex bacterial flora that includes *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa* (among other pathogens, see below) is routinely cultured from CF sputum. Robust pulmonary inflammation in the setting of inspissated mucus and chronic infection leads to collateral tissue injury and further aggravates respiratory decline. Organisms such as *P. aeruginosa* exhibit a stereotypic mode of pathogenesis; a sentinel and early colonization event often engenders lifelong pulmonary infection by the same genetic strain. Over a period of many years, *P. aeruginosa* evolves in CF lungs to adopt a mucoid phenotype (attributable to release of alginate exoproduct) that confers selective advantage for the pathogen and poor prognosis for the host. Radiographic evidence of sinusitis occurs in most patients with CF and can be associated with microorganisms similar to those recovered from lower airways, suggesting that CF sinus involvement may serve as a reservoir for bacterial seeding of the lung.

Pancreatic Findings The complete name of the disease, *cystic fibrosis of the pancreas*, refers to profound tissue destruction of the exocrine pancreas, with fibrotic scarring and/or fatty replacement, cyst formation, loss of acinar tissue, and ablation of normal pancreatic architecture. As in the lung, tenacious exocrine secretions (sometimes termed *concretions*) obstruct pancreatic ducts and impair production and flow of digestive enzymes to the duodenum. The sequelae of exocrine pancreatic insufficiency include chronic malabsorption, poor growth, fat-soluble vitamin deficiency, high levels of blood immunoreactive trypsinogen (a test used in newborn screening), low levels of fecal elastase-1, and loss of pancreatic islet cell mass. CF-related diabetes mellitus is a manifestation in >30% of adults with the disease and likely multifactorial in nature (attributable to progressive destruction/dysfunction of the endocrine pancreas and, in some cases, insulin resistance or other features).

Additional Organ System Damage As in CF lung and pancreas, thick and inspissated secretions compromise numerous exocrine tissues. Obstruction of intrahepatic bile ducts and parenchymal fibrosis are observed, with multilobular cirrhosis in 4–15% of patients with CF and significant hepatic insufficiency as a resulting manifestation among many adults. Hepatic steatosis, focal biliary fibrosis, and portal hypertension are other well-described findings of CF liver disease. Contents of the intestinal lumen are hyperviscous and often difficult to excrete, leading to meconium ileus (a clinical presentation in many newborns with CF) or distal intestinal obstructive syndrome in older individuals. Men typically exhibit complete involution of the vas deferens (despite functioning spermatogenesis), and ~99% of males with CF are infertile (i.e., unable to conceive children without in vitro fertilization). Abnormalities of female reproductive tract secretions are likely contributors to a higher incidence of infertility among women with the disease.

PATHOGENESIS

Cystic Fibrosis Transmembrane Conductance Regulator CFTR is an integral membrane protein that functions as an epithelial anion channel. The ~1480-amino-acid molecule encodes a passive conduit for chloride and bicarbonate transport across plasma membranes of epithelial tissues, with direction of ion flow dependent on the electrochemical driving force. Gating of CFTR involves conformational cycling between an open and closed configuration and is augmented by hydrolysis of adenosine triphosphate (ATP). Anion flux mediated by CFTR does not involve active transport against a concentration gradient but utilizes the energy provided from ATP hydrolysis as a central feature of ion channel mechanochemistry and gating.

CFTR is situated in the apical plasma membranes of acinar and other epithelial cells where it regulates the amount and composition of secretion by exocrine glands. In numerous epithelia, chloride and bicarbonate release via CFTR is followed passively by flow of water through other pathways, aiding mobilization and clearance of exocrine products. Along respiratory mucosa, CFTR is necessary to provide sufficient depth of the periciliary fluid layer (PCL), allowing normal ciliary extension and mucociliary transport. CFTR-deficient airway cells exhibit depleted PCL, causing ciliary collapse and failure to clear overlying mucus **(Video 302-1)**. In airway submucosal glands, CFTR is expressed in acini and may participate both in the formation of mucus and extrusion of glandular secretion onto the airway surface **(Fig. 302-1)**. In other exocrine glands characterized by abrogated mucus transport (e.g., pancreatic acini and ducts, as well as bile canaliculi, and intestinal tissues), similar pathogenic mechanisms have been implicated. In these cases, a driving force for apical chloride and/or bicarbonate secretion is believed to promote CFTR-mediated fluid and electrolyte release into the lumen, which confers proper rheologic properties and composition of mucins and other related exocrine products. Failure of this mechanism disrupts normal hydration and transport of glandular secretion—and is viewed as a proximate cause of obstruction, with concomitant tissue injury.

Pulmonary Inflammation and Remodeling The CF airway is characterized by an aggressive, unrelenting, neutrophilic inflammatory response with release of proteases and oxidants leading to airway remodeling and bronchiectasis. Intense pulmonary inflammation is largely driven by chronic respiratory pathogens, although some measure of inflammatory responsiveness may occur very early in the disease and prior to bacterial infection. Macrophages and other cells resident in CF lungs augment elaboration of proinflammatory cytokines, which contribute to innate and adaptive immune reactivity. CFTR-dependent abnormalities of airway surface fluid composition (e.g., low pH) have been reported as contributors to impaired bacterial killing in CF lungs. The role of CFTR activity as a direct mediator of cellular immune hyperresponsiveness and/or pulmonary remodeling (i.e., intensifying damage caused by mucoobstruction and bacterial infection) represent important areas of investigation.

MOLECULAR GENETICS

DNA sequencing from CF patients (and others) worldwide has revealed >2000 allelic mutations in *CFTR*; several hundred of these are well characterized as disease-causing variants. Distinguishing the single nucleotide transversions or other polymorphisms with causal relevance can sometimes present a significant challenge. The CFTR2 resource (*www.cftr2.org/*) helps delineate gene variants with a clear etiologic role.

CFTR defects known to elicit disease have been categorized based on molecular mechanism. For example, the common F508del mutation (nomenclature denotes omission of a single phenylalanine residue [F] at CFTR position 508) leads to a protein folding abnormality recognized by cellular quality control pathways. CFTR encoding F508del retains partial ion channel function, but protein maturation is arrested in the endoplasmic reticulum, and CFTR fails to arrive at the plasma membrane. Instead, F508del CFTR is misrouted and undergoes endoplasmic reticulum–associated degradation via the proteasome. *CFTR* mutations that disrupt protein maturation in this manner are termed

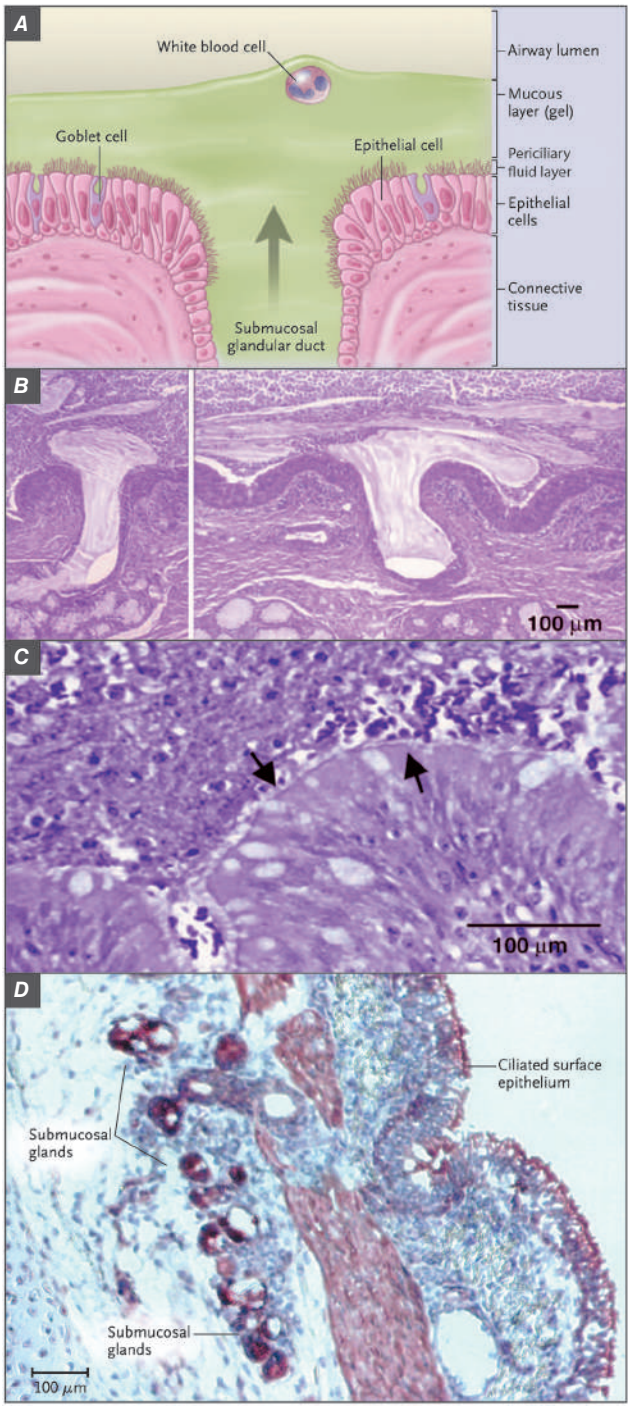

FIGURE 302-1 Extrusion of mucus secretion onto the epithelial surface of airways in cystic fibrosis (CF). ***A.*** Schematic of the surface epithelium and supporting glandular structure of the human airway. ***B.*** The submucosal glands of a patient with CF are filled with mucus, and mucopurulent debris overlies the airway surfaces, essentially burying the epithelium. ***C.*** A higher magnification view of a mucus plug tightly adhering to the airway surface, with *arrows* indicating the interface between infected and inflamed secretions and the underlying epithelium to which the secretions adhere. (Both ***B*** and ***C*** were stained with hematoxylin and eosin, with the colors modified to highlight structures.) Infected secretions obstruct airways and, over time, dramatically disrupt the normal architecture of the lung. ***D.*** CFTR is expressed in surface epithelium and serous cells at the base of submucosal glands in a porcine lung sample, as shown by the dark staining, signifying binding by CFTR antibodies to epithelial structures (aminoethylcarbazole detection of horseradish peroxidase with hematoxylin counterstain). *(From SM Rowe, S Miller, EJ Sorscher: Cystic Fibrosis. N Engl J Med 352:1992, 2005. Copyright © 2005 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

class II defects and are by far the most common genetic abnormalities. F508del alone accounts for ~85% of defective *CFTR* alleles in the United States.

Other gene defects include CFTR ion channels properly trafficked to the apical cell surface but unable to open and/or gate. Such channel proteins include G551D (a glycine to aspartic acid replacement at CFTR position 551), which abrogates transport of Cl^- or HCO_3^- (a class III abnormality). Individuals with at least one G551D allele represent ~4% of patients with CF. *CFTR* nonsense mutations such as G542X, R553X, or W1282X (premature termination codon replaces glycine, arginine, or tryptophan at positions 542, 553, or 1282, respectively) are among the common class I defects, in addition to large deletions or other major disruptions of the gene. The W1282X mutation, for example, is prevalent among individuals of Ashkenazi descent and a predominant CF genotype in Israel. Additional categories of *CFTR* mutation include impairment of the ion channel pore (class IV), RNA splicing (class V), and increased plasma membrane turnover (class VI) **(Fig. 302-2)**.

DIAGNOSIS

CF classically presented in childhood with chronic productive cough, malabsorption including steatorrhea, and failure to thrive. During the past decade, newborn screening has led to most CF diagnoses, with confirmation through *CFTR* mutation analysis and/or sweat electrolyte measurements as cardinal tests. The findings of disease-causing

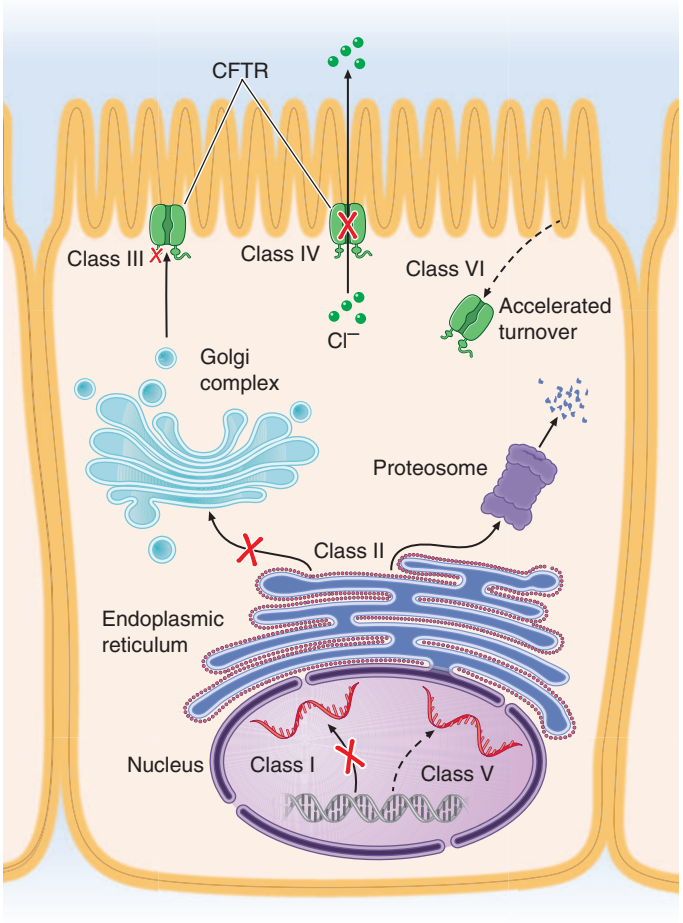

FIGURE 302-2 Categories of *CFTR* mutations. Classes of defects in the *CFTR* gene include the absence of synthesis (class I); defective protein maturation and premature degradation (class II); disordered gating/regulation, such as diminished adenosine triphosphate (ATP) binding and hydrolysis (class III); defective conductance through the ion channel pore (class IV); a reduced number of *CFTR* transcripts due to a promoter or splicing abnormality (class V); and accelerated turnover from the cell surface (class VI). *(From SM Rowe, S Miller, EJ Sorscher: N Engl J Med 352:1992, 2005.)*

variants on both *CFTR* alleles and/or sweat chloride ≥60 mEq/L, together with characteristic respiratory or other exocrine manifestations, are sufficient for confirming a diagnosis of CF. DNA-based evaluation typically surveys numerous disease-associated mutations; panels that identify several hundred *CFTR* variants are available through a variety of public health laboratories or commercial sources. Alternatively, complete *CFTR* DNA testing, or exonic sequencing together with analysis of splice junctions and key regulatory elements, can be obtained.

Sweat electrolytes following pilocarpine iontophoresis comprise an essential diagnostic element, with levels of chloride markedly elevated in CF compared to non-CF individuals. The sweat test result is highly specific and served as a mainstay of diagnosis for decades prior to availability of *CFTR* genotyping. Notably, hyperviscosity of eccrine sweat is not a clinical feature of the disease. Sweat ducts function to reabsorb chloride from a primary sweat secretion produced by the glandular coil. Malfunction of CFTR leads to diminished chloride uptake from the ductular lumen, and sweat emerges on the skin with elevated levels of chloride.

COMPLEXITY OF A CF-RELATED PHENOTYPE

Several "severe" defects that impair CFTR activity (including F508del, G551D, and nonsense alleles) are predictive of pancreatic insufficiency, which is evident in ~80% of those with the disease. In general, and with regard to projecting respiratory outcome for an individual patient, genotype has been of limited value for predicting the rate of clinical decline, respiratory prognosis, or longevity.

A spectrum of CFTR-related conditions with features resembling classic CF has been well described. In addition to multiorgan involvement, forme frustes, such as isolated congenital bilateral absence of the vas deferens or pancreatitis (without other organ system findings), are strongly associated with *CFTR* mutations in at least one allele. CF carrier status also predisposes to both non-CF bronchiectasis and chronic rhinosinusitis, indicating a contribution of relative CFTR deficiency in these prevalent illnesses. Although CF is a classic monogenic disease, the importance of non-*CFTR* gene modifiers and proteins that regulate ion flux, inflammatory pathways, and airway remodeling has been appreciated as influencing clinical course. For example, the magnitude of transepithelial sodium reabsorption in CF airways, which helps control periciliary fluid depth and composition, is strongly influenced by CFTR and has represented a molecular target for experimental intervention in the past.

CFTR MODULATORS

Potentiation of Mutant CFTR Gating A major effort directed toward high-throughput analysis of large compound libraries resulted in identification of effective new CFTR "modulator" therapies for CF. The first approved compound in this class, ivacaftor, robustly potentiates CFTR channel opening and stimulates ion transport. Ivacaftor overcomes the G551D CFTR gating defect, and individuals carrying this mutation exhibit pronounced improvement in lung function, respiratory outcomes (fewer hospital admissions for pulmonary exacerbation), weight gain, and other clinical benefits. Ivacaftor has been deemed "highly effective modulator therapy" (HEMT) for G551D-related CF and leads to substantial reduction of sweat chloride. Prior to ivacaftor, no clinical intervention of any sort had been shown to normalize the CF sweat phenotype. In addition to G551D, ivacaftor is approved in the United States for 96 other *CFTR* variants. Multiyear treatment analysis indicates durable respiratory palliation. The drug has been viewed as a harbinger of a new era for CF therapeutics directed toward addressing fundamental causes of the disease.

Correction of the F508del Processing Abnormality Lumacaftor and tezacaftor, two U.S. Food and Drug Administration (FDA)-approved "corrector" molecules that repair CFTR misfolding (as distinct from CFTR gating "potentiators" such as ivacaftor), partially overcome the F508del biogenesis defect. The drugs also promote cell surface localization of many other class II *CFTR* mutations. A different corrector molecule, elexacaftor, operates by a distinct mechanism of action and is FDA approved in combination with tezacaftor and ivacaftor for patients with CF encoding at least one F508del variant (irrespective of the second *CFTR* allele), as well as numerous less common CF mutations. This triple combination therapy (TCT) has been projected to benefit >90% of individuals with the disease. Marked enhancement of forced expiratory volume in 1 s (FEV_1), fewer respiratory exacerbations, improved quality of life, and diminished sweat chloride have all been demonstrated in patients following TCT, leading to designation as HEMT. For example, among individuals carrying one F508del together with a *CFTR* minimal function variant, TCT led to improved FEV_1 (% predicted) by ~14% over a 4- to 24-week treatment period. Monitoring liver function of patients on TCT and attention to pharmacologic interactions, including effects mediated by CYP3A, are required. **(See Video 302-2 A, B.)**

Personalized Molecular Therapies Based on the large number of disease-causing *CFTR* mutations, together with the ability to group these into molecular categories (Fig. 302-2), CF has been deemed a condition ideally suited for personalized (i.e., mechanistically tailored) drug treatment. That being said, many CFTR variants clearly exhibit multiple molecular abnormalities (across more than one mechanistic subclass), and modulator compounds can therefore provide benefit across numerous disease subcategories. CFTR drug discovery—while highly successful—might, therefore, be viewed as less "personalized" or "precise" than originally envisioned. Moreover, clinical data indicate that a subset of individuals with F508del respond poorly to TCTs. Understanding the multifactorial determinants that govern drug effectiveness and/or risk of toxicity (e.g., due to genomic loci other than *CFTR*, epigenetic/environmental features, or complex *CFTR* alleles with numerous polymorphisms) constitutes a major objective in the field.

Other Challenges Involving CFTR Modulators and Progress Toward Nucleotide-Based Therapeutics The high cost of modulator compounds has often restricted third-party reimbursement to include only the specific genotypes for which FDA or other regulatory approval has been obtained. As a consequence, access to potentially efficacious modulators among patients with very rare CFTR defects and off-label prescribing are largely precluded. Moreover, clinical trials intended to expand the drug label can be difficult to arrange based on small numbers of patients carrying a particular ultra-rare variant. In vitro models rigorously shown to predict clinical modulator benefit have proven useful in this setting (e.g., studies of primary airway and other well-validated epithelial monolayers, or organoid-type cultures) and represent a potential means to gain FDA approval or insurance reimbursement for those with uncommon *CFTR* abnormalities.

CF drug discovery is emblematic of what might be accomplished in other refractory inherited conditions using an approach grounded in molecular etiology and unbiased compound library screening. Beyond CFTR modulators, genetic manipulation (e.g., *CFTR* gene transfer, DNA editing) and airway progenitor cell engraftment comprise experimental approaches that may be less dependent on a specific (i.e., personalized) pathogenic mechanism. For example, efficient, safe, and durable delivery of wild-type *CFTR* using viral (e.g., adeno-associated), lipid nanoparticle, or other vehicles represents a potential means to address diverse molecular abnormalities, independent of the responsible *CFTR* mutation(s). In that context, rescue of secretory epithelial progenitor cells has been emphasized, with newer technologies such as single-cell RNA-seq or spatial transcriptomics available to track successful nucleotide-based transduction. Approaches to genetic correction are of particular urgency for patients with forms of CF unresponsive to CFTR modulation, such as disease caused by premature truncation codons or disruptive splice site abnormalities.

TREATMENTS DIRECTED TOWARD CF SEQUELAE

Chronic Outpatient Management, Including Relationship to Modulators Standard care for patients with CF is intensive, with outpatient regimens that include exogenous pancreatic enzymes

taken with meals, nutritional supplementation, anti-inflammatory medication, bronchodilators, and chronic or periodic dosing of oral or aerosolized antibiotics (e.g., as maintenance therapy for patients with *P. aeruginosa*). Recombinant DNAse aerosols (degrade DNA strands that contribute to mucus viscosity) and nebulized hypertonic saline or mannitol (augment PCL depth, activate mucociliary clearance, and mobilize inspissated airway secretions) have traditionally been administered. Chest physiotherapy several times each day is routinely used as a means to promote clearance of airway mucus, although rigorous evidence for clinical benefit is limited. Among adults with CF, intestinal malabsorption, chronic inflammation, and endocrine abnormalities can lead to poor bone mineralization requiring treatment with vitamin D, calcium, and other measures. The time, complexity, and expense of home care are considerable and take a significant toll on patients and their families. Important CF longitudinal trials are reevaluating the need for interventions, such as recombinant DNAse, and examining optimal guidelines for frequency of outpatient clinic visits, home monitoring, sputum culture surveillance, and other aspects of clinical care in the era of highly effective modulators.

Chronic sequelae of CF have received continued attention following the advent of HEMT, particularly since patients with established lung disease given TCT or other formulations continue to exhibit respiratory infection and inflammation despite substantial clinical improvement. Certain disease hallmarks, such as CF sinus involvement, are palliated by HEMT, and both exocrine pancreatic function and glucose tolerance have been shown to benefit from modulators in specific clinical settings. (Annual testing for diabetes mellitus continues to be recommended for adults with CF.) The impact of CFTR modulation has not been fully characterized for other extrapulmonary manifestations of the disease. Improved treatments that address ongoing nutritional deficits, hepatic and endocrine abnormalities, mucostasis, or additional features that persist despite modulators remain a priority. Sexual and reproductive health have become areas of considerable interest, since pregnancies are markedly increased among women on HEMT. Understanding potential relationship(s) between clinical depression, overall mental health, and chronic modulator therapy remains an important and emerging topic.

Pulmonary Exacerbation Severe CF respiratory exacerbation is commonly managed by hospital admission for parenteral antibiotics and frequent chest physiotherapy directed against (often multidrug-resistant) bacterial pathogens. Aggressive intervention in this setting can restore a large component of lung function, but ongoing and cumulative loss of pulmonary reserve has traditionally reflected the natural history of the disease. Poor prognostic indicators such as sputum culture containing *Burkholderia cepacia* complex, *Stenotrophomonas maltophilia*, *Achromobacter*, mucoid *P. aeruginosa*, or atypical mycobacteria are rigorously monitored in the CF patient population. Methicillin-resistant *S. aureus* in CF lungs may also be associated with less favorable outcomes. As noted above, while HEMT may diminish bacterial density in sputum samples, infection commonly persists despite modulator treatment. Typical inpatient antibiotic coverage includes combination drug therapy with an aminoglycoside and β-lactam (if *Pseudomonas* is present) for ~14 days. Maximal improvement in lung function is often achieved by 8–10 days, although optimal duration of therapy is a subject of continuing investigation. Many families elect parenteral antibiotic treatment at home, but additional studies are needed to evaluate specific drug combinations, duration of therapy, and home versus inpatient management. Other CF respiratory sequelae that may require hospitalization include hemoptysis and pneumothorax. Hypersensitivity to *Aspergillus* (allergic bronchopulmonary aspergillosis) occurs in ~5% of individuals with CF and should be suspected in the absence of a beneficial response to aggressive inpatient antibiotics.

Lung Transplantation For end-stage CF pulmonary failure, transplantation is a viable therapeutic option with median survival >9 years among adults with the disease. Determining optimal timing for surgery presents a substantial challenge in patients with severe respiratory compromise, particularly since the rate of continued functional decline, as well as individualized mortality risk from transplantation, can be difficult to predict. FEV_1 measurements <30% predicted, together with an assortment of other clinical parameters (e.g., hospitalization frequency, need for supplemental oxygen, modulator treatment), are employed as thresholds for transplant referral, although patients with conditions such as significant pulmonary hypertension may merit consultation at higher FEV_1. In general, evaluation for pulmonary transplant has often been underutilized among patients with CF. The decision is best approached based on early input from providers specializing in both CF clinical management and transplant medicine.

CYSTIC FIBROSIS QUALITY IMPROVEMENT AND HEALTHSPAN

As a direct result of advances in basic research, modulator and other therapies have transformed CF from a disease that historically led to death in early childhood to a condition with frequent survival well into the fifth decade of life and beyond. Initiating modulator treatment in young children with CF is expected to further promote longevity by forestalling pulmonary damage, although this assertion will require formal testing in patients on long-term HEMT. Care of aging individuals with CF (in which older patients with the disease experience obesity, cancer, vascular, and other age-related comorbidities commonly observed in the general population) has become an emerging priority. As modulatory therapies advance, standardized approaches to treatment will be essential. Well-defined protocols for general CF management are already widely established, including guidance regarding hospital admission, antibiotic regimens, nutritional intervention, periodicity of diagnostic tests, and other clinical parameters. These recommendations are implemented by specialized CF care centers and similarly accredited programs. Such measures have led to markedly improved pulmonary function, weight gain, body mass index, and other clinical endpoints among patients with the disease. The same approach is being applied to help optimize care of individuals given new CFTR modulators, as well as older patients with CF. Standardized protocols for CF therapy can be accessed at *https://www.cff.org/managing-cf/new-era-cf-care-possible-future-changes* or through a number of excellent reviews.

GLOBAL CONSIDERATIONS

Newborn screening for CF is universal throughout the United States and Canadian provinces, Australia, New Zealand, and most of Europe, and facilitates early intervention. Although the disease has traditionally been viewed as most common among whites (~1 in 3300 live U.S. births), there is growing concern that CF has been underdiagnosed in certain parts of the world, including regions such as Eastern Europe, Latin America, Asia, and India. CF in these areas—as well as among minority populations in the United States—is sometimes associated with rare variants that are less well defined and/or poorly characterized. In many clinical settings, therefore, enhanced attention to diagnosis is needed, particularly when specialized DNA testing and sweat chloride measurements are unavailable and patients with CF may be missed. Failure to identify CF properly in early childhood has important implications, since nutritional and other therapies at a young age are believed to promote quality of life and increase longevity. As one example, median survival among individuals with CF is <30 years in much of Latin America (compared to >60 years in the United States). The less favorable prognosis is attributable in part to lack of widespread diagnostic capabilities (i.e., newborn screening, sweat testing, and genetic analysis tailored to ethnic background), together with insufficient access to leading-edge, interdisciplinary treatment. Efforts to apply state-of-the-art management to underdiagnosed and underserved CF patient populations will help improve outcomes and mitigate CF health disparities in the future.

VIDEO 302-1 Role of CFTR during airway mucociliary clearance. Initial video sequences depict establishment of the normal periciliary fluid layer bathing the surface airway epithelium, with spheres representing chloride and bicarbonate ions secreted through CFTR and across the apical (mucosal) respiratory surface. Later video describes failure of CFTR anion transport and resulting depletion of the periciliary layer, "plastering" of cilia against the mucosal surface, and accumulation of mucus in the airway with resulting bacterial infection. *(Reproduced with permission from Cystic Fibrosis Foundation.)*

VIDEO 302-2 Pharmacologic modulation of mutant CFTR. Initial video (***A***) illustrates CFTR encoding an ion transport gating (class III) defect. The cystic fibrosis (CF) gene product is localized to the plasma membrane but incapable of conducting anions (*yellow spheres*) until a potentiator molecule (shown in *green*) binds and facilitates channel opening. Later video (***B***) describes CFTR encoding a maturational processing (protein biogenesis, class II) defect. The mutant protein is misfolded, fails to traffic to the cell surface, and is degraded by the proteasome. Binding of corrector molecules (*red spheres*) improves folding and facilitates CFTR stabilization and cell surface localization/function. *(Reproduced with permission from Cystic Fibrosis Foundation.)*

303 Chronic Obstructive Pulmonary Disease

Craig P. Hersh, Edwin K. Silverman, Dawn DeMeo

Chronic obstructive pulmonary disease (COPD) is defined as a disease state characterized by persistent respiratory symptoms and airflow obstruction (*https://goldcopd.org/2024-gold-report/*). COPD includes *emphysema*, an anatomically defined condition characterized by destruction of the lung alveoli with air space enlargement; *chronic bronchitis*, a clinically defined condition with chronic cough and phlegm; and/or *small airway disease*, a condition in which small bronchioles are narrowed and reduced in number. The *classic definition* of COPD requires the presence of chronic airflow obstruction, determined by spirometry, that usually occurs in the setting of noxious environmental exposures, most commonly products of combustion, including cigarette smoking in the United States and biomass fuels in some other countries. The increasing prevalence of vaping and use of inhaled cannabis are of increasing concern, especially in adolescent populations. Other factors including abnormal lung development, respiratory infections, asthma, and genetics, can lead to COPD. Emphysema, chronic bronchitis, and small airway disease are present in varying degrees in different COPD patients. Patients with a history of cigarette smoking without chronic airflow obstruction may have chronic bronchitis, emphysema, respiratory symptoms including dyspnea, and acute exacerbations. Although these patients are not included within the classic definition of COPD, they may have similar disease processes. Investigators in the COPDGene study proposed a multidimensional approach to COPD diagnosis, which is based on domains of environmental exposures, respiratory symptoms, imaging abnormalities, and physiologic abnormalities.

COPD is the fourth leading cause of death and affects >15 million persons in the United States. COPD is also a disease of increasing public health importance around the world. Globally, there are an estimated 480 million individuals with COPD, with a projection of 592 million by 2050.

PATHOGENESIS AND PATHOLOGY

Airflow obstruction, the primary physiologic marker of COPD, can result from airway disease and/or emphysema. Cigarette smoke exposure may affect the large airways, small airways (≤2 mm diameter), and alveoli. Changes in large airways cause cough and sputum production, while changes in small airways and alveoli are responsible for physiologic alterations. Airway inflammation, small airway destruction, and the development of emphysema are present in most persons with COPD; however, their relative contributions to airflow obstruction vary from one person to another. The early development of chronic airflow obstruction is driven by small airway disease. Small airways may become narrowed by cells (hyperplasia and accumulation), mucus, and fibrosis. Advanced stages of COPD are typically characterized by extensive emphysema, although there are a small number of subjects with very severe airflow obstruction with airway disease and virtually no emphysema. The subjects at greatest risk of progression in COPD are those with both aggressive airway disease and emphysema.

LARGE AIRWAY DISEASE

Cigarette smoking often results in mucus gland enlargement and goblet cell hyperplasia, leading to cough and mucus production that define chronic bronchitis. Mucus plugs have been frequently observed on chest computed tomography (CT) scans of COPD patients, and they have recently been associated with increased mortality risk. In response to cigarette smoking or other inhaled exposures, goblet cells increase not only in number but also in extent through the bronchial tree. Bronchi also undergo squamous metaplasia, predisposing to carcinogenesis and disrupting mucociliary clearance. Although not as prominent as in asthma, patients with COPD may have bronchial hyperreactivity leading to airflow obstruction. Neutrophil influx has been associated with purulent sputum during respiratory tract infections. Independent of its proteolytic activity, neutrophil elastase is among the most potent secretagogues identified.

SMALL AIRWAY DISEASE

The major site of increased airflow resistance in most individuals with COPD is in airways ≤2 mm diameter. Characteristic cellular changes include goblet cell metaplasia, with these mucus-secreting cells replacing surfactant-secreting club cells. Smooth-muscle hypertrophy may also be present. Luminal narrowing can occur by fibrosis, excess mucus, edema, and cellular infiltration. Reduced surfactant may increase surface tension at the air-tissue interface, predisposing to airway narrowing or collapse. Respiratory bronchiolitis with mononuclear inflammatory cells collecting in distal airway tissues may cause proteolytic destruction of elastic fibers in the respiratory bronchioles and alveolar ducts where the fibers are concentrated as rings around alveolar entrances. Narrowing and drop-out of small airways precede the onset of emphysematous destruction. Advanced COPD has been shown to be associated with a loss of many of the smaller airways and a similar significant loss of the lung microvasculature.

LUNG PARENCHYMAL DESTRUCTION

Emphysema is characterized by destruction of gas-exchanging air spaces, i.e., the respiratory bronchioles, alveolar ducts, and alveoli. Large numbers of macrophages accumulate in respiratory bronchioles of essentially all smokers. Neutrophils, B lymphocytes, and

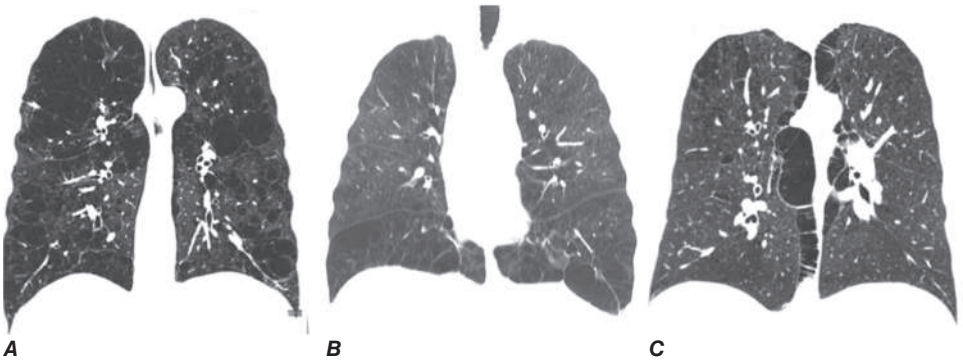

FIGURE 303-1 Computed tomography (CT) patterns of emphysema. ***A.*** Centrilobular emphysema with severe upper lobe involvement in a 68-year-old man with a 70-pack-year smoking history but forced expiratory volume in 1 s (FEV_1) 81% predicted (Global Initiative for Chronic Obstructive Lung Disease [GOLD] spirometry grade 1). ***B.*** Panlobular emphysema with diffuse loss of lung parenchymal detail predominantly in the lower lobes in a 64-year-old man with severe α_1-antitrypsin (α_1AT) deficiency. ***C.*** Paraseptal emphysema with marked airway inflammation in a 52-year-old woman with a 37-pack-year smoking history and FEV_1 40% predicted.

T lymphocytes, particularly CD8+ cells, are also increased in the alveolar space of smokers. Alveolar walls become perforated and later obliterated with coalescence of the delicate alveolar structure into large emphysematous air spaces.

Emphysema is classified into distinct pathologic types, which include centrilobular, panlobular, and paraseptal (Fig. 303-1). *Centrilobular emphysema*, the type most frequently associated with cigarette smoking, is characterized by enlarged air spaces found (initially) in association with respiratory bronchioles. Centrilobular emphysema is usually most prominent in the upper lobes and superior segments of lower lobes. *Panlobular emphysema* refers to abnormally large air spaces evenly distributed within and across acinar units. Panlobular emphysema is commonly observed in patients with α_1-antitrypsin (α_1AT) deficiency, which has a predilection for the lower lobes. Paraseptal emphysema is distributed along the pleural margins with relative sparing of the lung core or central regions. Except for α_1AT deficiency, pathobiological mechanisms related to different emphysema pathophenotypes are not well understood. Radiographic imaging can be used to quantify the amount and distribution of emphysema.

DISEASE MECHANISMS

Although the precise biological mechanisms leading to COPD have not been determined, a number of key cell types, molecules, and pathways have been identified from cell-based and animal model studies. The pathogenesis of emphysema (shown in Fig. 303-2) is more clearly defined than the pathogenesis of small airway disease. Pulmonary vascular destruction occurs in concert with small airway disease and emphysema.

The current dominant paradigm for the pathogenesis of emphysema comprises a series of four interrelated events: (1) Chronic inhaled exposures (typically cigarette smoke) in genetically susceptible individuals triggers inflammatory and immune cell recruitment within large and small airways and in the terminal air spaces of the lung. (2) Inflammatory cells release proteinases that damage the extracellular matrix supporting airways, vasculature, and gas exchange surfaces of the lung. (3) Structural cell death occurs through oxidant-induced

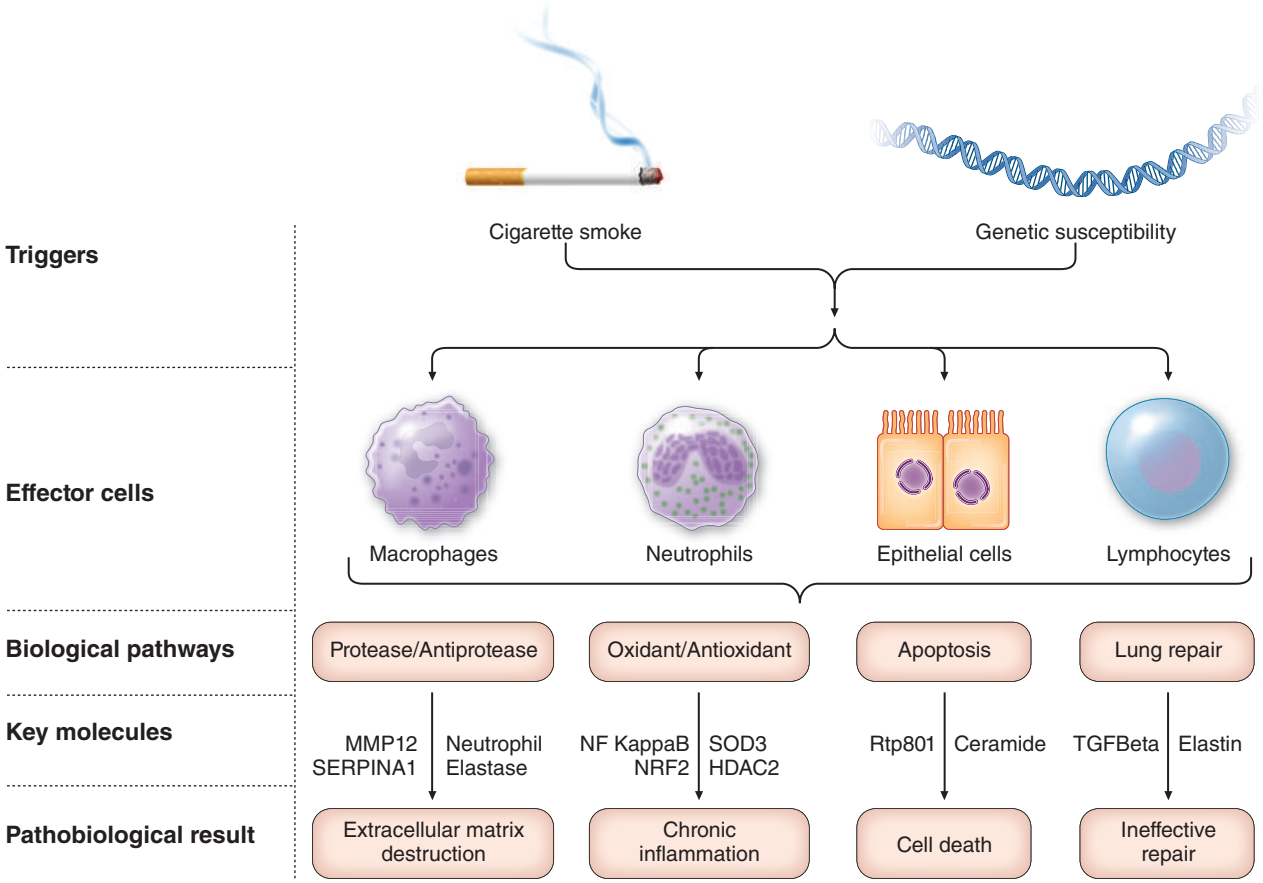

FIGURE 303-2 Pathogenesis of emphysema. Upon long-term exposure to cigarette smoke in genetically susceptible individuals, lung epithelial cells and T and B lymphocytes recruit inflammatory cells to the lung. Biological pathways of protease-antiprotease imbalance, oxidant/antioxidant imbalance, apoptosis, and lung repair lead to extracellular matrix destruction, cell death, chronic inflammation, and ineffective repair. Although most of these biological pathways influence multiple pathobiological results, only a single relationship between pathways and results is shown. A subset of key molecules related to these biological pathways is listed.

damage, cellular senescence, and proteolytic loss of cellular-matrix attachments leading to extensive loss of smaller airways, vascular pruning, and alveolar destruction. (4) Disordered repair of elastin and other extracellular matrix components contributes to air space enlargement and emphysema.

Inflammation and Extracellular Matrix Proteolysis Elastin, the principal component of elastic fibers, is a highly stable component of the extracellular matrix that is critical to the integrity of the lung. The elastase:antielastase hypothesis, proposed in the mid-1960s, postulated that the balance of elastin-degrading enzymes and their inhibitors determines the susceptibility of the lung to destruction, resulting in air space enlargement. This hypothesis was based on the clinical observation that patients with genetic deficiency in α_1AT, the inhibitor of the serine proteinase neutrophil elastase, were at increased risk of emphysema, and that instillation of elastases, including neutrophil elastase, into experimental animals resulted in emphysema. The elastase:antielastase hypothesis remains a prevailing mechanism for the development of emphysema. However, a complex network of immune and inflammatory cells and additional biological mechanisms that contribute to emphysema have subsequently been identified. Both innate and adaptive immune systems are likely involved in COPD pathogenesis. Upon exposure to oxidants from cigarette smoke, lung macrophages and epithelial cells become activated, producing proteinases and chemokines that attract other inflammatory and immune cells. Single-cell transcriptomics revealed that a subset of alveolar type 2 cells is the predominant site of lung gene expression of *HHIP*, one of the top COPD susceptibility genes identified by genome-wide association studies. Oxidative stress is a key component of COPD pathobiology; the transcription factor NRF2, a major regulator of oxidant-antioxidant balance, and SOD3, a potent antioxidant, have been implicated in emphysema pathogenesis by animal models. Mitochondrial dysfunction in COPD may worsen oxidative stress. One mechanism of macrophage activation occurs via oxidant-induced inactivation of histone deacetylase-2 (HDAC2), shifting the balance toward acetylated or open chromatin, exposing nuclear factor-κB sites, and resulting in transcription of matrix metalloproteinases and proinflammatory cytokines such as interleukin 8 (IL-8) and tumor necrosis factor α (TNF-α); this leads to neutrophil recruitment. CD8+ T cells are also recruited in response to cigarette smoke and release interferon-inducible protein-10 (IP-10, CXCL-7), which in turn leads to macrophage production of macrophage elastase (matrix metalloproteinase-12 [MMP12]).

Matrix metalloproteinases and serine proteinases, most notably neutrophil elastase, work together by degrading the inhibitor of the other, leading to lung destruction. Extracellular vesicles induced by cigarette smoke and expressing neutrophil elastase or MMP12 on their surface have been recently implicated as important sources of these destructive proteinases. Proteolytic cleavage products of elastin serve as a macrophage chemokine, and proline-glycine-proline (generated by proteolytic cleavage of collagen) is a neutrophil chemokine, fueling this damaging positive feedback loop. Elastin degradation and disordered repair are thought to be primary mechanisms in the development of emphysema.

There is some evidence that autoimmune mechanisms may promote the progression of disease. Lymphoid follicles composed of B cells and T cells are present around the airways of COPD patients, particularly in patients with advanced disease. T_H1 and T_H17 lymphocytes may activate innate immune cells (including neutrophils, macrophages, and innate lymphoid cells), contributing to a cycle of chronic inflammation. Antibodies have been found against elastin fragments as well; IgG autoantibodies with avidity for pulmonary epithelium and the potential to mediate cytotoxicity have been detected.

Concomitant cigarette smoke–induced loss of cilia in the airway epithelium and impaired macrophage phagocytosis predispose to bacterial infection with neutrophilia. In end-stage lung disease, long after smoking cessation, there remains an exuberant inflammatory response, suggesting that cigarette smoke–induced inflammation both initiates the disease and, in susceptible individuals, establishes a chronic process that can continue disease progression even after smoking cessation.

Cell Death Cigarette smoke oxidant-mediated structural cell death occurs via a variety of mechanisms including excessive ceramide production and Rtp801 inhibition of mammalian target of rapamycin (mTOR), leading to cell death as well as inflammation and proteolysis. Involvement of mTOR and other cellular senescence markers has led to the concept that emphysema resembles premature aging of the lung; emphysema has been identified in the lung tissue of lifetime never smokers of advanced age. Heterozygous gene targeting of hedgehog interacting protein (*HHIP*) in a murine model leads to aging-related emphysema.

Ineffective Repair The ability of the adult lung to replace lost smaller airways and microvasculature and to repair damaged alveoli appears limited. Uptake of apoptotic cells by macrophages normally results in production of growth factors and dampens inflammation, promoting lung repair. Cigarette smoke and other inhaled exposures impair macrophage uptake of apoptotic cells, limiting repair. It is unlikely that the intricate and dynamic process of septation that is responsible for alveologenesis during lung development can be reinitiated in the adult human lung.

PATHOPHYSIOLOGY

Persistent irreversible reduction in forced expiratory flow rates is the classic definition of COPD. Hyperinflation with increases in the residual volume and the residual volume/total lung capacity ratio, nonuniform distribution of ventilation, and ventilation-perfusion mismatching also occur.

AIRFLOW OBSTRUCTION

Airflow obstruction, also known as airflow limitation, is typically determined for clinical purposes by spirometry, which involves maximal forced expiratory maneuvers after the subject has inhaled to total lung capacity. Key parameters obtained from spirometry include the volume of air exhaled within the first second of the forced expiratory maneuver (FEV_1) and the total volume of air exhaled during the entire spirometric maneuver (forced vital capacity [FVC]). Patients with fixed airflow obstruction have a chronically reduced ratio of FEV_1/FVC that does not normalize following bronchodilator treatment.

HYPERINFLATION

Lung volumes are also commonly assessed in pulmonary function testing. In COPD, there is often "air trapping" (increased residual volume and increased ratio of residual volume to total lung capacity) and progressive hyperinflation (increased total lung capacity) in more advanced disease. Hyperinflation of the thorax during tidal breathing preserves maximum expiratory airflow because as lung volume increases, elastic recoil pressure increases and airways enlarge so that airway resistance decreases.

Despite compensating for airway obstruction, hyperinflation can push the diaphragm into a flattened position with a number of adverse effects. First, by decreasing the zone of apposition between the diaphragm and the abdominal wall, positive abdominal pressure during inspiration is not applied as effectively to the chest wall, hindering rib cage movement and impairing inspiration. Second, because the muscle fibers of the flattened diaphragm are shorter than those of a more normally curved diaphragm, they are less capable of generating normal inspiratory pressures. Third, the flattened diaphragm must generate greater tension to develop the transpulmonary pressure required to produce tidal breathing. Fourth, the thoracic cage is distended beyond its normal resting volume, and during tidal breathing, the inspiratory muscles must do work to overcome the resistance of the thoracic cage to further inflation instead of gaining the normal assistance from the chest wall recoiling outward toward its resting volume.

GAS EXCHANGE

Although there is considerable variability in the relationships between the FEV_1 and other physiologic abnormalities in COPD, certain generalizations may be made. The partial pressure of oxygen in arterial blood Pao_2 usually remains near normal until the FEV_1 is decreased

to below 50% of predicted, and even much lower FEV_1 values can be associated with a normal Pao_2, at least at rest. An elevation of arterial level of carbon dioxide ($Paco_2$) is not expected until the FEV_1 is <25% of predicted and even then may not occur. Pulmonary arterial hypertension severe enough to cause cor pulmonale and right ventricular failure due to COPD typically occurs in individuals who have marked decreases in FEV_1 (<25% of predicted) and chronic hypoxemia (Pao_2 <55 mmHg); however, some patients develop significant pulmonary arterial hypertension likely due to vascular destruction, independent of COPD severity **(Chap. 294)**.

Nonuniform ventilation and ventilation-perfusion mismatching are characteristic of COPD, reflecting the heterogeneous nature of the disease process within the airways and lung parenchyma. Physiologic studies are consistent with multiple parenchymal compartments having different rates of ventilation due to regional differences in compliance and airway resistance. Ventilation-perfusion mismatching accounts for essentially all of the reduction in Pao_2 that occurs in COPD; shunting is minimal. This finding explains the effectiveness of modest elevations of inspired oxygen in treating hypoxemia due to COPD and therefore the need to consider problems other than COPD when hypoxemia is difficult to correct with modest levels of supplemental oxygen.

RISK FACTORS

CIGARETTE SMOKING

By 1964, the Advisory Committee to the Surgeon General of the United States had concluded that cigarette smoking was a major risk factor for mortality from chronic bronchitis and emphysema. Subsequent longitudinal studies have shown accelerated decline in FEV_1 in a dose-response relationship to the intensity of cigarette smoking, which is typically expressed as pack-years (average number of packs of cigarettes smoked per day multiplied by the total number of years of smoking). This dose-response relationship between reduced pulmonary function and cigarette smoking intensity accounts, at least in part, for the higher prevalence rates of COPD with increasing age. The historically higher rate of smoking among males is the likely explanation for the historically higher prevalence of COPD among males; however, the prevalence of COPD among females has increased to the point that it is the same or exceeds the prevalence of COPD in men.

Although the causal relationship between cigarette smoking and the development of COPD has been absolutely proved, there is considerable individual variability in the response to smoking. Pack-years of cigarette smoking is the most highly significant predictor of FEV_1 **(Fig. 303-3)**, but only 15% of the variability in FEV_1 is explained by pack-years. This finding suggests that additional developmental, environmental, and/or genetic factors contribute to the impact of smoking on the development of chronic airflow obstruction. Nonetheless, many patients with a history of cigarette smoking with normal spirometry have evidence for worse health-related quality of life, reduced exercise capacity, and emphysema and/or airway disease on chest CT scans; thus, they have not escaped the harmful effects of cigarette smoking and may present with respiratory exacerbations despite normal spirometry. While they do not meet the classic definition of COPD based on population normals for FEV_1 and FEV_1/FVC, studies have shown that these subjects overall have a shift toward lower FEV_1 values, which is consistent with obstruction on an individual level.

Although cigar and pipe smoking may also be associated with the development of COPD, the evidence supporting such associations is less compelling, likely related to the lower dose of inhaled tobacco by-products during cigar and pipe smoking. The impact of electronic cigarettes and vaping on the development and progression of COPD is a growing area of concern; emerging literature identifies increased risk for pulmonary symptoms. Inhaled cannabis use is increasing in prevalence and may increase risk for cough, sputum production, and wheeze. However, it remains unclear whether there is an elevated risk for COPD from cannabis inhalation. A large study of lung function observed heavy cannabis use associated with steeper decline in FEV_1, although other studies have not observed accelerated lung function decline.

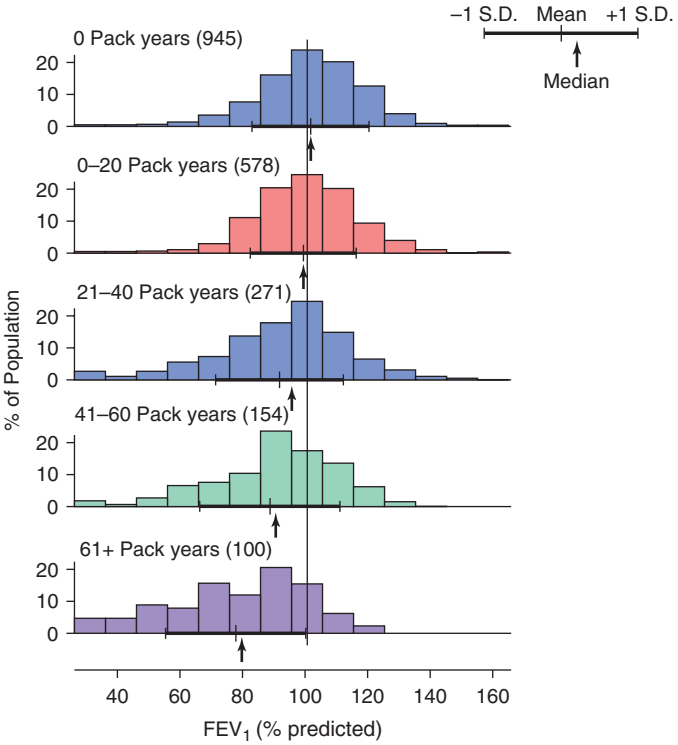

FIGURE 303-3 Distributions of forced expiratory volume in 1 s (FEV_1) values in a general population sample, stratified by pack-years of smoking. Means, medians, and ±1 standard deviation of percent predicted FEV_1 are shown for each smoking group. Although a dose-response relationship between smoking intensity and FEV_1 was found, marked variability in pulmonary function was observed among subjects with similar smoking histories. S.D., standard deviation. *(Reproduced with permission from B Burrows: Quantitative relationships between cigarette smoking and ventilatory function. Am Rev Respir Dis 115:195, 1977.)*

AIRWAY RESPONSIVENESS AND COPD

A tendency for increased reversible bronchoconstriction in response to a variety of exogenous stimuli, including methacholine and histamine, is one of the defining features of asthma **(Chap. 298)**. However, many patients with COPD also share this feature of airway hyperresponsiveness. In older subjects, there is considerable overlap between persons with a history of chronic asthma and COPD in terms of airway responsiveness, airflow obstruction, and pulmonary symptoms. The origin of asthma is viewed in many patients as an allergic disease, while COPD is thought to primarily result from smoking-related inflammation and damage; however, they likely share common environmental and genetic factors, and the chronic form in older subjects can present similarly. This is particularly relevant for childhood asthmatic subjects who chronically smoke throughout adulthood.

Longitudinal studies that compared airway responsiveness to subsequent decline in pulmonary function have demonstrated that increased airway responsiveness is clearly a significant predictor of subsequent decline in pulmonary function. A study from the Childhood Asthma Management Program identified four lung function trajectories in children with persistent asthma. Asthmatics with reduced lung function early in life were more likely to develop persistent airflow obstruction in early adulthood. Both asthma and airway hyperresponsiveness are risk factors for COPD.

RESPIRATORY INFECTIONS

The impact of adult respiratory infections on decline in pulmonary function is controversial, but significant long-term reductions in pulmonary function are not typically seen following an individual episode of acute bronchitis or pneumonia. However, respiratory infections are important causes of COPD exacerbations, and results from the COPDGene and ECLIPSE studies suggest that COPD exacerbations are associated with increased loss of lung function longitudinally, particularly among those individuals with better baseline lung function

levels. The impact of the effects of childhood respiratory illnesses on the subsequent development of COPD has been difficult to assess due to a lack of adequate longitudinal data, but recent studies have suggested that childhood pneumonia may lead to increased risk for COPD later in life. Globally, tuberculosis infection has been associated with chronic airflow limitation and may be an important risk factor in the absence of a personal tobacco use history; tuberculosis-associated COPD may present with both emphysematous and fibrotic changes in the lung and with extensive airway remodeling. Infection with human immunodeficiency virus (HIV) leads to an increased risk for COPD and emphysema, especially with lower CD4 cell counts; COPD is frequently underdiagnosed in this setting.

OCCUPATIONAL EXPOSURES

Increased respiratory symptoms and airflow obstruction have been suggested to result from exposure to vapors, gas, dust, or fumes (VGDF). Several specific occupational exposures, including coal mining, gold mining, and cotton textile dust, have been implicated as risk factors for chronic airflow obstruction. Although nonsmokers in these occupations can develop some reductions in FEV_1, the importance of dust exposure as a risk factor for COPD, independent of cigarette smoking, is not certain for most of these exposures. However, among coal miners, coal mine dust exposure was a significant risk factor for emphysema in both smokers and nonsmokers. Given general underrecognition of VGDF and other occupational drivers and exacerbants of COPD, clinical history taking should include past and current occupational exposures, and referral to occupational health specialists as relevant.

AIR POLLUTION AND CLIMATE CHANGE

Some investigators have reported increased respiratory symptoms in those living in urban compared to rural areas, which may relate to increased ambient air pollution in urban settings, especially fine and ultrafine particulate pollution. However, the relationship of air pollution to chronic airflow obstruction remains unproved. Prolonged exposure to smoke produced by biomass combustion—a common mode of cooking in some countries—is a significant risk factor for COPD, particularly among women. The future impact of global warming on COPD is not clear, although increased extreme hot days are associated with respiratory exacerbations.

EARLY LIFE PASSIVE SMOKE EXPOSURE

Maternal tobacco smoking during in utero lung development contributes to significant reductions in postnatal lung development and pulmonary function. Exposure of children to environmental smoke related to tobacco and biomass fuel may also result in reduced lung growth and respiratory exacerbations. Early life exposure to environmental tobacco smoke has been linked to emphysema in adulthood.

GENETICS

Although cigarette smoking is the major environmental risk factor for the development of COPD, the development of airflow obstruction in smokers is highly variable. Severe α_1AT deficiency is a proven genetic risk factor for COPD; there is increasing evidence that other genetic determinants also exist.

α_1-Antitrypsin Deficiency Many variants of the protease inhibitor (PI or *SERPINA1*) gene that encodes α_1AT have been described. The common M allele is associated with normal α_1AT levels. The S allele, associated with slightly reduced α_1AT levels, and the Z allele, associated with markedly reduced α_1AT levels, also occur with frequencies of >1% in most white populations. Rare individuals inherit null alleles, which lead to the absence of any α_1AT production through a heterogeneous collection of mutations. Individuals with two Z alleles or one Z and one null allele are referred to as Pi^Z, which is the most common form of severe α_1AT deficiency.

Although only ~1% of COPD patients are found to have severe α_1AT deficiency as a contributing cause of COPD, these patients demonstrate that genetic factors can have a profound influence on the susceptibility for developing COPD. Pi^Z individuals often develop early-onset COPD, but the ascertainment bias in the published series of Pi^Z individuals—which have usually included many Pi^Z subjects who were tested for α_1AT deficiency because they had COPD—means that the fraction of Pi^Z individuals who will develop COPD and the age-of-onset distribution for the development of COPD in Pi^Z subjects remain unknown. Approximately 1 in 3000 individuals in the United States inherits severe α_1AT deficiency, but only a small minority of these individuals has been identified. The clinical laboratory test used most frequently to test for α_1AT deficiency is measurement of the immunologic level of α_1AT in serum (see "Laboratory Findings").

A significant percentage of the variability in pulmonary function among Pi^Z individuals is explained by cigarette smoking; cigarette smokers with severe α_1AT deficiency are more likely to develop COPD at early ages. However, the development of COPD in Pi^Z subjects, even among current or ex-smokers, is not absolute. Among Pi^Z nonsmokers, impressive variability has been noted in the development of airflow obstruction. Asthma and male gender also appear to increase the risk of COPD in Pi^Z subjects. Other genetic and/or environmental factors likely contribute to this variability.

Specific treatment in the form of α_1AT augmentation therapy is available for severe α_1AT deficiency as a weekly IV infusion (see "Treatment," below).

Several recent studies have demonstrated that heterozygous Pi^{MZ} subjects (who have intermediate serum levels of α_1AT) who smoke are at increased risk for the development of COPD. However, α_1AT augmentation therapy is not recommended for use in Pi^{MZ} subjects.

Other Genetic Risk Factors Studies of pulmonary function measurements performed in general population samples have indicated that genetic factors other than PI type influence variation in pulmonary function. Familial aggregation of airflow obstruction within families of COPD patients has also been demonstrated.

Genome-wide association studies (GWAS) have identified >80 regions of the genome that contain COPD susceptibility loci, including a region near the *HHIP* gene on chromosome 4, a cluster of genes on chromosome 15 (including components of the nicotinic acetylcholine receptor and another gene, *IREB2*, related to mitochondrial iron regulation), and *FAM13A* on chromosome 4, which is involved in Wnt/beta-catenin signaling. As with most other complex diseases, the risk associated with individual GWAS loci is modest, but these genetic determinants may identify important biological pathways related to COPD. Gene-targeted murine models for *HHIP*, *FAM13A*, and *IREB2* exposed to chronic cigarette smoke had altered emphysema susceptibility, suggesting that those genes are likely to be involved in COPD pathogenesis. An elevated polygenic risk score, which sums the effects of multiple genetic variants, is associated with increased COPD risk.

NATURAL HISTORY

The effects of cigarette smoking on pulmonary function appear to depend on the intensity of smoking exposure, the timing of smoking exposure during lung growth and development, and the baseline lung function of the individual; other environmental factors may have similar effects. Most individuals follow a steady trajectory of increasing pulmonary function with growth during childhood and adolescence, followed by a plateau in early adulthood, and then gradual decline with aging starting in the fourth decade of life. Individuals appear to track in their quantile of pulmonary function based on environmental and genetic factors that put them on different tracks. The risk of eventual mortality from COPD is closely associated with reduced levels of FEV_1 and the presence of emphysema. A graphic depiction of the natural history of COPD is shown as a function of the influences on tracking curves of FEV_1 in **Fig. 303-4**. Death or disability from COPD can result from a normal rate of decline after a reduced growth phase (curve *C*), an early initiation of pulmonary function decline after normal growth (curve *B*), or an accelerated decline after normal growth (curve *D*). Although accelerated rates of lung function decline have classically been associated with COPD, analyses of several population-based cohorts demonstrated that many subjects with fixed airflow obstruction had reduced growth but normal rates of lung function decline.

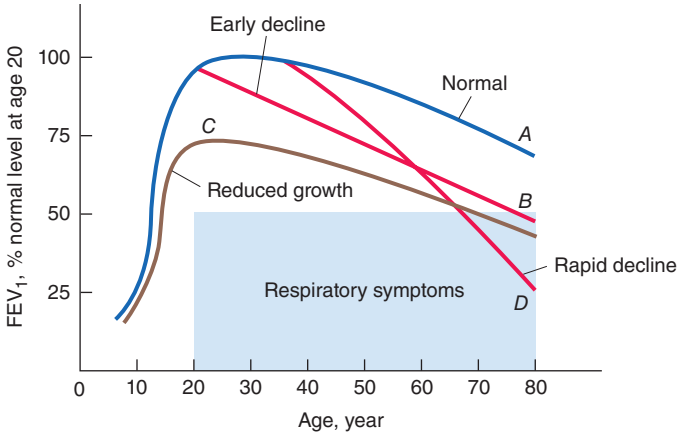

FIGURE 303-4 Hypothetical tracking curves of forced expiratory volume in 1 s (FEV_1) for individuals throughout their life spans. The normal pattern of growth and decline with age is shown by curve *A*. Significantly reduced FEV_1 (<65% of predicted value at age 20) can develop from a normal rate of decline after a reduced pulmonary function growth phase (curve *C*), early initiation of pulmonary function decline after normal growth (curve *B*), or accelerated decline after normal growth (curve *D*). *(From B Rijcken: Doctoral dissertation, p 133, University of Groningen, 1991.)*

The rate of decline in pulmonary function can be modified by changing environmental exposures (i.e., quitting smoking), with smoking cessation at an earlier age providing a more beneficial effect than smoking cessation after marked reductions in pulmonary function have already developed. The absolute annual loss in FEV_1 tends to be highest in mild COPD and lowest in very severe COPD. Multiple genetic factors influence the level of pulmonary function achieved during growth.

In chronic smokers, a group at risk for COPD (sometimes called pre-COPD) based on substantial chest CT changes (emphysema and airway wall thickening) has been identified in subjects with normal physiology (normal FEV_1 and FEV_1/FVC). COPD in these subjects commonly progresses in two primary patterns. Subjects with an emphysema-predominant pattern show emphysema early and classically progress through COPD severity grades. Subjects with an airway disease–predominant pattern typically show initial evidence of airway inflammation and progress with little emphysema early as FEV_1 falls while retaining a normal FEV_1/FVC ratio. This is termed *preserved ratio–impaired spirometry* (PRISm) physiology. The natural history of patients classified as having PRISm revealed an increased risk of mortality and respiratory and cardiovascular events. Although advanced age is an important risk factor for COPD, early COPD is an important area of research given advances in understanding cellular and molecular features and the importance of slowing lung function decline.

CLINICAL PRESENTATION

HISTORY

The three most common symptoms in COPD are cough, sputum production, and exertional dyspnea. Many patients have such symptoms for months or years before seeking medical attention. Although the development of airflow obstruction is a gradual process, many patients date the onset of their disease to an acute illness or exacerbation. A careful history, however, usually reveals the presence of respiratory symptoms prior to the acute exacerbation. The development of exertional dyspnea, often described as increased effort to breathe, heaviness, air hunger, or gasping, can be insidious. It is best elicited by a careful history focused on typical physical activities and how the patient's ability to perform them has changed. Activities involving significant arm work, particularly at or above shoulder level, are particularly difficult for many patients with COPD. Conversely, activities that allow the patient to brace the arms and use accessory muscles of respiration are better tolerated. Examples of such activities include pushing a shopping cart or walking on a treadmill. As COPD advances, the principal feature is worsening dyspnea on exertion with increasing intrusion on the ability to perform vocational or avocational activities. In the most advanced stages, patients are breathless doing basic activities of daily living. Validated questionnaires such as the COPD Assessment Test (CAT) and Modified Medical Research Council dyspnea scale may be used to reliably capture symptoms and activity limitations.

Accompanying worsening airflow obstruction is an increased frequency of exacerbations (described below). Patients may also develop resting hypoxemia and require institution of supplemental oxygen. A thorough history must consider symptoms of common comorbidities, such cardiovascular disease, gastroesophageal reflux, osteoporosis, frailty, depression, and anxiety.

PHYSICAL EXAMINATION

In the early stages of COPD, patients usually have an entirely normal physical examination. In patients with more severe disease, the physical examination of the lungs is notable for a prolonged expiratory phase and may include expiratory wheezing. In addition, signs of hyperinflation include a barrel chest and enlarged lung volumes with poor diaphragmatic excursion as assessed by percussion. Patients with severe airflow obstruction may also exhibit use of accessory muscles of respiration, sitting in the characteristic "tripod" position to facilitate the actions of the sternocleidomastoid, scalene, and intercostal muscles. Patients may develop cyanosis, visible in the lips and nail beds.

Advanced disease may be accompanied by cachexia, with significant weight loss and diffuse loss of subcutaneous adipose tissue. This syndrome has been associated with both inadequate oral intake and elevated levels of inflammatory cytokines (e.g., TNF-α). Such wasting is an independent poor prognostic factor in COPD.

Signs of overt right heart failure, termed *cor pulmonale*, are relatively infrequent since the advent of supplemental oxygen therapy, but pulmonary hypertension must be considered in patients with persistent activity limitations or lower extremity edema.

Clubbing of the digits is not a sign of COPD, and its presence should alert the clinician to initiate an investigation for causes of clubbing. In COPD patients, the development of lung cancer is the most likely explanation for newly developed clubbing.

LABORATORY FINDINGS

The hallmark of COPD is airflow obstruction (discussed above). Pulmonary function testing shows airflow obstruction with a reduction in FEV_1 and FEV_1/FVC **(Chap. 296)**. With worsening disease severity, lung volumes may increase, resulting in an increase in total lung capacity, functional residual capacity, and residual volume. In patients with emphysema, the diffusing capacity may be reduced, reflecting the lung parenchymal destruction characteristic of the disease. The degree of airflow obstruction is an important prognostic factor in COPD. For spirometric severity grading, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) has consistently used thresholds of FEV_1 as a percentage of predicted value based on population reference equations. The American Thoracic Society and European Respiratory Society have recently advocated grading severity of lung function impairment using population-defined Z-scores **(Table 303-1)**. Pulmonary function interpretation has traditionally used race-specific reference values; however, race-neutral interpretation of pulmonary function tests may be preferable. Although the degree of airflow obstruction *generally* correlates with the presence and severity of respiratory symptoms, exacerbations, emphysema, and hypoxemia, the correlations are far from perfect. Thus, clinical features should be carefully assessed in each individual patient with COPD to determine the most appropriate therapies. It has been shown that a multifactorial index (BODE), incorporating body mass index, airflow obstruction, dyspnea, and exercise performance, is a better predictor of mortality. Exercise capacity can be quantified by the distance a patient is able to walk in 6 min. The GOLD COPD classification system incorporates respiratory symptoms and exacerbation history; these metrics are used to guide COPD treatment (see below).

Arterial blood gases and oximetry may demonstrate resting or exertional hypoxemia. Arterial blood gases provide additional information about alveolar ventilation and acid-base status by measuring arterial

TABLE 303-1 Comparison of GOLD and ATS/ERS Criteria for Severity of Airflow Obstruction

GOLD		ERS/ATS	
SEVERITY	SPIROMETRY	SEVERITY	SPIROMETRY
Mild	FEV_1/FVC <0.7 and FEV_1 ≥80% predicted	[a]	FEV_1/FVC <LLN and $zFEV_1$ > –1.645
Moderate	FEV_1/FVC <0.7 and FEV_1 ≥50% but <80% predicted	Mild	FEV_1/FVC <LLN and $zFEV_1$ between –1.65 and –2.5
Severe	FEV_1/FVC <0.7 and FEV_1 ≥30% but <50% predicted	Moderate	FEV_1/FVC <LLN and $zFEV_1$ between –2.51 and –4
Very severe	FEV_1/FVC <0.7 and FEV_1 <30% predicted	Severe	FEV_1/FVC <LLN and $zFEV_1$ < –4.1

[a]The ERS/ATS document does not provide a term for this category. Some authors have called it "borderline" or "minimal."

Abbreviations: ATS, American Thoracic Society; COPD, chronic obstructive pulmonary disease; ERS, European Respiratory Society; FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity; GOLD, Global Initiative for Chronic Obstructive Lung Disease; LLN, lower limit of normal; $zFEV_1$, z-score of FEV_1.

Pco_2 and pH. The change in pH with Pco_2 is 0.08 units/10 mmHg acutely and 0.03 units/10 mmHg in the chronic state. Knowledge of the arterial pH therefore allows the classification of ventilatory failure, defined as Pco_2 >45 mmHg, into acute or chronic conditions with acute respiratory failure being associated with acidemia. The arterial blood gas is an important component of the evaluation of patients presenting with symptoms of an exacerbation. An elevated hematocrit suggests the presence of chronic hypoxemia, as does the presence of signs of right ventricular hypertrophy. The blood eosinophil count, measured on a complete blood count with differential, is used to guide therapy, with the goal of reducing exacerbation risk

Radiographic studies may assist in the classification of the type of COPD. Chest x-ray findings may be consistent with COPD but cannot be used reliably to make the diagnosis. Increased lung volumes and flattening of the diaphragm suggest hyperinflation but do not provide information about chronicity of the changes. Obvious bullae, paucity of parenchymal markings, or hyperlucency on chest x-ray suggests the presence of emphysema. Chest CT scan is the current definitive test for establishing the presence or absence of emphysema, the pattern of emphysema, and the presence of significant disease involving medium and large airways (Fig. 303-1). It also enables the discovery of coexisting interstitial lung disease and bronchiectasis. Smokers with COPD are at high risk for development of lung cancer; annual low-dose chest CT scans for lung cancer screening have been demonstrated to reduce mortality in selected current and former smokers. In advanced COPD, CT scans can help determine the possible value of surgical or bronchoscopic therapy (described below).

Guidelines suggest testing for α_1AT deficiency in all subjects with COPD or asthma with chronic airflow obstruction. Measurement of the serum α_1AT level is the usual initial test. For subjects with low α_1AT levels, the definitive diagnosis of α_1AT deficiency requires PI type determination. This is typically performed by isoelectric focusing of serum or plasma, which reflects the genotype at the PI locus for the common alleles and many of the rare PI alleles as well. Mass spectrometry or molecular genotyping can be performed for the common PI variants (M, S, and Z), and DNA sequencing can detect other rare deficiency variants.

TREATMENT

Chronic Obstructive Pulmonary Disease

STABLE COPD

The two main goals of COPD therapy are to provide symptomatic relief (reduce respiratory symptoms, improve exercise tolerance, and improve health status) and reduce future risk (prevent disease progression, prevent and treat exacerbations, and reduce mortality). The institution of therapies should be based on symptom assessment, benefits of therapy, potential risks, and costs. **Figure 303-5** provides the currently suggested assessment of COPD patients based on spirometry, respiratory symptoms and risk for exacerbations. Response to therapy should be assessed, and decisions should be made whether or not to continue or alter treatment.

Three interventions—smoking cessation, oxygen therapy in chronically hypoxemic patients, and lung volume reduction surgery (LVRS) in selected patients with emphysema—have been demonstrated to improve survival of patients with COPD. Evidence is less strong that other nonpharmacologic interventions also reduce mortality, such as pulmonary rehabilitation after a COPD hospitalization, noninvasive positive-pressure ventilation in severe hypercapnia, and possibly lung transplantation. Triple inhaled therapy (long-acting beta-agonist bronchodilator, long-acting muscarinic antagonist bronchodilator, and inhaled corticosteroid) reduces mortality in selected patients with COPD.

PHARMACOTHERAPY

Smoking Cessation **(See also Chap. 465)** It has been shown that middle-aged smokers who were able to successfully stop smoking experienced a significant improvement in the rate of decline in pulmonary function, often returning to annual changes similar to that of nonsmoking patients. In addition, smoking cessation improves survival. Thus, all smokers with COPD should be strongly urged to quit smoking and educated about the benefits of quitting. An emerging body of evidence demonstrates that combining pharmacotherapy with traditional supportive approaches considerably enhances the chances of successful smoking cessation. There are three principal pharmacologic approaches to the problem: nicotine replacement therapy available as gum, transdermal patch, lozenge, inhaler, and nasal spray; bupropion; and varenicline, a nicotinic acid receptor agonist/antagonist. The use of electronic cigarettes as a harm reduction strategy remains controversial. Current recommendations from the U.S. Surgeon General are that all adult, nonpregnant smokers considering quitting be offered pharmacotherapy, in the absence of any contraindication to treatment. Smoking cessation counseling is also recommended, and free counseling is available through state Smoking Quitlines.

Bronchodilators In general, inhaled bronchodilators are the primary treatment for almost all patients with COPD and are used for symptomatic benefit and to reduce exacerbation risk. In symptomatic patients, both regularly scheduled use of long-acting agents and as-needed short-acting medications are indicated. **Figure 303-6** provides suggestions for prescribing inhaled medication therapy based on grouping patients by severity of symptoms and risk of exacerbations.

Muscarinic Antagonists Short-acting ipratropium bromide improves symptoms with acute improvement in FEV_1. Long-acting muscarinic antagonists (LAMA; including aclidinium, glycopyrrolate, glycopyrronium, revefenacin, tiotropium, and umeclidinium) improve symptoms and reduce exacerbations. Side effects are minor; dry mouth is the most frequent.

Beta Agonists Short-acting beta agonists ease symptoms with acute improvements in lung function. Long-acting beta agonists (LABAs) provide symptomatic benefit and reduce exacerbations, though to a lesser extent than a LAMA. Currently available long-acting inhaled beta agonists are arformoterol, formoterol, indacaterol, olodaterol, salmeterol, and vilanterol. The main side effects are tremor and tachycardia.

Combinations of Beta Agonist–Muscarinic Antagonist Combination inhaled LABA and LAMA therapy has been demonstrated to

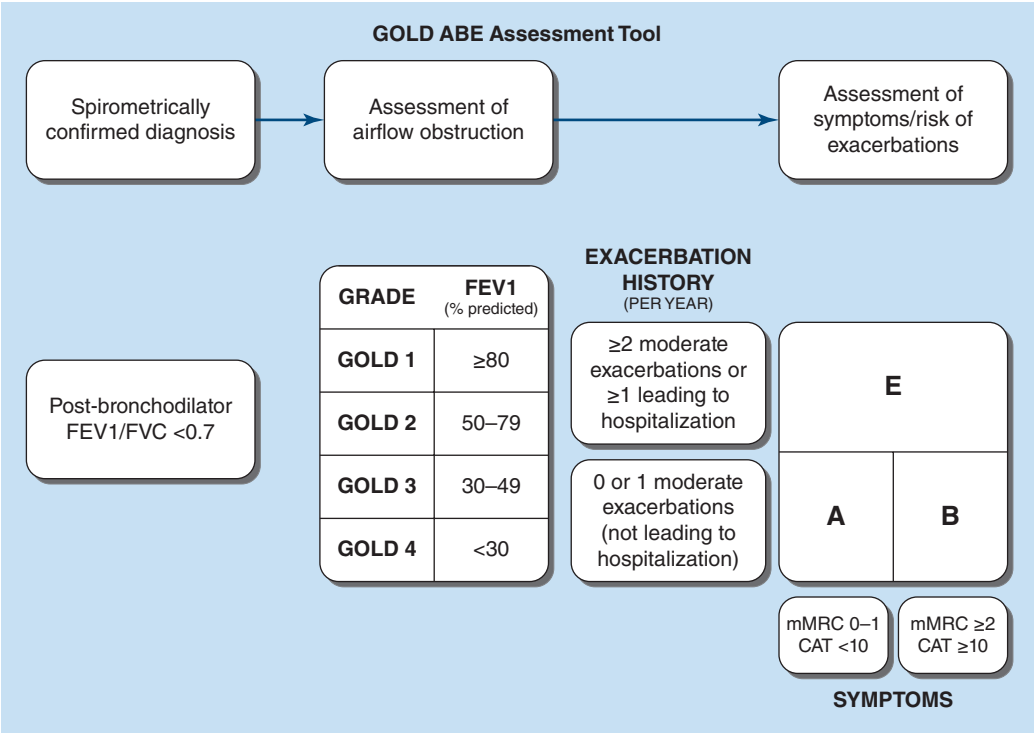

FIGURE 303-5 Chronic obstructive pulmonary disease (COPD) severity assessment. COPD severity categories are defined using respiratory symptoms (based on the Modified Medical Research Council Dyspnea Scale [mMRC] or COPD Assessment Test [CAT]) and annual frequency of COPD exacerbations. The mMRC provides a single number for degree of breathlessness: 0—only with strenuous activity; 1—hurrying on level ground or walking up a slight hill; 2—walk slower than peers or stop walking at their own pace; 3—walking about 100 yards or after a few minutes on level ground; 4—too breathless to leave the house or when dressing. The CAT is an eight-item COPD health status measure with Likert scale responses for questions about cough, phlegm, chest tightness, dyspnea after climbing one flight of stairs, limitation in home activities, confidence in leaving the home, sleep, and energy. Range of total score is 0–40. Both mMRC and CAT are available from Global Strategy for the Diagnosis, Management and Prevention of COPD, Global Initiative for Chronic Obstructive Lung Disease (GOLD) 2024. *(Reproduced with permission from 2025 GOLD Report-Global initiative for chronic obstructive lung disease; 2025.)*

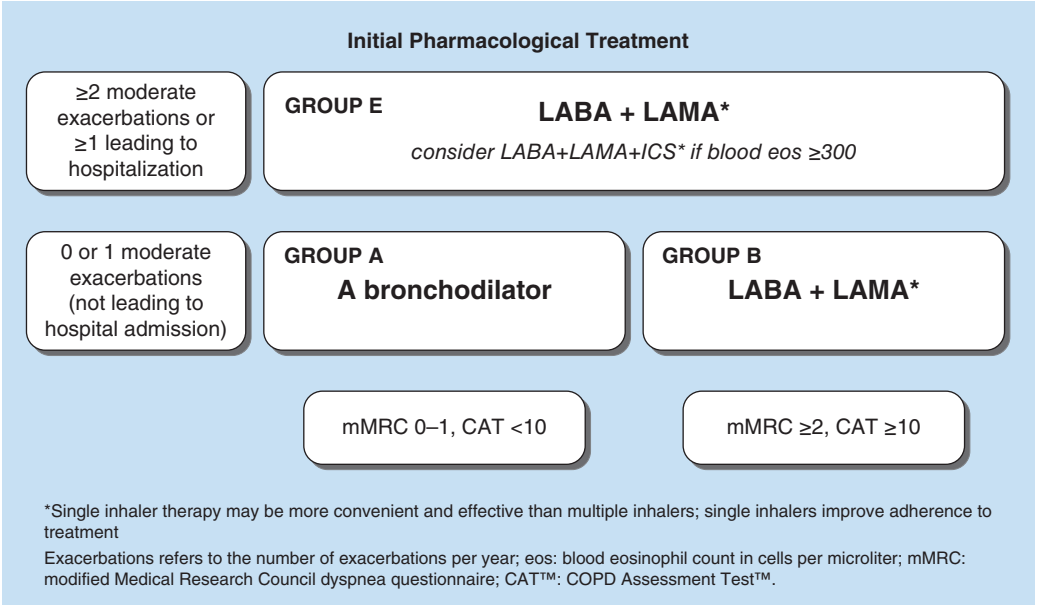
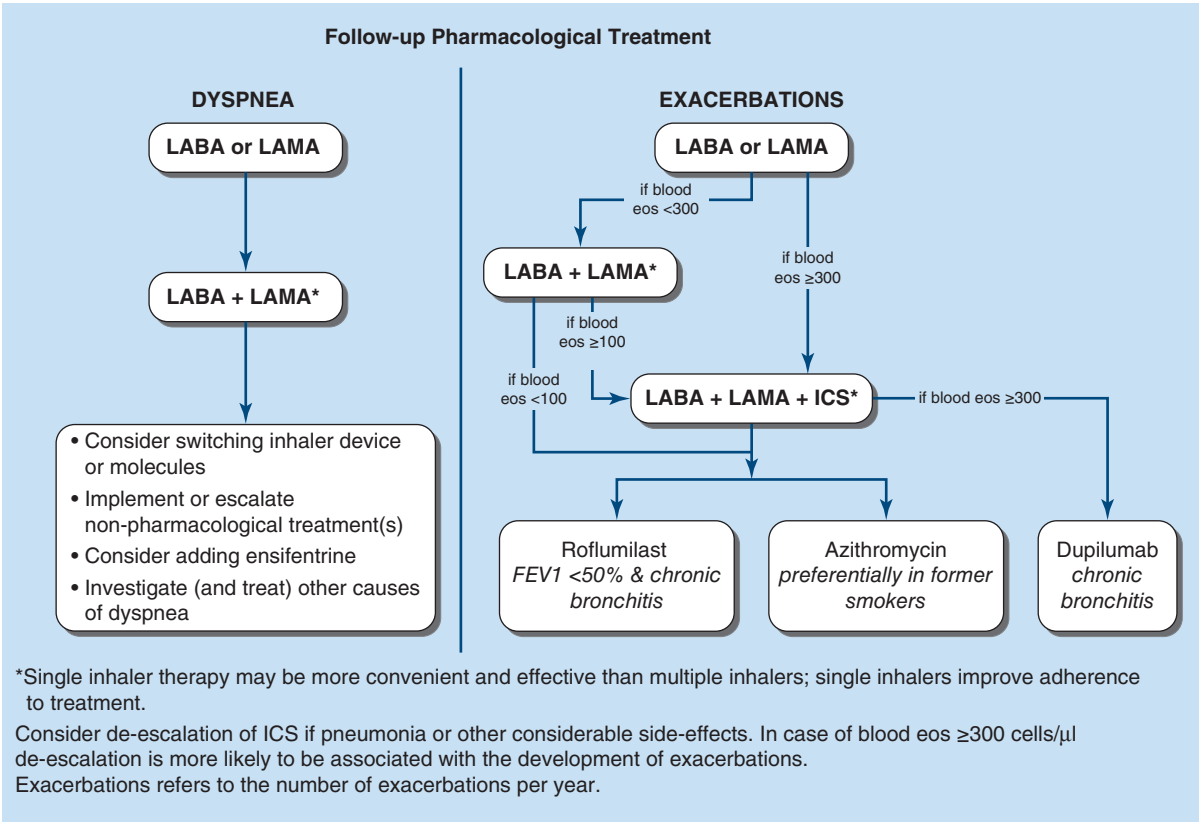
provide improvement in lung function that is greater than either agent alone and reduces exacerbations. Dual bronchodilators are recommended as first-line treatments in patients with symptoms and/or increased exacerbation risk. There are multiple approved drug-device combinations, and some patients may find improved symptoms or increased ease of use for a particular inhaler or nebulizer device.



Inhaled Corticosteroids The main role of inhaled corticosteroids (ICS) is to reduce exacerbations. In population studies, patients with an eosinophil count of <100 cells per microliter do not benefit, while benefit increases as eosinophil counts rise above 100; ICS are recommended as part of the initial treatment regimen for eosinophil counts above 300. ICS are never used alone in COPD due to little symptomatic benefit but, rather, are combined with a LABA or used with a LABA and LAMA. Triple-therapy inhalers (LAMA-LABA-ICS) may be preferred over multiple inhalers. ICS use has been associated with increased rates of oropharyngeal candidiasis and pneumonia and, in some studies, an increased rate of loss of bone density and development of cataracts. ICS can be added when patients with eosinophils counts above 100 continue to have exacerbations despite dual bronchodilator therapy. In stable patients without exacerbations, ICS withdrawal may be considered. Although ICS withdrawal does not lead to an increase in exacerbations, there may be a small decline in lung function.

Oral Glucocorticoids The chronic use of oral glucocorticoids for treatment of COPD is not recommended because of an unfavorable benefit/risk ratio. The chronic use of oral glucocorticoids is associated with significant side effects, including osteoporosis, weight gain, cataracts, glucose intolerance, and increased risk of infection. A study demonstrated that patients tapered off chronic low-dose prednisone (~10 mg/d) did not experience any adverse effect on the frequency of exacerbations, health-related quality of life, or lung function.



PDE4 Inhibitors The selective phosphodiesterase 4 (PDE4) inhibitor roflumilast has been demonstrated to reduce exacerbation frequency in patients with severe COPD, chronic bronchitis, and a prior history of exacerbations; its effects on airflow obstruction and respiratory symptoms are modest, and side effects (including nausea, diarrhea, and weight loss) are common.

Antibiotics There are strong data implicating bacterial infection as a precipitant of COPD exacerbations. A randomized clinical trial of azithromycin, chosen for both its anti-inflammatory and antimicrobial properties, administered daily to subjects with a history of exacerbation in the past 6 months, demonstrated a reduced exacerbation frequency and longer time to first exacerbation. Azithromycin was most effective in older patients, former smokers, and milder COPD. Side effects include hearing loss and development of macrolide-resistant organisms; chronic azithromycin should be avoided in the setting of a prolonged QTc interval.

Oxygen Supplemental O_2 has been demonstrated to unequivocally decrease mortality in hypoxemic patients with COPD. For patients with resting hypoxemia (resting O_2 saturation ≤88% in any patient or ≤89% with signs of pulmonary arterial hypertension, right heart failure, or erythrocytosis), the use of O_2 has been demonstrated to have a significant impact on mortality. Patients meeting these criteria should be on continuous oxygen supplementation because the mortality benefit is proportional to the number of hours per day oxygen is used. Various delivery systems are available, including portable systems that patients may carry to allow mobility outside the home. A recent study failed to demonstrate mortality or symptomatic benefits to COPD patients with moderate hypoxemia at rest or with hypoxemia only with activity. Long-term nocturnal noninvasive mechanical ventilation may be beneficial in stable COPD patients with chronic hypercapnia; a sleep study is recommended prior to initiation to exclude concurrent obstructive sleep apnea.

FIGURE 303-6 Medication therapy for stable chronic obstructive pulmonary disease (COPD). Initial pharmacologic therapy (***A***) is based on both COPD exacerbations and respiratory symptoms (assessed through the Modified Medical Research Council Dyspnea Scale [mMRC] or the COPD Assessment Test [CAT]). Follow-up pharmacologic therapy (***B***) is based on response to treatment initiation and reassessment of symptoms and exacerbations. Global Strategy for the Diagnosis, Management and Prevention of COPD, Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2024. *For ***B***: Single-inhaler therapy may be more convenient and effective than multiple inhalers. **Consider deescalation of ICS if pneumonia or other side effects occur. Eos, blood eosinophil count in cells per microliter; FEV_1, forced expiratory volume in 1 s; ICS, inhaled corticosteroid; LABA, long-acting beta agonist; LAMA, long-acting muscarinic antagonist. *(Reproduced with permission from 2025 GOLD Report-Global initiative for chronic obstructive lung disease; 2025.)*

α_1AT Augmentation Therapy Specific treatment in the form of IV α_1AT augmentation therapy is available for individuals with severe α_1AT deficiency. Although biochemical efficacy of α_1AT augmentation therapy has been shown, the benefits of α_1AT augmentation therapy are controversial. A randomized study suggested a reduction in emphysema progression in patients receiving α_1AT augmentation therapy. Eligibility for α_1AT augmentation therapy requires a serum α_1AT level <11 µ*M* (~55 mg/dL). Typically, Pi^Z individuals

will qualify, although other rare types associated with severe deficiency (e.g., null-null) are also eligible. Because only a fraction of individuals with severe α_1AT deficiency will develop COPD, α_1AT augmentation therapy is not recommended for severely α_1AT-deficient persons with normal pulmonary function and a normal chest CT scan.

Other Biologic Therapies Dupilumab is a monoclonal antibody targeting IL-4 and IL-13, delivered by subcutaneous injection. It is approved for use in allergic diseases including asthma, atopic dermatitis, chronic rhinosinusitis with nasal polyps, and eosinophilic esophagitis. A recent study showed that dupilumab injections reduced the exacerbation rate in symptomatic COPD patients with high exacerbation risk and elevated blood eosinophils of at least 300 cells per microliter, when added to triple inhaled therapy.

NONPHARMACOLOGIC THERAPIES

Patients with COPD should receive the influenza vaccine annually. Pneumococcal, COVID-19, and respiratory syncytial virus (RSV) vaccines are recommended; vaccination for *Bordetella pertussis* is recommended for those not vaccinated in adolescence.

Pulmonary Rehabilitation Pulmonary rehabilitation is a comprehensive treatment program that incorporates exercise, education, and psychosocial and nutritional counseling. In COPD, pulmonary rehabilitation has been demonstrated to improve health-related quality of life, dyspnea, and exercise capacity. It has also been shown to reduce rates of hospitalization over a 6- to 12-month period.

Lung Volume Reduction In carefully selected patients with emphysema, surgery to remove the most emphysematous portions of lung improves exercise capacity, lung function, and survival. The anatomic distribution of emphysema and postrehabilitation exercise capacity are important prognostic characteristics. Patients with upper lobe–predominant emphysema and a low postrehabilitation exercise capacity are most likely to benefit from LVRS. Patients with an FEV_1 <20% of predicted and either diffusely distributed emphysema on CT scan or diffusing capacity of lung for carbon monoxide (D_{LCO}) <20% of predicted have increased mortality after the procedure and thus are not candidates for LVRS.

Two different endobronchial one-way valves for bronchoscopic lung volume reduction (BLVR) have been approved by the U.S. Food and Drug Administration. The indications are largely similar to those for LVRS, although valves can be used to treat emphysema in any lung lobe. Patients should not have interlobar collateral ventilation, either measured by intact fissures on chest CT scan or a bronchoscopic device. The main postprocedure complication is pneumothorax, which usually occurs within the first 3 days. A small study suggested similar outcomes at 12 months for BLVR compared to LVRS.

Lung Transplantation **(See Chap. 309)** COPD is currently the second leading indication for lung transplantation. Current recommendations are that candidates for lung transplantation should have very severe airflow obstruction; have severe disability despite maximal medical therapy; be free of significant comorbid conditions such as liver, renal, or cardiac disease; and not be a candidate for LVRS or BLVR. Currently, there is no cure for COPD except lung transplantation. Current efforts focus on early diagnosis and comprehensive treatment as well as mitigation of environmental risk factors.

EXACERBATIONS OF COPD

Exacerbations are often a prominent feature of the natural history of COPD. Exacerbations are episodic acute worsening of respiratory symptoms, including increased dyspnea, cough, and/or change in the amount and character of sputum, usually over a period of <14 days. They may or may not be accompanied by other signs of illness, including fever, myalgias, and sore throat. The strongest single predictor of exacerbations is a history of a previous exacerbation. The frequency of exacerbations increases as airflow obstruction worsens; patients with severe airflow obstruction (FEV_1 <50% predicted) on average have 1–3 episodes per year. However, some individuals with severe airflow obstruction do not have frequent exacerbations. Other factors, such as current smoking, an elevated ratio of the diameter of the pulmonary artery to aorta on chest CT, and gastroesophageal reflux, are also associated with increased risk of COPD exacerbations. Economic analyses have shown that a majority of the $50 billion annual COPD-related health care expenditures in the United States are due to COPD exacerbations.

Precipitating Causes and Strategies to Reduce Frequency of Exacerbations A variety of stimuli may result in the final common pathway of airway inflammation and increased respiratory symptoms that are characteristic of COPD exacerbations. Viral respiratory infections had been thought to be a less common cause of COPD exacerbations than bacterial infection, although polymerase chain reaction–based studies have shown that viral infections may be a cause of >50% of exacerbations. Studies suggest that acquiring a new strain of bacteria is associated with increased near-term risk of exacerbation. Other inciting factors include air pollution, allergens, pulmonary embolism, and medication nonadherence. In a significant minority of instances, no specific precipitant can be identified.

Patient Assessment An attempt should be made to establish the severity of the exacerbation as well as the severity of preexisting COPD. The more severe either of these two components, the more likely it is that the patient will require hospital admission. The history should include quantification of the degree and change in dyspnea by asking about breathlessness during activities of daily living and typical activities for the patient. The patient should be asked about fever; change in character of sputum; and associated symptoms such as wheezing, nausea, vomiting, diarrhea, myalgias, and chills. Inquiring about the frequency and severity of prior exacerbations can provide important information; the single greatest risk factor for hospitalization with an exacerbation is a history of previous hospitalization.

The physical examination should incorporate an assessment of the degree of distress of the patient. Specific attention should be focused on tachycardia, tachypnea, use of accessory muscles, signs of perioral or peripheral cyanosis, the ability to speak in complete sentences, and the patient's mental status. The chest examination should establish the presence or absence of focal findings, degree of air movement, presence or absence of wheezing, asymmetry in the chest examination (suggesting large airway obstruction or pneumothorax mimicking an exacerbation), and the presence or absence of paradoxical motion of the abdominal wall.

Patients with severe underlying COPD, who are in moderate or severe distress, or those with focal findings should have a chest x-ray or chest CT scan. Approximately 25% of x-rays in this clinical situation will be abnormal, with the most frequent findings being pneumonia and congestive heart failure, and occasionally pneumothorax. Patients with advanced COPD, a history of hypercarbia, or mental status changes (confusion, sleepiness) or those in significant distress should have an arterial blood gas measurement. The presence of hypercarbia, defined as a P_{CO_2} >45 mmHg, has important implications for treatment (discussed below). In contrast to its utility in the management of exacerbations of asthma, measurement of pulmonary function has not been demonstrated to be helpful in the diagnosis or management of exacerbations of COPD. Pulmonary embolus (PE) should also be considered because the incidence of PE is increased in COPD exacerbations.

The need for inpatient treatment of exacerbations is suggested by the presence of respiratory acidosis and hypercarbia, new or worsening hypoxemia, severe underlying COPD, significant comorbidities such as heart failure, and those whose living situation is not conducive to careful observation and the delivery of prescribed treatment. COPD exacerbation is a clinical diagnosis. A recent expert consensus has developed more objective criteria to diagnose and stage the severity of COPD exacerbations, based on dyspnea, vital signs, and testing of C-reactive protein and arterial blood

gases. However, this schema may have more utility in the emergency department than in the outpatient setting.

TREATMENT OF ACUTE EXACERBATIONS

Bronchodilators Typically, patients are treated with inhaled beta agonists and muscarinic antagonists. These may be administered separately or together, and the frequency of administration depends on the severity of the exacerbation. Patients are often treated initially with nebulized therapy, as such treatment is often easier to administer in those in respiratory distress. It has been shown, however, that conversion to metered-dose inhalers is effective when accompanied by education and training of patients and staff. This approach has significant economic benefits and also allows an easier transition to outpatient care.

Antibiotics Patients with COPD are frequently colonized with potential respiratory pathogens, and it is often difficult to identify conclusively a specific species of bacteria responsible for a particular clinical event. Bacteria frequently implicated in COPD exacerbations include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis,* and *Chlamydia pneumoniae;* viral pathogens are also common etiologies of exacerbations. The choice of antibiotic should be based on local patterns of antibiotic susceptibility of the above bacterial pathogens as well as the patient's clinical condition. Patients with moderate or severe exacerbations are usually treated with 5–7 days of antibiotics, even in the absence of data implicating a specific pathogen.

Glucocorticoids In patients admitted to the hospital, the use of systemic glucocorticoids reduces the length of stay, hastens recovery, and reduces the chance of subsequent exacerbation or relapse. Current recommendations suggest 40 mg of oral prednisone or its equivalent typically for a period of 5 days. Hyperglycemia, particularly in patients with preexisting diagnosis of diabetes, is the most frequently reported acute complication of glucocorticoid treatment.

Oxygen Supplemental O_2 should be supplied with a target oxygen saturation of 88–92%. Studies have demonstrated that in patients with both acute and chronic hypercarbia, the administration of supplemental O_2 does not reduce minute ventilation. It does, in some patients, result in modest increases in arterial P_{CO_2}, chiefly by altering ventilation-perfusion relationships within the lung. This should not deter practitioners from providing the oxygen needed to correct hypoxemia.

Mechanical Ventilatory Support The initiation of noninvasive positive-pressure ventilation (NIPPV) in patients with acute respiratory acidosis, defined as P_{aCO_2} >45 mmHg and pH ≤7.35, results in a significant reduction in mortality rate, need for intubation, complications of therapy, and hospital length of stay. Contraindications to NIPPV include cardiovascular instability, impaired mental status, inability to cooperate, copious secretions or the inability to clear secretions, or craniofacial abnormalities or trauma precluding effective fitting of the mask.

Invasive (conventional) mechanical ventilation via an endotracheal tube is indicated for patients with severe respiratory distress, hypoxemia, severe hypercarbia and/or acidosis despite noninvasive ventilation, markedly impaired mental status, respiratory arrest, hemodynamic instability, or other complications. The goal of mechanical ventilation is to correct the aforementioned conditions. Factors to consider during mechanical ventilatory support include the need to provide sufficient expiratory time in patients with severe airflow obstruction and the presence of auto-PEEP (positive end-expiratory pressure), which can result in patients having to generate significant respiratory effort to trigger a breath during a demand mode of ventilation.

The mortality rate of patients requiring mechanical ventilatory support for a COPD exacerbation is 17–49% for that particular hospitalization. Owing to the high mortality of invasive mechanical ventilation in COPD exacerbations, patient preferences for advanced directives (e.g., do not resuscitate) should be discussed in the outpatient setting. Following a hospitalization for COPD, ~20% of patients are rehospitalized in the next 30 days and 45% in the next year. Mortality is ~20% in the year following hospital discharge.

304 Interstitial Lung Disease

Gary M. Hunninghake, Ivan O. Rosas

Diffuse parenchymal lung diseases include a large number (>200) of heterogeneous conditions that affect the lung parenchyma with varying degrees of inflammation and fibrosis. While remodeling of the interstitial space, the region between the epithelium and endothelium, tends to be the dominant site of involvement for most of the interstitial lung diseases (ILDs), it is important to recognize the prominent role of the alveolar epithelium and endothelial cells (including both airways and vessels) in the pathogenesis of these ILDs.

Despite the diverse array of conditions, most patients ultimately diagnosed with an ILD will come to medical attention with reports of progressive exertional dyspnea or a persistent dry cough. However, because some ILDs are part of multisystem disorders, some patients will be identified based on nonrespiratory symptomatology (e.g., skin thickening in the setting of systemic sclerosis, **Chap. 372**) or physical examination findings (e.g., ulnar deviation of the fingers in the setting of rheumatoid arthritis [RA], **Chap. 370**). Additionally, ILDs can also be identified incidentally based on the results of abnormal pulmonary function tests, chest x-rays (CXRs), and computed tomography (CT) studies of both the chest and abdomen (which can both visualize at least a portion, of the lung parenchyma), and positron emission tomography (PET) scans. It is important to remember that ILDs can be associated with high rates of morbidity and mortality, and although prognosis depends on both disease extent and specificity, this fact makes these important disorders to recognize in a timely manner.

TABLE 304-1 Common Interstitial Lung Disease (ILD) Findings

	IPF	NONSPECIFIC INTERSTITIAL PNEUMONIA	RESPIRATORY BRONCHIOLITIS–ASSOCIATED ILD	SYSTEMIC SCLEROSIS–ASSOCIATED ILD	SARCOIDOSIS
Clinical symptoms	Gradual onset of SOB, dry cough. More common in older adults.	Subacute onset of SOB, dry cough. Frequently associated with other conditions.	Can be asymptomatic, or have SOB and cough.	Gradual onset of SOB, dry cough. Fatigue, tightening of skin, exaggerated cold response, reflux, and difficulty swallowing.	Can be asymptomatic, or have SOB and cough. Can also have fatigue, palpitations, and eye, skin, and joint findings.
Physical exam findings	Frequent rales at lung bases; digital clubbing is common.	Frequent rales. Clubbing is less common.	Rales common. Clubbing is rare.	Can have rales in isolation. Also skin thickening, joint swelling, and telangiectasias.	Can be normal; rales may be present. Can have skin findings, joint pain, and enlarged lymph nodes.
Exposures	Idiopathic but many exposed to smoke. Genetic findings may explain more than one-third of the risk of the disease.	Can be idiopathic but should prompt consideration for associated conditions.	Strong association with smoking.	Mostly unknown; some debate about solvent and silicate exposures.	Mostly unknown, although silicate dusts thought to play a role in some cases.
HRCT findings	Bilateral subpleural reticular changes most prominent in lower, posterior lung zones. Traction bronchiectasis and honeycombing common. Classic usual interstitial pneumonia (UIP) pattern is considered diagnostic.	Peripheral subpleural ground-glass and reticular patterns. Traction bronchiectasis is common, but honeycombing is rare. HRCT not diagnostic.	Diffuse patchy centrilobular ground glass nodules.	Can have UIP or nonspecific interstitial pneumonia (NSIP) patterns, also dilated esophagus, occasional mediastinal calcifications, and pulmonary vascular enlargement.	Can have mediastinal and hilar lymphadenopathy. Peribronchovascular reticular-nodular findings.
Histopathology	UIP pattern including fibroblastic foci, temporal and spatial heterogeneity, honeycombing.	Cellular or fibrotic pattern of NSIP. More uniform than a UIP pattern.	Respiratory bronchiolitis with adjacent inflammatory and fibrosing changes. Pigment-laden macrophages.	Both UIP or NSIP patterns can occur.	Noncaseating granulomas.
Clinical course	50% 3- to 5-year mortality.	18% 5-year mortality.	25% 7-year mortality.	20–30% 10-year mortality.	Generally low but varies by state.

Abbreviations: HRCT, high-resolution computed tomography; IPF, idiopathic pulmonary fibrosis; SOB, shortness of breath.

Owing to a variety of clinical presentations, as well as overlapping imaging and histopathologic findings (Table 304-1), ILDs can be difficult to diagnose. A generally accepted central tenet of ILD diagnosis is that the combined weight of clinical data, laboratory studies, pulmonary function testing, imaging findings, and histopathology (if obtained) are jointly required to make a confident diagnosis. No single piece of data confers a diagnosis alone. For example, a lung biopsy demonstrating the usual interstitial pneumonia (UIP) pattern is helpful in diagnosing a patient with idiopathic pulmonary fibrosis (IPF) but can also be present in some connective tissue diseases (CTDs) (e.g., RA-associated ILD, Chap. 370). In light of this challenge, most ILD centers recommend a multidisciplinary approach to the diagnosis (and, in some cases, the management) of ILDs. An example of a multidisciplinary approach is a conference attended by pulmonologists, rheumatologists, radiologists, and pathologists where all of the data generated on a patient can be discussed and reviewed jointly by those with unique sets of expertise in the care of patients with ILD.

While there are numerous ways to categorize the ILDs, one classic approach is to divide them into those of known and unknown causes (Fig. 304-1). Although even this approach has limitations (e.g., a growing number of genetic studies demonstrate that a significant portion of familial and sporadic pulmonary fibrosis or IPF may be explained, in part, by genetic factors), it is a useful place to start. Known causes of ILD include occupational exposures (e.g., asbestosis), medications (e.g., nitrofurantoin), and those related to an underlying systemic disease (e.g., cryptogenic organizing pneumonia [COP] in the setting of polymyositis). Unknown causes of ILD include groups of rare disorders often with classic presentations (e.g., a spontaneous pneumothorax in a young female with diffuse cystic changes on a chest CT might suggest lymphangioleiomyomatosis [LAM]) and the most common group of ILDs, the idiopathic interstitial pneumonias (IIPs). Granulomatous lung diseases straddle both known (e.g., hypersensitivity pneumonitis [HP] due to chronic bird exposure, Chap. 299) and unknown (e.g., sarcoidosis, Chap. 379) causes and are often separated due to their unique presentations, imaging findings, and diagnostic evaluation. Equally important to knowledge of disease classification is knowledge of disease prevalence. Although there is variability within different demographic groups, most studies demonstrate that IPF, sarcoidosis (Chap. 379), and ILDs related to CTDs (Chap. 425) as a group are among the most common forms of ILD.

DIAGNOSTIC APPROACH

The initial diagnostic approach to diffuse parenchymal lung disease is often broader than a focus on ILD and should include an evaluation for alternate causes, including cardiovascular disease (e.g., heart failure, Chap. 265), diffuse infections (e.g., *pneumocystis* pneumonia, Chap. 227), and malignancy (e.g., bronchoalveolar cell carcinoma). This chapter will focus on the diagnostic evaluation that helps to distinguish among the various forms of ILD.

HISTORY

Age The age of onset of clinical symptoms has a strong influence on the pretest probability that IPF, in particular, is present. For example, IPF occurs most commonly in patients aged >60 and is quite rare among patients aged <50. In fact, in patients aged >65 without strong evidence for an alternate diagnosis, atypical chest CT findings are still more likely to result in a histopathologic diagnosis of UIP (a pathologic hallmark of IPF) than they are to result in an alternate IIP diagnosis. Other common ILDs, such as sarcoidosis and CTD-associated ILD, and less common ILDs, such as LAM and pulmonary Langerhans cell histiocytosis (PLCH), tend to present between the ages of 20 and 40.

Sex Although less influential than age, sex has some influence on the likelihood of various ILDs. LAM (and the related disorder tuberous sclerosis) is a disorder that is frequently diagnosed in young women. Many CTD-associated ILDs are more common among women, except for RA-associated ILD, which is more common among men. IPF and occupational/exposure-related ILDs (likely due to work-related exposures that tend to differ between men and women) are more common among men.

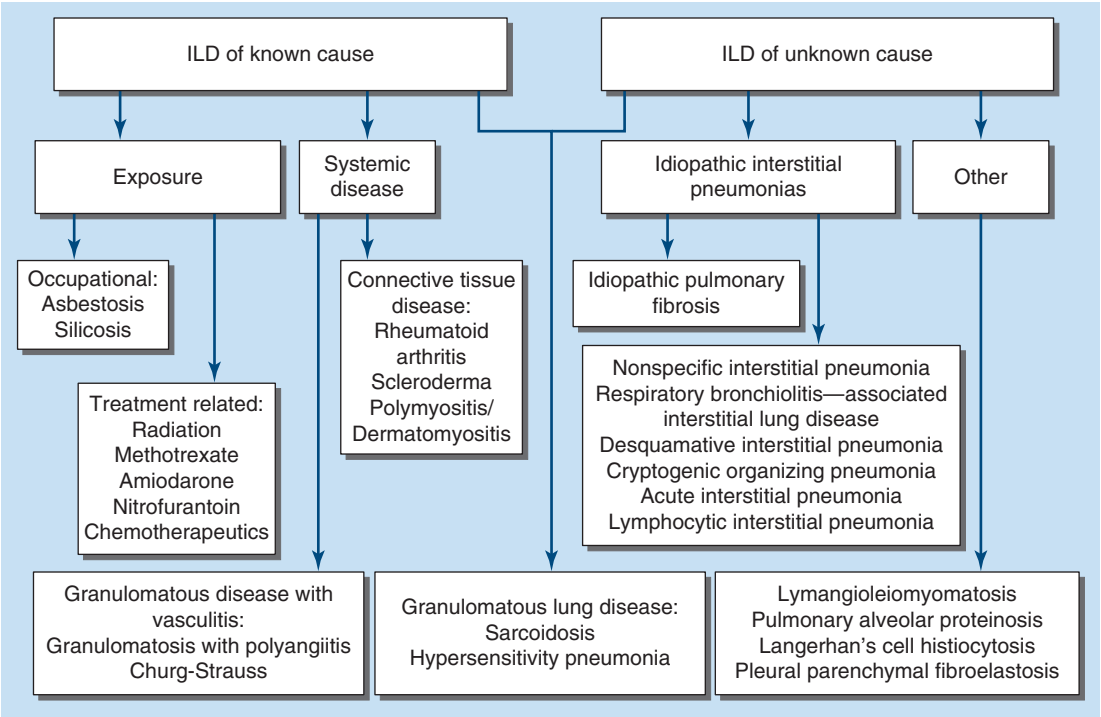

FIGURE 304-1 Classification of interstitial lung disease. This algorithm represents a common approach to subclassifying the interstitial lung diseases. It is typical to divide the interstitial lung diseases into those of known and unknown causes (although it is important to note that genetic studies demonstrate that a significant portion of familial and idiopathic pulmonary fibrosis [classically described as diseases of unknown cause] may be explained, in part, by genetic factors). The idiopathic interstitial pneumonias were more precisely defined by a 2002 study as described in Am J Respir Crit Care Med 165:277, 2002, referenced in the Further Reading list.

Duration of Symptoms Acute presentations (*days to weeks*) of ILD are unusual and are commonly misdiagnosed as more common diseases such as pneumonia, a chronic obstructive pulmonary disease (COPD) exacerbation, or heart failure. ILDs that can present acutely include eosinophilic pneumonia, acute interstitial pneumonia (AIP), HP, and granulomatosis with polyangiitis (GPA). An acute exacerbation of IPF as the initial presentation of this disease should also be a consideration given its prevalence. ILDs most commonly have a chronic indolent presentation (*months to years*) typified by IPF. However, subacute presentations (*weeks to months*) can occur in most of the ILDs but, in the right context, could suggest sarcoidosis, CTD-associated ILD, drug-induced ILD, or COP.

Respiratory Symptoms Progressive dyspnea, most frequently noted with exertion, is the most common complaint in patients presenting with an ILD. Despite this fact, both research studies of general population samples and clinical experiences of asymptomatic patient referrals with abnormal chest CT imaging patterns have also demonstrated that some patients, even those with more extensive disease, may not report dyspnea. Cough, particularly a dry cough, is also common and can be the most prominent symptom in patients with IPF. Cough is often reported in other ILDs, particularly those with prominent airway involvement including sarcoidosis and HP. Cough with hemoptysis is rare and could suggest an ILD associated with diffuse alveolar hemorrhage (DAH) (e.g., Goodpasture's syndrome), GPA, or LAM. Cough with hemoptysis could also suggest a secondary pulmonary infection that can be seen in patients with traction bronchiectasis and in those receiving immunosuppressive therapy. Chest pain is rare in most of the ILDs, with the exception of sarcoidosis, where chest discomfort is not uncommon. Fatigue is common to all of the ILDs.

Past Medical History The most pertinent history includes a personal history of a CTD or a history of symptoms commonly associated with a CTD (e.g., Raynaud's phenomena). It is also important to remember that ILD associated with a CTD can be the initial presenting symptom of the disease and can precede the development of additional symptomatology by many years. A history of malignancy is important, because some malignancies can be associated with dermatomyositis-associated COP and sarcoid-like reactions. A history of asthma and allergic rhinitis might suggest a diagnosis of eosinophilic GPA.

Medications Many medications have been associated with ILD, and to complicate matters further, many medications commonly used to treat inflammatory and granulomatous lung disease are also associated with ILD development (e.g., methotrexate, azathioprine, rituximab, and the tumor necrosis factor α–blocking agents). Specific medications in many classes are also known to cause ILD, including antibiotics (e.g., nitrofurantoin), antiarrhythmics (e.g., amiodarone), and many of the antineoplastic agents (e.g., bleomycin).

Family History A family history of ILD (of almost any type) is important to ascertain. The percentage of pulmonary fibrosis that is familial, as opposed to idiopathic, varies by study, and could be as high as 20%. Despite the variability, most studies suggest the presence of a close relative with an IIP is among the strongest risk factors for IPF. Family studies have consistently noted familial aggregation of diverse forms of IIP (such as IPF, nonspecific interstitial pneumonia [NSIP], and desquamative interstitial pneumonia [DIP] running in the same family) and, in some cases, other forms of ILD. To date, the most well-replicated genetic factors for pulmonary fibrosis (a promoter variant of a mucin gene [*MUC5B*]) and various genetic determinants known to influence telomere length (e.g., variants in the telomerase reverse transcriptase gene [*TERT*]) **(Chap. 495)** appear to be associated with both familial and idiopathic forms of pulmonary fibrosis similarly.

Social History A history of smoking is nearly always present in some forms of ILD (e.g., respiratory bronchiolitis and DIP—sometimes referred to by pathologists jointly as smoking-related ILD) where it is felt to be causative. A history of smoking is also noted in approximately three-quarters of IPF patients. Occupational and environmental exposure histories are also important to obtain as they might identify exposures known to cause pulmonary fibrosis (e.g., significant asbestos exposure) or HP (pigeon breeder's lung).

PHYSICAL EXAMINATION

End-inspiratory fine crackles, or rales, noted at the lung bases are found in most patients with IPF and may be one of the earliest signs of

the disease. However, rales are nonspecific and can be found in many forms of ILD and other disorders. Wheezing is uncommon in most forms of ILD but can be present in some disorders, such as sarcoidosis, HP, and eosinophilic GPA. Signs of advanced disease include cyanosis, digital clubbing, and cor pulmonale.

LABORATORY STUDIES

Laboratory studies can be particularly helpful in the workup for an underlying CTD-associated ILD. As noted previously, these tests can reveal the presence of an underlying CTD as the cause of an ILD (e.g., a positive anti-cyclic citrullinated peptide [anti-CCP] antibody for RA) even when no other symptomatology or physical examination findings suggestive of the disorder are present. However, the cost-effectiveness and the extent of laboratory testing that should be ordered in various clinical contexts have yet to be determined (as there is a relatively long list of autoantibody tests that could be ordered).

PULMONARY FUNCTION TESTS

Most forms of ILD will eventually result in a restrictive deficit in pulmonary function testing. A restrictive deficit is typified by a reduced total lung capacity (TLC) and symmetrically reduced measures of forced expiratory volume in 1 s (FEV_1) and forced vital capacity (FVC). A reduction in the diffusing capacity of the lung for carbon monoxide (D_{LCO}) is also common and may precede a reduction in lung volumes; however, there is more measurement variability in D_{LCO} measurement and the test is less specific for ILD. A reduced FEV_1 to FVC ratio, which is diagnostic of airway obstruction, is unusual in many forms of ILD but can be present as an isolated finding or in conjunction with an additional restrictive deficit in ILDs involving the airways such as sarcoidosis, HP, and LAM. Although pulmonary function testing is rarely diagnostic, reductions in lung function help to characterize the extent of disease, and evidence for a decline in repeated measures of pulmonary function (e.g., FVC) has been correlated with an elevated mortality rate.

CHEST IMAGING STUDIES

Chest X-Ray Findings on CXR can be the first clinical indication that an ILD might be present. For example, enlarged hilar lymph nodes and a pattern of central nodular opacities in the mid to upper lung zones can suggest sarcoidosis. A basilar reticular pattern, with small cystic spaces, in the absence of clinical evidence for heart failure, might suggest IPF. With a few exceptions, CXRs alone rarely lead to a specific diagnosis.

Chest CT High-resolution CT (HRCT) chest imaging is now considered to be standard of care in the initial evaluation of a patient with a suspected ILD. HRCT can be diagnostic for some ILDs (e.g., IPF) in the right clinical context and may preclude the need for, and spare the patient the risk of, a lung biopsy. HRCT also helps to define the extent of the ILD, determine the presence of more concerning features suggestive of advanced disease (e.g., honeycombing), provide information on coexisting diseases (e.g., emphysema and lung cancer), and when not diagnostic, provide the most useful locations for obtaining lung biopsy specimens.

LUNG BIOPSY

Fiberoptic Bronchoscopy A bronchoscopy can be helpful in establishing a specific ILD diagnosis, and can help to establish an alternate diagnosis, in select cases. Examination of serial lavage fluid can be helpful in establishing DAH, which can be present in ILDs with vasculitis (e.g., GPA), and in some cases, cellular examination can suggest a specific diagnosis (eosinophilia >25% in chronic eosinophilic pneumonia or fat globules in macrophages in lipoid pneumonia). Transbronchial lung biopsies and lymph node biopsies (particularly in sarcoidosis) can lead to a confident diagnosis in patients with likely granulomatous lung disease (e.g., sarcoidosis and HP). However, in general, bronchoscopically obtained tissue samples are often felt to be insufficient to diagnose most of the IIPs. To date, studies have been mixed on whether bronchoscopically obtained cryobiopsies, which can result in yields larger than those obtained by transbronchial forceps biopsies, could improve the diagnostic yield of bronchoscopy; however, the precise role of cryobiopsies in the diagnostic workup of ILD has yet to be determined.

Surgical Lung Biopsy A surgically obtained lung biopsy specimen can help solidify the diagnosis of ILD. In many cases, these are now obtained through a video-assisted thoracoscopic (VATS) approach (as compared to an open thoracotomy), which tends to reduce the length of operative times and hospital stays. The diagnostic yield of biopsies tends to be higher if obtained prior to treatment. The desire to obtain a surgical lung biopsy should be weighed against the risks, which can include a short-term mortality rate of as high as 5%. These risks are reported to be higher in biopsies of patients ultimately diagnosed with IPF and in those presenting acutely.

INDIVIDUAL FORMS OF ILD

The ILDs include a diverse group of lung pathologies that can be subclassified into those disorders of unknown cause (e.g., IIPs) and those of known cause (e.g., sometimes referred to as secondary interstitial pneumonias [CTD-associated ILDs]) (see Fig. 304-1). Although this remains a useful approach to classifying these disorders, it is important to recognize that genetic studies are challenging this classic categorization. For example, numerous ILDs commonly listed as having an "unknown cause" have been determined to have significant genetic underpinnings (e.g., IPF and LAM), while the pathophysiologic processes that result in ILDs of "known cause" (e.g., CTD) remain incompletely understood. Diagnosis is based on combined information obtained from a patient's clinical presentation, measures of pulmonary function, imaging, immune serologies, and histopathology. It is important to remember that prognosis and treatment vary widely by disorder (and disease extent). In some cases, medical therapy that is felt to be effective for some ILDs has been proven to be harmful for others. Medical treatments range from immune modulators to antifibrotic medications, whereas lung transplantation remains the standard of care for patients with advanced and rapidly progressive ILDs.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

IDIOPATHIC PULMONARY FIBROSIS

Clinical Manifestations IPF is the most common ILD of unknown cause. Prevalence increases with age and is estimated at 50–200:100,000. IPF is commonly diagnosed in the fifth or sixth decade of life, affects men more than women, and is frequently associated with a history of smoking or other environmental exposures. IPF is a variably progressive disease that carries a poor prognosis with an estimated 50% 3- to 5-year survival.

HRCT Image Findings Chest CT findings include subpleural reticulation with a posterior basal predominance usually including more advanced fibrotic features, such as honeycombing and traction bronchiectasis. Collectively, these imaging findings are referred to as a UIP pattern. The presence of extensive ground-glass opacities, bronchovascular changes, micronodules, mosaic attenuation, or an upper lung predominance should raise suspicion for an alternative diagnosis **(Fig. 304-2)**.

Histopathology Diagnostic VATS biopsy findings include subpleural reticulation associated with honeycomb changes and fibroblast foci (subepithelial collections of myofibroblasts and collagen). These fibrotic changes alternate with areas of preserved normal alveolar architecture consistent with temporal and spatial heterogeneity **(Fig. 304-3)**. Collectively, these pathologic findings are referred to as UIP.

Treatment Historically, IPF was felt to be refractory to medical therapy, with lung transplantation the only viable therapeutic option. This dogma changed in 2014 with large clinical trials that demonstrated that antifibrotic therapy (pirfenidone and nintedanib) can slow the decline of lung function in IPF patients. Further meta-analyses

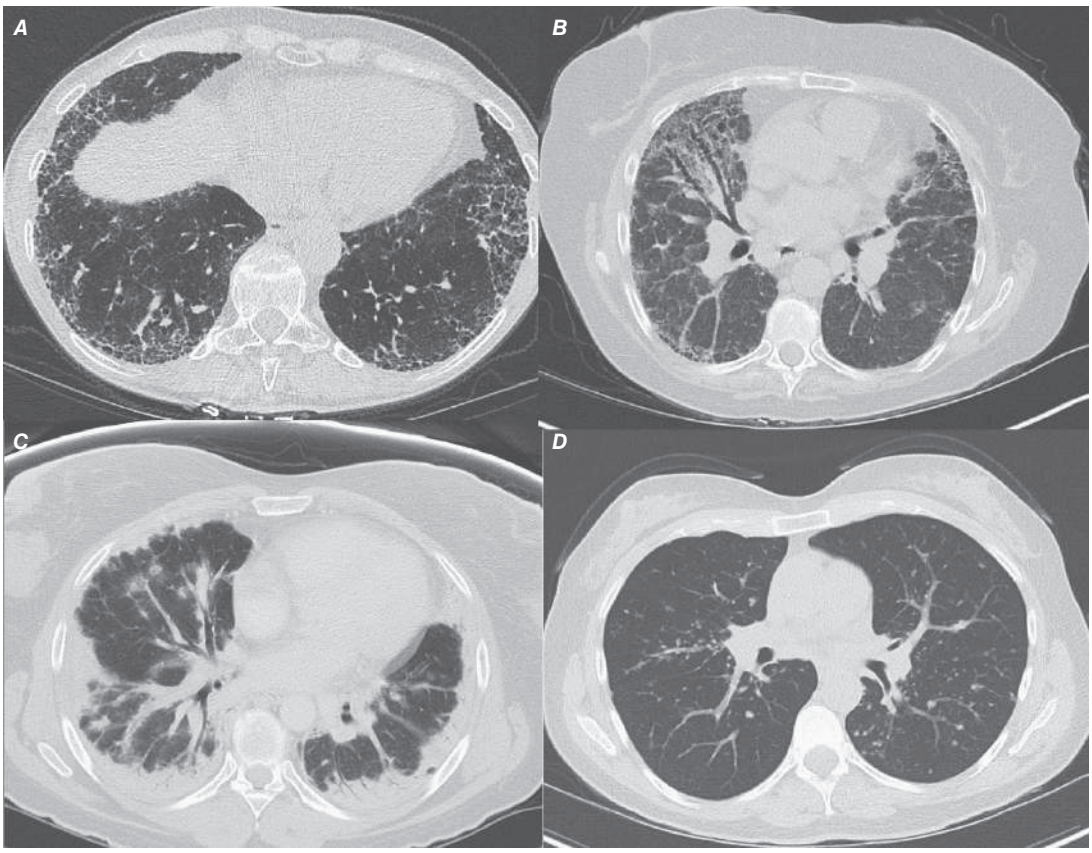

FIGURE 304-2 Chest CT imaging and interstitial lung disease. ***A.*** Idiopathic pulmonary fibrosis (IPF): Classic findings of IPF (apparent on this image) include a posterior, basilar predominance of subpleural reticular markings and more advanced features of pulmonary fibrosis including traction bronchiectasis and honeycombing. This constellation of findings is often referred to as a usual interstitial pneumonia (UIP) pattern. ***B.*** Nonspecific interstitial pneumonia (NSIP): Chest CT findings of NSIP can overlap with those of a UIP pattern but tend to include a bilateral, symmetric pattern that presents with a greater percentage of ground-glass opacities than is apparent in a UIP pattern. Additional unique findings include more diffuse imaging abnormalities with a predominance not limited to the lung bases, imaging abnormalities that spare the subpleural regions, and thickening of the bronchovascular bundles (as is apparent in the right mid lung zone on this image). ***C.*** Cryptogenic organizing pneumonia: Chest CT findings include patchy, sometimes migratory, subpleural consolidative opacities (as is apparent on this image) often with associated ground-glass opacities. Peribronchiolar or perilobar opacities can be present, and sometimes a rim of subpleural sparing (often referred to as a reversed halo or atoll sign) can be seen, which can help to aid in the diagnosis. ***D.*** Sarcoidosis: Sarcoidosis can present with varied imaging abnormalities, but a pattern of mediastinal and hilar lymphadenopathy with a pattern of reticular-nodular opacities involving the bronchovascular bundles (apparent in this image) is a common feature. Additional findings can include diffuse small nodules in a miliary pattern, larger nodular opacities, extensive ground-glass infiltrates, and mosaic attenuation suggestive of small airways involvement, and, in more advanced cases, signs of pulmonary fibrosis.

have suggested that antifibrotic therapy may also improve survival. More recent trials suggest that antifibrotic therapy may also be effective in other forms of progressive pulmonary fibrosis. In contrast, treatment with immunosuppression, which had been commonly prescribed to many IPF patients, has been shown to be associated with increased morbidity and mortality. Physical therapy and supplemental oxygen, when indicated, can improve exercise tolerance and reduce the likelihood of developing pulmonary hypertension. Lung transplantation can extend survival and improve the quality of life in a subset of IPF patients who meet the criteria to undergo transplant.

NONSPECIFIC INTERSTITIAL PNEUMONIA

Clinical Manifestations Idiopathic NSIP is a distinct clinical entity with characteristic clinical, radiologic, and pathologic features; however, NSIP is also commonly observed in patients with CTD and less frequently with familial interstitial pneumonia, drug toxicity, and infection. Although the prevalence of NSIP is not well established, it is commonly diagnosed in nonsmoking females in their fifth decade of life. Positive serologic tests for CTD are frequently observed. Idiopathic NSIP has a relatively good prognosis, with a 5-year survival of >80%; patients with a predominant cellular NSIP pattern have a more favorable prognosis than those with a fibrosing NSIP pattern.

HRCT Image Findings Diffuse subpleural, symmetric, ground-glass, and reticular opacities are common. Volume loss and traction bronchiectasis involving the lower lung zones can also be found. Occasionally subpleural sparing is noted, while peribronchiolar thickening and honeycombing are uncommon.

Histopathology Diagnostic lung biopsy findings include varying amounts of interstitial inflammation and fibrosis with a uniform appearance. Honeycomb changes are usually absent, and fibroblast foci are rare. NSIP is often referred to histopathologically as being either predominantly cellular (and potentially more responsive to medical therapy) or fibrotic (and potentially less likely to resolve with medical therapy).

Treatment Pulmonary fibrosis associated with CTD is commonly treated with immunosuppression despite the paucity of randomized clinical trials to demonstrate efficacy. Idiopathic NSIP is often treated with oral steroids (prednisone), cytotoxic agents (mycophenolate, azathioprine, and cyclophosphamide), or biologics (rituximab and tocilizumab). Recent trials suggest that NSIP patients with progressive pulmonary fibrosis may benefit from antifibrotic therapy. Oxygen therapy, pulmonary rehabilitation, and lung transplantation may be required in patients with progressive disease.

SMOKING-RELATED ILD

Although smoking-related ILDs, including respiratory bronchiolitis with interstitial lung disease (RB-ILD), and DIP are frequently subclassified with the IIPs, these disorders (along with PLCH, an ILD with unique clinical, imaging, and histopathologic manifestations) are commonly felt to be the result of active or prior tobacco smoke exposure.

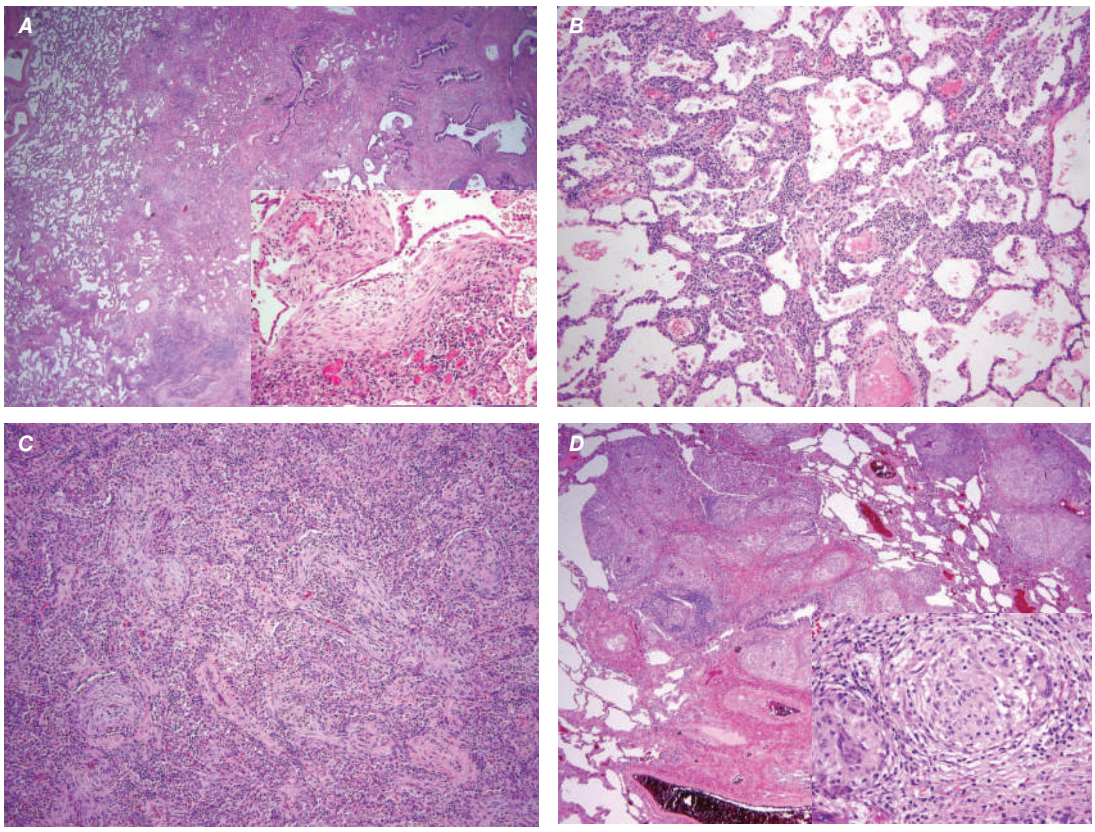

FIGURE 304-3 Histopathology of interstitial lung disease. ***A.*** Idiopathic pulmonary fibrosis (IPF): Histopathologic findings include subpleural reticulation associated with honeycomb changes alternating with areas of preserved normal lung architecture referred to as temporal and spatial heterogeneity (as is apparent in the low-power image above). Additional important diagnostic findings include fibroblast foci, which are subepithelial collections of myofibroblasts and collagen (as is apparent in the higher-powered inset of this image). Collectively, these pathologic findings are referred to as usual interstitial pneumonia (UIP). ***B.*** Nonspecific interstitial pneumonia (NSIP): Histopathologic findings of NSIP include varying amounts of interstitial inflammation and fibrosis with a uniform appearance (as is apparent in this image). Honeycomb changes are usually absent and fibroblast foci are rare. NSIP is often referred to histopathologically as being either predominantly cellular or fibrotic. ***C.*** Cryptogenic organizing pneumonia (COP): Histopathologic findings of COP include patchy regions of organizing pneumonia with granulation tissue that commonly involves the small airways, alveolar ducts, and alveoli with surrounding inflammation that can involve the alveolar walls (as is apparent in this image). ***D.*** Sarcoidosis: The hallmark histopathologic feature of sarcoidosis is presence of granulomas (as are apparent numerously in the low-powered image and more closely visualized in the higher-powered inset image). Typically, these are referred to as noncaseating, which suggests the absence of necrosis. Caseating granulomas are rare in sarcoid and should prompt additional evaluation for an underlying infection. Because malignancy can result in a granulomatous reaction, it is important to closely survey biopsy specimens with granulomatous involvement for additional signs of malignancy.

DIP has also been known to occur in children with familial pulmonary fibrosis (FPF). Smokers, particularly elderly smokers, frequently have radiologic (centrilobular) interstitial abnormalities. These interstitial abnormalities are often incidentally found on routine CXR or chest CT studies in asymptomatic or minimally symptomatic individuals. Respiratory bronchiolitis is felt to correlate histopathologically with these imaging findings. However, in some cases, these imaging findings can progress to more advanced radiologic changes where more diffuse signs of interstitial pneumonia tend to be present.

Clinical Manifestations These disorders predominantly occur in active, and in many cases heavy, smokers who are typically between 40 and 50 years of age. In those ultimately diagnosed with RB-ILD or DIP, dyspnea and cough are relatively common and symptomatic wheezing is not rare. The prevalence of smoking-related ILDs is not well understood, but they are generally felt to account for <10% of the IIPs. While there are minimal data on the natural histories and prognoses of these conditions, prolonged survival can be expected in most patients with RB-ILD and death secondary to progressive ILD is felt to be rare.

HRCT Image Findings Prominent and common findings in RB-ILD include central bronchial wall thickening, peripheral bronchial wall thickening, centrilobular nodules, and ground-glass opacities. Septal lines and a reticular pattern are also not uncommon. Honeycombing is generally felt to be rare (and indicates a worse prognosis). Similar findings are noted in patients with DIP where diffuse (or patchy) bilateral symmetric ground-glass opacities tend to be even more prominent.

Histopathology Common features of RB-ILD include the accumulation of pigmented macrophages within the lumens of respiratory bronchioles and alveolar ducts, accompanied by chronic inflammation of the respiratory bronchiolar walls and both bronchiolar and peribronchiolar alveolar fibrosis causing architectural distortion. These features are patchy and confined to the peribronchiolar region. DIP tends to include similar changes but has a more diffuse pattern characterized by pigmented macrophage accumulation, pneumocyte hyperplasia, and prominent interstitial thickening.

Treatment Patients with smoking-related ILD should be counseled to discontinue smoking and/or encouraged to enroll in a formal smoking cessation program. Small studies have evaluated treatment with immunosuppressive (e.g., prednisone) and cytotoxic (e.g., azathioprine and cyclophosphamide) agents and, in some cases, bronchodilators. To date, there is no strong evidence that these therapies result in significant improvements in symptoms or measures of pulmonary function or prevent clinical deterioration.

CRYPTOGENIC ORGANIZING PNEUMONIA

Clinical Manifestations COP typically involves patients in their 50–60s and often presents as a subacute flulike illness with cough, dyspnea, fever, and fatigue. Inspiratory rales are often present on examination, and most patients are noted to have restrictive lung deficits on pulmonary function testing with hypoxemia. COP is commonly mistaken for pneumonia. It is important to note that this syndrome can occur in isolation, can be secondary to an underlying CTD

(e.g., polymyositis) or medications, or can result from an underlying malignancy. Laboratory testing for various CTDs is helpful as testing can both be diagnostic and suggest the need for prolonged medical therapy.

HRCT Image Findings The most common imaging findings include patchy, sometimes migratory, subpleural consolidative opacities often with associated ground-glass opacities. Peribronchiolar or perilobar opacities can be present, and sometimes a rim of subpleural sparing (often referred to as a reversed halo or atoll sign) can be seen, which can aid in the diagnosis.

Histopathology Surgical lung biopsy specimens tend to reveal patchy regions of organizing pneumonia with granulation tissue that commonly involves the small airways, alveolar ducts, and alveoli with surrounding inflammation that can involve the alveolar walls (see Fig. 304-3).

Treatment Corticosteroids can result in substantial clinical improvement in many patients but usually need to be continued for at least 6 months as relapse rates are high. Evidence is growing that alternate cytotoxic (e.g., mycophenolate, cyclophosphamide) or biologic (e.g., rituximab) therapies can be helpful in both treating the disease and reducing the need for steroids. In some patients with secondary forms of the disease, long-term therapy may be needed.

ACUTE OR SUBACUTE IIPS

ACUTE INTERSTITIAL PNEUMONIA (HAMMAN-RICH SYNDROME)

Clinical Manifestations AIP is a rare and often fatal lung disorder that is characterized by an acute onset of respiratory distress and hypoxemia. A prodromal period of symptoms consistent with an acute upper respiratory infection is common. The mortality rate within 6 months of presentation can be quite high (>50%), and recurrences are common. In those who recover, lung function improvement can be substantial. AIP can be difficult to distinguish from acute respiratory distress syndrome (ARDS) and an acute exacerbation of an unsuspected underlying pulmonary fibrotic process.

HRCT Image Findings The most common imaging findings are patchy bilateral ground-glass opacities. Dependent regions of air-space consolidation are also common.

Histopathology Similar to ARDS and acute exacerbations of underlying pulmonary fibrosis, AIP presents histopathologically as diffuse alveolar damage (DAD) demonstrated on a surgical lung biopsy.

Treatment Treatment is mostly supportive and often includes mechanical ventilation. There is no proven drug therapy for AIP. Glucocorticoids are often given, but they are not clearly effective, and data on their use in other forms of DAD (e.g., ARDS) is controversial.

ACUTE EXACERBATIONS OF IIPS

Clinical Manifestations Acute exacerbations are not separate disorders, but rather an accelerated phase of lung injury that can occur in any form of ILD with pulmonary fibrosis. Acute exacerbations are most common and most severe in patients with known IPF. Acute exacerbations are characterized by an acute onset (<30 days) of respiratory distress and hypoxemia occurring in a patient with underlying pulmonary fibrosis not explained by an alternate cause (e.g., pneumonia, left heart failure). Reported mortality rates are very high (>85%), and mean survival periods range from as little as days to months.

HRCT Image Findings The most common imaging findings include patchy bilateral ground-glass opacities and dependent regions of air-space consolidation that can be appreciated on the background of the imaging findings characteristic of the underlying IIP. However, at times, they obscure the preceding imaging findings.

Histopathology Acute exacerbations of underlying pulmonary fibrosis present histopathologically as DAD, although sometimes organizing pneumonia can also be demonstrated on a surgical lung biopsy.

Treatment Overall, treatment is supportive. Mechanical ventilation, when not being used as a bridge to lung transplantation, is controversial as the survival rate in these patients tends to be poor. There is some evidence that drug therapy (e.g., nintedanib) may reduce the rate of acute exacerbations in patients with IPF. Drug therapy, in the context of an acute exacerbation, is also controversial. Immunosuppressive (e.g., prednisone) and cytotoxic (e.g., cyclophosphamide) therapies are commonly used without proven benefit.

ILD ASSOCIATED WITH CONNECTIVE TISSUE DISEASE

ILD is a common disease manifestation of many CTDs. Disease progression, response to therapy, and survival are variable and associated with specific radiologic and histopathologic patterns. ILD occurs most commonly in patients with scleroderma (systemic sclerosis form, or SSc), RA, polymyositis/dermatomyositis, and less frequently Sjögren's syndrome and systemic lupus erythematosus (SLE). ILD may precede the development of extrapulmonary manifestations of a specific CTD or may present as part of a poorly defined CTD. In rare cases, lung manifestations may be the sole feature of the patient's clinical presentation.

SYSTEMIC SCLEROSIS

Clinical Manifestations (Chap. 372) ILD is the most common pulmonary manifestation of SSc. ILD occurs in ~50% of SSc patients with diffuse disease and in ~30% of patients with limited disease. Pulmonary hypertension can occur separately or concomitantly with ILD and is more frequent in patients with limited SSc.

HRCT Image Findings Imaging features observed in patients with NSIP and IPF can be present, although less common findings present in COP and DAD may also be found. Additional HRCT findings may include a dilated esophagus and pulmonary artery enlargement.

Histopathology Comparable to the imaging overlap, histopathologic changes commonly noted in patients with NSIP and IPF are frequently identified. COP and DAD patterns may be observed and could be secondary to aspiration due to esophageal dysmotility, which is common in SSc.

Treatment Cyclophosphamide has a modest benefit in the preservation of lung function and is associated with significant toxicity. Mycophenolate has recently been shown to have similar efficacy and improved tolerability. Recent trials suggest that SSc patients with ILD may benefit from anti–interleukin 6 therapy (e.g., tocilizumab) and antifibrotic therapy (e.g., nintedanib). Minimizing the risk of reflux by using high-dose proton pump inhibitors or antireflux surgery should be considered in SSc with progressive ILD, as gastroesophageal reflux disease may contribute to lung injury and fibrosis. Lung transplantation can potentially be offered to select patients without significant aspiration or chest wall restriction.

RHEUMATOID ARTHRITIS

Clinical Manifestations (Chap. 370) A common extraarticular complication of RA is ILD. Although RA is more common in females, RA-ILD is more frequent in males and in patients with a history of tobacco exposure. In a small subset of patients, ILD is the first disease manifestation of RA. Clinically evident RA-ILD occurs in nearly 10% of the RA population; however, up to 40–50% of RA patients have radiologic abnormalities on chest CT, suggesting that ILD in the context of RA may be underdiagnosed.

HRCT Image Findings The most common imaging pattern of ILD in patients with RA is a UIP pattern, although NSIP patterns are not uncommon. There is evidence that survival in patients with RA is decreased in patients with a UIP pattern and among those with more extensive fibrosis in general.

Histopathology Histopathologic findings of UIP and NSIP are the most common. Some studies suggest that UIP in the context of RA

(as compared to IPF) may present with a reduced number of fibroblastic foci and an increased amount of germinal centers. Comparable to the imaging findings, UIP (and DAD) patterns in patients with RA are associated with reduced survival.

Treatment In contrast with SSc, there are no published clinical trials testing the role of immune suppression in RA-ILD. Extrapolating from the scleroderma experience, immunosuppressive (e.g., prednisone) and cytotoxic (e.g., mycophenolate, azathioprine, cyclophosphamide, and calcineurin inhibitors) agents have been used with variable success. However, RA patients with progressive pulmonary fibrosis may have less of a decline in lung function in response to antifibrotic therapy. Lung transplantation is a viable therapeutic approach for eligible patients with progressive disease that is not responsive to medical therapy.

DERMATOMYOSITIS/POLYMYOSITIS

Clinical Manifestations **(Chap. 377)** The idiopathic inflammatory myopathies are disorders characterized by immune-mediated destruction and dysfunction of muscle; however, these disorders can affect the skin, joints, cardiovascular system, and lungs. The prevalence of ILD associated with inflammatory myopathy varies by report; however, ILD is present in up to 45% of patients with positive anti-synthetase antibodies. The anti-synthetase syndrome is characterized by positive anti-synthetase antibodies, myositis, fever, Raynaud's phenomenon, mechanic's hands, arthritis, and progressive ILD. There is a subset of anti–Jo-1 antibody–positive individuals who develop a rapidly progressive form of ILD consistent with an acute exacerbation. Some studies have suggested that ILD may be more common in those with other antibodies (e.g., anti-PL-12). Dermatomyositis/polymyositis can occur as an isolated CTD or as a process associated with an underlying malignancy.

HRCT Image Findings Common imaging patterns of ILD in patients with dermatomyositis/polymyositis include those consistent with NSIP with or without evidence for COP. A UIP pattern can also occur. Some studies have suggested that a UIP pattern may be more common among those with anti-PL-12 antibodies.

Histopathology The anti-synthetase syndrome is associated with multiple histopathologic subtypes including NSIP, COP, and UIP. DAD, a histopathologic pattern observed in AIP and acute exacerbations, is associated with rapidly progressive ILD in myositis patients.

Treatment Immunosuppressive (e.g., prednisone) and cytotoxic (e.g., mycophenolate, azathioprine, cyclophosphamide, and calcineurin inhibitors) agents are often used in patients with progressive ILD. Some patients (particularly those with less fibrosis) have been noted to have improved or resolved ILD in response to medical therapy. In small studies, relapses have been more common in patients treated with prednisone alone. Patients who fail immune-suppressive therapy can benefit from lung transplantation.

GRANULOMATOUS ILDS

The most common granulomatous ILD is sarcoidosis, a multisystem disorder of unknown cause where lung involvement is often the most dominant feature; sarcoidosis is discussed in **Chap. 379**. HP, a granulomatous reaction due to inhalation of organic (e.g., bird fancier's lung secondary to exposure to bird feathers) and inorganic (e.g., coal worker's pneumoconiosis secondary to exposure to coal dusts) dusts, is also an important and common cause of ILD and is discussed in **Chap. 299**.

Granulomatous Vasculitides **(See Chap. 67)** These disorders are characterized by blood vessels with inflammatory infiltrates and associated granulomatous lesions with or without the presence of tissue necrosis. The lungs are commonly involved, and a unique feature of these disorders is that hemoptysis can be a presenting symptom. Although laboratory testing is helpful and can provide specific information, biopsies of involved tissue can be essential for making a diagnosis. Many of these disorders include additional systemic manifestations. GPA, previously referred to as Wegener's disease, is an example of a granulomatous vasculitis that commonly affects the lung (including inflammatory infiltrates in small to medium-sized vessels), ears, nose, throat, and kidney (resulting in glomerulonephritis). Common imaging abnormalities of GPA include nodules, patchy ground-glass and consolidative opacities that can be migratory, and hilar lymphadenopathy. Eosinophilic GPA (EG; also referred to as Churg-Strauss syndrome) is another example of a granulomatous vasculitis that affects the lung (including eosinophilic infiltrates in small to medium-sized vessels) and can result in numerous clinical manifestations but frequently includes chronic sinusitis, asthma, and peripheral blood eosinophilia. Common imaging abnormalities of EG include peripheral consolidative opacities that can be migratory and small pleural effusions.

GENETICS AND ILD

Studies of genetic epidemiology have led to important insights in our understanding of ILD. First, studies of families with FPF have demonstrated that unique IIPs can cosegregate with specific genetic variants known to be associated with IPF. This suggests that many genetic variants appear to predispose to interstitial lung injury patterns more broadly than to unique diagnoses specifically. Second, most of the genetic variants associated with FPF are also associated with more sporadic forms of the disease. Third, at least one of the genetic factors most strongly associated with FPF and IPF is common and confers a large increase in the risk of these diseases. At least one copy of a mucin 5B (*MUC5B*) promoter variant is present in ~20% of Caucasian populations and 35–45% of patients with IPF and confers an approximate sixfold increase in the risk of this disease. Fourth, studies of general population samples demonstrate that imaging abnormalities suggestive of an early stage of pulmonary fibrosis in research participants without known ILD are not uncommon (occurring in ~7–9% of adults) and are also associated with the same genetic variants known to be associated with IPF (e.g., the *MUC5B* promoter variant). This latter finding suggests a path forward toward an early detection of IPF. Additional genetic findings demonstrating replicable associations with pulmonary fibrosis include numerous genetic variants in, and adjacent to, genes known to be involved in the regulation of telomere length (e.g., the *TERT* gene, the telomerase RNA component [*TERC*] gene, and the regulator of telomere elongation helicase 1 [*RTEL1*] gene) and surfactant protein genes (e.g., surfactant protein A2 [*SFTPA2*] gene) **(Chap. 495)**, and aggregates of effect estimates from the combined effect of thousands of genetic variants (polygenic risk) score.

Genetic studies have also provided some insights into other forms of ILD. Genome-wide association studies of sarcoidosis have demonstrated numerous variants in genes and in genomic regions that are associated with the disease. Some of these disease-associated variants in sarcoidosis fall in human leukocyte antigen (*HLA*) regions, in regions of genes involved in immune regulation (e.g., interleukin 12B [*IL12B*]), and in regions of genes that are less well understood (butyrophilin-like 2 [*BTNL2*]) but also appear to be involved in T-cell activation. LAM is often associated with genetic variants in the tuberous sclerosis complex genes (e.g., *TSC1* and *TSC2*), consistent with the known evidence that this disease can occur in isolation but also in patients with known tuberous sclerosis. Many genetic factors for rare diseases such as Hermansky-Pudlak syndrome (a rare autosomal recessive disorder that results in pulmonary fibrosis but also includes oculocutaneous albinism, bleeding diatheses, and horizontal nystagmus) have also been discovered (e.g., *HSP1* and *HSP3–7*).

GLOBAL CONSIDERATIONS

The prevalence, clinical presentation, and natural history of most ILDs in European countries resemble those described in the United States. However, as expected, there is growing evidence for racial differences in clinical (rate of acute exacerbations) and genetic (*MUC5B*) attributes between Caucasian and Asian populations. To date, there are limited data on the prevalence of ILD in Hispanics, subjects of African descent, and many other ethnic groups.

305 Disorders of the Pleura

Khalid Ismail, Hilary J. Goldberg, Rebecca M. Baron

The pleural space lies between the lung and the chest wall and normally contains a very thin layer of fluid, which serves as a coupling system. This space is maintained around −3 to −5 cmH_2O because of a constant balance between the elastic recoil of the lung, with its attached visceral pleura, and the counter expansion of the chest wall with attached parietal pleura. Invasion of this space with organisms, inflammatory or cancer cells, or introduction of air, blood, or chyle can lead to significant disease.

PLEURAL EFFUSION

A pleural effusion is present when there is an excess quantity of fluid in the pleural space.

Etiology Under normal conditions, fluid enters the pleural space from the capillaries in the parietal pleura and is removed via the lymphatics in the parietal pleura. Fluid also can enter the pleural space from the interstitial spaces of the lung via the visceral pleura or from the peritoneal cavity via small holes in the diaphragm. The lymphatics have the capacity to absorb 20 times more fluid than is formed normally. Hydrostatic and oncotic pressures play a fundamental role. A pleural effusion develops when there is disturbance in hydrostatic-oncotic balance, leading to pleural fluid formation that overwhelms fluid removal by the lymphatics. It is estimated that 1.5 million Americans per year develop pleural effusion. The most common presentation is that of shortness of breath and occasionally chest pain.

Diagnostic Approach Patients suspected of having a pleural effusion should undergo chest imaging to evaluate its extent. Although chest x-ray with lateral decubitus films have been the standard diagnostic modality (and remains so in some parts of the world), advances in chest ultrasound and computed tomography (CT) imaging have made them invaluable, for both identifying characteristics of the effusion and guiding pleural sampling and/or drainage. When a patient is found to have a pleural effusion, an effort should be made to determine the cause (Fig. 305-1). The first step is to determine whether the effusion is a transudate or an exudate, which requires thoracentesis. A transudative pleural effusion occurs when systemic factors (hydrostatic-oncotic pressures) that influence the formation and absorption of pleural fluid are altered. The leading causes of transudative pleural effusions in the United States are left ventricular failure and cirrhosis. An exudative pleural effusion occurs when local factors that influence the formation and absorption of pleural fluid are altered. The leading causes

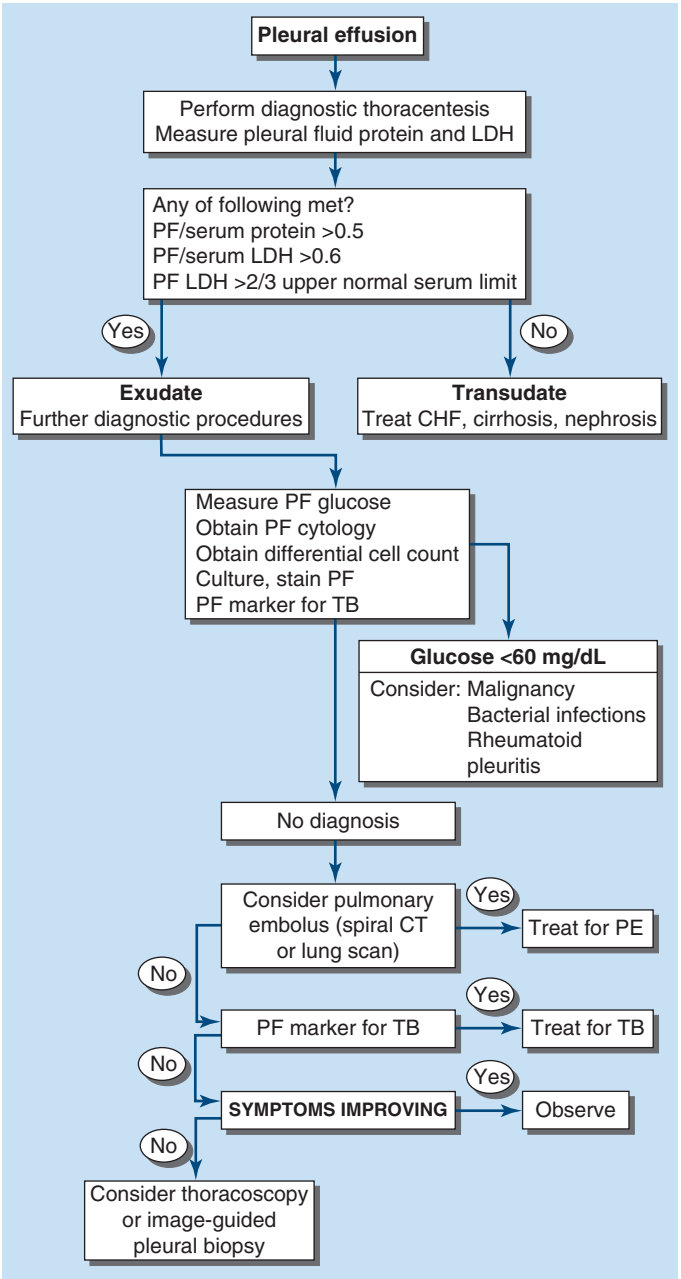

FIGURE 305-1 Approach to the diagnosis of pleural effusions. CHF, congestive heart failure; CT, computed tomography; LDH, lactate dehydrogenase; PE, pulmonary embolism; PF, pleural fluid; TB, tuberculosis.

of exudative pleural effusions are bacterial pneumonia, malignancy, viral infection, and pulmonary embolism (Table 305-1). The primary reason for making this differentiation is that additional diagnostic procedures are indicated with exudative effusions to define the cause.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none:

1. Pleural fluid protein/serum protein >0.5
2. Pleural fluid LDH/serum LDH >0.6
3. Pleural fluid LDH more than two-thirds the normal upper limit for serum

These criteria misidentify ~25% of transudates as exudates ("pseudoexudates"), often felt to be related to a "diuresed transudate." If one or more of the exudative criteria are met and the patient is clinically thought to have a condition producing a transudative effusion, alternative criteria can be used. Serum to pleural fluid protein gradient (SPPG) and serum to pleural fluid albumin gradient (SPAG) >3.1 g/dL and

>1.2 g/dL, respectively, together can identify pseudoexudates with 100% sensitivity in heart failure and 99% sensitivity in hepatothorax. Elevated pleural fluid cholesterol has also been used, especially when combined with elevated LDH, to favor a true exudate. In addition to describing the appearance of pleural fluid, the following pleural fluid tests should be obtained: glucose level, differential cell count, microbiologic studies, and cytology. More disease-specific diagnostic tests can be obtained depending on the clinical scenario (see examples in **Table 305-2**).

TABLE 305-2 Disease-Specific Pleural Fluid Tests

SUSPECTED DISEASE	TESTS
Pancreatic disease or esophageal rupture	Pleural fluid amylase
Drug-induced pleural effusion	Pleural fluid eosinophils
Congestive heart failure	Pleural fluid N-terminal pro-brain natriuretic peptide (NT-proBNP)
Chylothorax	Pleural fluid cholesterol and triglycerides
Hemothorax	Pleural fluid hematocrit
Rheumatoid disease	Pleural fluid glucose and pH
Amyloidosis	Congo red staining
Lymphoma	Flow cytometry

Effusion Due to Heart Failure The most common cause of pleural effusion is left ventricular dysfunction. Elevated left atrial pressure with elevated pulmonary venous pressure leads to increased amounts of fluid in the lung interstitial spaces exiting in part across the visceral pleura (a classic example of increased hydrostatic pressure), and this overwhelms the capacity of the lymphatics in the parietal pleura to remove the fluid. In patients with heart failure, a diagnostic thoracentesis should be performed if the effusions are not bilateral and comparable in size, if the patient is febrile, or if the patient has pleuritic chest pain, to verify that the patient has a transudative effusion. Otherwise, the patient's heart failure is treated. If the effusion persists despite therapy, a diagnostic thoracentesis should be performed. A pleural fluid N-terminal pro-brain natriuretic peptide (NT-proBNP) level >1500 pg/mL is suggestive of an effusion that is secondary to congestive heart failure and correlates well with serum values.

Parapneumonic Effusion Parapneumonic effusions (PPEs) can be seen in up to 50% of patients with community-acquired pneumonia and are generally the most common cause of exudative pleural effusion in the United States. PPEs are usually reactive (i.e., no organisms identified on culture). In 10% of patients with PPE, infection of the pleural space sets in, leading to a complicated PPE or an empyema, which refers to a fibrinopurulent or grossly purulent effusion, respectively.

Patients with aerobic bacterial pneumonia and pleural effusion may present with an acute febrile illness consisting of pleuritic chest pain, sputum production, and leukocytosis. Patients with anaerobic infections can present with a subacute illness with weight loss, leukocytosis, mild anemia, and a history of some factor that predisposes them to aspiration. These patients can have minimal parenchymal infiltrates with a large effusion.

The possibility of a PPE should be considered whenever a patient with bacterial pneumonia is initially evaluated. Thoracentesis is usually indicated to exclude infection of the pleural space if significant pleural fluid is present. The presence of free-flowing pleural fluid can be demonstrated with a lateral decubitus radiograph, CT of the chest, or ultrasound **(Fig. 305-2*A*, *C*)**. Traditionally, a minimum of 10 mm of free fluid on a lateral decubitus film suggests the safety of thoracentesis. Presently, CT/ultrasound guidance permits a better determination, both for safety of thoracentesis as well as likelihood of a complicated PPE (usually indicated by loculation or septations in the fluid; **Fig. 305-2*B*, *D***) that might make bedside thoracentesis more challenging. Factors indicating the likely need for evacuation of the pleural space by more advanced intervention (in increasing order of importance) include the following:

1. Loculated pleural fluid
2. Pleural fluid pH <7.20
3. Pleural fluid glucose <3.3 mmol/L (<60 mg/dL)
4. Positive Gram's stain or culture of the pleural fluid
5. Presence of gross pus in the pleural space

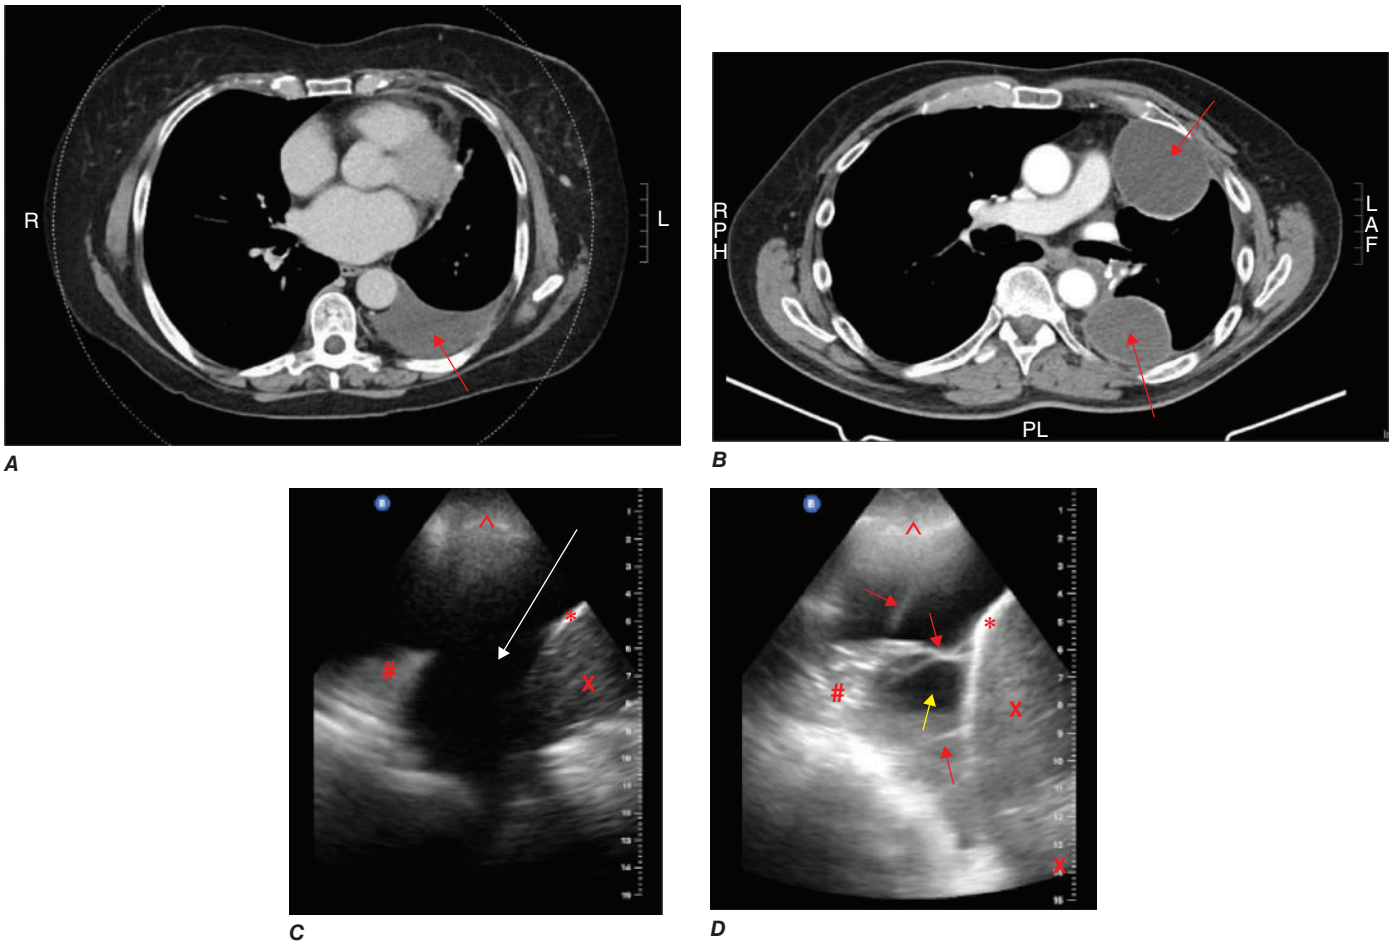

FIGURE 305-2 ***A.*** CT scan from a patient with simple pleural effusion, demonstrating free-flowing fluid in the left pleural space (red arrow). ***B.*** CT scan from a patient with loculated pleural effusion, demonstrating two pockets of fluids (*red arrows*). ***C.*** Ultrasound image of a simple pleural effusion, demonstrating free-flowing fluid (*arrow*), atelectatic lung (#), chest wall (^), diaphragm (*), and liver (x). ***D.*** Ultrasound image of a complex pleural effusion, with loculations (*yellow arrow*) and septations (*red arrows*), diaphragm (*), consolidated lung (#), chest wall (^), and liver (x).

An elevated pleural fluid LDH (>900 IU/L) is another feature that suggests the need for pleural fluid evacuation.

Effusions can progress from exudative to fibrinopurulent to an organizing phase (pleural peel) **(Fig. 305-3)**. If the fluid is fibrinopurulent and cannot be completely drained by thoracentesis, consideration should be given to insertion of a chest tube for drainage and possible instillation of the combination of a fibrinolytic agent (e.g., tissue plasminogen activator, 10 mg) and deoxyribonuclease (5 mg), or performing a thoracoscopy with the breakdown of adhesions if chest tube drainage does not completely evacuate the pleural space. Surgical decortication should be considered when these measures are ineffective.

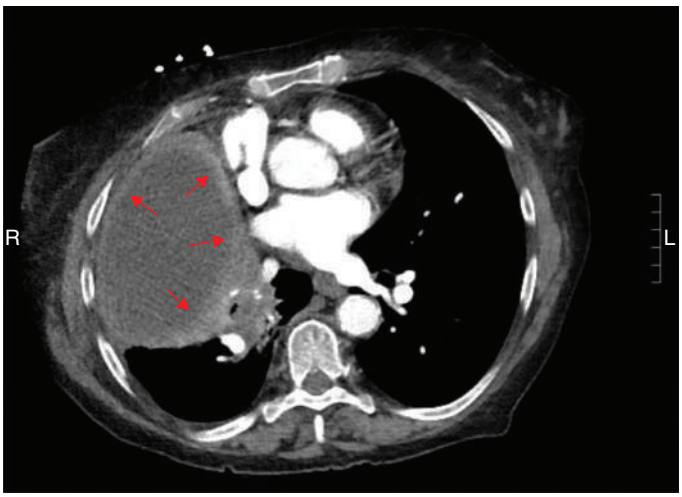

FIGURE 305-3 CT scan from a patient with empyema. Note thick pleural rind with that enhances with contrast (*red arrows*).

Trapped lung (i.e., a lung that cannot re-expand) might develop if a fibrous restrictive peel forms around the visceral pleura, usually in the setting of long-standing pleuro-pulmonary pathology. Although measuring pleural pressure at the time of thoracentesis (pleural manometry) can help confirm trapped lung, a thick pleural rind, presence of air on chest imaging after thoracentesis (termed pneumothorax ex vacuo), and recurrence of effusion shortly after drainage are suggestive of a lung that will not re-expand without decortication.

Effusion Secondary to Malignancy Malignant pleural effusions are the second most common type of exudative pleural effusion. The three tumors that cause ~75% of all malignant pleural effusions are lung carcinoma, breast carcinoma, and lymphoma. Its presence usually portends poor prognosis (<6-month survival). Most patients complain of dyspnea, which is frequently out of proportion to the size of the effusion. The pleural fluid is usually an exudate (although it can rarely be a transudate), and its glucose level may be reduced if the tumor burden in the pleural space is high.

The diagnosis usually is made via cytology of the pleural fluid. If the initial cytologic examination is negative, CT- or ultrasound-guided needle biopsy of pleural thickening or nodules can confirm the diagnosis. Ultimately, thoracoscopic biopsy is most definitive if malignancy is strongly suspected.

Patients with a malignant pleural effusion are treated symptomatically for the most part, since the presence of the effusion indicates disseminated disease, and most malignancies associated with pleural effusion are not curable with chemotherapy. If the patient's lifestyle

is compromised by dyspnea and if the dyspnea is not relieved with a therapeutic thoracentesis, one of the following procedures should be considered: (1) insertion of a small indwelling catheter for regular home drainage (improves dyspnea) or (2) tube thoracostomy with the instillation of a sclerosing agent (chemical pleurodesis) versus thoracoscopy with drainage of the effusion and surgical pleurodesis.

Mesothelioma Malignant mesotheliomas are primary tumors that arise from the mesothelial cells that line the pleural cavity; most are related to asbestos exposure. Incidence has dropped because of asbestos remediation measures. Patients with mesothelioma often present with chest pain and shortness of breath. The chest radiograph reveals a pleural effusion, generalized pleural thickening, and a shrunken hemithorax. The diagnosis is usually established with image-guided needle biopsy or thoracoscopy.

Hepatic Hydrothorax Pleural effusions occur in ~5% of patients with cirrhosis and ascites. The predominant mechanism is the direct movement of peritoneal fluid through small openings in the diaphragm into the pleural space. Ascites is common, and the effusion is usually right-sided and often large enough to produce severe dyspnea. Like ascitic fluid, it is usually low in protein (transudative) but can develop into a spontaneous bacterial empyema. Treatment is that of ascites, but if recurrent or persistent, pleurodesis, transjugular intrahepatic portosystemic shunt, or liver transplant might be required.

Effusion Secondary to Pulmonary Embolism The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is pulmonary embolism. Dyspnea is the most common symptom. The pleural fluid is almost always an exudate. The diagnosis is established most often by CT angiography (Chap. 290). Treatment of a patient with a pleural effusion secondary to pulmonary embolism is the same as it is for any patient with pulmonary emboli. If the pleural effusion increases in size after anticoagulation, the patient may have recurrent emboli or another complication, such as a hemothorax or a pleural infection.

Tuberculous Pleuritis/Effusion (See also Chap. 183) In many parts of the world, the most common cause of an exudative pleural effusion is tuberculosis (TB), but tuberculous effusions are relatively uncommon in the United States. Tuberculous pleural effusions usually are associated with primary TB and are thought to be due primarily to a hypersensitivity reaction to tuberculous protein in the pleural space. Patients with tuberculous pleuritis present with fever, weight loss, dyspnea, and/or pleuritic chest pain. The pleural fluid is exudative and predominantly lymphocytic. The diagnosis is suggested by demonstrating high levels of TB markers in the pleural fluid (adenosine deaminase >40 IU/L or interferon γ >140 pg/mL).

Diagnosis is established by culture of the pleural fluid for acid-fast bacilli, needle biopsy of the pleura, or thoracoscopy. Guided percutaneous needle biopsy has largely replaced closed needle biopsy, except in parts of the world where TB is prevalent. The culture yield of pleural biopsy is higher than that of pleural fluid. The recommended treatment of pleural and pulmonary TB is identical (Chap. 183).

Effusion Secondary to Viral Infection Viral infections are probably responsible for a sizable percentage of undiagnosed exudative pleural effusions. In many series, no diagnosis is established for ~20% of exudative effusions, and these effusions usually resolve spontaneously with no long-term residua. The importance of these effusions is that one should not be too aggressive in trying to establish a diagnosis for the undiagnosed effusion if the patient is improving clinically.

Chylothorax A chylothorax occurs when the thoracic duct is disrupted and chyle accumulates in the pleural space. The most common cause of chylothorax is trauma (most frequently thoracic surgery), but it also may result from tumors in the mediastinum. Patients with chylothorax may present with dyspnea, and a large pleural effusion is often present on the chest radiograph. Thoracentesis usually reveals milky fluid, and biochemical analysis reveals a triglyceride level that exceeds 1.2 mmol/L (110 mg/dL). Patients with chylothorax and no obvious trauma should have a lymphangiogram and a chest CT scan to assess the mediastinum for lymphadenopathy. The treatment of choice for most chylothoraces is insertion of a chest tube plus the administration of octreotide and modification of diet to eliminate enteral fat intake. If these modalities fail, percutaneous transabdominal thoracic duct blockage effectively controls most chylothoraces. An alternative treatment is ligation of the thoracic duct. Patients with chylothoraces should not undergo prolonged tube thoracostomy with chest tube drainage because this can lead to malnutrition and immunologic incompetence.

Hemothorax When a diagnostic thoracentesis reveals bloody pleural fluid, a hematocrit should be obtained on the pleural fluid. If the hematocrit is more than one-half of that in the peripheral blood, the patient is considered to have a hemothorax. Most hemothoraces are the result of trauma; other causes include rupture of a blood vessel or tumor. Most patients with hemothorax should be treated with tube thoracostomy, which allows continuous quantification of bleeding. If the bleeding emanates from a laceration of the pleura, apposition of the two pleural surfaces is likely to stop the bleeding. If the pleural hemorrhage exceeds 200 mL/h, consideration should be given to angiographic coil embolization, thoracoscopy, or thoracotomy.

Miscellaneous Causes of Pleural Effusion There are many other causes of pleural effusion (Table 305-2). Key features of some of these conditions are as follows: If the pleural fluid amylase level is elevated, the diagnosis of esophageal rupture or pancreatic disease is likely. If the patient is febrile, has predominantly polymorphonuclear cells in the pleural fluid, and has no pulmonary parenchymal abnormalities, an intraabdominal abscess should be considered. The diagnosis of an asbestos pleural effusion is one of exclusion. Benign ovarian tumors can produce ascites and a pleural effusion (Meigs' syndrome), as can the ovarian hyperstimulation syndrome. Several drugs can cause pleural effusion; the associated fluid may be eosinophilic. Pleural effusions commonly occur after coronary artery bypass graft (CABG) surgery. Effusions occurring within the first weeks after CABG are typically left-sided and bloody, with large numbers of eosinophils, and respond to one or two therapeutic thoracenteses. Effusions occurring after the first few weeks of CABG are typically left-sided and clear yellow, with lymphocytic predominance, and tend to recur. Other medical manipulations that induce pleural effusions include abdominal surgery; radiation therapy; liver, lung, or heart transplantation; and complications of the intravascular insertion of central lines.

PNEUMOTHORAX

Pneumothorax is the presence of gas in the pleural space. A spontaneous pneumothorax is one that occurs without antecedent trauma to the thorax. A primary spontaneous pneumothorax occurs in the absence of underlying lung disease, whereas a secondary pneumothorax occurs in its presence. A traumatic pneumothorax results from penetrating or nonpenetrating chest injuries. A tension pneumothorax is a pneumothorax in which the pressure in the pleural space is positive throughout the respiratory cycle.

Primary Spontaneous Pneumothorax Primary spontaneous pneumothoraces are usually due to rupture of apical pleural blebs, small cystic spaces that lie within or immediately under the visceral pleura. Approximately one-half of patients with an initial primary spontaneous pneumothorax will have a recurrence. Conservative management with careful observation can be considered in adults who are asymptomatic or minimally symptomatic. Outpatient observational management is an option for low-risk patients with a good support system. Otherwise, the initial recommended treatment is needle aspiration or tube drainage. If the lung does not expand or if the patient has a recurrent pneumothorax, thoracoscopy with stapling of blebs and pleurodesis is usually indicated. Thoracoscopy or thoracotomy with surgical pleurodesis is almost 100% successful in preventing recurrences.

Secondary Pneumothorax Most secondary pneumothoraces are due to chronic obstructive pulmonary disease, but pneumothoraces have been reported with virtually every lung disease. Pneumothorax in patients with lung disease can be more life-threatening than it is in normal individuals because of the lack of pulmonary reserve in these

patients. Nearly all patients with secondary pneumothorax should be treated with tube drainage. Many will need thoracoscopy or thoracotomy with stapling of blebs and surgical pleurodesis. If the patient is not a good operative candidate or refuses surgery, chemical pleurodesis should be considered.

Traumatic Pneumothorax Traumatic pneumothoraces can result from both penetrating and nonpenetrating chest trauma. Traumatic pneumothoraces are usually treated with tube drainage unless they are very small. If a hemopneumothorax is present, one chest tube might be placed in the superior part of the hemithorax to evacuate the air and another in the inferior part of the hemithorax to remove the blood. Iatrogenic pneumothorax is a type of traumatic pneumothorax that is becoming more common. The leading causes are transthoracic needle aspiration, thoracentesis, and complications of the insertion of central intravenous catheters. Most can be managed with supplemental oxygen or aspiration, but if these measures are unsuccessful, tube drainage should be performed.

Tension Pneumothorax This condition usually occurs during mechanical ventilation or resuscitative efforts. The positive pleural pressure is life-threatening both because ventilation is severely compromised and because the positive pressure is transmitted to the mediastinum, resulting in decreased venous return to the heart and reduced cardiac output. Difficulty in ventilation during resuscitation or high peak inspiratory pressures during mechanical ventilation strongly suggest the diagnosis. The diagnosis is made by physical examination showing an enlarged hemithorax with no breath sounds, hyperresonance to percussion, shift of the mediastinum to the contralateral side, and hypotension. Tension pneumothorax must be treated as a medical emergency. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or marked hypoxemia. A large-bore needle should be inserted into the pleural space through the second anterior intercostal space. If large amounts of gas escape from the needle after insertion, the diagnosis is confirmed. The needle should be left in place until a chest tube can be inserted.

306 Disorders of the Mediastinum

Stefi F. Lee, Rebecca M. Baron, Hilary J. Goldberg

The mediastinum is the region between the pleural sacs bound by the thoracic inlet superiorly and the diaphragm inferiorly. It is separated into three compartments, and diseases can arise from the anatomical structures residing in each respective compartment (Fig. 306-1). The *anterior mediastinum* comprises the retrosternal space anterior to the pericardium and brachiocephalic vasculature; it contains the thymus gland, the anterior mediastinal lymph nodes, and the internal mammary arteries and veins, and can give rise to several neoplasms. The *middle mediastinum* lies between the anterior and posterior mediastina and contains the heart; the ascending and transverse arches of the aorta; the venae cavae; the brachiocephalic arteries and veins; the phrenic nerves; the trachea, the main bronchi, and their contiguous lymph nodes; and the pulmonary arteries and veins. The *posterior mediastinum* extends from the posterior border of the heart and trachea to the vertebral column posteriorly. It contains the descending thoracic aorta, the esophagus, the thoracic duct, the azygos and hemiazygos veins, and the posterior group of mediastinal lymph nodes. Disorders of the mediastinum encompass a broad range of diseases including but not exclusive to neoplastic and nonneoplastic masses, congenital or acquired malformations of anatomical structures, infections, and chronic fibrosing mediastinitis, which will be addressed in this chapter.

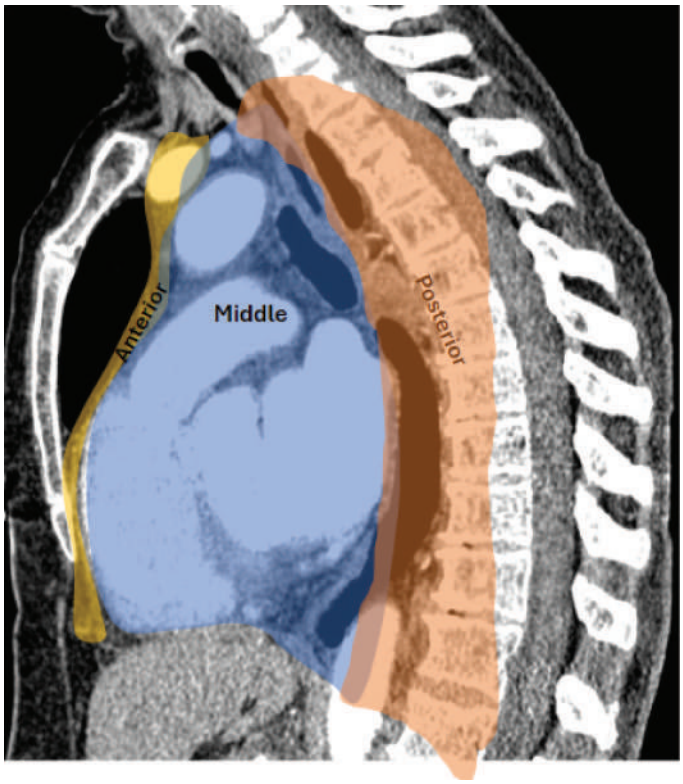

FIGURE 306-1 Sagittal chest CT of the mediastinum and its three separate compartments.

MEDIASTINAL MASSES

The first step in evaluating a mediastinal mass is to place it in one of the three mediastinal compartments, since each has different characteristic lesions (Table 306-1). The anterior mediastinum can give rise to neoplasms including thymomas, germ cell tumors, teratomas, lymphomas, and thyroid goiter. Thymomas are the most common neoplasm in the anterior mediastinum and are closely tied to paraneoplastic syndromes, most notably, myasthenia gravis, the diagnosis of which is supported by the presence of serum anti-acetylcholine receptor antibodies. Teratomas, the most common type of germ cell tumor, are multilobulated cystic lesions that contain fat, soft tissue, and calcium. Elevated tumor markers, α fetoprotein and β-human chorionic gonadotropin, distinguish between seminomatous and nonseminomatous germ cell tumors, which can guide treatment. Seminomas are generally responsive to radiation therapy, whereas nonseminomatous germ cell tumors are treated with standard chemotherapy. Computed tomography (CT) scanning is an important imaging technique for evaluating mediastinal masses as it can attenuate fat, water, calcifications, and air in most instances. Diffusion-weighted magnetic resonance imaging aids in improved tumor characterization and differentiation between cystic and solid structures. Lymphomas appear as homogeneous soft

TABLE 306-1 The Three Compartments of the Mediastinum

	ANTERIOR COMPARTMENT	MIDDLE COMPARTMENT	POSTERIOR COMPARTMENT
Anatomical boundaries	Manubrium and sternum anteriorly; pericardium, aorta, and brachiocephalic vessels posteriorly	Anterior mediastinum anteriorly; posterior mediastinum posteriorly	Pericardium and trachea anteriorly; vertebral column posteriorly
Contents	Thymus gland, anterior mediastinal lymph nodes, internal mammary arteries, and veins	Pericardium, heart, ascending and transverse arch of aorta, superior and inferior vena cavae, brachiocephalic arteries and veins, phrenic nerves, trachea, and mainstem bronchi and their contiguous lymph nodes, pulmonary arteries, and veins	Descending thoracic aorta, esophagus, thoracic duct, azygos and hemiazygos veins, sympathetic chains, and the posterior group of mediastinal lymph nodes
Common abnormalities	Thymoma, lymphomas, teratomatous neoplasms, thyroid masses, parathyroid masses, mesenchymal tumors, giant lymph node hyperplasia, hernia through foramen of Morgagni	Metastatic lymph node enlargement, granulomatous lymph node enlargement, pleuropericardial cysts, bronchogenic cysts, masses of vascular origin	Neurogenic tumors, meningocele, meningomyelocele, gastroenteric cysts, esophageal diverticula, hernia through foramen of Bochdalek, extramedullary hematopoiesis

tissue structures and can present at various stages. At more advanced stages, lymphomas can present with anterior and middle mediastinal lymphadenopathy. Mediastinoscopy is often performed for sampling of paratracheal and subcarinal lymph nodes. Biopsy can also be achieved via percutaneous fine-needle aspiration or endoscopic transesophageal or endobronchial ultrasound. Scintigraphy with radioactive iodine scan can efficiently establish the diagnosis of an intrathoracic goiter that can also lie in the anterior mediastinum.

Surgical resection is the mainstay of treatment for most anterior mediastinal masses like in localized early stages of thymic carcinomas, symptomatic teratomas, and mediastinal goiters. Lymphoma is treated with multimodal therapy with a combination of radiation and chemotherapy; surgery is rarely indicated. Ultimately, the involvement of a multidisciplinary interprofessional team of oncologists, pulmonologists, radiologists, and cardiothoracic surgeons is necessary to guide best treatment practices and provide personalized care for each patient.

The middle mediastinum consists of central vascular and bronchogenic structures. Most middle mediastinal masses are benign and result from abnormalities in embryonic development, such as bronchogenic cysts (that arise from abnormal ventral foregut budding), duplication cysts (that arise from persistent diverticulum of the dorsal bud of the foregut), and pericardial cysts (that arise from abnormal fusion of pericardial recesses). In contrast, advanced stages of malignancy often do not remain localized within one compartment and can traverse borders through hematogenous and lymphatic spread **(Fig. 306-2)**. It is also important to note that, due to the presence of central vasculature in the middle mediastinum, disruption of these structures can lead to acute life-threatening disease. For example, superior vena cava (SVC) syndrome is a medical emergency that presents with severe dyspnea and facial and upper extremity edema from venous distension because of compression of the SVC. SVC obstruction often occurs due to a malignant process; lung cancer, particularly small-cell lung carcinoma, accounts for up to 50% of cases. Endovenous recanalization, usually performed via an interventional radiology approach, restores venous return and reduces the risk of respiratory failure and death.

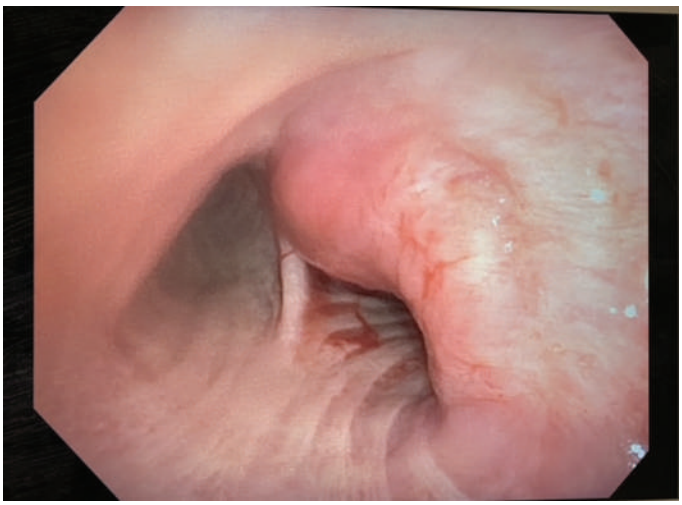

FIGURE 306-2 Bronchoscopic view of main carina with a malignant mass encroaching on the right mainstem airway. *(Courtesy of Dr. Majid Shafiq.)*

Neurogenic tumors are the most common cause of posterior mediastinal tumors. They may arise from peripheral, autonomic or paraganglionic nervous systems and are often benign. Other causes include diaphragmatic hernia, meningoceles, esophageal diverticula, or extramedullary hematopoiesis. Barium studies of the gastrointestinal tract are indicated in many patients with posterior mediastinal lesions because hernias, diverticula, and achalasia are readily diagnosed in this manner. Finally, mediastinal masses have a wide spectrum of disease severity, for which reason it may be difficult to determine the best course of action. When presented with a mediastinal mass, considering factors such as clinical symptoms, age of the patient, and location of the mediastinal tumor helps to determine the likelihood of malignancy and need for intervention.

ACUTE MEDIASTINITIS

Mediastinitis refers to an acute inflammatory and/or infectious condition involving the mediastinum. Cases of acute mediastinitis are usually due to esophageal perforation, occur after median sternotomy for cardiac surgery, or are seen related to infections descending from the neck, oral cavity, or facial area. Patients with esophageal rupture are acutely ill with chest pain and dyspnea due to the mediastinal infection. The esophageal rupture can occur spontaneously or as a complication of esophagoscopy or the insertion of a Blakemore tube. Appropriate treatment consists of exploration of the mediastinum with primary repair of the esophageal tear and drainage of the pleural space and the mediastinum.

The incidence of mediastinitis after median sternotomy is 0.4–5.0%. Patients most commonly present with wound drainage. Other presentations include sepsis and a widened mediastinum. The diagnosis usually is established with mediastinal needle aspiration. Treatment includes immediate drainage, debridement, and parenteral antibiotic therapy, but the mortality rate still exceeds 20%.

CHRONIC MEDIASTINITIS AND FIBROSING MEDIASTINITIS

The spectrum of chronic mediastinitis ranges from granulomatous inflammation of the lymph nodes in the mediastinum to fibrosing mediastinitis. Most cases of fibrosing mediastinitis follow a history of granulomatous infections, commonly due to histoplasmosis or tuberculosis, but sarcoidosis, silicosis, and fungal diseases are at times causative. Patients with granulomatous mediastinitis are usually asymptomatic. Those with fibrosing mediastinitis usually have variable symptoms depending on the extent and location of invasion of mediastinal structures such as the SVC or large airways, phrenic or recurrent laryngeal nerve paralysis, or obstruction of the pulmonary artery or proximal pulmonary veins. Fibrosing mediastinitis can be devastating in severe cases. Common clinical manifestations include dyspnea, chest pain, SVC syndrome, hemoptysis, dysphagia, and Horner's syndrome. Diagnosis involves a combination of clinical, radiologic, and histopathologic findings. Imaging modalities such as CT and magnetic resonance imaging

can delineate the extent of fibrosis. Tissue biopsy may be necessary to rule out malignancy. Treatment in chronic fibrosing mediastinitis is focused on relieving symptoms and preventing further complications. Therapy often includes a combination of surgical debulking or resection and endovascular interventions, including stenting, if veins or arteries are involved. Glucocorticoids have been used with variable success in cases of autoimmune-related and fibro-inflammatory causes of fibrosing mediastinitis. In cases of active fungal infection, antifungal therapies can be used, although they are generally ineffective. Emerging reports have shown success with the use of rituximab in mitigating symptoms and reducing metabolic activity in refractory disease.

PNEUMOMEDIASTINUM

In this condition, gas is noted in the interstices of the mediastinum. The three main causes are (1) alveolar rupture with dissection of air into the mediastinum; (2) perforation or rupture of the esophagus, trachea, or main bronchi; and (3) dissection of air from the neck or the abdomen into the mediastinum. Typically, there is severe substernal chest pain with or without radiation into the neck and arms. The physical examination usually reveals subcutaneous emphysema in the suprasternal notch and *Hamman's sign*, which is a crunching or clicking noise synchronous with the beating heart and is best heard with a stethoscope applied to the anterior chest wall in the left lateral decubitus position. The diagnosis is confirmed with a chest radiograph. Usually no treatment is required, but the mediastinal air will be absorbed faster if the patient inspires high concentrations of oxygen. If mediastinal structures are compressed, the compression can be relieved with needle aspiration.

307 Disorders of Ventilation

Khalid Ismail, George R. Washko

DEFINITION AND PHYSIOLOGY

In health, the arterial level of carbon dioxide ($Paco_2$) is maintained between 37 and 43 mmHg at sea level. All acute and chronic disorders of ventilation result in abnormal measurements of the partial pressure of carbon dioxide in the arterial blood, $Paco_2$. $Paco_2$ will be above the normal physiologic range if production exceeds clearance by the lung. This chapter reviews chronic ventilatory disorders.

The continuous production of carbon dioxide (CO_2) by cellular metabolism necessitates its efficient elimination by the respiratory system. The relationship between CO_2 production and $Paco_2$ is described by the equation: $Paco_2 = (k)\ (\dot{V}CO_2)/\dot{V}A$, where $\dot{V}CO_2$ represents the carbon dioxide production, k is a constant, and $\dot{V}A$ is fresh gas alveolar ventilation **(Chap. 296)**. Alveolar ventilation is not equivalent to minute ventilation (calculated as the product of respiratory rate and tidal breath volume) because not all parts of the ventilated respiratory system participate in gas exchange. The portion of each tidal breath that remains within the conducting airways is called the dead space fraction, represented as V_d/V_t. $\dot{V}A$ is the minute ventilation minus that portion of minute ventilation apportioned to dead space and is calculated as minute ventilation $\times (1 - V_d/V_t)$. As such, all disturbances of $Paco_2$ must reflect altered CO_2 production, minute ventilation, or dead space fraction.

Diseases that alter $\dot{V}CO_2$ are often acute (e.g., sepsis, burns, or pyrexia), and their contribution to ventilatory abnormalities and/or respiratory failure is reviewed elsewhere. Chronic ventilatory disorders typically involve inappropriate levels of minute ventilation or increased dead space fraction, both of which result in insufficient alveolar ventilation to maintain the $Paco_2$ in the normal physiologic range. This is called alveolar hypoventilation. Note that a person may exhibit abnormally rapid breathing and have an elevated minute ventilation but still suffer from alveolar hypoventilation (because of an increased fraction of dead space ventilation). An understanding of this apparent paradox and more general disorders of ventilation requires a review of the normal respiratory cycle.

The spontaneous cycle of inspiration and expiration is automatically generated in the brainstem. Two groups of neurons located within the medulla are particularly important: the dorsal respiratory group (DRG) and the ventral respiratory column (VRC). These neurons have widespread projections including the descending projections into the contralateral spinal cord where they perform many functions. They initiate activity in the phrenic nerve/diaphragm, project to the upper airway muscle groups and spinal respiratory neurons, and innervate the intercostal and abdominal muscles that participate in normal respiration. The DRG acts as the initial integration site for many of the afferent nerves relaying information about Pao_2, $Paco_2$, pH, and blood pressure from the carotid and aortic chemoreceptors and baroreceptors to the central nervous system (CNS). In addition, the vagus nerve relays information from stretch receptors and juxtapulmonary-capillary receptors in the lung parenchyma and chest wall to the DRG. The respiratory rhythm is generated within the VRC as well as the more rostrally located parafacial respiratory group (pFRG), which is particularly important for the generation of active expiration. One particularly important area within the VRC is the so-called pre-Bötzinger complex. This area is responsible for the generation of various forms of inspiratory activity, and lesioning of the pre-Bötzinger complex leads to the complete cessation of breathing. The neural output of these medullary respiratory networks can be voluntarily suppressed or augmented by input from higher brain centers and the autonomic nervous system. During normal sleep, there is an attenuated response to hypercapnia and hypoxemia, resulting in mild nocturnal hypoventilation that corrects upon awakening.

Once neural input has been delivered to the respiratory pump muscles, normal gas exchange requires an adequate amount of respiratory muscle strength to overcome the elastic and resistive loads of the respiratory system **(Fig. 307-1*A*) (also see Chap. 296)**. In health, the strength of the respiratory muscles readily accomplishes this important functional response, and normal respiration continues indefinitely. Reduction in respiratory drive or neuromuscular competence or substantial increase in respiratory load can diminish minute ventilation, resulting in hypercapnia **(Fig. 307-1*B*)**. Alternatively, if normal respiratory muscle strength is coupled with excessive respiratory drive, then alveolar hyperventilation ensues and leads to hypocapnia **(Fig. 307-1*C*)**.

HYPOVENTILATION

CLINICAL FEATURES

Diseases that reduce minute ventilation or increase dead space fall into four major categories: parenchymal lung and chest wall disease, obesity

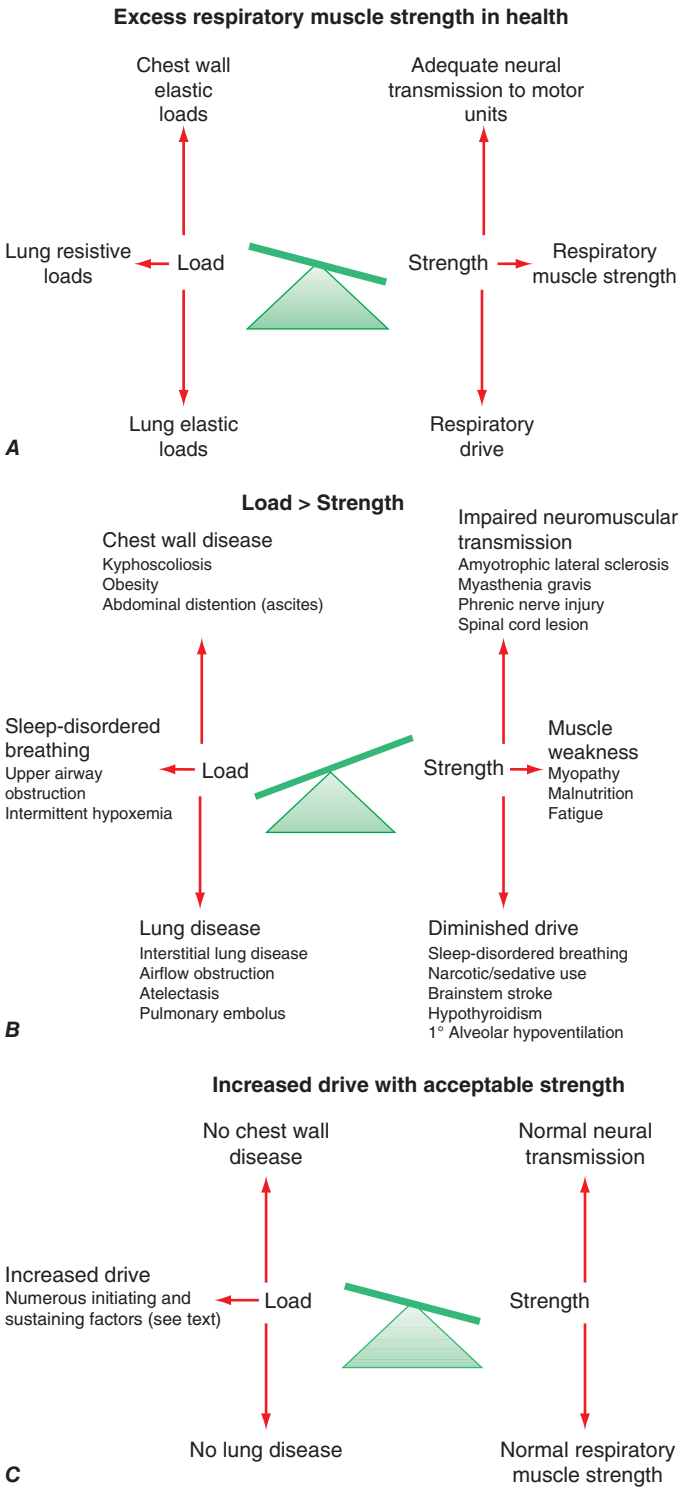

FIGURE 307-1 Examples of balance between respiratory system strength and load. ***A.*** Excess respiratory muscle strength in health. ***B.*** Load greater than strength. ***C.*** Increased drive with acceptable strength.

hypoventilation syndrome, neuromuscular disease, and respiratory drive disorders (Fig. 307-1*B*). "Pump failure" refers to disorders affecting the respiratory drive, neuronal pathways, neuromuscular junction, and muscles. The clinical manifestations of hypoventilation syndromes are nonspecific (Table 307-1) and vary depending on the severity of hypoventilation, the rate at which hypercapnia develops, the degree of compensation for respiratory acidosis, and the underlying disorder. Patients with parenchymal lung or chest wall disease typically present with shortness of breath and diminished exercise tolerance. Episodes of increased dyspnea and sputum production are hallmarks of obstructive lung diseases such as chronic obstructive pulmonary disease (COPD),

TABLE 307-1 Signs and Symptoms of Hypoventilation

Dyspnea during activities of daily living
Orthopnea in diseases affecting diaphragm function
Poor-quality sleep
Daytime hypersomnolence
Early morning headaches
Anxiety
Impaired cough in neuromuscular diseases

whereas progressive dyspnea and cough are common in interstitial lung diseases. Excessive daytime somnolence, poor-quality sleep, and snoring are common among patients with sleep-disordered breathing and obesity hypoventilation syndrome. Sleep disturbance and orthopnea are also described in neuromuscular disorders. As neuromuscular weakness progresses, the respiratory muscles, including the diaphragm, are placed at a mechanical disadvantage in the recumbent position owing to the upward movement of the abdominal contents. New-onset orthopnea is one of the earliest symptoms and often heralds reduced respiratory muscle force generation. More commonly, however, extremity weakness or bulbar symptoms develop prior to respiratory muscle involvement in neuromuscular diseases such as amyotrophic lateral sclerosis (ALS) or muscular dystrophy. The characteristic finding of "paradoxical breathing" on physical examination (the abdomen moving inward instead of outward with deep inspiration while supine) indicates significant diaphragmatic weakness or paralysis.

Patients with respiratory drive disorders do not have symptoms distinguishable from other causes of chronic hypoventilation and are usually secondary in nature. A cause can usually be identified with a detailed medical history, including medications, or illicit drug use. The diagnosis of a primary respiratory drive disorder is otherwise that of exclusion.

The clinical course of patients with chronic hypoventilation follows a characteristic sequence: an asymptomatic stage where daytime P_{AO_2} and P_{aCO_2} are normal, then nocturnal hypoventilation develops, initially during rapid eye movement (REM) sleep and later in non-REM sleep. As disease progresses, the vital capacity and corresponding volume of the tidal breaths decrease, leading to a further drop in alveolar ventilation. Eventually daytime hypercapnia develops. Symptoms can develop at any point along this time course and often depend on the pace of underlying disease progression. Regardless of cause, the hallmark of all alveolar hypoventilation syndromes is an increase in alveolar P_{CO_2} (P_{ACO_2}) and therefore in P_{aCO_2}. The resulting continuous respiratory acidosis eventually leads to a compensatory increase in plasma bicarbonate concentration. The increase in P_{aCO_2} displaces oxygen in the alveolus, leading to a decrease in P_{AO_2}, often resulting in hypoxemia. If chronic, hypoxemia can stimulate erythropoiesis and thereby induce secondary erythrocytosis. The combination of chronic hypoxemia and hypercapnia may also induce pulmonary vasoconstriction, leading eventually to pulmonary hypertension, right ventricular hypertrophy, and right heart failure.

DIAGNOSIS

The hallmark of the diagnosis of hypoventilation is a P_{aCO_2} ≥45 mmHg, measured in arterial blood gas (ABG) analysis. A venous blood gas can be an alternative if ABG is not available, keeping in mind that venous P_{CO_2} is normally several points higher than P_{aCO_2}. Elevated serum bicarbonate (i.e., total serum CO_2, which equals calculated bicarbonate plus dissolved CO_2) in the absence of volume depletion is suggestive of hypoventilation. However, it is important to point out that a serum bicarbonate level <27 mmol/L in the setting of normal renal function makes the diagnosis of hypoventilation very unlikely. By contrast, a serum bicarbonate level ≥27 mmol/L should trigger clinicians to measure P_{aCO_2} as a confirmatory diagnostic test. Therefore, serum bicarbonate can be used as a sensitive but not specific test to detect hypercapnia. An ABG demonstrating elevated P_{aCO_2} combined with normal pH confirms chronic alveolar hypoventilation.

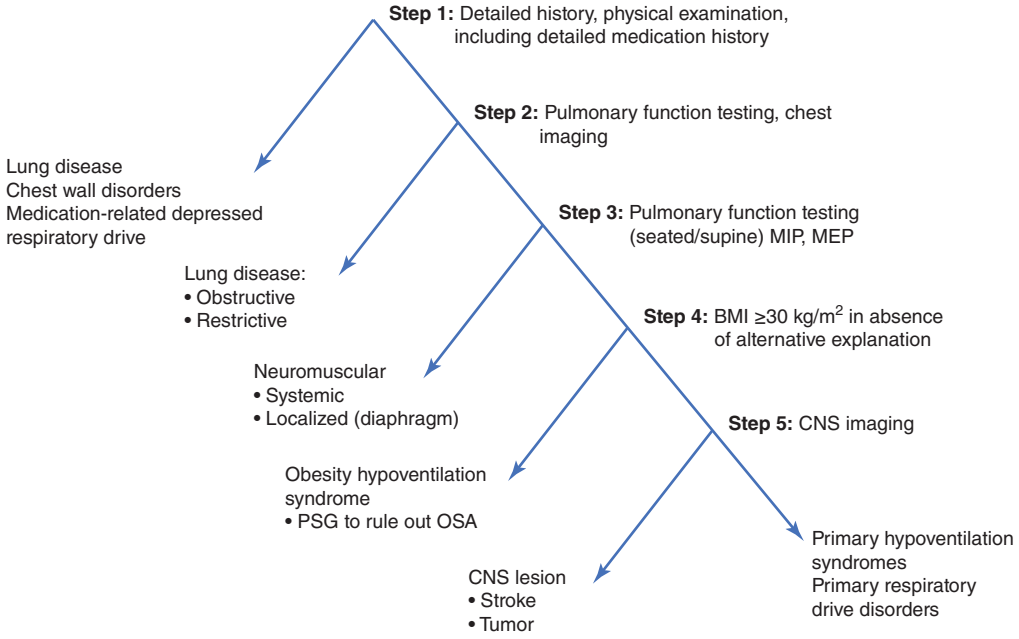

FIGURE 307-2 A diagnostic algorithm to determine the etiology of hypoventilation. Note that more than one condition may be present. BMI, body mass index; CNS, central nervous system; MEP, maximal expiratory pressure; MIP, maximal inspiratory pressure; OSA, obstructive sleep apnea; PSG, polysomnography.

The subsequent evaluation to identify an etiology should initially focus on whether the patient has lung disease or chest wall abnormalities. Physical examination, imaging studies (chest x-ray and/or computed tomography [CT] scan), and pulmonary function tests are sufficient to identify most lung/chest wall disorders leading to hypercapnia **(Fig. 307-2)**. If the ventilatory apparatus (lung, airways, chest wall) is not responsible for chronic hypercapnia, then the focus should shift to the respiratory pump (i.e., respiratory drive and neuromuscular disorders). In respiratory drive disorders, there is a blunted response in minute ventilation to elevated CO_2 and/or low O_2. As mentioned earlier, secondary forms of the disease are far more common and can be excluded by careful review of medications, including sedating medications and chronic narcotic use, or metabolic derangements including significant hypothyroidism. Brain imaging (CT scan or magnetic resonance imaging) can sometimes identify structural abnormalities in the pons or medulla that can result in hypoventilation. Primary forms of the disease are difficult to diagnose and should be suspected when patients with hypercapnia are found to have normal respiratory muscle strength, normal pulmonary function, and normal alveolar-arterial Po_2 difference. Hypoventilation is more marked during sleep in patients with respiratory drive defects, and polysomnography often reveals elevation in nocturnal CO_2, in addition to central apnea and hypopneas.

In neuromuscular disorders, typically physical examination reveals decreased strength in major muscle groups prior to the development of hypercapnia. Measurement of maximum inspiratory and expiratory pressures or forced vital capacity (FVC) can be used to assess for respiratory muscle involvement in diseases with progressive muscle weakness. Decrease in vital capacity is first seen in the recumbent position, which makes testing for a 15–25% drop in FVC, from seated to supine position in the pulmonary function test laboratory, an invaluable screening tool for impending chronic respiratory failure in these patients. Polysomnography, although unnecessary for diagnosis in most cases, can confirm nocturnal hypercapnia and demonstrate pseudo-central apnea/hypopnea (due to decreased muscle tone, especially in REM sleep) and obstructive apneas, especially with bulbar involvement.

If these evaluations are unrevealing, the clinician should screen for obesity hypoventilation syndrome (OHS). The diagnosis requires the following: body mass index (BMI) ≥30 kg/m^2 and chronic daytime alveolar hypoventilation, defined as $Paco_2$ ≥45 mmHg at sea level in the absence of other known causes of hypercapnia. In almost 90% of cases, obstructive sleep apnea (OSA) is present, with close to 70% exhibiting severe OSA. The population at risk for the development of OHS continues to rise as the worldwide obesity epidemic persists. Although no population-based prevalence studies of OHS have been performed, some estimates suggest it may be as high as 0.4% of the U.S. adult population (or 1 in 263 adults). Some, but not all, studies suggest that severe obesity (BMI >40 kg/m^2) and severe OSA (apnea-hypopnea index [AHI] >30 events per h) are risk factors for the development of OHS. Several screening tools have been developed to identify patients at risk for OSA, including the Epworth Sleepiness Scale (ESS), which measures daytime sleepiness, but it is neither sensitive enough nor specific enough to screen for OSA. The Berlin Questionnaire has been validated in a primary care setting and identifies patients likely to have OSA. Another often used screening questionnaire is the STOP-Bang survey, which has been used in preoperative anesthesia clinics to identify patients at risk of having OSA. Ultimately, polysomnography is needed for the diagnosis of OSA in that patient population and to screen for nocturnal hypoventilation if suspected. These diagnostic recommendations are summarized in Fig. 307-2.

TREATMENT

Hypoventilation

Nocturnal noninvasive positive-pressure ventilation (NIPPV) has been used successfully in the treatment of hypoventilation. It has been shown to improve daytime hypercapnia, prolong survival, and improve health-related quality of life when daytime hypercapnia is documented. There is accumulating evidence to guide timing of initiation of NIPPV and the choice of particular modes in specific disease processes, but more robust research is needed for more concrete recommendations.

NEUROMUSCULAR DISEASE

In patients with neuromuscular disease, the use of NIPPV has been best studied in the ALS patient population. ALS guidelines recommend consideration of nocturnal NIPPV if symptoms of hypoventilation exist and one of the following criteria are present: $Paco_2$ ≥45 mmHg; nocturnal oximetry demonstrates oxygen saturation ≤88% for

5 consecutive min; maximal inspiratory pressure <60 cmH_2O; or sniff nasal pressure <40 cmH_2O and FVC <50% predicted. However, at present, there is inconclusive evidence to support preemptive nocturnal NIPPV use in all patients with neuromuscular and chest wall disorders who demonstrate nocturnal but not daytime hypercapnia. Once NIPPV is initiated, many of these patients will go from using it only during sleep to needing support while awake, as their disease progresses. The advent of new modern home ventilation devices, with advanced modes of ventilation, and a multitude of comfortable mask interfaces, including mouthpiece ventilation, have all revolutionized the way we manage these patients at home. In addition to improved survival and quality of life, we are able to delay the need for tracheostomy or long-term institutionalization significantly. Smaller portable ventilators, with longer battery life, allow patients to remain functional until late in their disease. Cough assist devices have helped patients cope with ineffective cough and reduced the risk of recurrent pneumonia, a common cause for acute deterioration in these patients.

If NIPPV is initiated, the goal is to gradually correct hypoventilation and bring $Paco_2$ back to a level below 52 mmHg, or at least a 20% reduction from pretreatment levels. Excessive metabolic alkalosis should also be corrected, as serum bicarbonate levels elevated out of proportion for the degree of chronic respiratory acidosis can result in additional hypoventilation. When indicated, administration of supplemental oxygen is effective in attenuating hypoxemia, polycythemia, and pulmonary hypertension. However, in some patients, supplemental oxygen, even at low concentrations, can worsen hypercapnia.

In addition to NIPPV, if available, treatment, should be directed at the underlying disorder. Pharmacologic agents that stimulate respiration, such as medroxyprogesterone and acetazolamide, have been poorly studied in chronic hypoventilation and should not replace treatment of the underlying disease process. Phrenic nerve or diaphragm pacing is a potential therapy for patients with hypoventilation from high cervical spinal cord lesions or respiratory drive disorders. Prior to surgical implantation, patients should have nerve conduction studies to ensure normal bilateral phrenic nerve function. Small case series suggest that effective diaphragmatic pacing can improve quality of life in these patients.

OBESITY HYPOVENTILATION SYNDROME

The pathogenesis of hypoventilation in patients with OHS is multifactorial and includes OSA, increased work of breathing, respiratory muscle impairment relative to the increased load because of excess adiposity, ventilation-perfusion mismatching, and depressed central ventilatory responsiveness to hypoxemia and hypercapnia. Treatment requires addressing all these variables. Defects in central respiratory drive often improve with treatment of sleep-disordered breathing and correction of hypoventilation with continuous positive airway pressure (CPAP) or NIPPV without any significant change in body weight, which suggests that decreased ventilatory responsiveness is a consequence rather than a primary cause of OHS.

The treatment of OSA follows standard guidelines: weight reduction and positive airway pressure therapy during sleep with either CPAP or NIPPV. There is evidence that substantial weight loss (i.e., 20–25% of actual body weight) alone normalizes $Paco_2$ in patients with OHS. Unfortunately, achieving and sustaining this degree of weight loss without bariatric surgery are very challenging for most patients. CPAP improves daytime hypercapnia and hypoxemia in more than half of patients with OHS and concomitant severe OSA. Bilevel positive airway pressure (BiPAP) without a backup rate (BiPAP spontaneous mode) should be reserved for patients who are not able to tolerate high levels of CPAP support or when obstructive respiratory events persist despite reaching the maximum CPAP pressure of 20 cmH_2O. NIPPV in the form of BiPAP with a backup rate (BiPAP ST or spontaneous timed) or volume-assured pressure support modes should be strongly considered if hypercapnia persists after several weeks of CPAP therapy with objectively proven adherence. There is now evidence from randomized controlled trials that both CPAP and NIPPV equally improve nocturnal and daytime symptoms, long-term $Paco_2$ and bicarbonate levels, and cardiovascular as well as overall mortality in patients with OHS and severe OSA (AHI >30 events per h). Otherwise, patients with OHS who have no evidence of significant OSA are typically started on BiPAP ST or volume-assured pressure support modes, as are patients presenting with acute decompensated OHS.

CHRONIC HYPERCAPNIC COPD

Chronic hypercapnia in COPD is known to indicate a more advanced disease but has been shown to be associated with worse survival compared to patients with equal disease severity who were normocapnic. Use of NIPPV in patients with COPD has been well established in the acute setting, when patients present with acute-on-chronic hypercapnic respiratory failure. Home NIPPV, on the other hand, has been controversial. It has gained significant momentum over the past decade with the advent and success of high-intensity BiPAP. In patients with severe but stable chronic hypercapnic COPD ($Paco_2$ >52 mmHg and a normal pH), the use of high-intensity BiPAP (inspiratory positive airway pressure 24–28 cmH_2O, with a backup rate), aimed to reduce $Paco_2$ to <48 mmHg or a >20% drop from baseline, was associated with improved 1-year mortality in addition to improved physiologic and quality of life parameters, compared with standard of care (home oxygen).

If patients are hospitalized with acute-on-chronic exacerbation, evidence suggests retesting for $Paco_2$ elevation 2–4 weeks after discharge and only considering NIPPV in patients with persistent hypercapnia ($Paco_2$ >52 mmHg) after their exacerbation has resolved. This approach has been shown to reduce hospital readmissions and 1-year mortality.

CENTRAL HYPOVENTILATION SYNDROME

This syndrome can present later in life or in the neonatal period when it is often called Ondine's curse or congenital central hypoventilation syndrome (CCHS). Abnormalities in the gene encoding PHOX2b, a transcription factor with a role in neuronal development, have been implicated in the pathogenesis of CCHS. Regardless of the age of onset, these patients have absent respiratory response to hypoxia or hypercapnia, mildly elevated $Paco_2$ while awake, and markedly elevated $Paco_2$ during non-REM sleep. Interestingly, these patients are able to augment their ventilation and "normalize" $Paco_2$ during exercise and during REM sleep. These patients typically require NIPPV or mechanical ventilation as therapy and should be considered for phrenic nerve or diaphragmatic pacing at centers with experience performing these procedures.

HYPERVENTILATION

CLINICAL FEATURES

Hyperventilation is defined as ventilation in excess of metabolic requirements (CO_2 production) leading to a reduction in $Paco_2$. The physiology of patients with chronic hyperventilation is poorly understood, and there is no typical clinical presentation. Symptoms can include dyspnea, paresthesias, tetany, headache, dizziness, visual disturbances, and atypical chest pain. Because symptoms can be so diverse, patients with chronic hyperventilation present to a variety of health care providers, including internists, neurologists, psychologists, psychiatrists, and pulmonologists.

It is helpful to think of hyperventilation as having initiating and sustaining factors. Some investigators believe that an initial event leads to increased alveolar ventilation and a drop in $Paco_2$ to ~20 mmHg. The ensuing onset of chest pain, breathlessness, paresthesia, or altered consciousness can be alarming. The resultant increase in minute volume to relieve these acute symptoms only serves to exacerbate symptoms that are often misattributed by the patient and health care workers to cardiopulmonary disorders. An unrevealing evaluation for causes of these symptoms often results in patients being anxious and fearful of additional attacks. It is important to note that anxiety disorders and panic attacks are *not* synonymous with hyperventilation. Anxiety disorders can be both an initiating and sustaining factor in the pathogenesis of chronic hyperventilation, but these are not necessary for the development of chronic hypocapnia.

DIAGNOSIS

Respiratory symptoms associated with acute hyperventilation can be the initial manifestation of systemic illnesses such as diabetic ketoacidosis. Causes of acute hyperventilation need to be excluded before a diagnosis of chronic hyperventilation is considered. Arterial blood gas sampling that demonstrates a compensated respiratory alkalosis with a near normal pH, low $Paco_2$, and low calculated bicarbonate is necessary to confirm chronic hyperventilation. Other causes of respiratory alkalosis, such as mild asthma, need to be diagnosed and treated before chronic hyperventilation can be considered. A high index of suspicion is required as increased minute ventilation can be difficult to detect on physical examination. Once chronic hyperventilation is established, a sustained 10% increase in alveolar ventilation is sufficient to perpetuate hypocapnia. This increase can be accomplished with subtle changes in the respiratory pattern, such as occasional sigh breaths or yawning 2–3 times per min.

TREATMENT

There are few well-controlled treatment studies of chronic hyperventilation owing to its diverse features and the lack of a universally accepted diagnostic process. Clinicians often spend considerable time identifying initiating factors, excluding alternative diagnoses, and discussing the patient's concerns and fears. In some patients, reassurance and frank discussion about hyperventilation can be liberating. Identifying and eliminating habits that perpetuate hypocapnia, such as frequent yawning or sigh breathing, can be helpful. Some evidence suggests that breathing exercises and diaphragmatic retraining may be beneficial for some patients. The evidence for using medications to treat hyperventilation is scant. Beta blockers may be helpful in patients with sympathetically mediated symptoms such as palpitations and tremors.

308 Sleep Apnea

Andrew Wellman, Daniel J. Gottlieb, Susan Redline

Obstructive sleep apnea (OSA) and central sleep apnea (CSA) are both classified as sleep-related breathing disorders. OSA and CSA share some risk factors and physiologic bases but also have unique features. Each disorder is associated with impaired ventilation during sleep and disruption of sleep, and each diagnosis requires careful elicitation of the patient's history, physical examination, and physiologic testing. OSA, the more common disorder, causes daytime sleepiness and impaired daily function. It is a cause of hypertension and is strongly associated with cardiovascular disease in adults and behavioral problems in children. CSA is less common and may occur alone or in combination with OSA. It can occur as a primary condition, as a response to high altitude, or secondary to a medical condition (such as heart failure) or medication (such as opioids). Patients with CSA often report frequent awakenings and daytime fatigue and are at increased risk for heart failure and atrial fibrillation.

OBSTRUCTIVE SLEEP APNEA/HYPOPNEA SYNDROME

Definition OSA is defined on the basis of nocturnal and daytime symptoms as well as sleep study findings. Diagnosis requires the patient to have (1) either symptoms of nocturnal breathing disturbances (snoring, snorting, gasping, or breathing pauses during sleep) that impair quality of life or daytime sleepiness or fatigue that occurs despite sufficient opportunity to sleep and is unexplained by other medical problems; and (2) five or more episodes of obstructive apnea or hypopnea per hour of sleep (the apnea-hypopnea index [AHI], calculated as the number of episodes divided by the number of hours of sleep) documented during a sleep study. OSA also may be diagnosed in the absence of symptoms if the AHI is ≥15 episodes/h. Each episode of apnea or hypopnea represents a reduction in breathing for at least 10 s and commonly results in a ≥3% drop in oxygen saturation or a brain cortical arousal. OSA severity can be characterized by the frequency of breathing disturbances (AHI), the amount of oxyhemoglobin desaturation with respiratory events, the duration of apneas and hypopneas, the degree of sleep fragmentation, and the level of reported daytime sleepiness or functional impairment.

Pathophysiology During inspiration, intraluminal pharyngeal pressure becomes increasingly negative, creating a "suctioning" force. Because the pharyngeal airway has no fixed bone or cartilage, airway patency is dependent on the stabilizing influence of the pharyngeal dilator muscles. Although these muscles are continuously activated during wakefulness, neuromuscular output declines with sleep onset. In patients with a collapsible airway, the reduction in neuromuscular output results in transient episodes of pharyngeal collapse (manifesting as an "apnea") or near collapse (manifesting as a "hypopnea"). The episodes of collapse are typically terminated when ventilatory reflexes are activated and cause arousal, thus stimulating an increase in neuromuscular activity and opening of the airway. The airway may collapse at different sites, such as the soft palate (most common), tongue base, lateral pharyngeal walls, and/or epiglottis **(Fig. 308-1)**. OSA may be most severe during rapid eye movement (REM) sleep, when neuromuscular output to the skeletal muscles is particularly low, and in the supine position due to gravitational forces.

Individuals with a small pharyngeal lumen require relatively high levels of neuromuscular activation to maintain patency during wakefulness and thus are predisposed to airway collapse following the normal sleep-related reduction in pharyngeal muscle activity during sleep. The airway lumen may be narrowed by enlargement of soft tissue structures (tongue, palate, and uvula) due to fat deposition, increased lymphoid tissue, or genetic variation. Craniofacial factors such as

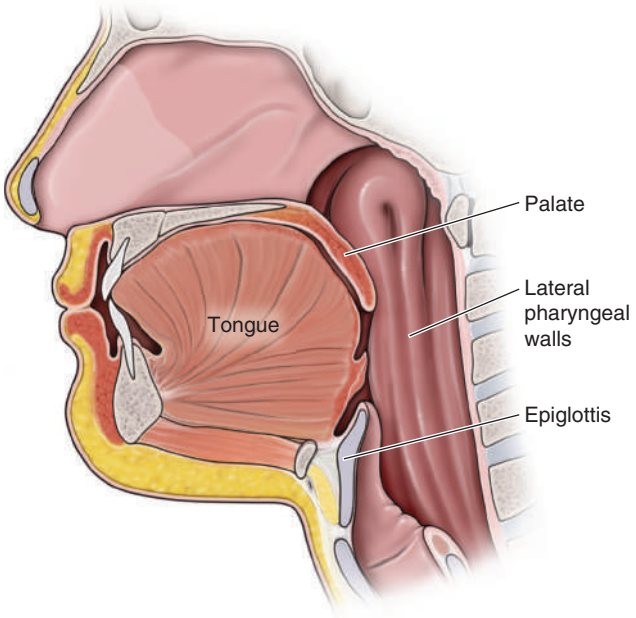

FIGURE 308-1 The structures causing airway collapse in obstructive sleep apnea include the palate, the tongue, and/or the epiglottis. In addition, collapse can also occur due to the lateral pharyngeal walls.

mandibular retroposition or micrognathia, reflecting genetic variation or developmental influences, also can reduce lumen dimensions. In addition, lung volumes influence the caudal traction on the pharynx and consequently the stiffness of the pharyngeal wall. Accordingly, low lung volume in the recumbent position, which is particularly pronounced in the obese, contributes to collapse (less caudal traction). A high degree of nasal resistance (e.g., due to nasal septal deviation or polyps) can contribute to airway collapse by reducing intraluminal pressure downstream in the pharynx. High-level nasal resistance also may trigger mouth opening during sleep, which breaks the seal between the tongue and the palate and allows the tongue to fall posteriorly and occlude the airway.

Pharyngeal muscle activation is integrally linked to ventilatory drive. Thus, factors related to ventilatory control, particularly ventilatory sensitivity, arousal threshold, and neuromuscular responses to carbon dioxide (CO_2), contribute to the pathogenesis of OSA. A buildup in CO_2 during sleep activates both the diaphragm and the pharyngeal muscles. Pharyngeal activation stiffens the upper airway and can counteract inspiratory suction pressure and maintain airway patency to an extent that depends on the anatomic predisposition to collapse. However, pharyngeal collapse can occur when the ventilatory control system is overly sensitive to CO_2, with resultant wide fluctuations in ventilation, ventilatory drive, and upper airway stiffness. Moreover, increasing levels of CO_2 during sleep result in central nervous system arousal, causing the individual to move from a deeper to a lighter level of sleep or to awaken. A low arousal threshold (i.e., awakening to a low level of CO_2 or ventilatory drive) can preempt the CO_2-mediated process of pharyngeal muscle compensation and prevent airway stabilization. A high arousal threshold, conversely, may prevent appropriate termination of apneas, prolonging apnea duration and exacerbating oxyhemoglobin desaturation. Finally, any impairment in the ability of the muscles to compensate during sleep can contribute to collapse of the pharynx. The relative contributions of risk factors vary by age, sex, body mass index, and other factors. Approaches to the measurement of these factors in clinical settings, with consequent enhancement of "personalized" therapeutic interventions, are being actively investigated.

Risk Factors and Prevalence The major risk factors for OSA are obesity, male sex, and older age. Additional risk factors include mandibular retrognathia and micrognathia, a positive family history of OSA, sedentary lifestyle, genetic syndromes that reduce upper airway patency (e.g., Down syndrome, Treacher-Collins syndrome), adenotonsillar hypertrophy (especially in children), menopause (in women), and various endocrine syndromes (e.g., acromegaly, hypothyroidism).

Approximately 40–60% of cases of OSA are attributable to excess weight. Obesity predisposes to OSA through the narrowing effects of upper airway fat on the pharyngeal lumen. Obesity also reduces chest wall compliance and decreases lung volumes, resulting in a loss of caudal traction on upper airway structures. Obese individuals are at a fourfold or greater risk for OSA than their normal-weight counterparts, although the association of OSA with obesity is weaker in the elderly than in younger adults. A 10% weight gain is associated with a >30% increase in AHI. Even modest weight loss or weight gain can influence the risk and severity of OSA. However, the absence of obesity does not exclude this diagnosis.

The prevalence of OSA is twofold higher among men than among women. Factors that predispose men to OSA include android pattern of obesity (resulting in upper-airway and abdominal fat deposition) and relatively greater pharyngeal length, which increases collapsibility. Premenopausal women are relatively protected from OSA by the influence of sex hormones on ventilatory drive. The decline in sex difference in older age reflects an increased OSA prevalence in women after menopause. The pathogenesis and presentation of OSA also differ in men and women: compared to men, women have a lower arousal threshold and less neuromuscular collapsibility. Women tend to have shorter duration of apneas and apneas that occur predominantly in REM sleep. Failure to recognize these differences can contribute to underrecognition of OSA in women.

Variations in craniofacial morphology that reduce the size of the posterior airway space increase OSA risk. The contribution of skeletal structural features to OSA is most evident in nonobese patients. Identification of features such as retrognathia can influence therapeutic decision-making.

OSA has a strong genetic basis, as evidenced by its significant familial aggregation and heritability. For a first-degree relative of a patient with OSA, the odds of having OSA are approximately twofold higher than that of someone without an affected relative. Several genetic variants have been associated with prevalence of OSA or with related traits, such as the frequency of apneas and hypopneas, the duration of respiratory events, and degree of overnight levels of hypoxemia.

OSA prevalence varies with age, from 5 to 15% among middle-aged adults to >20% among elderly individuals, although in a majority of affected adults, the disorder is undiagnosed. There is a peak due to lymphoid hypertrophy among children between the ages of 3 and 8 years; with airway growth and lymphoid tissue regression during later childhood, prevalence declines. Then, as obesity prevalence increases in adolescence and adulthood, OSA prevalence again increases.

The prevalence of OSA is especially high among patients with certain medical conditions, including diabetes mellitus, hypertension, and atrial fibrillation. Individuals of East Asian ancestry appear to be at increased risk of OSA at relatively low levels of body mass index, reflecting the greater influence of craniofacial risk factors. In the United States, African Americans, especially children and young adults, are at higher risk for OSA than their white counterparts.

Course of the Disorder The precise onset of OSA is usually hard to identify. A person may snore for many years, often beginning in childhood, before OSA is identified. Weight gain may precipitate an increase in symptoms, which in turn may lead the patient to pursue an evaluation. OSA may become less severe with weight loss, particularly after bariatric surgery. In adults, there is a gradual increase in AHI with age, although marked increases and decreases in the AHI are uncommon unless accompanied by weight change.

APPROACH TO THE PATIENT

Obstructive Sleep Apnea/Hypopnea Syndrome

An evaluation for OSA should be considered in patients with symptoms of OSA and one or more risk factors. Screening also should

be considered in patients who report symptoms consistent with OSA and who are at high risk for OSA-related morbidities, such as hypertension, diabetes mellitus, and cardiac and cerebrovascular diseases.

SYMPTOMS AND HISTORY

When possible, a sleep history should be obtained with assistance from a bed partner or household member. Snoring is the most common symptom; however, its absence does not exclude the diagnosis, as pharyngeal collapse may occur without tissue vibration. Gasping or snorting during sleep may also be reported, reflecting termination of individual apneas with abrupt airway opening. Dyspnea is unusual, and its absence generally distinguishes OSA from paroxysmal nocturnal dyspnea, nocturnal asthma, and acid reflux with laryngospasm. Patients also may describe frequent awakening or sleep disruption, which is more common among women and older adults. The most common daytime symptom is excessive daytime sleepiness, identified by a history of difficulty maintaining alertness or involuntary periods of dozing. However, many women preferentially report fatigue rather than sleepiness. Other symptoms include a dry mouth, nocturnal heartburn, diaphoresis of the chest and neck, nocturia, morning headaches, trouble concentrating, irritability, and mood disturbances. Insomnia, which is common in the general population, may coexist with OSA. Although difficulty falling sleep is rarely caused by OSA, awakening at apnea termination may cause difficulty maintaining sleep, a symptom more likely to be reported by women than by men, and often responds to treatment of OSA. Several questionnaires that evaluate snoring frequency, self-reported apneas, and daytime sleepiness can facilitate OSA screening. The predictive ability of a questionnaire can be enhanced by a consideration of whether the patient is male or has risk factors such as obesity or hypertension.

PHYSICAL FINDINGS

Physical findings often reflect the etiologic factors for the disorder as well as comorbid conditions, particularly vascular disease. On examination, patients may exhibit hypertension and regional (central) obesity, as indicated by a large waist and neck circumference. The oropharynx may reveal a small orifice with crowding due to an enlarged tongue, a low-lying soft palate with a bulky uvula, large tonsils, a high-arched palate, or micro-/retrognathia. Since nasal resistance can increase the propensity to pharyngeal collapse, the nasal cavity should be inspected for polyps, septal deviation, allergic rhinitis, and other signs of obstruction. Because patients with heart failure are at increased risk for both OSA and CSA, a careful cardiac examination should be conducted to detect possible left- or right-sided cardiac dysfunction. Evidence of cor pulmonale suggests a comorbid cardiopulmonary condition; OSA alone is not thought to cause right-heart failure. A neurologic evaluation is needed to evaluate for conditions such as neuromuscular and cerebrovascular diseases, which increase OSA risk.

LABORATORY FINDINGS

Diagnostic Findings Since symptoms and signs do not accurately predict the severity of sleep-related breathing disturbances, specific diagnosis and categorization of OSA severity require objective measurement of breathing during sleep. The gold standard for diagnosis of OSA is an overnight polysomnogram (PSG). A negative in-laboratory PSG usually rules out OSA. However, false-negative studies can result from night-to-night variation in OSA severity, particularly if there was insufficient REM sleep or less supine sleep during testing than is typical for the patient. Home sleep tests that record only respiratory and cardiac channels are commonly used as a cost-effective means for diagnosing OSA. However, a home study may yield a false-negative result if sleep time is not accurately estimated or in individuals experiencing hypopneas with arousals rather than oxyhemoglobin desaturation. Therefore, if there is a high prior probability of OSA, a negative home study should be followed by PSG.

The key physiologic information collected during a sleep study for OSA assessment includes measurement of breathing (changes in airflow, respiratory excursion), oxygenation (hemoglobin oxygen saturation), body position, and cardiac rhythm. In addition, PSGs and some home sleep studies measure sleep continuity and sleep stages (by electroencephalography, chin electromyography, electrooculography, and actigraphy), leg movements, and snoring intensity. This information is used to quantify the frequency and subtypes of abnormal respiratory events during sleep as well as associated changes in oxygen hemoglobin saturation, arousals, and sleep stage distributions. **Tables 308-1** and **308-2** define the respiratory events scored and the severity guidelines employed during a sleep study. **Fig. 308-2** shows examples of sleep-related respiratory events. A typical sleep study report provides quantitative data such as the AHI (number of apneas plus hypopneas per hour of sleep) and the profile of oxygen saturation over the night (mean, nadir, time at low levels). Reports may also include the respiratory disturbance index, which includes the number of respiratory effort–related arousals in addition to the AHI. In-laboratory PSG also quantifies sleep latency (time from "lights off" to first sleep onset), the frequency of periodic limb movements during sleep, sleep efficiency (percentage of time asleep relative to time in bed), arousal index (number of cortical arousals per hour of sleep), and time in each sleep stage. These metrics can further characterize the severity of OSA, which is associated with an increased arousal index, low sleep efficiency, and a reduction of time in deep (stage N3) and REM sleep and increase in light (stage N1) sleep. The detection of autonomic responses to apneas and hypopneas, such as surges in blood pressure, changes in heart rate, and abnormalities in cardiac rhythm, also provides relevant information on OSA severity.

While the AHI is the chief disease-defining measurement derived from sleep studies, metrics that quantify respiratory event–related hypoxemia, heart rate response, and ventilatory reduction have been shown to predict adverse cardiovascular outcomes and mortality and may soon be incorporated into clinical decision-making.

Other Laboratory Findings Various imaging studies, including cephalometric radiography, upper airway magnetic resonance imaging (MRI) and computed tomography (CT), and fiberoptic endoscopy, can be used to identify anatomic risk factors for OSA. While these may be useful for planning surgical interventions, they are not indicated in the routine evaluation of OSA. Cardiac testing may yield evidence of impaired systolic or diastolic ventricular function or abnormal cardiac structure. Overnight blood pressure monitoring often displays a "nondipping" pattern (absence of the typical 10% fall of blood pressure during sleep compared to wakefulness). Arterial blood gas measurements made during wakefulness are usually normal. Waking hypoxemia or hypercarbia suggests coexisting cardiopulmonary disease or hypoventilation syndromes. Patients with severe nocturnal hypoxemia may have elevated hemoglobin values. A multiple sleep latency test or a maintenance of wakefulness test can be useful in quantifying sleepiness and helping to distinguish OSA from narcolepsy.

TABLE 308-1 Respiratory Event Definitions

- *Apnea:* Cessation of airflow for ≥10 s during sleep, accompanied by:
- Persistent respiratory effort (obstructive apneas, **Fig. 308-2*A***), or
- Absence of respiratory effort (central apneas, **Fig. 308-2*B***)
- *Hypopnea:* A ≥30% reduction in airflow for at least 10 s during sleep that is accompanied by either a ≥3% desaturation or an arousal **(Fig. 308-2*C*)**
- *Respiratory effort–related arousal (RERA):* Partial obstruction that does not meet the criteria for hypopnea but provides evidence of increasing inspiratory effort (usually through pleural pressure monitoring) punctuated by an arousal **(Fig. 308-2*D*)**
- *Flow-limited breath:* A partially obstructed breath, typically within a hypopnea or RERA, identified by a flattened or "scooped-out" inspiratory flow shape **(Fig. 308-3)**

TABLE 308-2 Obstructive Sleep Apnea/Hypopnea Syndrome (OSAHS): Quantification and Severity Scale

- *Apnea-hypopnea index (AHI)*[a]: Number of apneas plus hypopneas per hour of sleep
- *Respiratory disturbance index (RDI):* Number of apneas plus hypopneas plus RERAs per hour of sleep
- *Mild OSAHS:* AHI of 5–14 events/h
- *Moderate OSAHS:* AHI of 15–29 events/h
- *Severe OSAHS:* AHI of ≥30 events/h

[a]Each level of AHI can be further quantified by level of sleepiness and associated hypoxemia.

Abbreviation: RERAs, respiratory effort–related arousals.

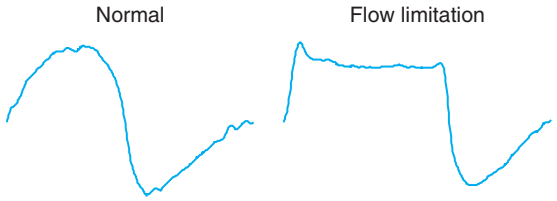

FIGURE 308-3 Example of flow limitation. The inspiratory flow pattern in a patent airway is rounded and peaks in the middle. In contrast, a partially obstructed airway exhibits an early peak followed by mid-inspiratory flattening, yielding a scooped-out appearance.

Health Consequences and Comorbidities OSA is the most common medical cause of daytime sleepiness and negatively influences quality of life. It is also strongly associated with cardiac, cerebrovascular, and metabolic disorders and with premature death and increased risk for certain cancers. This broad range of health effects is attributable to the impact of sleep fragmentation, cortical arousal, and intermittent hypoxemia and hypercapnia on vascular, cardiac, metabolic, and neurohumoral functions. OSA-related respiratory events stimulate sympathetic overactivity, leading to acute blood pressure surges during sleep and nocturnal as well as daytime hypertension. OSA-related hypoxemia also stimulates release of acute-phase proteins and reactive oxygen species that exacerbate insulin resistance and lipolysis and cause an augmented prothrombotic and proinflammatory state. Inspiratory effort against an occluded airway causes large intrathoracic negative pressure swings, altering cardiac preload and afterload and resulting in cardiac remodeling and reduced cardiac function. Hypoxemia and sympathetic-parasympathetic imbalance also may cause electrical remodeling of the heart and myocyte injury.

HYPERTENSION OSA can raise blood pressure to prehypertensive and hypertensive ranges, increase the prevalence of a nondipping overnight blood pressure pattern, and increase the risk of uncontrolled and resistant hypertension. Elevations in blood pressure are due to augmented sympathetic nervous system activation as well as alterations in the renin-angiotensin-aldosterone system and fluid balance. Treatment of OSA with nocturnal continuous positive airway pressure (CPAP) has been shown to reduce 24-h ambulatory blood pressure. Although the overall impact of CPAP on blood pressure levels is relatively modest (averaging 2–4 mmHg), larger improvements are observed among

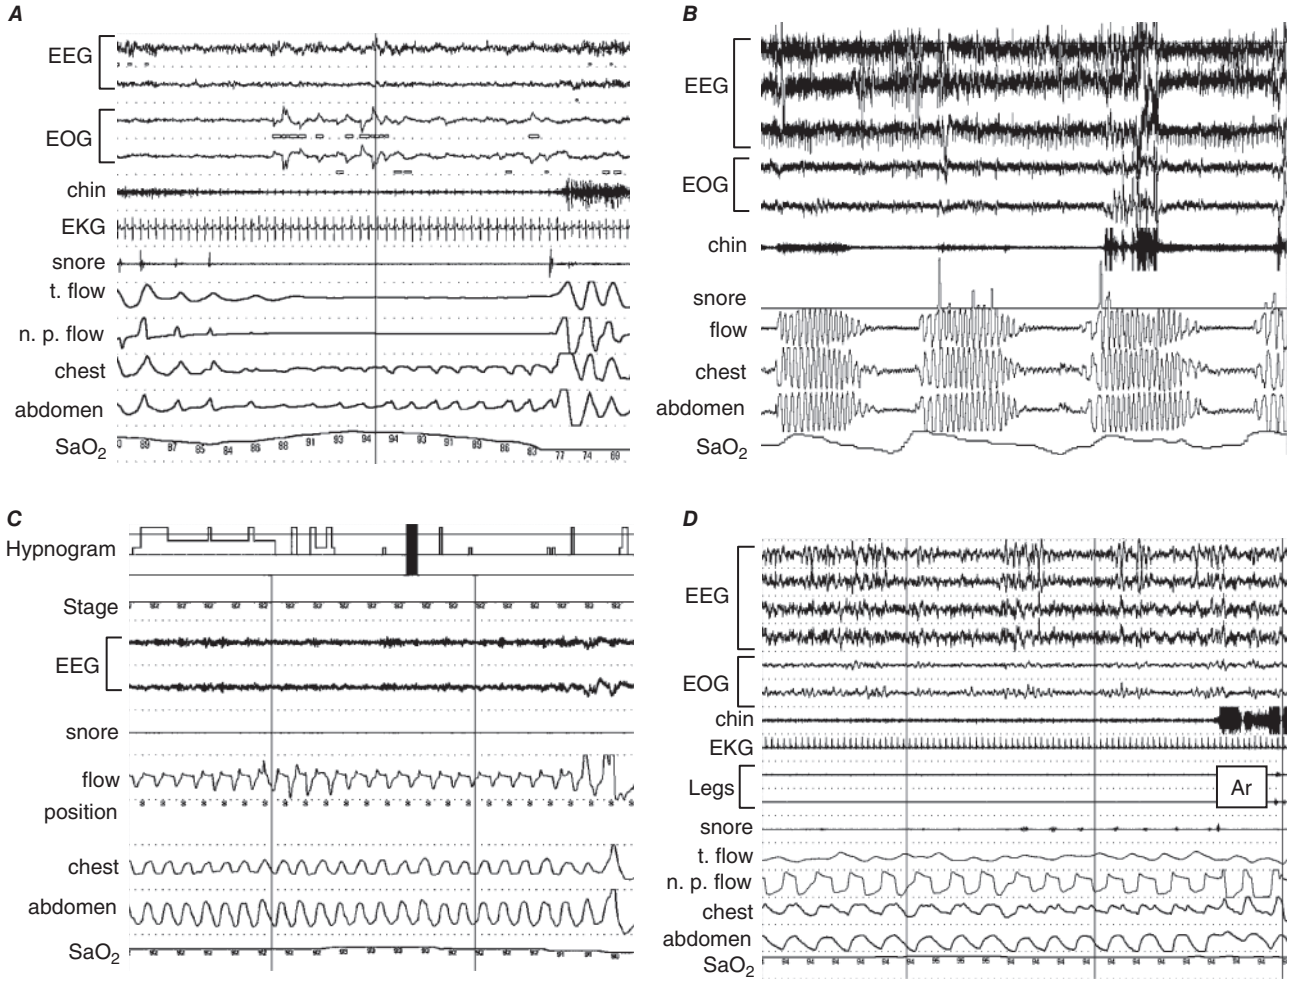

FIGURE 308-2 Obstructive apnea. ***A.*** There are 30 s of no airflow, as shown in the nasal pressure (n. p. flow) and thermistor-measured flow (t. flow). Note the presence of chest-abdomen paradox, indicating respiratory effort against an occluded airway. ***B.*** Central apnea in a patient with Cheyne-Stokes respiration due to congestive heart failure. The flat chest-abdomen tracings indicate the absence of inspiratory effort during the central apneas. ***C.*** Hypopnea. Partial obstruction of the pharyngeal airway can limit ventilation, leading to desaturation (a mild decrease in this patient, from 93 to 90%) and arousal. ***D.*** Respiratory effort–related arousal (RERA). Minimal flow reduction terminated by an arousal (Ar) without desaturation constitutes an RERA. EEG, electroencephalogram; EKG, electrocardiogram; EOG, electro-oculogram.

patients who have a high AHI, report daytime sleepiness, or have resistant hypertension.

CARDIOVASCULAR, CEREBROVASCULAR, AND METABOLIC DISEASES Among the most serious health consequences of OSA may be its impact on cardiac and metabolic functions. Strong epidemiologic evidence indicates that OSA significantly increases the risk of coronary artery disease, heart failure with and without reduced ejection fraction, atrial and ventricular arrhythmias, atherosclerosis and coronary artery disease, stroke, and diabetes. Treatment of OSA has been shown to reduce several markers of cardiovascular risk and improve insulin resistance and, in uncontrolled studies, is associated with a decreased recurrence rate of atrial fibrillation. Large randomized clinical trials, however, have failed to demonstrate that OSA treatment with CPAP reduces cardiovascular and stroke event rates or prolongs survival. These outcomes may reflect exclusion from these trials of patients with excessive sleepiness, as there is evidence that sleepy patients may have the greatest OSA-related cardiovascular risk. Limited adherence to treatment among trial participants or the widespread use of other effective secondary prevention measures, such as beta blockade, antiplatelet agents, and lipid-lowering therapy, may also limit the impact of CPAP on cardiovascular risk.

SLEEPINESS AND ASSOCIATED RISKS More than 50% of patients with moderate to severe OSA report daytime sleepiness. However, there is not a strong association between AHI level and degree of sleepiness. Patients with OSA symptoms have a twofold increased risk of occupational accidents. Individuals with elevated AHIs are involved in motor vehicle crashes approximately two to three times as often as persons with normal AHIs. Randomized controlled trials have shown that treatment of OSA with CPAP alleviates sleepiness as measured by either questionnaire or objective testing in patients with both mild and more severe disease. However, the degree of improvement varies widely. Residual sleepiness may be due to several factors, including suboptimal treatment adherence, insufficient sleep duration, other sleep disorders, or prior hypoxia-mediated damage in brain areas involved in alertness. Moreover, visceral adipose tissue, which is present in higher amounts in patients with OSA, releases somnogenic cytokines that may contribute to sleepiness. Thus, even after treatment, it is important to assess and monitor patients for residual sleepiness and to optimize treatment adherence, improve sleep patterns, and identify other disorders that may contribute to sleepiness. Careful and supervised use of alerting agents may be appropriate as adjunctive treatment in patients in whom sleepiness does not respond to CPAP alone.

QUALITY OF LIFE AND MOOD Reductions in health-related quality of life are common in patients with OSA, with the largest decrements observed in scales that measure physical functioning and energy levels. Work-related productivity also has been shown to improve in patients with moderate to severe OSA treated with CPAP. Numerous studies, including a large-scale trial of minimally symptomatic patients, have shown that treatment with CPAP can improve these patient-reported outcomes. Depressive symptoms, in particular somatic symptoms (irritability, fatigue, lack of energy), are commonly reported in OSA and improve with CPAP.

TREATMENT

Obstructive Sleep Apnea

A comprehensive approach to the management of OSA is needed to reduce risk factors and comorbidities. The clinician should seek to identify and address lifestyle and behavioral factors as well as comorbidities that may be exacerbating OSA. As appropriate, treatment should aim to reduce weight; optimize sleep duration (7–9 h per night); regulate sleep schedules (with similar bedtimes and wake times across the week); encourage the patient to avoid sleeping in the supine position; treat nasal allergies; increase physical activity; eliminate alcohol ingestion (which impairs pharyngeal muscle activity) within 3 h of bedtime; and minimize use of opiate medications. Sedative-hypnotic medications have inconsistent effects on OSA but should be avoided in most patients with moderate to severe OSA. Patients should be counseled to avoid drowsy driving.

CPAP is the standard medical therapy with the highest level of evidence for efficacy. Delivered through a nasal or nasal-oral mask, CPAP works as a mechanical splint to hold the airway open, thus maintaining airway patency during sleep. An overnight CPAP titration study can determine the optimal pressure setting that reduces the number of apneas/hypopneas during sleep, improves gas exchange, and reduces arousals; however, the use of "auto-titrating" CPAP (APAP) devices used in home settings has eliminated the need for titration sleep studies in many patients. Rates of adherence to CPAP treatment are highly variable (average, 50–80%) and may be improved with support by a skilled health care team who can address side effects, help the patient "problem solve," and provide motivational education **(Table 308-3)**. Online CPAP support tools can provide the patient personalized support and feedback. Despite the limitations of CPAP, controlled studies have demonstrated its beneficial effect on alertness, mood, quality of life, work-related productivity, blood pressure, and insulin sensitivity. Uncontrolled studies also indicate a favorable effect on cardiovascular outcomes, cardiac ejection fraction, atrial fibrillation recurrence, and mortality risk.

Oral appliances for OSA work by advancing the mandible, thus opening the airway by repositioning the lower jaw and pulling the tongue forward. These devices generally work better when customized for patient use; maximal adaptation can take several weeks. Efficacy studies show that these devices can reduce the AHI by ≥50% in two-thirds of individuals, although these data are based largely on patients with mild OSA. Some patients with moderate or severe OSA respond to oral appliances as well, although no consistent predictors of success have been identified in these groups, and thus, follow-up sleep testing is recommended. Side effects of oral appliances include temporomandibular joint pain and tooth movement; thus, they require that the patient have adequate dental and periodontal structures. Oral appliances are most often used for treating patients with mild/moderate OSA or patients who do not tolerate CPAP. However, as some patients are more adherent to oral appliances than to CPAP, these devices are under investigation for treatment of more severe disease. In some patients, more consistent treatment of OSA may be obtained by alternating between CPAP and oral appliance therapy.

Upper airway surgery for OSA is less efficacious than CPAP and is mostly reserved for the treatment of patients who snore, have mild OSA, or cannot tolerate CPAP. Uvulopalatopharyngoplasty (UPPP, removal of the uvula and the margin of the soft palate) is the most commonly performed surgery for OSA. However, results vary greatly, and as a standalone procedure, UPPP often has limited efficacy, particularly in severe OSA and in obese patients. Thus, palatal surgery is often combined with other procedures ("multilevel surgery" involving more than one pharyngeal site/structure) performed by an experienced surgeon, but the selection of patients is an important factor and relies on careful targeting of culprit areas for surgical resection. Bariatric surgery is an option

TABLE 308-3 Side Effects of Continuous Positive Airway Pressure (CPAP) and Their Treatments

SIDE EFFECT	TREATMENT
Nasal congestion	Provide heated humidification, administer saline/steroid nasal sprays
Claustrophobia	Change mask interface (e.g., to nasal prongs), promote habituation (i.e., practice breathing on CPAP while awake)
Difficulty exhaling	Temporarily reduce pressure, provide bilevel positive airway pressure
Bruised nasal ridge	Change mask interface, provide protective padding
Aerophagia	Administer antacids

for obese patients with OSA and can improve not only OSA but also other obesity-associated health conditions. Other procedures that can decrease snoring but have minimal effects on OSA include injection of a hardening agent to the soft palate (resulting in stiffening), radiofrequency ablation, laser-assisted uvulopalatoplasty, and palatal implants.

Upper airway neurostimulation is a recently tested alternative treatment for OSA. Unilateral stimulation of the hypoglossal nerve through a surgically implanted device was shown to significantly decrease the AHI and improve a number of patient-reported outcomes, such as sleepiness and quality of life, for a duration of at least 5 years after treatment in carefully selected patients. This therapy is reserved for patients who cannot tolerate or fail CPAP therapy. Current inclusion criteria are moderate to severe OSA (AHI 15–65), body mass index <35 kg/m^2, and absence of complete concentric collapse at the level of the velum documented by awake and drug-induced endoscopy (a predictor of response to surgery). This therapy is also approved for use in children ages 13 or older and adults with Down's syndrome who have an AHI of 10–50. Additional research is underway to further evaluate longer-term effectiveness and potential utility of this treatment in other patient groups.

Vibrotactile positional therapy (devices that emit incremental vibratory stimuli in response to body position in the supine position) can reduce AHI by as much as 50% in individuals with OSA occurring predominantly in the supine position.

Supplemental oxygen can improve oxygen saturation, but there is little evidence that it improves OSA symptoms or the AHI in unselected patients. There is conflicting evidence regarding the effect of supplemental oxygen on blood pressure in patients with OSA.

Orofacial myofunctional therapy (OMT), which involves exercises designed to enhance the strength and coordination of orofacial muscles, has been tested in several small studies of OSA. These studies predominantly focused on individuals suffering from mild-to-moderate OSA and showed modest improvements in snoring and AHI, as well as in overall sleep quality. However, larger and more comprehensive studies are necessary to evaluate fully the efficacy of myofunctional therapy in treating OSA.

Currently, there are no U.S. Food and Drug Administration (FDA)-approved medications for the treatment of OSA. However, ongoing research is exploring the efficacy of weight loss medications and drugs that enhance pharyngeal muscle activity during sleep. Among weight loss drugs, anorectics are generally not favored for OSA due to their side effects and potential for abuse. However, glucagon-like peptide 1 (GLP-1) receptor agonists have garnered recent interest because of their substantial impact on weight loss. Given the strong correlation between weight and OSA, drugs that facilitate weight reduction, such as GLP-1 agonists, which slow gastric emptying and suppress appetite, are being investigated for their potential in improving OSA symptoms. Liraglutide, a GLP-1 agonist, has shown small effects on OSA severity, but tirzepatide, which targets both GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) receptors, may offer more significant weight loss and is currently under trial for OSA. Sodium-glucose cotransporter 2 (SGLT-2) inhibitors also promote weight loss and are under investigation for the treatment of OSA.

Concerning drugs that stimulate pharyngeal muscle activity, studies have shown that sleep-related withdrawal of norepinephrine from cranial motor neurons leads to pharyngeal hypotonia and consequent upper airway obstruction in patients with OSA. Pharyngeal hypotonia is further exacerbated by muscarinic inhibition during REM sleep. Based on these mechanisms, drugs with noradrenergic and antimuscarinic properties have been tested for their potential in OSA management. Early studies have reported notable reductions in AHI, and more advanced phase 3 trials of these drug combinations are in progress.

CENTRAL SLEEP APNEA

CSA, which is less common than OSA, may occur in isolation or, more often, in combination with obstructive events in the form of "mixed" apneas. CSA is often caused by an increased sensitivity to P_{CO_2}, which leads to an unstable breathing pattern that manifests as hyperventilation alternating with apnea. A prolonged circulation delay between the pulmonary capillaries and carotid chemoreceptors is also a contributing cause; thus, individuals with congestive heart failure are at risk for CSA. With prolonged circulation delay, there is a crescendo-decrescendo breathing pattern known as *Cheyne-Stokes breathing* (Fig. 308-2*B*). Other risk factors for CSA include opioid medications (which appear to have a dose-dependent effect on CSA) and hypoxia (e.g., breathing at high altitude). In some individuals, CPAP—particularly at high pressures—seems to induce central apnea; this condition is referred to as *complex sleep apnea* or *treatment-emergent central sleep apnea*. Rarely, CSA may be caused by blunted chemosensitivity due to congenital disorders (congenital central hypoventilation syndrome) or acquired factors. CSA is associated with increased risk for the development of both heart failure and atrial fibrillation. This is possibly related to elevations in sympathetic nervous system activity that accompany this disorder; alternatively, CSA may be an early marker of subclinical myocardial dysfunction. Patients with CSA may report symptoms of frequent awakenings as well as daytime fatigue. Treatment of CSA is difficult and depends on the underlying cause. As treatment of CSA has not been shown to improve long-term health outcomes, specific treatment is generally indicated only for treatment of symptomatic CSA.

Limited data suggest that supplemental oxygen can reduce the frequency of central apneas, particularly in patients with hypoxemia; however, the effectiveness of supplemental oxygen on clinical outcomes is unknown.

In patients with CSA or Cheyne-Stokes breathing associated with heart failure, treatment is directed at optimizing therapy for heart failure. Device-based therapies that adjust pressure support on a breath-by-breath basis (adaptive servoventilation [ASV]) can be effective for regularizing breathing; however, two large international trials showed that ASV resulted in no cardiovascular or mortality benefit. The first trial unexpectedly reported increased mortality, leading to an FDA warning to avoid ASV in patients with CSA who have a left ventricular ejection fraction <45%. The second trial tested an ASV device that delivered lower pressure and reported no evidence of harm along with small improvements in symptoms, raising the possibility that ASV may have a role as adjunctive therapy for patients with heart failure and CSA.

Moderate to severe CSA in adults can be treated with an FDA-approved transvenous phrenic nerve stimulator. A clinical trial testing this therapy in patients with CSA from various etiologies showed an ~50% reduction in AHI and a near elimination of central apneas, along with improvements in sleep quality and quality of life. Ongoing research is addressing long-term safety and effectiveness, as well as subgroups who may benefit the most from this intervention.

309 Lung Transplantation

Hilary J. Goldberg, Hari R. Mallidi

END-STAGE LUNG DISEASE AND INDICATIONS FOR LUNG TRANSPLANTATION

The Lung Allocation Score (LAS) was implemented in 2005 for the purpose of prioritizing organ allocation. In this model, the United Network for Organ Sharing (UNOS) divides advanced lung disease diagnoses into four categories: (A) obstructive lung disease (including non–cystic fibrosis-related bronchiectasis and obliterative bronchiolitis), (B) pulmonary vascular disease, (C) cystic fibrosis, and (D) restrictive lung disease. Historically, obstructive lung disease was the most common indication for transplantation, but after the implementation of the LAS system, idiopathic pulmonary fibrosis (IPF), the most common restrictive lung disease, has become an increasingly frequent indication. In 2023, UNOS transitioned to the lung Composite Allocation Score (CAS) system in the United States. This system is designed to incorporate factors beyond survival, including ethical considerations such as access and practical considerations such as efficiency, as well as efforts to optimize survival.

Prior to the era of antifibrotic therapy, the average life expectancy from the time of diagnosis of IPF was 3–5 years, making patients with this disease the cohort to experience most clearly a survival benefit from lung transplantation. As a result, the LAS prioritizes patients with IPF. Similarly, patients who experience secondary effects of their lung disease, including pulmonary hypertension, right heart dysfunction, and hypercarbia, are prioritized for allocation and should be considered for referral for transplant evaluation irrespective of other markers of disease severity.

Generally, the trajectory of decline and evolution of disease are key indicators of the appropriate timing of referral and listing for lung transplantation, rather than absolute thresholds of disease severity. However, suggested guidelines for referral have been elucidated for specific disease states. For example, in chronic obstructive pulmonary disease, the most common obstructive lung disease for which transplantation is considered, the Body-Mass Index, Airflow Obstruction, Dyspnea, and Exercise Capacity (BODE) Index is often used as a marker of disease severity, with an index of 5 being an appropriate indication for referral for evaluation, and 7 for listing for transplantation. Other suggested markers for transplant consideration in obstructive lung disease include pulmonary function test (PFT) data, such as a forced expiratory volume in 1 s (FEV_1) of <25% predicted. The frequency and severity of exacerbations of disease should also be considered in determining the appropriate timing of referral.

With the marked advances in medical therapy for pulmonary vascular disease over the past decade, transplantation for pulmonary vascular disease has become less frequent but is still an important consideration for patients who progress despite, or are refractory to, treatment. Functional assessments, such as New York Heart Association class III or IV limitations, and hemodynamic measurements, such as cardiac index <2 L/min per m^2, would suggest consideration for evaluation and listing. Patients with diagnoses generally poorly responsive to therapy such as pulmonary veno-occlusive disease should be referred early for evaluation.

Patients with cystic fibrosis (CF) have historically been considered for evaluation when the FEV_1 reaches ~30% predicted. However, with the exciting development of therapies targeting the CF transmembrane receptor, providers should keep in mind the potential for improvement in pulmonary function after treatment initiation. Despite this potential for pharmacotherapeutic response, referral and completion of testing should be considered so that patients are prepared for listing should they fail to see improvement or experience worsening of disease on therapy, and for patients who do not qualify for treatment. Moreover, patients who experience acceleration of acute exacerbation rate, recurrent hemoptysis, worsening functional and/or nutritional status, or colonization with resistant bacteria should also be assessed for transplantation irrespective of pulmonary function results.

Despite treatment progress with the development of antifibrotic therapy for IPF and other progressive fibrosing interstitial lung diseases, these therapies do not reverse the disease but only slow the rate of lung function decline. Therefore, transplant referral for patients with IPF and other fibrosing lung diseases should still be considered at the time of diagnosis. Forced vital capacity <80% predicted or diffusing capacity for carbon monoxide <40% predicted, failure to respond to medical therapy, decline in pulmonary function tests on therapy, and functional decline are additional indications for transplant consideration in patients with other restrictive lung diseases.

CONTRAINDICATIONS TO LUNG TRANSPLANTATION

Absolute Contraindications As experience with lung transplantation increases, and as lung allocation policy has prioritized patients with higher acuity of disease and with diseases affecting older age groups, recipient selection criteria have become more liberal compared to prior eras. While published guidelines suggest absolute and relative contraindications to transplantation, these criteria are in constant evolution, and each program ultimately establishes its own selection algorithms based upon clinical expertise, experience, program size and resources, and referral patterns.

Examples of absolute contraindications to lung transplantation (Table 309-1) include anatomic and technical considerations that would affect the ability to complete the transplant procedure, such as chest wall or spinal deformities or malacia of the large airways. Surgical input is critical in making such determinations. In addition, untreatable and/or irreversible organ dysfunction may preclude isolated lung transplantation. Cirrhosis of the liver, uncorrectable disease of the coronary arteries not amenable to combined surgical intervention during the transplant procedure, or other forms of uncorrectable atherosclerotic or vascular disease may make transplantation too high risk

TABLE 309-1 Contraindications to Lung Transplantation

	ABSOLUTE CONTRAINDICATIONS	RELATIVE CONTRAINDICATIONS
Surgical considerations	Anatomic abnormalities not amenable to transplant procedure	
Age		>65 years
Functional status	Immobility, inability to participate in physical therapy/rehabilitation	Limited functional status as defined by 6-minute walk distance
Medical comorbidities	Untreatable, irreversible organ dysfunction	Chronic kidney disease
	Active malignancy or malignancy with insufficient remission period	
	Active bacterial bloodstream infection	Infection resistant to treatment or of high risk for posttransplant morbidity/mortality (*Burkholderia cenocepacia, Mycobacterium abscessus*)
	Uncontrolled viral infection (HIV, hepatitis)	
Nutritional		BMI <18 or >30–35
Psychosocial	Untreatable, irreversible psychiatric disorder with potential to impact transplant outcome	
	Active substance abuse	Limited social supports
	Other circumstances that would impede ability to participate in and comply with posttransplant care	History of noncompliance with medical treatment

Abbreviations: BMI, body mass index; HIV, human immunodeficiency virus.

for consideration. Renal dysfunction is of particular concern given the known nephrotoxicity of calcineurin inhibitors, which are the mainstay of posttransplant immune suppression.

Relative Contraindications Age in and of itself is typically not a contraindication to transplantation at most centers. However, older patients with significant medical comorbidities may be at prohibitive risk for transplantation, and functional status and frailty may worsen in this setting. Published analyses of the Scientific Registry of Transplant Recipients, a comprehensive database of transplant outcomes, have consistently shown that functional capacity, as assessed by 6-minute walk distance, is inversely correlated with both wait list and posttransplant mortality. As a result, most programs utilize some assessment of functional status as a criterion for transplant candidacy.
