remission. His skin examination reveals findings of both acute and chronic atopic dermatitis, with typical lesion location and description.

Product Selection

Case 39-5, Question 2: P.K. received a prescription for halcinonide 0.25% cream, 30 g, to be applied at bedtime to nonfacial areas and mometasone furoate cream 0.1%, 30 g, twice daily to the facial lesions. Based on pertinent biopharmaceutic considerations, why is this treatment appropriate for P.K.?

P.K.'s regimen includes two topical corticosteroids, one higher-potency agent (halcinonide) to apply to nonfacial lesions and one lower-potency agent (mometasone furoate) for use on the face. This is appropriate owing to the desire to limit the potential for adverse effects from the use of high-potency topical corticosteroids on the face. Results from P.K.'s treatment regimen should include more frequent (twice daily) application or a more potent preparation to control inflamed lesions, which the prescriptions reflect. Once any weeping is stopped, a less potent preparation in the ointment form should be used for maintenance and the number of applications may be reduced. Because of the reservoir effect, control can be maintained in many cases with intermittent regimens such as once daily, every other day, or every third day use of topical corticosteroids. In addition, intermittent regimens can involve alternating corticosteroids and agents such as topical pimecrolimus or tacrolimus to maintain control and minimize adverse effects of either agent.

Because the calcineurin inhibitors are as effective as mid-potency topical corticosteroids without causing atrophy, telangiectasias, or striae, many dermatologists would use either tacrolimus or pimecrolimus on the face in preference to mometasone.[22]

Topical Antibiotics With Corticosteroids

Case 39-5, Question 3: P.K.'s atopic dermatitis presentation is complicated with areas of erythematous, honey-colored, crusted lesions on his arm, and leg. Can a corticosteroid and an antibiotic preparation be used together? What are the risks associated with topical antibiotics?

It is determined that P.K. has impetigo superimposed on his atopic dermatitis. Because impetigo can be treated with topical antibiotics such as mupirocin, combination therapy with a corticosteroid–antibiotic preparation would appear to be a logical choice. Although mupirocin may be an appropriate alternative for some topical dermatologic infections, the current over-the-counter topical antibiotics (bacitracin, neomycin, and polymyxin) are ineffective for most dermatologic infections and are indicated only for the prophylaxis of skin infections. In addition, because staphylococcal toxins act as superantigens, eliciting the production of IgE, thus worsening the atopic dermatitis, almost all clinicians treat atopic dermatitis-associated impetigo with oral antibiotics such as dicloxacillin, macrolides, or cephalexin, in combination with topical corticosteroids for the atopic dermatitis.[22] Oral antibiotics reduce the bacterial counts faster and have a lower incidence of recurrent impetigo compared with topical agents. In areas in which community methicillin-resistant *Staphylococcus aureus* rates are high, more effective antibiotic therapy might be indicated as an alternative. P.K. would most likely benefit from a treatment course of an oral antibiotic plus a topical corticosteroid preparation.

P.K. is prone to repeated infections and atopic dermatitis flares because his skin is colonized with staphylococci. Many dermatologists upon clearance of the impetigo would initiate dilute bleach baths. These consist of 5- to 10-minute baths twice a week, made by adding 120 cc (1/2 cup) of household bleach (6%) to a full bathtub (~40 gallons) to create a 0.005% solution. Because of the variety of tub sizes, the amount of bleach should be adjusted to the size of the bathtub and the amount of water in the tub.[23]

Pruritus

Case 39-5, Question 4: As stated in Case 39-5, Question 1, one of P.K.'s problems is pruritus. What could you recommend for relief of pruritus?

As previously noted, pruritus (itching) is the most common cutaneous symptom in atopic dermatitis.[21] Scratching, which can damage or fatigue receptor nerve endings, is the most common method of relieving pruritus. Topically applied local anesthetics or antihistamines could also be effective in dulling the sensation. However, this approach is often disappointing, probably because the intact epidermis poorly absorbs the salt forms of these drugs. In addition, low concentrations are used in many over-the-counter preparations. If adequate concentrations of local anesthetics are used (lidocaine 3%–4%), pruritus or pain may be reduced for up to 45 minutes. These agents are most useful for relieving pruritus or pain for short periods (eg, when trying to go to sleep at night).[21] A serious drawback to the use of topical benzocaine and antihistamine preparations is their propensity to induce allergic contact dermatitis.[24]

P.K. could also try cold water or ice cubes, which effectively relieve pruritus via vasoconstriction, as do products containing aluminum acetate (Burow solution), tannic acid, or calamine. A cool bath may be useful for the relief of pruritus from dermatologic lesions if they are widespread.

Moisturizing mixtures such as Eucerin, Nivea, Lubriderm, or even simply mineral or baby oil are useful in the treatment of pruritus caused by dry skin in patients with atopic dermatitis. Bathing should be restricted to avoid washing away normal body oils, the drying effect of water, the irritant effect of alkaline soaps, and the trauma of toweling.[6]

Topical corticosteroid applications can be very effective if dermatologic lesions exist. They reduce inflammation, which helps soothe the affected area.

Systemic antihistamines are effective antipruritic agents, although their major beneficial effect may be attributable to sedation. The newer, nonsedating antihistamines are notably ineffective at relieving

itch, with the exception of cetirizine.[25] There is disagreement over which antihistamine or antiserotonin agents are most effective for treatment of pruritus.[21,25,26] Oral hydroxyzine is a commonly used antihistamine; doses of 10 to 25 mg three to four times a day are commonly used. Oral cyproheptadine is another option. There is little evidence that antihistamines are effective in treating non–histamine-mediated pruritus, except that their inherent sedative effect may be somewhat beneficial in all pruritic conditions. Doxepin, a tricyclic antidepressant with potent H_1-blocking properties, is valuable as a second-line antihistamine topically or systemically if others fail.[27] Because P.K.'s pruritus is worse at night, as is typical with atopic dermatitis, the use of any of the three H_1-blockers mentioned at bedtime would be appropriate.[22]

Self-Care Recommendations for Atopic Dermatitis

Case 39-5, Question 5: In addition to prescriptions for topical corticosteroids, a systemic antibiotic (cephalexin 500 mg four times daily for 10 days), and an oral antihistamine (hydroxyzine 25 mg, one to two tablets by mouth at bedtime as needed), what self-care interventions should be suggested for P.K.?

The general goals of therapy for atopic dermatitis are to decrease pruritus, suppress inflammation, and moisturize the skin. The self-care recommendations shown in **Table 39-7** are useful adjuncts and mainstays for use between disease flares for patients such as P.K. with atopic dermatitis or any other irritant dermatitis. Often careful attention to nonpharmacologic measures can markedly reduce the incidence of disease flare. Because even nonlesional skin in patients with atopic dermatitis has reduced moisture, the use of emollients should include all skin surfaces.[28]

Table 39-7
Self-Care Recommendations for Patients With Atopic Dermatitis

or Other Irritant Dermatoses

- Clothing should be soft and light. Cotton or corduroy is preferred. Wools and coarse, heavy synthetics should be avoided.
- Heat should be avoided because it often makes eczema worse. The environment should be well ventilated, cool, and low in humidity (30%–50%). Rapid changes in ambient temperature should be avoided.
- Bathing should be kept to a minimum (no longer than 5 minutes), and the patient should use a nonirritating soap (eg, Basis soap). A colloid bath or the use of appropriate amounts of bath oil may be useful.
- The skin should be kept moist with frequent applications of emollients (eg, Lubriderm, Nivea, Aquaphor®, Eucerin, or petrolatum).
- Primary irritants such as paints, cleansers, solvents, and chemical sprays should be avoided.

P.K. should be warned to avoid people with active herpes simplex infections because severe disseminated infections can occur.

Tachyphylaxis and Calcineurin Inhibitors

Clinicians commonly misdiagnose tachyphylaxis because of corticosteroids. Failure of topical corticosteroids to clear difficult atopic dermatitis after an initial improvement may give the false impression of tachyphylaxis, when the actual problem is a primary failure of the treatment.[29] This could be caused by either inappropriate application technique by the patient or the choice of a product with inadequate potency. Tachyphylaxis can occur within 1 week of therapy, but generally takes several weeks to a month to occur.[29] To treat this problem, patients should discontinue the corticosteroid for a week and restart at an appropriate dose. Alternatively, patients may be switched to topical tacrolimus or pimecrolimus.

Topical tacrolimus or pimecrolimus is an effective alternative to moderate-potency topical corticosteroids and is safe for use in children.[22],[23],[27] In addition to inhibitory effect on cytokine production,

calcineurin inhibitors result in decreased immunologic response to antigens. Transient burning, erythema, and pruritus are the most common adverse effects. Neither pimecrolimus nor tacrolimus causes skin atrophy, making them attractive alternatives for patients with lesions on the face and the neck. Issues regarding the long-term safety of these products have led the US Food and Drug Administration to place a boxed warning in the manufacturer's literature regarding a potential increased cancer risk.[22]

ALLERGIC CONTACT DERMATITIS: POISON IVY, POISON OAK, OR POISON SUMAC

Contact dermatitis is an inflammation of the skin that occurs when a substance comes in direct contact with the epidermal surface. The most common form is irritant contact dermatitis caused by solvents or other chemicals that irritate the skin resulting in red, painful lesions, for example, dish pan hands or diaper dermatitis. Allergic contact dermatitis is a type IV delayed hypersensitivity reaction controlled by allergen-specific T cells. The resulting dermatitis is pruritic and many times vesicular in nature.[1–6]

Poison ivy (*Rhus*) dermatitis is a major cause of allergic contact dermatitis in the United States, exceeding all other causes combined. Other allergens include latex, leather, nickel, and laundry detergents. It is estimated that 50% to 95% of the population is sensitive to the plants to some degree. The severity of the condition varies from mild discomfort to an extremely painful, debilitating condition. *Rhus* dermatitis is caused by sensitization to an allergic substance in the leaves, stems, and roots of poison ivy, poison oak, and poison sumac plants. All three plants contain the same sensitizing oleoresin, urushiol oil, which contains pentadecacatechol, the actual sensitizing agent. Therefore, the dermatitis caused by the three different plants is identical.

Direct contact with the plant is unnecessary for the rash to occur. Highly sensitive persons may develop severe dermatitis merely from exposure to *Rhus* oleoresin carried by pollen or by smoke from burning leaves. This can be especially important in patients presenting with respiratory or dermatologic signs and symptoms but no memory or report of direct exposure to the resin. The oleoresin may remain active for months on clothing, shoes, tools, and sporting equipment. Once the toxic substance is exposed to the skin, it can be spread by the hands to other areas of the body (eg, genitals or eyes) or to people who may come into close contact with the exposed person. Although washing with soap and water may not prevent the dermatitis, even if it is done within 15 minutes of exposure, it will prevent spread of the oleoresin to other parts of the body.

Sensitive individuals should be instructed to avoid contact with the offending plant. If contact is inevitable, every effort should be made to shield exposed areas of the skin with appropriate clothing.

Exposed individuals should bathe or shower as soon as they come in from outdoors and should wash their clothes. Nonprescription topical cleansers (Tecnu, Zanfel, Mean Green Hand Scrub) claim to remove urushiol oil embedded in the skin through the action of microfine scrubbing beads and surfactants, thus possibly preventing the rash or limiting spread. They are applied to exposed areas of the skin, followed by vigorous scrubbing, and rinsed off after application.

After an initial incubation period of 5 to 21 days, a patient would be expected to react to the oleoresin in 12 to 48 hours after re-exposure. A mild exposure to these plants in a sensitized person results in a typical erythematous, vesicular, linear, and sometimes, oozing rash after 2 to 3 days; complete clearing occurs in 1 to 3 weeks.

If a large area is exposed, lesions appear within 6 to 12 hours and may appear blistered and eroded; in some cases, ulcers may appear. Healing occurs more slowly, often requiring 2 to 3 weeks for complete resolution. It is important to determine the areas of the body that are affected. If the eyes, genital areas, mouth, respiratory

tract, or >15% of the body is affected, the patient should receive a course of systemic corticosteroids. See Case 39-7 below.

Treatment

CASE 39-6

QUESTION 1: K.P., a 27-year-old female, has recently returned from an outing in the woods. She now has vesicular eruptions that appear in a linear pattern on one arm and hand. She believes that she has had a poison oak reaction and requests therapy.

What should be recommended at this point? What should be recommended if the condition becomes more severe?

Weeping lesions should be treated with aqueous vehicles (eg, Burow solution or saline). Lesions that are not wet or weeping should be treated with calamine lotion applied two to four times daily. The zinc oxide in calamine lotion may act as a mild astringent, although some people find this preparation to be unacceptable because of its pink color, which can stain clothes. Alternatively, a topical corticosteroid appropriate for the body part affected could be used. If K.P.'s poison oak reaction becomes more severe, additional treatment with prednisone 1 mg/kg/day for at least 2 or 3 weeks will be required; such therapy should be tapered slowly over 1 to 2 weeks to prevent recurrence of the lesions.

SYSTEMIC THERAPY

Relapse

CASE 39-7

QUESTION 1: Z.T., a 19-year-old male, has just returned from a fishing trip and now has an erythematous, linear, dry eruption on his leg and arm, and a generalized eruption on his hands and face. He has been in areas that have dense poison ivy growth, and he may have burned some in the campfire. Z.T. has washed himself and his clothes thoroughly. Z.T.'s physician prescribed oral prednisone for his rash. He was instructed to take 80 mg/day for 14 days and to

decrease the dose by 5 mg/day each day thereafter. Calamine lotion (three times daily to affected areas) also was prescribed. After 12 days, Z.T. reports that the lesions seem to be getting worse. The lesions had cleared after 8 days of treatment, and he began rapidly tapering the prednisone at that time.

Why is he experiencing a relapse?

Two weeks is the minimum course of treatment when systemic corticosteroids are used for severe cases of poison ivy, poison oak, or poison sumac. The oleoresin remains fixed in the skin, and if the systemic corticosteroid is withdrawn too soon, the lesions return. This is probably the most common reason for treatment failure with systemic corticosteroids. Alternatively, systemic corticosteroids can be discontinued before 2 weeks of treatment and a moderate-potency topical corticosteroid preparation can be started 24 hours before discontinuation of systemic corticosteroids and continued for 7 to 10 days to prevent relapse.

DRUG ERUPTIONS

Clinically recognizable adverse drug reactions are manifested on the skin more often than any other organ or organ system.[30–33] An estimated 1% to 5% of hospitalized patients experience a drug eruption.[31]

Acneiform Eruptions

Acneiform eruptions appear very much like common acne. They may be distinguished from acne by their sudden occurrence, the absence of comedones, uniform appearance (ie, all at the same stage of development), and the fact that they may occur on any part of the body. Cysts and scarring are rarely associated with drug-induced acne. Eruptions can also occur during any period of the patient's life; thus, drug-induced acne should be suspected when the lesions appear in persons outside the typical age bracket for acne. Drugs

implicated include adrenocorticotropic hormone, anabolic steroids, azathioprine, danazol, glucocorticoids, iodides, bromides, lithium, gefitinib, erlotinib. lapatinib, and oral contraceptives. For patients with acne vulgaris, these drugs may worsen existing lesions (see Chapter 40, Acne).

Allergic Contact Dermatitis

Topical administration of a sensitizing agent produces localized papulovesicular lesions. These lesions are limited only to areas that are exposed to the topical product. Neomycin, bacitracin, and many fragrances are well-known topical sensitizers, as well as metals like nickel and cobalt.[34–37] Systemic administration of a drug to a patient previously sensitized to the drug by topical application can provoke widespread dermatitis. Implicated systemically or topically administered drugs that reactivate allergic contact dermatitis include procaine or benzocaine, radiographic contrast media or iodine, and streptomycin and gentamicin, among others.

Erythema Multiforme

As the name implies, erythema multiforme (EM) eruptions take on a varied spectrum of morphologic forms, ranging from the mildest with tiny maculovesicular lesions to more severe forms such as Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) with extensive bullous lesions and routine involvement of mucous membranes. Although all forms have been reported to have oral lesions, they are much more severe in SJS and TEN, in which genital, nasal, and ocular mucosae can also be involved. Target lesions are usually present in all forms of the disorder, which characteristically are erythematous, iris-shaped papules, and vesiculobullous lesions typically involving the extremities, especially the palms and soles in EM and the torso in SJS and TEN. The lesions take on the appearance of a circular target with a bull's-eye in the middle, thus the term "target lesion." Questions have recently

been raised about the shared pathologic nature of these forms of EM.[38] EM in its mildest forms, EM minor and EM major, is more common in children and young adults, and is self-limited in nature with only transient hypopigmentation or hyperpigmentation as complications. Sometimes malaise, a low-grade fever, and itching or burning may accompany this type of eruption. Etiologic factors associated with EM include drugs, mycoplasma and herpes infections, radiation therapy, foods, and sometimes neoplasms. Allopurinol, barbiturates, phenothiazine, and sulfonamides are the drugs most often implicated in EM eruptions.

Stevens–Johnson Syndrome

SJS is one of the most common types of severe drug eruptions. The syndrome is usually a moderate mucocutaneous and systemic reaction. Blisters and atypical target lesions involve <10% of the body surface area (BSA), with some epidermal detachment, which can cause scarring in some cases. Besides drugs, this syndrome has been associated with infections, pregnancy, foods, deep radiographic therapy, and neoplasms. Mortality is estimated to be in the range of 5% to 18%. The duration of the syndrome is usually 4 to 6 weeks. The long-acting sulfonamides are most often implicated. Allopurinol, carbamazepine, fluoroquinolones, hydantoin, phenylbutazone, piroxicam, and other sulfa derivatives such as sulfonylureas are also possible causative agents.

Toxic Epidermal Necrolysis

TEN is a severe, life-threatening mucocutaneous and systemic reaction that has the same pathophysiology as SJS, only differing in the amount of BSA involved (>30% of BSA vs <10% with SJS). TEN may be preceded by a prodrome characterized by malaise, lethargy, fever, and occasionally throat or mucous membrane soreness. Epidermal changes follow and consist of erythema and massive bullae formations that easily rupture and peel, giving the skin a

scalded appearance. Mortality in TEN patients is roughly 30%, often within 8 days after bullae appear. The usual cause of death is infection complicated by massive fluid and electrolyte loss, similar to patients with extensive burns. In addition to drugs, certain bacterial infections and foods are believed to cause this type of eruption. Most causes of TEN in children are because of infection (eg, *S. aureus*). A higher incidence of this type of drug eruption appears to occur in HIV-positive patients. Similar to SJS, drugs most frequently implicated include allopurinol, aminopenicillins, carbamazepine, hydantoin, phenylbutazone, piroxicam, and sulfa drugs.

Urticaria

Urticarial eruptions are immediate hypersensitivity reactions (IgE-mediated) and usually appear as sharply circumscribed (raised), edematous, and erythematous lesions (wheals) with an abrupt onset.

In most cases, individual lesions disappear within 24 hours. These are replaced with new lesions elsewhere until the offending allergen is cleared from the body. Urticarial lesions are associated with an intense itching, stinging, or prickling sensation. Commonly called *hives*, urticarial eruptions are frequently associated with certain drugs, foods, psychic upsets, and serum sickness. The most frequently implicated drugs with this type of reaction are aspirin, penicillin, and blood products. Patients who exhibit urticaria attributable to a drug are at increased risk of anaphylaxis if re-exposed to the same medication in the future.

CASE 39-8

Question 1: D.Z., a 42-year-old male with a chronic seizure disorder and long-standing anxiety, was recently given a prescription for penicillin V 250 mg four times daily for a group A, α-hemolytic streptococcal-positive pharyngitis. Chronic medications include carbamazepine 200 mg three times daily and clonazepam 2 mg two times daily. One week later, D.Z. presents with urticarial lesions on his chest and arms.

Is this a typical time of onset for a drug-induced dermatologic reaction? How should the drug eruption in D.Z. be managed?

Although most drug eruptions occur within 1 to 2 weeks after starting therapy, it may take 3 to 4 weeks after an initial exposure to a medication for the reaction to occur. Repeated exposure to the same offending agent can reduce the time of onset of the reaction to a few days or even within hours of ingestion. Because D.Z. has been taking clonazepam and carbamazepine chronically and penicillin for only 8 days, the temporal relationship would logically lead to the conclusion that penicillin is a highly probable cause. Almost all cases of urticaria are associated with extensive eosinophilia; however, it is not specific for any particular antigen. However, before labeling penicillin as the cause of his drug eruption, a thorough history to rule out other common nondrug causes should be taken.

For D.Z., a different antibiotic (macrolide) should be substituted for penicillin (to complete the 10-day course of therapy). The individual lesions should begin to clear in 24 hours of eruption (if the penicillin is the cause of the urticaria). If the urticaria does not begin to clear in a few days, another cause should be investigated.

Treatment is primarily supportive, and use of an oral antihistamine (eg, diphenhydramine 25–50 mg four times daily) for several days would be recommended. If the reaction is severe, a 1- to 2-week course of prednisone 40 to 60 mg/day will control most symptoms within 48 hours.

CORE PRINCIPLES		CHAPTER CASES
1	Acne is a condition in which the pilosebaceous units of the skin become plugged and distended, presenting as comedones, papules, pustules, or nodules.	**Case 40-1 (Question 1, 2)** **Case 40-3 (Question 1)** **Case 40-4 (Question 1)** **Case 40-5 (Question 1)**
2	Drug therapies work by reducing sebum production, normalizing keratinization in the pilosebaceous units, reducing *Propionibacterium acnes*, or reducing inflammation.	**Case 40-1 (Question 1, 2)** **Case 40-3 (Question 1)** **Case 40-4 (Question 1)** **Case 40-5 (Question 1)**
3	Patients must be counseled that pharmacotherapy works best to prevent future lesions, not to resolve current	**Case 40-1 (Question 2)** **Case 40-2 (Question 1)**

	ones. Therefore, topical therapies should be applied regularly to the entire acne-prone area(s), not just to lesions. Full treatment effect takes weeks to months for most treatment options.	**Case 40-3 (Question 1, 2)** **Case 40-4 (Question 2)**
4	Appropriate choice of topical vehicle ensures efficacy and tolerability of topical therapy. Gels should be used in patients with normal to oily skin. Lotions and creams should be reserved for those with drier skin types.	**Case 40-1 (Question 3)**
5	Topical retinoids are first-line monotherapy for comedonal acne. They are also key components of combination therapies in maculopustular acne and preferred agents to continue for maintenance therapy once acne is under control. If comedonal acne cannot be controlled with topical retinoids alone, then salicylic acid or azelaic acid may be used as adjunctive therapy.	**Case 40-1 (Question 2, 3)** **Case 40-2 (Question 1)** **Table 40-1**
6	Initial treatment for maculopustular acne is a topical retinoid in combination with topical or oral antibiotics. If treatment with topical antibiotics is selected, the regimen should also include topical benzoyl peroxide to reduce the development of antibiotic resistance. Antibiotic duration should be limited to the period needed to obtain control of acne; then the retinoid, with or without benzoyl peroxide, should be continued as maintenance therapy.	**Case 40-3 (Question 1, 2), Table 40-1**

7	Antiandrogenic therapies, such as combined oral contraceptives or spironolactone, are useful alternative treatment options for maculopustular acne in nonpregnant females.	**Case 40-4 (Question 1, 2), Table 40-1**
8	Oral isotretinoin monotherapy should be used to treat nodular acne. Isotretinoin is extremely effective and can induce a lengthy remission of acne, but the adverse effect profile and the need for laboratory monitoring preclude use in comedonal or maculopustular acne. The iPLEDGE risk management program controls isotretinoin distribution to prevent accidental prescription of this severe teratogen to pregnant females.	**Case 40-5 (Question 1, 2), Table 40-1**

INTRODUCTION

Acne prevalence is estimated to be 40 to 50 million individuals within the United States, and impacts 85% of adolescents in the United States. Acne often begins when sebaceous gland activity increases in puberty and can persist into adulthood.[1]

PATHOPHYSIOLOGY

Four primary mechanisms are responsible for acne: increased sebum production, hyperkeratinization, colonization of *Propionibacterium acnes* (*P. acnes*), and release of inflammatory

mediators to the skin. Acne begins with the overproduction of sebum, often secondary to an increase in androgen levels.[2]

CLINICAL PRESENTATION

Acne presents as comedones or inflammatory papules, pustules, or nodules, and generally appears in areas with the highest density of pilosebaceous units including the face, neck, upper chest, shoulders, and back. There is limited evidence to suggest that factors such as sunlight or diet are risk factors for worsening acne. However, family history, increased body mass index, and stress have been found to potentially contribute to worsening acne symptoms.[2]

DIAGNOSIS

The differential diagnosis of acneiform eruptions includes acne vulgaris, rosacea, bacterial folliculitis, drug-induced acne, and perioral dermatitis.[3] Detailed discussions of severe acne variants, such as acne conglobata and acne fulminans, are beyond the scope of this chapter.

Initial treatment should be selected based on patient-specific factors including the presence of comedonal (**Fig. 40-1**), maculopustular (**Fig. 40-2**), and nodular acne (**Fig. 40-3**), which are used to guide treatment decisions. Although there are no standard grading systems for acne severity, clinicians may choose to adopt an acne severity scale to assist in their assessment of therapy response.[4,5]

OVERVIEW OF THERAPY

Treatment is individualized and depends on the clinical presentation of the patient. The goals of treatment are to relieve discomfort, improve skin appearance, prevent scarring, and minimize the psychosocial impact of the condition.

Treatment is largely preventive because little can be done for existing lesions. Slow improvement over the course of weeks to months is expected for all treatments. Therefore, treatment regimens should not be modified more often than every 6 to 8 weeks. It is important to counsel patients that inflammatory acne may result in scarring or hyperpigmentation, which may take several months to

resolve and delay patient recognition of acne improvement.[6] Patients should be counseled on the basic pathophysiology of acne, proper drug administration or application technique, delay in onset of therapeutic effect, potential adverse effects of any recommended therapy, and steps to take if adverse effects occur. Clinical practice guidelines are available. **Table 40-1** outlines a general approach to the treatment of acne.[4–6]

Table 40-1
Treatment Selection by Acne Type

Type	Treatment Options
Comedonal acne	Topical retinoid, azelaic acid *or* Salicylic acid
Maculopapular acne	Topical retinoid + topical antimicrobial (antibiotic or benzoyl peroxide) *or* Topical retinoid + oral antibiotic + benzoyl peroxide *or* (additional options for female patients) Combination oral contraceptive Androgen receptor antagonist
Nodular acne	Isotretinoin

Nonpharmacologic Therapy

Nonpharmacologic therapy plays a minimal role in the management of acne. There is insufficient evidence to suggest washing as either an exacerbating factor or a treatment option. To minimize scarring, patients must resist squeezing or picking at acne lesions. Oil-based cosmetics should be avoided. Oil-free moisturizers formulated for facial skin can improve the penetration and tolerability of many topical acne drugs by improving the skin's hydration, especially in patients with sensitive skin.[1] Drugs known to cause acne, such as corticosteroids, androgens, and anabolic steroids, should be avoided when possible.[3]

Dermatologists may use procedures such as surgical comedone extraction, chemical peels, and microdermabrasion as adjunct therapy to improve cosmetic appearance. Current guidelines prefer drug therapy to light and laser therapies because there are less stringent clinical testing for devices compared to medications, a concern about long-term effects of therapies aimed at sebaceous gland function, and inadequate postmarketing clinical evidence for light and laser therapies.[4,5] Acne scarring may be treated with various microsurgical techniques such as dermabrasion, laser therapy, chemical peels, and tissue augmentation.[7]

Pharmacotherapy

Available drug therapies exhibit one or more of the following mechanisms: normalizing follicular keratinization (retinoids, benzoyl peroxide, azelaic acid, isotretinoin), decreasing sebum production (isotretinoin, hormonal therapies), suppressing *P. acnes* (antibiotics, benzoyl peroxide, azelaic acid, isotretinoin), and reducing inflammation (antibiotics, retinoids, isotretinoin).

COMEDONAL ACNE

Pharmacotherapy

Topical therapies are the most appropriate first-line treatment for comedonal acne. Options include retinoids, azelaic acid, and salicylic acid.

TOPICAL RETINOIDS AND RETINOID ACID DERIVATIVES

Retinoids, analogs of vitamin A, normalize keratinization by decreasing horny cell cohesiveness and stimulating epidermal cell turnover. These actions combine to unplug follicles and prevent microcomedo formation. Retinoids reduce inflammation by inhibiting

the production of inflammatory mediators. Topical retinoids have no antibacterial properties.[8]

As the most potent comedolytic agents, topical retinoids are preferred therapy in comedonal acne.[4,5] They are also a core component of combination therapies for maculopapular/pustule acne and a first-line treatment to maintain remission of acne once it is controlled. Tretinoin, all-*trans*-retinoic acid, is the naturally occurring form of vitamin A acid and is a first-generation topical retinoid. It is generally well tolerated, although it can cause retinoid dermatitis leading to further hyperpigmentation if used too aggressively in patients with darker skin types. Starting at a low dose or using creams over gels can minimize the risk of worsening hyperpigmentation.[9] If hyperpigmentation is a concern, adapalene, a retinoid acid derivative, is preferred. It is generally well tolerated and, in addition to decreasing risk for hyperpigmentation, has a greater anti-inflammatory effect than has tretinoin. In addition, adapalene 0.1% gel is available over the counter (OTC), making it easily accessible and a good option for patients who may be concerned with cost. Tazarotene is a second-generation topical retinoid that has demonstrated efficacy, but may be less tolerable compared to adapalene.[4]

Topical retinoids and adapalene should be applied once daily at bedtime. Tretinoin specifically may be subject to degradation in ultraviolet light. Common adverse effects of this class include skin irritation, peeling, erythema, and dryness. Irritation may be correlated to drug concentration and vehicle selected. Patients should be counseled to apply daily sunscreen and gentle moisturizing cream while using these agents.[4] Patients should be aware that acne might initially worsen during treatment because pustular flares can occur.

AZELAIC ACID

Azelaic acid is a dicarboxylic acid that works to normalize keratinization and indirectly reduces inflammation through suppression of *P. acnes*.[10,11] Formulations in the 20% strength are indicated for the treatment of acne, whereas the 15% gel is indicated

for rosacea. Although azelaic acid hits several of the pathways leading to acne formation, the evidence for use is not as robust as are other topical agents.[8] It is applied twice daily to the skin and may be an option for patients who are unable to tolerate other topical therapies.

SALICYLIC ACID

Topical salicylic acid works as a concentration-dependent keratolytic agent. Studies have demonstrated that topical salicylic acid is less effective than either topical retinoids or benzoyl peroxide. Thus, it is commonly reserved for patients with comedonal acne who cannot tolerate other comedolytic therapies or as augmentation to other therapies. It is typically applied twice daily and is not effective when used only as needed. Patients should be cautioned not to regularly apply over large body surfaces owing to increased risk of percutaneous absorption, which can lead to systemic salicylate toxicity.[11]

CASE 40-1

QUESTION 1: L.Y. is a 15-year-old female who presents to the pharmacy asking for the best way to treat her "zits." She notes that she developed acne earlier this year around the same time that she joined the track team. Upon examination, you can see that her skin is dark brown and slightly oily. She has several closed comedones on her nose and chin and open comedones dispersed across her forehead covered by makeup. She has been scrubbing her face with exfoliating gloves and mild soap several times per day.

What factors could be contributing to her acne?

Increased sweat encountered while running track can lead to favorable conditions for the colonization of *P. acnes*. Frequent washing of her face may lead to increased sebum production. The exfoliation of her skin may lead to disruption of the skin barrier and bacterial colonization. Finally, it is important to ask L.Y. whether her makeup is oil based, because oil-based products can be comedogenic.

Case 40-1, Question 2: What are the treatment options for L.Y.'s acne?

Adapalene gel is the preferred first-line treatment agent for comedonal acne. It is available OTC, is well tolerated, and has a lower risk of hyperpigmentation compared to retinoids. Start adapalene every other night for 2 weeks, then increase to nightly. She should be instructed to wash her face with a mild cleanser in the evening, wait 30 minutes, and then apply adapalene. In the morning, she should wash her face again. If she experiences excessive skin dryness or peeling occurs, she may wash the adapalene off after several hours instead of waiting until morning. It is important to let L.Y. know that adapalene should be used as scheduled (daily for most patients) and not as needed to be effective. Effectiveness should be evaluated several weeks after initiation.

Case 40-1, Question 3: What vehicle would you recommend for L.Y.?

L.Y. has slightly oily skin. Therefore, using a gel is the vehicle of choice because it has more drying effects compared to lotions and creams. If she experiences excessive dryness or peeling, she can switch to adapalene cream. The cream, however, is not available OTC.

CASE 40-2

Question 1: M.G. is a 27-year-old female who presents to the dermatology clinic with open and closed comedones spread across her cheeks and forehead. She was recently prescribed adapalene 0.1% cream, which she has been applying daily for the past 6 months without much success. She is currently using a mild soap to wash her face twice daily. She is not sure what else she can do to manage her acne.

What would you recommend?

Although topical retinoids are first-line treatment for comedonal acne, some patients require additional agents to achieve satisfactory results. M.G. should be instructed to continue adapalene and initiate

salicylic acid wash daily. This wash should be used on her entire face, not just areas with active breakouts, twice daily. It is important to remind her that it may take several weeks before she sees an effect.

MACULOPAPULAR ACNE

Pharmacotherapy

BENZOYL PEROXIDE

Benzoyl peroxide is an effective agent for patients with maculopapular acne. It works through antimicrobial, anti-inflammatory, and keratolytic effects. It is important to note that there is no reported resistance of *P. acnes* to benzoyl peroxide. Benzoyl peroxide is available OTC and by prescription in a variety of dosage forms. Benzoyl peroxide inactivates some formulations of tretinoin. Therefore, if benzoyl peroxide is added on to tretinoin, patients should be instructed to apply them at different times (morning and evening, respectively).[4],[11] Benzoyl peroxide is usually applied to the affected area once or twice daily. The most common adverse effects of benzoyl peroxide include contact dermatitis (≤2.5%), erythema, peeling, and skin drying.[11] Those who develop contact dermatitis should be instructed to stop using benzoyl peroxide. Patients should be counseled that benzoyl peroxide can bleach hair and dyed fabrics.

ANTIBIOTICS

Although *P. acnes* is part of the skin's normal flora, under the conditions leading to acne it can transform comedones into inflammatory pustules or papules. Although antibiotics do not resolve existing lesions, they can prevent future lesions by decreasing both *P. acnes* colonization and inflammation through antioxidant properties and, in turn, reduced leukocyte recruitment.[12] Owing to this multifactorial mechanism of action, clinical efficacy does not

correlate with reductions in bacterial load, and successful antibiotic courses do not necessarily eradicate *P. acnes*.[13]

Topical antibiotics

Topically applied antibiotics avoid systemic exposure and achieve high follicular concentrations. They can augment topical retinoids when initiating therapy for comedonal and papular acne with inflammatory lesions, or they can be added to regimens for patients failing monotherapy. Topical antibiotics should be used with benzoyl peroxide to limit bacterial resistance.[8] Clindamycin is the preferred topical antibiotic, and is available in fixed combination with benzoyl peroxide, which may aid adherence and reduce the risk of bacterial resistance.[4]

Topical antibiotics should be applied once or twice daily for 3 months. Local irritation, including stinging, are the most common adverse effects. The local adverse effects of topical antibiotics occur less frequently when compared to other topical therapies for acne.[11]

Oral antibiotics

Oral antibiotics are preferred in combination with benzoyl peroxide and a topical retinoid in the treatment of moderate-to-severe inflammatory acne. In addition, they are also used as a step-up therapy when topical antibiotic regimens have failed to suppress acne or in cases where lesions are widespread or difficult to reach. Oral antibiotics should not be used as monotherapy. Most oral antibiotics are given twice daily for 3 months, followed by continuation of a topical retinoid for maintenance therapy. Minocycline and doxycycline have both been found to be efficacious and are guideline recommended. Tetracyclines should not be prescribed for children younger than age 9 years owing to the potential risk of impairment in bone growth and discoloration of forming teeth. Pregnant females must avoid tetracyclines because of bone growth effects on the fetus. Trimethoprim/sulfamethoxazole is also effective, but has a less favorable adverse effect profile when compared to doxycycline and minocycline. It is reserved for

situations when tetracyclines are contraindicated. In patients who are unable to take the abovementioned oral antibiotics (including pregnant patients), erythromycin may be another option despite association with higher rates of resistance.[4,13]

Antibiotic resistance

Antibiotic resistance of *P. acnes* is increasing, and correlates with prescribing patterns. Erythromycin has the highest rate of resistance. Resistance to tetracyclines is less common, and is increasing at a slower rate than is resistance to other antibiotics. In an effort to minimize resistance, guidelines emphasize that antibiotics should be reserved for acne of at least maculopapular subtype. Antibiotics should be used in combination with drugs exerting additional mechanisms of action, ideally topical retinoids and benzoyl peroxide, rather than used as monotherapy. Antibiotic use should be limited to the shortest effective duration to obtain acne control. Antibiotics should not be used for maintenance of control (rather, retinoids should be continued for maintenance).[4,5,8,13] Dual antibiotic use is inappropriate because it increases the risk of bacterial resistance without offering therapeutic benefit, because bacterial eradication is not a therapeutic goal.

CASE 40-3

Question 1: R.P. is an 18-year-old male who has had acne since his early teens. He started out with comedonal acne alone, but now has a number of inflammatory pustules across his forehead and nose. R.P. was prescribed tretinoin 0.1% gel in the past, but he stopped this because of skin irritation and dryness. He has been using adapalene 0.1% cream and salicylic acid washes daily, without success.

What changes to R.P.'s medication regimen do you recommend?

Because he presents with pustules, R.P. can stop his salicylic acid wash, continue adapalene, and should start on a topical antimicrobial agent such as a topical clindamycin with benzoyl peroxide. The topical antibiotic should be continued for 3 months and

then R.P. may transition to adapalene and benzoyl peroxide or a trial of adapalene monotherapy.

Case 40-3, Question 2: R.P. returns to the pharmacy and reports that his acne therapy is "not working." He saw his dermatologist and has been using clindamycin lotion 1% every morning, adapalene cream 0.1% every night, and benzoyl peroxide lotion 4% daily for 12 weeks. Upon examination, you notice that he continues to have maculopapular acne in addition to a few nodules. What changes do you recommend to his treatment regimen?

Given that R.P. has now progressed to maculopapular acne mixed with nodules, he should stop his topical antibiotic and start an oral antibiotic, such as doxycycline. If he is able to tolerate doxycycline, he should continue this medication for 6 to 8 weeks, at which point changes should be made if there is no improvement. If the response is adequate, R.P. should try to stop doxycycline after a total treatment course of 3 months. Topical adapalene and benzoyl peroxide should be continued during doxycycline therapy and then continued after the antibiotic course to maintain treatment benefit. If R.P. were to experience a treatment relapse after successful use of an oral antibiotic, another course of the same antibiotic should be used. Switching antibiotics offers no therapeutic benefit, and can promote multidrug resistance.[4,5]

HORMONAL THERAPIES

Hormonal therapies with antiandrogenic effects, such as androgen receptor antagonists and combination oral contraceptives, are the only treatments besides oral isotretinoin to attack acne by reducing sebum production. Hormonal therapies may be helpful even in patients with normal serum androgen levels because hypersensitivity to androgens can occur at the follicular level with normal circulating androgen levels. These treatments are good options for females with acne who are not pregnant and desire contraception or have polycystic ovary syndrome or other hyperandrogenic conditions or symptoms. Systemic effects of hormonal therapy generally preclude their use in male patients. Response to hormonal therapies can take

3 to 6 months because their mechanism of action, reducing sebum production, is an early step in the cascade of acne pathology.[14]

Androgen receptor antagonists

Spironolactone at doses of 25 to 100 mg/day reduces acne because it is an androgen receptor antagonist and inhibits 5-α reductase. Tolerability and serum potassium should be monitored every 3 weeks until maximum tolerated dose or 100 mg/day is achieved, titrating in 25-mg increments. Spironolactone is generally well tolerated, although gynecomastia, menstrual irregularities, hypotension, and hyperkalemia are possible. Spironolactone should not be initiated in patients with baseline hypotension or hyperkalemia. Female patients should use contraception because of the potential for antiandrogen exposure to impair the sexual development of male fetuses. Spironolactone should be used with caution in male patients given the risk of gynecomastia and, possibly, lower efficacy when compared to female patients.[14]

Combination oral contraceptives

When considering initiation of combination oral contraceptives in patients with acne, it is important to review the risk of treatment versus benefit for acne. Potential long-term risks associated with use include increased risk of venous thromboembolic events, myocardial infarction, and the potential increased risk of breast cancer.[4],[14]

Estrogen, usually administered as ethinyl estradiol in a combination oral contraceptive, improves acne in females by reducing ovarian androgen production and by increasing sex hormone–binding globulin concentrations in the serum, thereby lowering free testosterone levels. Currently, there are four combination oral contraceptives approved by the U.S. Food and Drug Administration (FDA) for the treatment of acne: ethinyl estradiol/norgestimate, ethinyl estradiol/norethindrone, ethinyl estradiol/drospirenone, ethinyl estradiol/drospirenone/levomefolate. Comparative trials have not yet clearly established clinically significant superiority of one product over another.[14] In individual

patients, products containing progestins with androgenic effects (eg, norgestrel, levonorgestrel) may override the effect of ethinyl estradiol and worsen acne. Conversely, patients already on a combination oral contraceptive may improve when switched to a formulation with a less androgenic progestin (norgestimate, desogestrel).[15] Other estrogen-containing contraceptives (transdermal patches, vaginal rings) may have similar beneficial effects to combination oral contraceptives, but studies have not been conducted.

CASE 40-4

QUESTION 1: M.J. is a 24-year-old female who presents to the clinic with maculopapular acne. She is currently using adapalene gel 0.1% nightly. She reports that her acne typically worsens 1 week before her menstrual cycle starts and improves once menses begins. Her last menses began 1 week ago, and she is not interested in pregnancy within the next few years.

What factors may make hormonal therapy a good treatment option for M.J.?

M.J. is female, not currently pregnant, not interested in pregnancy in the near future, and has noted fluctuations in her acne severity that correlate with her menstrual cycle are all factors that may make hormonal therapy a good treatment option.

CASE 40-4, QUESTION 2: M.J. is prescribed a combination oral contraceptive, ethinyl estradiol/norethindrone. Should she continue adapalene?

Because the onset of hormonal therapy is delayed, M.J. should be counseled to continue using her current treatment for at least 3 months after starting a combination oral contraceptive. At that time, if she has seen adequate improvement in acne symptoms, she may try hormonal therapy as an acne monotherapy.

NODULAR ACNE

Pharmacotherapy

ORAL ISOTRETINOIN

Oral isotretinoin is the only agent effective for the treatment of nodular acne. It exhibits all four of the mechanisms of action currently used to attack acne, making it a uniquely effective monotherapy. In most cases, one or two 5-month-long courses of therapy will induce a remission lasting for several months or even years after the drug is stopped. Although this medication is very effective in the suppression of acne, it is not utilized in more mild cases of acne because of its adverse effect profile. It should be reserved as a last-line therapy for patients with nodular acne and variants of acne that are prone to scarring.[16]

For the first month of treatment, isotretinoin should be dosed 0.5 mg/kg/day split into two doses administered with food. If tolerated, the dose should be increased to a target dose of 1 mg/kg/day. For best results and minimal risk of relapse, treatment should be continued until a cumulative dose of ~120 mg/kg is reached, usually in about 5 months. Higher dosages are associated with an increased risk of adverse effects.[16]

Isotretinoin is severely teratogenic, and has a risk of severe psychiatric adverse effects.[17],[18] An FDA-mandated Risk Evaluation Mitigation Strategy (REMS) strict risk management program called iPLEDGE regulates the prescription and distribution of isotretinoin in the United States. The iPLEDGE program system verifies that all criteria, including the requirements for pregnancy testing and two methods of contraception for female patients, have been met by the prescriber, patient, and pharmacy before granting the pharmacy authorization to fill and dispense isotretinoin.[17]

In addition to following the guidelines in the iPLEDGE program, patients should have baseline labs including fasting lipid panel and liver function tests. A fasting lipid panel should be rechecked at 4 and 8 weeks after initiating isotretinoin therapy because 20% of patients develop significant triglyceride elevations, and patients may require intervention to prevent pancreatitis. If pancreatitis develops, isotretinoin must be discontinued. Liver function tests and blood

counts only need to be redrawn during therapy if symptoms suggestive of hepatitis or blood dyscrasias appear.[4,19,20]

In addition to its teratogenic effects, oral isotretinoin can also cause numerous dermatologic effects including dryness, erythema, peeling, and photosensitivity.[4,16,20] To minimize this, patients should be instructed to use daily moisturizers, sunscreen, and protective clothing. Patients should avoid waxing, dermabrasions, and any other dermatologic procedures during and up to 6 months after the completion of treatment. Isotretinoin may cause hair dryness, hair thinning, and nail fragility.

CASE 40-5

Question 1: K.S. is a 24-year-old female who first noticed acne when she was 10 years old. As a teen, she used topical benzoyl peroxide, topical adapalene, and systemic doxycycline with limited success. Two years ago, she was diagnosed with polycystic ovary syndrome and began taking norgestimate/ethinyl estradiol along with her maintenance adapalene treatment, after which her acne improved, but was not eradicated. Ten months ago, she also began taking minocycline 100 mg orally twice daily. After a few months, she experienced significant improvement, but she has not been able to stop antibiotics because of recurrent flare-ups. She now has at least a dozen nodules widely distributed among multiple papules and pustules on her face and back.

What pharmacologic therapy would you recommend for K.S.?

The most effective medication for K.S. will be oral isotretinoin at an initial dose of 0.5 mg/kg/day in two divided doses. Before starting, baseline labs must be obtained and all iPLEDGE guidelines followed. The isotretinoin dose should be increased to 1 mg/kg/day in two divided doses after 1 month. The options for contraception should be discussed with K.S. and two methods selected. If her adherence is good with norgestimate/ethinyl estradiol, it may be continued as a primary form of contraception. K.S. should stop taking minocycline when isotretinoin therapy begins because isotretinoin is effective monotherapy, and coadministration of isotretinoin and tetracyclines increases the risk of intracranial hypertension.[21] Adapalene is also unnecessary once isotretinoin

begins. Her acne should significantly improve within the first month of therapy and gradually resolve by the third or fourth month. A second course of isotretinoin therapy is usually not necessary.

Case 40-5, Question 2: After 3 weeks of therapy, K.S. states she has dry eyes, dry skin, and cracks with bleeding at the corners of her mouth. How do you recommend managing these adverse effects?

K.S. should use artificial tears to relieve the discomfort of her dry eyes; if she is still uncomfortable after several days, she can also apply lubricating ophthalmic ointment at bedtime. She should liberally apply moisturizer to dry skin, particularly after bathing (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders). Frequent application of a lip balm or emollient, ideally one containing sunscreen, will treat cheilitis. If the symptoms become intolerable, a small reduction in the isotretinoin dose (eg, reduction of 10–20 mg/day) usually decreases the intensity of skin and mucous membrane reactions. Drug discontinuation is rarely necessary.[16]

Psoriasis

Rachel C. Long and Kelly A. Mullican

CORE PRINCIPLES		CHAPTER CASES
1	Psoriasis is a chronic, proliferative skin disease that is characterized by well-delineated, thickened erythematous skin plaques and is both topical and systemic in nature. Disease severity is classified based on effected body surface area (BSA) and recalcitrant disease.	**Case 41-1 (Question 1, 3)**
2	Precipitating factors for psoriasis include cold weather, anxiety and stress, viral or bacterial infections, epidermal trauma, or drugs.	**Case 41-1 (Question 2)**
3	Topical corticosteroids are first-line treatment for mild psoriasis given their prompt relief, convenience, and anti-	**Case 41-1 (Question 4)**

	inflammatory, immunosuppressant, and antipruritic properties.	
4	Alternative topical treatments for mild psoriasis—coal tar, anthralin, calcipotriene, calcitriol, and tazarotene—and phototherapy are not as convenient as topical corticosteroids but have well-established efficacy for initial management.	**Case 41-1 (Question 5)**
5	Treatment goals for severe psoriasis include both safe and effective resolution of the disease and long-term maintenance using agents to induce immunosuppressive or remittive cellular changes.	**Case 41-2 (Question 1)**
6	Use of immunosuppressive agents can be limited as a result of adverse effects, monitoring requirements, or toxicity. There is also a lack of evidence to support that they modify the long-term disease process. Immunomodulatory therapy, including T-cell agents and tumor necrosis factor-α (TNF-α) inhibitors and monoclonal antibodies, is thought to target the immune-mediated mechanism of psoriasis.	**Case 41-3 (Question 1, 2)**

INTRODUCTION

Definition and Epidemiology

Psoriasis is a chronic, proliferative skin disease that affects ~3% of the population in the United States and an estimated 125 million patients worldwide.[1,2] Plaque psoriasis is the most prevalent psoriasis variant, accounting for >80% of cases. It is characterized by well-delineated, thickened erythematous epidermis or dermal plaques covered with a distinctive silvery scale. Genetics plays a role in its development and certain environmental factors can exacerbate this disease. Although psoriasis can manifest at any age, a bimodal age distribution exists at ages 18 to 39 and 50 to 69 years.[1,3]

Pathogenesis

Psoriatic plaques are defined by epidermal hyperplasia, leukocyte infiltration, and changes in dermal microvasculature. Differentiation and activation of immune-mediated response systems are disrupted in psoriasis, resulting in an increase in the number of proliferating keratinocytes. This is accompanied by shortened time required for these cells to cast off into the epidermal layer (3–4 days rather than the usual 28–30 days) resulting clinically as diffuse scaling. T cells contribute to this keratinocyte hyperproliferation through the secretion of various growth factors.[4,5] In addition, T cells will release cytokines resulting in further inflammation, the recruitment of additional T cells, and, ultimately, the development of psoriatic lesions in susceptible persons.[4,5]

Prognosis

Similar to those with diabetes, cancer, or heart disease, patients with psoriasis experience a reduced quality of life related to an impairment of social, psychological, and physical functioning.[6–8] Although psoriasis is a treatable disease, there is no known cure. Shared decision-making is imperative, and patient preference should play a primary role in determining treatment because of the potentially awkward and messy topical treatments or systemic medications that have significant adverse effects. The goal of

therapy should be to achieve complete clearing of psoriatic lesions or a satisfactory improvement for the individual patient.

Clinical Presentation

A thorough medical history may reveal a cause of exacerbations of psoriatic lesions. Most patients report that hot weather, sunlight, and humidity help clear psoriasis, whereas cold weather has an adverse effect on its course. Anxiety or psychological stress is believed to contribute adversely. Viral or bacterial infections may precipitate the onset or flare-up of psoriasis. Trauma to the skin (ie, cuts, burns, abrasions, etc) can elicit the development of lesions.

Plaque psoriasis typically presents as sharply demarcated, erythematous, scaly patches or plaques, which are often symmetrical. The most commonly affected areas include the trunk, scalp, gluteal folds, elbows, and knees; however, plaque psoriasis can occur anywhere on the body including nail beds. Over 50% of patients experience pruritus.[9] The development of psoriatic lesions at the site of epidermal trauma is known as the *Koebner phenomenon*. Scratch marks, sunburn, or surgical wounds may heal, leaving psoriatic lesions in their place. The scales can be silvery or white in appearance. If the scale is lifted from the plaque, bleeding points can occur, called the *Auspitz sign*. In addition to skin manifestations, nail beds may show punctate pitting, profuse collections of keratotic material, yellow-brown discoloration ("oil spot"), or onycholysis (nail plate separation) in ~50% of patients.[10]

Although most patients (90%) have plaque psoriasis (also known as psoriasis vulgaris), several other presentations exist and can sometimes coexist in a person at any single time.[11] The most severe form of the disease is *erythrodermic psoriasis*, a condition of acute inflammatory erythema and scales involving >90% of the body surface area (BSA). *Pustular psoriasis* is generally localized to the palms and soles, but there is also a generalized version. Both generalized pustular psoriasis and erythrodermic psoriasis can be accompanied by systemic symptoms (eg, hyperthermia, tachycardia,

edema, dehydration, shortness of breath) and can have life-threatening consequences (ie, hypovolemia, electrolyte imbalance, septicemia) if not promptly treated.[12] Lesions of *guttate psoriasis* are small, fine, erythematous scales, usually found on the trunk, arms, or legs, classically after β-hemolytic streptococcal pharyngitis. *Flexural* or *inverse psoriasis* is shiny and red, and typically lacks scales and looks more like intertrigo.[13] Psoriatic arthritis is a seronegative inflammatory arthritis that occurs in ~25% of all patients with psoriasis, with combined features of both rheumatoid arthritis and the seronegative spondyloarthropathies.[9],[13]

CASE 41-1

Question 1: M.M., a 35-year-old male, presents with several thick, well-defined erythematous areas on both his elbows and knees that have silvery scales on them. He states he has itching in these areas, and that the areas bleed when he removes the scales. M.M. states that he has had these lesions for some time; however, he has used over-the-counter hydrocortisone and some of his friend's triamcinolone 0.025% cream for the itching. He feels that the lesions have gotten worse since he went on vacation in the Dominican Republic, when he had to take chloroquine for malaria prophylaxis and got "a pretty bad sunburn." On physical examination, M.M. also has a few scattered, circumscribed, erythematous, scaly plaques on the flexural surfaces of both arms and legs and a dense scale on his forehead and scalp. Approximately 4% of his BSA is estimated to be affected with psoriasis. The rest of M.M.'s physical examination and laboratory results are within normal limits.

What classic signs and symptoms suggestive of psoriasis are demonstrated by M.M.?

M.M. presents with many classic signs of psoriasis, including symmetric, distinctive, chronic, and erythematous plaques covered with silvery scales on the extensor surfaces of the elbows and knees as well as the flexural surface of his arms and legs. He also shows scalp involvement, but does not appear to have plaques on his trunk or nail or systemic involvement. He exhibits the Auspitz sign and evidence of the Koebner phenomenon because his lesions worsened after skin trauma from the sunburn. His report of pruritus is consistent with the presentation in 50% of patients.

Drug-Induced Psoriasis

A number of drugs have been reported to exacerbate preexisting psoriasis, induce psoriatic lesions on apparently normal skin in patients with psoriasis, or precipitate psoriasis in persons with or without a family history of psoriasis (**Table 41-1**).[14] Antimalarial agents, such as chloroquine, may have an adverse effect on the course of psoriasis and can cause exfoliative erythroderma.[15] Hydroxychloroquine, however, has not shared this association (except for one case report) and is preferred over chloroquine in patients with psoriasis who need prophylactic treatment for malaria.[15]

Table 41-1
Drugs Reported to Induce Psoriasis

Anesthetics	**Procaine**
Antimicrobial agents	Amoxicillin, ampicillin, imiquimod, penicillins, sulfonamides, terbinafine, tetracyclines, vancomycin, voriconazole
Anti-inflammatory drugs	Corticosteroids (after withdrawal), NSAIDs (indomethacin, salicylates), mesalamine
Antimalarial agents	Chloroquine, hydroxychloroquine
Cardiovascular drugs	Acetazolamide, amiodarone, angiotensin-converting enzyme inhibitors (enalapril, lisinopril), β-blockers (atenolol, metoprolol, propranolol, timolol), calcium channel blockers (dihydropyridines, diltiazem, verapamil), clonidine, digoxin, gemfibrozil, quinidine
H_2-antagonists	Cimetidine, ranitidine
Hormones	Oxandrolone, progesterone
Opioid analgesics	Morphine
Psychotropics and neurologic agents	Lithium carbonate, venlafaxine, fluoxetine, carbamazepine, olanzapine, gabapentin, oxcarbazepine, tiagabine, valproic acid, zaleplon
Miscellaneous	Potassium iodide, mercury, α-interferon, β-interferons, GM-CSF

GM-CSF, granulocyte-macrophage colony-stimulating factor; NSAIDs, nonsteroidal anti-inflammatory drugs.

Source: Kim GK, Del Rosso JQ. Drug-provoked psoriasis: is it drug induced or drug aggravated? *J Clin Aesthet Dermatol*. 2010;3:32–38; Basavaraj KH, Ashok NM, Rashmi R, Praveen TK. The role of drugs in the induction and/or exacerbation of psoriasis. *Int J Dermatol*. 2010;49:1351; Facts & Comparisons eAnswers. Accessed September 19, 2020. https://fco.factsandcomparisons.com/lco/action/home

Lithium also can precipitate psoriasis and contribute to resistance to treatment through its effects on cell kinetics (increase in circulating neutrophils, accelerated neutrophil turnover, increased epidermal cell proliferation), which may require more intensive treatment options for psoriasis.[16]

β-Blockers and some nonsteroidal anti-inflammatory drugs (NSAIDs) can precipitate a psoriasiform state.[16] Because both lithium and propranolol inhibit cyclic adenosine monophosphate (cAMP), cyclic nucleosides may play a role in the onset and clinical course of psoriasis.

When compared with other NSAIDs, indomethacin may selectively inhibit cyclooxygenase more than that by the lipoxygenase pathways of arachidonic acid metabolism. As a result, indomethacin may have a more significant adverse psoriatic effect than that of other NSAIDs.[16]

Flare-ups of pustular psoriasis also can be precipitated by withdrawal from systemic corticosteroids or withdrawal from high-potency topical corticosteroids that are applied under occlusion to large areas.[17] Because of this problem, systemic corticosteroids are not routinely used to treat psoriasis.

Case 41-1, Question 2: What are the factors that can precipitate or aggravate psoriasis? What are the potential causes of M.M.'s psoriatic exacerbation?

Chloroquine for malaria prophylaxis, a Caribbean sunburn, and triamcinolone tachyphylaxis probably all contributed to the exacerbation of M.M.'s psoriasis.

Classification of Psoriasis

Psoriasis Area and Severity Index (PASI) is the most commonly used validated scoring index in clinical trials. This scoring system quantifies the severity (ie, induration, erythema, desquamation) and extent of psoriasis lesions.[17],[18] Scores for PASI range from 0 to 72. PASI response rates indicate the percent decrease in PASI score compared to baseline. For example, PASI 75 represents a ≥75% decrease in PASI score at 3 months from baseline and is the most prominent marker to assess systemic agent efficacy.[19]

In the clinical setting, disease severity is usually categorized based on BSA and recalcitrant disease. Mild disease is defined as <5% BSA without face, genital, hand, or foot involvement in which topical therapies alone may be used to assist with clearance. Moderate disease applies to patients with ≥5 to <10% BSA involvement or those who may require escalation of therapy to phototherapy or nonbiologic systemic agents. Severe disease generally applies to patients with >10% BSA affected or those who require escalation to biologic therapies.[18],[19] Clinicians can determine the approximate BSA involvement by having a patient hold open their hand. The area from the patient's wrist to thumb and finger is ~1% of the patient's BSA. Each "hand-sized" area affected by plaques is added to come up with the total BSA affected. In general, the head can represent up to 9% of the BSA, the front and back of the torso represent up to18% BSA each, as well as each leg (including the buttocks) representing up to 18% each.

Case 41-1, Question 3: How would you classify M.M.'s psoriasis?

M.M. would be classified as having mild psoriasis and is a candidate for topical therapy because <5% of his BSA is currently affected by psoriasis.

TREATMENT OF MILD-TO-MODERATE PSORIASIS

Topical therapies are the cornerstone of psoriasis treatment and are considered first line for mild disease (**Table 41-2**). As a patient's disease progresses or becomes more recalcitrant, other treatment modalities may need to be added to obtain control. Consideration for the addition of agents is often based on disease severity, cost, and convenience (**Table 41-3**). Nonpharmacologic treatment is also very important. Nonpharmacologic treatment options range from spa therapy to support groups.

Table 41-2

Topical Agents for the Treatment of Psoriasis (Mild to Moderate; ≤5% Body Surface Area Involvement)

Treatment Modality	Advantages	Disadvantages
Emollients	Basic adjunct for all treatments; safe, inexpensive, reduce scaling, itching, and related discomfort	Provide minimal relief alone
Keratolytics (salicylic acid, urea, α-hydroxy acids [ie, glycolic and lactic acids])	Reduce hyperkeratosis; enable other topical modalities to better penetrate; inexpensive	Provide minimal relief individually; nonspecific; salicylism (tinnitus, nausea, vomiting) with salicylic acid if applied extensively

Treatment Modality	Advantages	Disadvantages
Topical corticosteroids	Rapid response; control inflammation and itching; best for intertriginous areas and face; convenient, not messy; mainstay topical treatment modality for psoriasis	Temporary relief; less effective with continued use (tachyphylaxis occurs); withdrawal can produce flare-ups; atrophy, telangiectasia, and striae with continued use after skin returns to normalized state; expensive; adrenal suppression possible
Coal tar	Particularly effective for “flaky” scalp lesions; newer preparations are more cosmetically appealing; efficacy enhanced in combination with UVB	Effective only for mild psoriasis or scalp psoriasis; inconvenient with difficult application; stains clothing and bedding, not skin; strong smelling; folliculitis and contact allergy (bronchospasm in atopic patients with asthma after inhalation of vapor); carcinogenicity in animals
Anthralin	Effective for widespread, refractory plaques; produces long remissions; short, concentrated programs preferred; enhanced efficacy in combination with UVB	Purple-brown staining (skin, clothing, and bath fixtures); irritating to normal skin and flexures; careful application is required; can precipitate generalized psoriasis
Vitamin D analogs	As effective as topical corticosteroids, although slower onset, without long-term corticosteroid adverse effects; convenient, well tolerated	Slow onset; expensive; potential effects on bone metabolism (hypercalcemia); irritant dermatitis on face and intertriginous areas; contraindicated during pregnancy

Treatment Modality	Advantages	Disadvantages
Tazarotene	Extended response; convenient (applied once daily, in gel formulation); maintenance therapy; effective on scalp and face; used in combination with topical corticosteroids	Slow onset; local irritation and pruritus; teratogenic (adequate contraception is required)
UVB	Effective as maintenance therapy; eliminates problems of topical corticosteroids	Office-based therapy (except NB-UVB); sunburn (exacerbates psoriasis); photoaging; skin cancers
PUVA	80% efficacy; “suntan” effect is cosmetically desirable	Time consuming; expensive, office-based therapy (restrictive); sunburn (exacerbates psoriasis); photoaging; both nonmelanoma skin cancer and melanoma; contraindicated during pregnancy and lactation

NB-UVB, narrowband ultraviolet B; PUVA, psoralens plus ultraviolet A light; UVB, ultraviolet B.

Table 41-3
Agents for the Treatment of Moderate-to-Severe Psoriasis (>5% Body Surface Area Involvement)

Treatment Modality	Advantages	Disadvantages

Treatment Modality	Advantages	Disadvantages
Acitretin	Less hepatotoxic than is methotrexate	Not as effective as other systemic agents; efficacy enhanced if given with PUVA or UVB (ie, RePUVA or ReUVB); teratogenic (contraception required); contraindicated with liver or renal dysfunction, drug or alcohol abuse, hypertriglyceridemia, hypervitaminosis A
Methotrexate	Effective for both skin lesions and arthritis, as well as psoriatic nail disease	Hepatotoxicity; bone marrow toxicity; folic acid protects against stomatitis (but not against hepatic or pulmonary toxicity); drug interactions; contraindicated during pregnancy and lactation, drug or alcohol abuse; use with caution during acute infections
Cyclosporine	Used in patients with extensive disease who are unresponsive to other agents; however, given changing pathophysiology and increasing experience at lower dosages, increasing role in rotational therapy to induce remissions	Toxicities and short-lived remissions; renal impairment; suppressive therapy (relapse occurs when discontinued); increased risk of skin cancer, lymphomas, and solid tumors; phototoxic; contraindicated during pregnancy and lactation, and with hypertension, hyperuricemia, hyperkalemia, acute infections

Treatment Modality	Advantages	Disadvantages
Immunomodulators (etanercept, infliximab, adalimumab, certolizumab, secukinumab, ixekizumab, brodalumab, guselkumab, tildrakizumab, risankizumab)	Specific, targeted therapy; effective for both moderate- to-severe skin lesions and arthritis; maintains remission	Expensive; parenteral therapy (often administered in an office-based practice); long-term safety unknown; increased risk of serious infections

PUVA, psoralens plus ultraviolet A light; RePUVA, retinoid-psoralens plus ultraviolet A light; ReUVB, retinoid-psoralens plus ultraviolet B light; UVB, ultraviolet B.

Nonpharmacologic Modalities

Psoriasis is often more emotionally or psychologically disturbing than is often recognized. It may cause reluctance in patients to participate in sports and other outdoor activities that may expose their skin to sunlight. Many patients alter their lifestyles or use nontraditional medications and modalities, often in desperation. Psychological encouragement and support should be part of every treatment plan.[20]

Topical Corticosteroids

Topical corticosteroids are the mainstay of treatment for localized or mild disease. This class exerts its effects through anti-inflammatory, antimitotic, immunosuppressant, and antipruritic properties.[21–23] Topical corticosteroids are classified based on their vasoconstrictive effects with class ranges from I (ultrahigh potency) to VII (low potency). Because psoriasis is generally a relatively corticosteroid-resistant disease, more potent corticosteroids are frequently required (see Table 39-8 in Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders, for a listing of topical corticosteroids by potency).

Selection of strength and vehicle should be based on location of the affected area and patient preference. For the trunk and extremities, high-to-moderate potency (classes II–V) should be used. For plaques that are thicker or harder to treat, consider escalating to ultrahigh-potency corticosteroid (class I). For facial, axillary, inframammary, or groin, low-potency corticosteroids are recommended because these areas are thinner and more prone to adverse effects of topical corticosteroids. Foams or solutions should be used for scalp involvement. Although ointments are more effective than creams, treatment with this vehicle is often not preferred by patients because of its greasiness.[24]

Although multiple treatment regimens exist, a proactive management strategy is one that is commonly used. This strategy encourages patients to apply topical corticosteroids twice daily until the affected areas are almost clear or quiescent. Patients are then instructed to decrease steroid frequency to only twice weekly (eg, weekends only) with the use of a maintenance steroid-sparing agent (eg, vitamin D analog, calcineurin inhibitor) for the remaining days of the week. If a new flare occurs, patients may repeat this process. Studies have shown that classes I to III topical corticosteroids can safely be used up to 4 weeks with minimal risk for skin atrophy. However, continuous use past 4 weeks should be discouraged.[24] Keratolytic agents, such as salicylic acid, can be used with topical steroids to help penetration and potentially increase efficacy.

Intertriginous and chronically treated areas are at the highest risk for some of the common adverse effects including skin atrophy, telangiectasia (also known as spider veins), striae, folliculitis, and purpura. Occasionally, topical corticosteroids can cause a reversible suppression of the hypothalamic–pituitary–adrenal (HPA) axis, as indicated by a decrease in the morning plasma cortisol level.[25] The risk of HPA axis suppression is highest in children and those applying classes I to III corticosteroids to >20% BSA or therapies applied longer than 4 weeks.[24]

Case 41-1, Question 4: What topical corticosteroid therapy is appropriate for M.M.?

A short course of a potent topical corticosteroid is appropriate for this flare-up of erythematous plaque psoriasis in M.M. This will help reduce inflammation, redness, and irritation before initiation of a steroid-sparing agent or more appropriate chronic topical treatment. Topical corticosteroids should be applied twice daily until the affected areas are almost clear or quiescent (no more than 4 weeks). A thin layer of steroid should be applied to each affected area and rubbed in completely. For his scalp involvement, the best formulations to use include solutions, foams, shampoos, oils, gels, or sprays. M.M. can use a betamethasone foam topical steroid for up to 2 weeks on his scalp. The foam should be applied to dry hair. The foam should not be dispensed directly into the hands because it will melt on touching the warm skin. Instead, it should be dispensed on a cool clean surface (ie, a small plate). M.M. should use his fingers to apply a thin layer over the affected area and rub in completely. M.M. should then make sure to wash his hands as soon as he is done.

Alternative Topical Treatments

Effective alternative topical therapies available for patients with localized, mild psoriasis include topical calcineurin inhibitors, vitamin D analogs, coal tar, anthralin, and tazarotene. Although these agents are available in various formulations, ointments are generally favored because they help moisturize the plaques (in contrast to creams, which dry the plaques further).[23] Tachyphylaxis does not occur with chronic use of any of these alternative agents.

TOPICAL CALCINEURIN INHIBITORS

Topical calcineurin inhibitors exert their effects through the inhibition of calcineurin, thus inhibiting T-cell activation and synthesis of several key pro-inflammatory cytokines. Available topical calcineurin inhibitors, tacrolimus and pimecrolimus, are commonly applied to areas where the skin is not as thick (eg, facial and intertriginous areas) and used as steroid-sparing agents for prolonged use (ie, >4

weeks). These agents are applied twice daily for up to 8 weeks.[24] After resolution of symptoms and the initial 8 weeks of treatment, patients can use the topical calcineurin inhibitors as proactive treatment as previously mentioned. The calcineurin inhibitors may be applied twice weekly on areas that are clinically quiescent but often involved in flare-ups. Adverse effects of this class include burning and pruritis, which can improve with continued application and by treating with topical corticosteroid before transitioning to this class.[24],[26]

TOPICAL VITAMIN D ANALOGS

This class exerts their effects through binding to vitamin D receptors, thus inhibiting keratinocyte proliferation and enhancing differentiation. Calcipotriene and calcitriol are the two most commonly used. Although calcipotriene comes in several different formulations, calcitriol is only available as an ointment. In the same vehicle, these agents have comparable efficacies. They should be applied twice daily (while avoiding the face, eyes, and lips) with peak effects occurring between 6 and 8 weeks of initiation.[22],[27],[28] Topical vitamin D analogs in combination with betamethasone dipropionate can be used in the treatment of mild-to-moderate nail disease.[29] However, use is not recommended for severe nail disease because of poor penetration.[30]

The most common side effects include burning, pruritis, edema, peeling, dryness, and erythema, which improve or disappear with continued use. In patients who experience these adverse effects, short-term treatment with topical corticosteroids may be added.[24] Systemic side effects including hypercalcemia and parathyroid suppression are extremely rare. However, patients applying >30% BSA, calcipotriene doses exceeding 100 g/week, or those with underlying renal disease are at highest risk.[31] Patients on concurrent phototherapy should be instructed to apply topical vitamin D analogs after phototherapy treatment because ultraviolet A (UVA) can decrease its efficacy, and the topical vitamin D analog, if applied too

thick, can block UVB rays. Combination with salicylic acid should also be avoided because it can inactivate calcipotriene.

TAZAROTENE

Tazarotene is a topical synthetic retinoid that is rapidly converted to its biologically active metabolite, tazarotenic acid.[23],[32] By interacting with the predominant retinoid receptors on the skin surface regulating gene transcription, retinoic acids normalize abnormal keratinocyte differentiation, reduce hyperproliferation, and decrease inflammation associated with psoriasis.[32] Tazarotene can be applied once daily and used for 8 to 12 weeks for the treatment of mild-to-moderate disease. It has been found to be particularly effective in nail disease.[33],[34] Clinical trials have found efficacy similar to that of fluocinonide cream and calcipotriene 0.005% ointment.[35],[36] However, as with calcipotriene, tazarotene works slowly.

Commonly reported adverse effects include burning, erythema, and pruritis. This is more prominent in those using higher concentrations. Risk for this can be mitigated by utilizing creams, lower concentrations, combining with a moisturizer, alternative day dosing or short contact dosing (eg, 30–60 minutes) or combining with topical corticosteroids.[24] Because oral retinoids are known teratogens, tazarotene is a category X drug and is contraindicated during pregnancy. Females should be warned of the potential risk and the need to use adequate contraception while using these preparations.[32],[37]

ANTHRALIN

Anthralin, a hydroxyanthrone derivative, has a proposed mechanism of inhibiting T-lymphocyte activation and promoting keratinocyte differentiation.[23],[38] It is effective for treatment of widespread, discrete psoriatic plaques, but its use has declined in recent years because of the availability of more cosmetically appealing preparations. When used, anthralin is started at 0.1% once daily and increased as tolerated. Clearance can appear within 3 weeks, and patients are then transitioned to maintenance dosing of one to two times per

week. The primary disadvantages of anthralin are its irritant nature and property of staining skin and clothing. Plastic gloves should be used, as well as old bed linen and clothing for sleep. If possible, because of irritant properties, contact with face, eyes, mucous membranes, and non–psoriatic skin should be avoided. To minimize the risk of irritant properties, short contact up to no more than 2 hours per day is recommended. Anthralin also can precipitate generalized psoriasis if applied to unstable psoriasis (ie, plaque transformation to pustular form).

COAL TAR

Crude coal tar is a complex mixture of thousands of hydrocarbon compounds.[23],[39] It affects psoriasis through its antiproliferative and anti-inflammatory effects.[39] Tar preparations of 2% to 10% are processed as creams, ointments, lotions, gels, oils, shampoos, and coal tar solution. Newer purified preparations, using refined coal tar, are less messy and more cosmetically acceptable, but perhaps not as effective.[39] Tar may be helpful for patients with mild-to-moderate disease. The potential severity of adverse drug effects from topical tar products is less than that from anthralin and much less than that from topical corticosteroids. Because tar, in every form, is messy, stains the skin, has an odor, and is low potency compared with anthralin, it has been relegated to second-line therapy for most patients, despite its moderate price and newer, more cosmetically appealing formulations.[25],[40] Tar preparations generally are used once or twice daily, and a bedtime application (as a shampoo or cream overnight) is particularly useful in psoriasis of the scalp. Patients should be warned about the staining properties of tar on clothing and bedding. Other adverse effects include photosensitivity, acneiform eruptions, folliculitis, and irritation dermatitis. Owing to the irritant properties of coal tar, care should be taken to avoid use on the face, flexures, and genitalia and with inflammatory psoriasis. Although not proved in human studies, the potential carcinogenicity of coal tar remains controversial because of the results of animal and occupational studies.[41],[42]

Case 41-1, Question 5: M.M.'s acute psoriasis flare-up has responded well to a short course of topical corticosteroid, and his plaques have now cleared. What maintenance therapies are available for M.M.?

M.M. can apply a steroid-sparing agent, such as a vitamin D analog in combination with the topical corticosteroid that may help with steroid rebound. M.M. should be instructed to decrease his topical corticosteroid frequency to weekend applications only. All other days of the week, he can apply calcipotriene or calcitriol twice daily.

TREATMENT OF MODERATE-TO-SEVERE PSORIASIS

Treatment modalities for moderate-to-severe disease include phototherapy, systemic nonbiologics, and biologic agents. Topical agents can continue to be used as an adjunct to systemic therapy but is not recommended as monotherapy in this population. Biologics have been the focus of research and development for the treatment of psoriasis most recently. Owing to superior efficacy, biologics are recommended as first line over systemic nonbiologics or phototherapy in patients with severe disease as well as in patients with psoriatic arthritis (Table 41-3).

Phototherapy

Although many patients may achieve disease control with topical therapies alone, one in six patients will progress to moderate or severe disease and require alternative treatment modalities.[43] Systemic nonbiologic and biologic agents, although effective for moderate-to-severe disease, come at a higher cost and risk for numerous adverse effects, including immunosuppression. Phototherapy with UV light has a long history of use in the treatment

of psoriasis and other skin disorders. In addition to its use in moderate-to-severe disease, phototherapy may also be considered for patients with mild disease refractory to topical therapies or as an adjunct to biologic or systemic regimens. Although there is no first-line phototherapy modality, selection should be individualized considering factors such as percentage of BSA affected, lifestyle, and treatment expenses. Phototherapy is available as psoralen plus ultraviolet A (PUVA), narrowband ultraviolet B (NB-UVB), and broadband ultraviolet B (BB-UVB).

Before initiating phototherapy, it is important to assess the patient for any personal or family history of skin cancer. Phototherapy, regardless of type, carries an increased risk of cutaneous malignancy. All patients should also be evaluated for their Fitzpatrick skin type (ie, ease of sunburn and inherent skin color) and have their medication list reviewed for identification of any photosensitizing agents (eg, thiazides, tetracyclines). Together, this can assist in determining the appropriate initial treatment dose and reduce risk of treatment-related adverse effects. Once an initial dose has been determined, doses will be titrated up at a rate of 5% to 10% with each treatment until the minimum erythema dose at 24 hours has been reached or the patient has reached their maximum phototherapy dose.[43] Patients should be evaluated throughout their treatment to determine the degree of treatment response and treatment-related adverse effects. Erythema lasting >48 hours or adverse effects, such as itching, stinging, or burning, are all indications for reducing a patient's dose to the last dose without such adverse effects. Phototherapy is administered at a frequency of two to three times per week with time with psoriasis clearance typically occurring at 8 to 12 weeks. Patients who miss doses of phototherapy may be required to restart at lower doses and titrate back up accordingly depending on the number of treatments missed. Once a patient's psoriatic lesions have cleared, patients may have their doses tapered or indefinitely continued as maintenance therapy. Patients who choose to taper may decrease treatment to twice weekly for 4 weeks, followed by once-weekly treatment for the second month. The maintenance dosage is held constant during the

taper. For patients who prefer indefinite maintenance therapy, treatment is administered every 1 to 2 weeks, with a maintenance dosage that is ~25% lower than is the original maintenance dose.[43]

Efforts must be made to minimize the potential risk of long-term effects of phototherapy. Development of cataracts is a recognized long-term effect of prolonged exposure, and therefore use of protective goggles is required to reduce the risk for ocular toxicity. Owing to the potential increased risk of genital cancer identified in BB-UVB studies, it is recommended that patients undergoing phototherapy wear underwear to reduce this risk. In addition, owing to the concern for risk of cutaneous malignancies (highest risk with oral PUVA), patients should apply sunscreen (SPF 50 or higher) to facial area (if not effected) when undergoing phototherapy treatments. They should also be encouraged to minimize exposure to the sun and to wear protective barriers when going out in the sun.

PSORALEN PLUS ULTRAVIOLET A

PUVA combines psoralens with UVA light in the 320- to 400-nm spectrum. The psoralens (methoxsalen, 8-methoxypsoralen [8-MOP], and trioxsalen) are a group of photoactive compounds that, on absorption of UV light, are both antiproliferative and immunomodulatory. Without UVA, psoralens are not active. PUVA has greater immunomodulatory effects on the skin than has UVB. Use of PUVA for scalp or nail involvement is limited because of inadequate exposure.[44]

The most widely used psoralen, 8-MOP, is taken ~1.5 hours before exposure to UVA light.[45] 8-MOP can be administered topically (as a solution), in bathwater, or orally. Topical PUVA is unique in that it has been shown to be particularly effective in the treatment of palmoplantar pustular psoriasis. Oral PUVA, although more effective than is NB-UVB, tends to be the least tolerated. Oral PUVA is contraindicated in patients age younger than 10 years, pregnant or nursing mothers, and those with a personal history of melanoma, lupus erythematosus, or xeroderma pigmentosum. Oral PUVA should be used in caution in patients ages 10 to 18 years, those with

a personal history of dysplastic nevi, nonmelanoma skin cancer, photosensitivity, and exposure to ionizing radiation or arsenic or immunosuppressive medications (eg, methotrexate, cyclosporine). Despite studies demonstrating its superiority to UVB therapies, fewer centers are offering PUVA because of its side effect profile, treatment requirements (eg, bath PUVA), and variable insurance coverage for treatments.[43]

NARROWBAND ULTRAVIOLET B

Narrowband ultraviolet B (NB-UVB) refers to wavelengths ranging from 311 to 313 nm. This is the range widely used for the treatment of generalized plaque psoriasis. Comparative studies conducted between PUVA and NB-UVB have shown that although there was no statistically significant difference at 3 months, PUVA resulted in quicker clearance with less treatment exposures compared to NB-UVB. However, oral PUVA is not well tolerated and comes with numerous adverse effects, as previously mentioned. Thus, given its superior short- and long-term safety, ease of use, and lower cost, NB-UVB has been the preferred phototherapy treatment for plaque psoriasis.[46–48] In addition, NB-UVB is preferred over BB-UVB, given its increased efficacy, quicker response to treatment, and lower rates of adverse effects.[48–50] NB-UVB is also favored in the treatment of guttate psoriasis.

One of the most common reasons for a patient's declining phototherapy has been the need for frequent trips to the clinic for therapies to be administered. Now, for patients who are unwilling or unable to come for in-office treatments, home NB-UVB is an option. Studies have found no difference in treatment outcome or treatment-related adverse effects when comparing in-office to home NB-UVB therapy. Studies also found significantly lower treatment burden and higher satisfaction rates among patients receiving home NB-UVB treatments.

BROADBAND ULTRAVIOLET B

UVB light, unlike UVA light, is effective without additional sensitizers (ie, psoralens). BB-UVB emits wavelengths ranging from 270 to 390 nm. Given the greater spectrum of radiation exposure, BB-UVB has a higher risk for sunburn and any theoretical form of sun-related damage. Although effective, comparison studies have found BB-UVB to be less effective than are oral PUVA and NB-UVB for the treatment of plaque psoriasis. It is also less effective than is topical PUVA for the treatment of palmoplantar psoriasis.[43]

CASE 41-2

Question 1: G.L., a 42-year-old male with a several-year history of psoriasis (localized), presents with diffuse, erythematous plaque-like lesions now extending over 8% of his body. The areas have become inflamed, and application of his maintenance topical medication (anthralin) causes pain and irritation. He expresses frustration with the messiness of the current topical regimen. He has reinstituted topical corticosteroids, which helped the redness and itching. However, he is concerned with long-term effects of chronic steroid use and is interested in trying something else to treat his psoriasis. He is free of cardiovascular, renal, or hepatic disease and takes no systemic medications. He is self-employed as a business consultant.

Which therapy would be most appropriate for G.L.'s psoriasis?

G.L. has moderate disease given that affected BSA is 5% to 10%. Given that treatment has not been successful with topical agents alone, the next step in therapy is the addition of phototherapy. Although PUVA is highly effective, side effect profile and variable insurance coverage limit its use. Therefore, NB-UVB may be the best option for him (either in-office or home use). It is important that G.L. be counseled on the cutaneous risk of adverse effects (both short- and long-term ones) associated with phototherapy use. He should also be counseled to apply topical therapies after phototherapy treatments. Initial NB-UVB dose should be based on his skin type and adjusted by 5% to 10% with each treatment until minimum erythema dose at 24 hours has been reached or the patient has reached their maximum phototherapy dose. Doses should be reduced if the patient experiences adverse effects or erythema 48 hours after treatment.

NONBIOLOGIC SYSTEMIC THERAPY

Acitretin

Acitretin is a second-generation systemic retinoid that exhibits antipsoriatic effects by its ability to modulate epidermal differentiation and immunologic function in addition to an anti-inflammatory action.[51] It is less beneficial in psoriasis compared to other systemic therapies, although there are no head-to-head studies. The side effect profile and onset of action (3–6 months) limit its utility for psoriasis, especially with newer medications on the market. However, because it does not have immunosuppressive properties, it can be beneficial in patients on highly active antiretroviral therapy.[52] Combination therapy with phototherapy is more beneficial than is acitretin alone because of the ability to decrease duration and frequency of therapy, lessen cumulative dose of phototherapy, and limit long-term adverse effects.[52,53] Most patients require maintenance or intermittent therapy to prevent relapses.[54] Response to acitretin should be assessed at 4-week intervals, with dose titrations to reach therapeutic effect with minimal adverse events.[55]

Numerous other adverse effects are associated with acitretin use, including hypervitaminosis A syndrome (ie, dry skin, skin thinning and fragility, chapped lips, dry nasal mucosa, skin peeling, alopecia, and nail dystrophy), retinoid rash, extraspinal tendon and ligament calcification and bone changes in children, hyperlipidemia with elevated levels of serum triglycerides and cholesterol, and liver enzyme alteration and hepatitis.[56] Many patients find the adverse effects of the retinoids intolerable and discontinue treatment. Topical corticosteroids can reduce some of the cutaneous retinoid adverse effects.

Acitretin is teratogenic and accumulates in fatty tissues, where it is slowly released into the bloodstream for up to 1 year after final administration.[51] Therefore, strict contraception during treatment and for 2 to 3 years afterward is recommended in females of childbearing age.[52,57] Patients also need to be advised not to donate blood while taking acitretin and up to 1 year after the end of treatment.[51]

Methotrexate

Methotrexate, a folic acid analog, at doses <25 mg/week, decreases the proliferation of lymphoid cells. It is believed that methotrexate exhibits its clinical benefit in psoriasis through its immunosuppressive effects.[58],[59] Methotrexate is usually given orally, although a parenteral preparation is available for subcutaneous administration. Methotrexate is initially dosed at 10 to 15 mg once weekly and titrated every 4 weeks as needed to a maximum dose of 25 mg/week.[52] In patients with renal impairment or who are at risk for hematologic toxicities, some clinicians may choose to initiate therapy with a 5-mg test dose with repeat complete blood count (CBC) checked 7 days after the dose. In those with minor gastrointestinal intolerances, methotrexate tablets may be given as three doses at 12-hour intervals weekly, or the patient may be switched to the solution for subcutaneous administration. It is recommended to supplement with folate to help minimize potential adverse effects with therapy.

Randomized clinical trials were not required for drug approval at the time methotrexate was approved for plaque psoriasis. However, methotrexate has been compared in studies with biologic agents and placebo. Based on the direct comparison studies, methotrexate was not found to be as effective as infliximab, adalimumab, etanercept, ustekinumab, and NB-UVB.[52],[60–63] Some studies have demonstrated additional benefit of methotrexate in combination with tumor necrosis factor-α (TNF-α) inhibitors compared to TNF-α monotherapy.[64],[65]

Common adverse events include fatigue, nausea, anorexia, and stomatitis, which tend to occur shortly after administering the methotrexate dose.[66],[67] These side effects may be lessened with folate supplementation, subcutaneous administration, dose splitting, taking tablet with food, or by administering at bedtime. Given the immunosuppressive effects of methotrexate, patients should receive hepatitis B and C screening at baseline as well as tuberculosis testing. Patients who are positive for latent or active tuberculosis must complete treatment before initiating methotrexate. It is also

recommended that tuberculosis screenings be repeated annually in high-risk patients.

Additional adverse effects include pneumonitis (rare), myelosuppression, and hepatotoxicity. The risk of hematologic and hepatic adverse effects is determined by patent characteristics and risk factors.[52] Hematologic toxicities are more common in patients with renal insufficiency, drug interactions, advanced age, and increased alcohol intake. As previously mentioned, initial test doses should be considered in these patients. CBC should be monitored at baseline and regularly thereafter (every 3–6 months).

Hepatotoxicity with methotrexate is more common in psoriasis than in rheumatoid arthritis. Patients with diabetes, obesity, and hyperlipidemia are at increased risk because these risk factors can contribute to nonalcoholic fatty liver disease as well as chronic liver disease (such as hepatitis B or hepatitis C). Additional risk factors include higher than moderate alcohol intake and abnormal liver function tests.[52,66] Patients initiated on methotrexate should complete a baseline noninvasive blood serology to assess fibrosis and a liver function test. Liver function tests should then be repeated every 3 to 6 months. Given that high cumulative doses are at an increased risk for hepatotoxicity, it is recommended that patients reaching cumulative doses ≥3.5 g receive a gastroenterology consult and/or vibration controlled transient elastography annually or as otherwise recommended by the gastroenterologist.[52]

Methotrexate is contraindicated in pregnancy because of fetal abnormalities. It is recommended that both females and males wait 3 months after discontinuing therapy before trying to conceive. The use of methotrexate is also contraindicated in patients with cirrhosis, thrombocytopenia, leukopenia, or anemia, and in nursing mothers. Relative contraindications to treatment with methotrexate include decreased renal function, significant abnormalities in liver function (ie, fibrosis, cirrhosis, hepatitis), infectious disease, alcohol abuse, and patient unreliability.[52]

Cyclosporine

In psoriasis, cyclosporine primarily acts by inhibition of calcineurin, which is necessary for interleukin-2 (IL-2) production that amplifies helper T cells and cytotoxic lymphocytes. Cyclosporine also inhibits TNF-α and interferon-α_2.[68] Owing to potential toxicity, long-term use of cyclosporine for psoriasis is not recommended. However, it does play a role in patients who are seeking rapid improvement in recalcitrant disease, those with acute flares, and erythroderma.[69] Many patients relapse 2 to 4 months after the discontinuation of cyclosporine therapy if not started on other treatment. It is recommended to slowly taper off cyclosporine rather than abruptly discontinue.[52]

The most common side effects of cyclosporine in psoriasis include renal dysfunction and hypertension. Nephrotoxicity is usually reversible, but if treatment extends beyond 2 years, the risk of fibrosis and irreversible damage increases. Serum creatinine should be routinely monitored. Hypertension is more common in elderly patients and often resolves after discontinuation of cyclosporine. Frequent blood pressure monitoring is recommended, and if patients have two separate abnormal values, the dose of cyclosporine should be decreased or patients can be treated with additional antihypertensive therapy, particularly calcium channel blockers.[52] Other common side effects include headache, musculoskeletal pain, and paresthesia.

Patients should not receive concurrent UVB or PUVA treatment during cyclosporine therapy because of an increased risk of nonmelanoma skin cancers.[52,69]

Phosphodiesterase 4 inhibitors

Apremilast, an oral phosphodiesterase 4 (PDE4) inhibitor, reduces immune responses by increasing intracellular cAMP in T cells. This results in decreased expression of cytokines and other pro-inflammatory mediators but increased expression of anti-inflammatory mediators.[70] Mesenchymal cells, which express PDE4, are found in keratinocytes within the dermis, smooth muscle, and vascular endothelium.[71]

The most common adverse effects with apremilast include gastrointestinal (ie, diarrhea and nausea) and headache. Other adverse effects include upper respiratory infections and rebound psoriasis in 0.3% of patients after discontinuation of therapy. Apremilast is metabolized via the cytochrome P 450 3A4 (CYP 3A4) pathway, and therefore should be evaluated for any drug–drug interactions before starting therapy.[52,72]

Biologic Systemic Therapy

Biologic agents used in the treatment of psoriasis include TNF inhibitors, IL-12/23 inhibitors, IL-17 inhibitors, and IL-23 inhibitors. All biologics used in the treatment of psoriasis are available as subcutaneous injections, with the exception of infliximab. Common adverse effects associated with biologics include injection site reaction and increased risk for infections. Before starting biologic therapies, patients must receive tuberculosis and hepatitis (both B and C serologies) screening. Patients who are positive for latent or active tuberculosis must receive and complete treatment before starting biologic therapies. Tuberculosis screenings should be repeated annually in high-risk patients. Patients may be instructed to hold their biologic doses in cases of complicated infections or in other cases as determined by a treating dermatologist. Patients who require treatments to be held may restart their biologic therapy once infection symptoms have fully resolved and the antibiotic course has been completed. Loading doses may need to be repeated in patients with active flares and/or more than three to four half-lives have passed since their previous dose. Caution should be used in patients with concomitant human immunodeficiency virus (HIV). Biologics may be initiated in those without a recent history of opportunistic infections.[26,73]

Patients requiring moderate- to high-risk surgical procedures may have their biologic treatment held on a case-by-case basis based on individual risk factors and comorbidities. If a decision is made to stop biologic therapy before surgery, the agent can be discontinued three

to four half-lives before and until 1 to 2 weeks after surgery pending there are no postoperative complications.[73]

In cases where biologic agents require discontinuation, repeat loading doses may be required on restarting the agent if more than three to four half-lives have passed since previous dosing. A small percentage of patients may be unable to recapture previous treatment responses when retreated after discontinuation of the agent. If an agent needs to be switched, either for clinical reasons or owing to a change in insurance coverage, the agent may be switched with a different biologic agent with the possibility of improved efficacy and/or tolerability. It is important to stress that not all switches may result in improved efficacy. At this time, there are no specific guideline recommendations for switching between biologics.[73]

TUMOR NECROSIS FACTOR-α INHIBITORS: ETANERCEPT, INFLIXIMAB, ADALIMUMAB, CERTOLIZUMAB

TNF inhibitors inhibit TNF-α, which then decreases the downstream inflammatory effects central to psoriasis. There are four different agents in this class indicated for the treatment of psoriasis: etanercept, infliximab, adalimumab, and certolizumab. Although there are no head-to-head trials, infliximab is thought to be the most efficacious, followed by certolizumab and adalimumab (similar efficacies) and etanercept.[26],[74]

Despite its efficacy, use of infliximab is limited because of the need for intravenous administration, whereas other agents in this class can be self-administered subcutaneously. An additional concern with infliximab use is antibody development, particularly in those with prolonged time between injections, which can decrease its efficacy and increase risk of infusion reactions. Risk of antibody development can be decreased by not prolonging the dosing interval and the concomitant use of methotrexate with infliximab. In addition, studies have shown that use of acetaminophen, hydroxyzine, ranitidine, and methylprednisolone before infliximab infusion may prolong drug survival.[73] Compared to lower weight patients, patients who are

overweight or obese may be less likely to respond to this class and will frequently require shortened dosing intervals to achieve satisfactory response. Infliximab is often recommended for these patients because of its weight-based dosing.

Patients started on TNF inhibitors typically achieve a response within 8 to 10 weeks for infliximab and 12 to 16 weeks for the remainder of the class. In patients who do not see effects with approved TNF inhibitor dosing (eg, adalimumab 40 mg every 2 weeks) dosing frequency should be shortened (eg, adalimumab 40 mg every 10 days) rather than increasing dose administered per injection. Partial responders to TNF inhibitors may also consider adding on adjunct therapies such as phototherapy or topical agents.

The most commonly reported adverse effects for this class include headache, nausea, injection site reactions, and increased risk of infections. Less frequently reported adverse effects include multiple sclerosis, hepatotoxicity (primarily infliximab), exacerbation or new-onset heart failure, and cytopenia. Relative contraindications to treatment include preexisting multiple sclerosis, New York Heart Class III to IV, untreated hepatitis B, and history of lymphoreticular malignancy. For patients who are pregnant or trying to conceive, certolizumab is preferred.[73]

INTERLEUKIN-12/23 INHIBITORS

Ustekinumab is the only approved IL-12/23 inhibitor and is used in the treatment of both psoriasis and psoriatic arthritis. It works to suppress IL-12/23–mediated inflammation. Ustekinumab is administered subcutaneously every 12 weeks (**Table 41-4**). Treatment effect is seen after 12 weeks of continued therapy. For patients with partial response, treatment frequency can be decreased to every 8 weeks or the dose may be increased from 45 to 90 mg.[73] When compared to other agents, post hoc analysis of six major trials found that ustekinumab is less efficacious compared with secukinumab 300 mg.[75]

Table 41-4

Systemic Agents and Dosing for the Treatment of Moderate-to-Severe Psoriasis

Drug Class	Medication	Dosing
TNF inhibitor	Adalimumab	Plaque psoriasis: Initial, 80 mg SUBQ once Maintenance: 40 mg every 2 weeks PsA: 40 mg SUBQ every other week
	Certolizumab	Plaque psoriasis and PsA: Initial, 400 mg SUBQ at weeks 0, 2, and 4 Maintenance: 200 mg every 2 weeks or 400 mg every 4 weeks
	Etanercept	Plaque psoriasis: Initial, 50 mg SUBQ twice weekly for 3 months[a] Maintenance: 50 mg once weekly PsA: 50 mg once weekly
	Infliximab	Plaque psoriasis and PsA: Initial, 5 mg/kg IV at weeks 0, 2, and 6 Maintenance: 5 mg/kg every 8 weeks and every 8 weeks thereafter
IL-12/23 inhibitor	Ustekinumab	Plaque psoriasis: ▪ Weight of ≤100 kg: 45 mg IV or SUBQ at weeks 0 and 4, then every 12 weeks ▪ Weight of >100 kg: 90 mg IV or SUBQ at weeks 0 and 4, then every 12 weeks PsA: 45 mg IV or SUBQ at weeks 0 and 4, then every 12 weeks
IL-17 inhibitors	Secukinumab	Plaque psoriasis: Initial, 300 mg SUBQ once weekly at weeks 0, 1, 2, 3, and 4 Maintenance: 300 mg SUBQ every 4 weeks[b] PsA: Initial, 150 mg SUBQ at weeks 0, 1, 2, 3, and 4[a] Maintenance: 150 mg SUBQ every 4 weeks
	Ixekizumab	Plaque psoriasis and PsA: Initial, 160 mg SUBQ once, followed by 80 mg at weeks 2, 4, 6, 8, 10, and 12 Maintenance: 80 mg SUBQ every 4 weeks

Drug Class	Medication	Dosing
	Brodalumab	Plaque psoriasis: Initial, 210 mg SUBQ at weeks 0, 1, and 2 Maintenance: 210 mg SUBQ every 2 weeks[c]
IL-23 inhibitors	Guselkumab	Plaque psoriasis and PsA: Initial, 100 mg SUBQ at weeks 0 and 4 Maintenance:100 mg SUBQ every 8 weeks
	Tildrakizumab	Plaque psoriasis: Initial, 100 mg SUBQ at weeks 0 and 4 Maintenance: 100 mg SUBQ every 12 weeks thereafter
	Risankizumab	Plaque psoriasis: Initial, two consecutive SUBQ injections (75 mg each) for a total dose of 150 mg at weeks 0 and 4 Maintenance: 75 mg SUBQ every 12 weeks thereafter
Retinoid-like compound	Acitretin	Plaque psoriasis: 25–50 mg by mouth daily with main meal
Antimetabolite	Methotrexate	Plaque psoriasis and PsA: 10–25 mg PO/SUBQ given once weekly; adjust dose gradually to optimal response (≤25 mg/week recommended) 5-mg test dose may be considered for those at increased risk for hematologic toxicities
Calcineurin inhibitor	Cyclosporine	Plaque psoriasis: 2.5 mg/kg/day by mouth in two divided doses; increase by 0.5 mg/kg/day with maximum dose of 5 mg/kg/day
Phosphodiesterase-4 enzyme inhibitor	Apremilast	Plaque psoriasis: Initial, 10 mg by mouth in the morning on day 1. Day 2: 10 mg twice daily; day 3: 10 mg in the morning and 20 mg in the evening; day 4: 20 mg twice daily; day 5: 20 mg in the morning and 30 mg in the evening Maintenance: 30 mg twice daily starting on day 6

IV, intravenous; PO, by mouth; PsA: psoriatic arthritis; SUBQ: subcutaneous.

[a]Can skip initial dosing and start with maintenance.

[b]May consider decreasing to 150 mg per dose in select patients.

[c]Consider discontinuing if an adequate response is not achieved after 12 to 16 weeks.

INTERLEUKIN-17 INHIBITORS

IL-17 inhibitors work via targeting the IL-17 ligand (secukinumab and ixekizumab) or receptor (brodalumab). They are approved for the treatment of both psoriasis and psoriatic arthritis. Given their similar mechanisms of action, they are considered to have comparable efficacy.[73] As a class, response should be seen within 12 weeks of use. Clinical trials comparing IL-17 inhibitors to ustekinumab have demonstrated higher efficacy with IL-17 inhibitors.[76–80] In addition, secukinumab and ixekizumab have also demonstrated improved efficacy when compared to etanercept.[80],[81] For patients with partial response, an increase in dose or addition of adjunct therapy (eg, phototherapy, topical agents, etc.) may be considered. This class has an acceptable safety profile, with no increased risk of serious infections or malignancies. Increased risk of mucocutaneous candidiasis and inflammatory bowel disease exacerbations has been reported. Rare cases of suicidal ideations and completions have been seen with brodalumab, and thus a boxed warning has been placed for this agent.[82]

INTERLEUKIN-23 INHIBITORS

IL-23 inhibitors work by binding to the p19 unit of IL-23. Available agents include guselkumab, tildrakizumab, and risankizumab. These agents are the most convenient in terms of dosing frequency (Table 41-4). Although individual short- and long-term efficacies vary, the majority of effects can be seen within 12 weeks of use. Patients with partial response should consider the addition of adjunct therapy (eg, phototherapy, topical agents). Clinical head-to-head trials have demonstrated superior efficacy with IL-23 inhibitors compared to both etanercept and adalimumab.[83],[84] Risankizumab has also demonstrated improved efficacy compared to ustekinumab.[85] The most commonly reported adverse reactions include injection site reaction and upper respiratory infections.

Primary and secondary treatment failure

Primary treatment failure is the initial nonresponse to treatment. For patients with failure to respond to TNF inhibitors, another agent in this class may be tried (although efficacy within the class may continue to be reduced).

Secondary failure occurs in patients who initially have treatment response but lose efficacy over time. Secondary failure may be attributed to the presence of antidrug antibodies. Concomitant use of methotrexate with biologic agents has been shown to decrease risk of antibody formation and thereby increase the duration of use for the biologic agent.[73]

CASE 41-3

Question 1: R.T. is a 46-year-old male aerospace technician with psoriasis. His skin disease has once again become active, despite nightly betamethasone dipropionate administration. Patient does report spending a lot of time traveling because of his job. Active psoriatic lesions are noted on trunk and arms and cover 8% of his body.

What therapy would be most appropriate?

Given that the patient has 8% of BSA affected, this would be classified as moderate disease. He is not having an adequate response to topical treatment. Given disease severity, the next recommendation is to consider phototherapy or nonbiologic systemic agents. Phototherapy may not be feasible given the patient's job travel requirements. Therefore, nonbiologic systemic agents may be considered. Given the side effect profile and onset of action, consider avoiding acitretin and instead of starting methotrexate or apremilast. Apremilast may be the best option because of decreased laboratory monitoring compared to methotrexate. Apremilast is gradually titrated for 5 days up to a maintenance dose of 30 mg twice daily to minimize adverse effects. R.T. should be counseled on potential side effects such as diarrhea, nausea, headache, and weight loss. Before starting therapy, it is important to discuss risk of new or worsening depression with apremilast and when to seek medical attention.

Case 41-3, Question 2: R.T. presents to the office concerned about his new psoriasis flare. Although previously controlled for several years with apremilast and topical therapies, his plaques have now spread to over 10% of his body, and he has also been noticing psoriatic nail changes. What option does he have now to assist with treatment of his psoriasis?

Given the extent of his psoriasis and lack of control with apremilast, biologic agents should now be considered. First-line systemic therapy would be an IL-12/IL-23 (ustekinumab) or IL-23 inhibitor (guselkumab, risankizumab, tildrakizumab) because of superior efficacy in clinical trials when compared to TNF-α inhibitors. Tildrakizumab must be administered in-office, and therefore may not be as convenient as the other self-administered options. Ustekinumab and guselkumab have shown efficacy in nail psoriasis as well as in plaque psoriasis.[86],[87] Before starting therapy, R.T. should be assessed for tuberculosis as well as have a CBC and comprehensive metabolic panel to assess for any active infection. R.T. should be assessed 12 weeks after continuous therapy to determine response to the chosen therapy.

42

Photosensitivity, Photoaging, and Burn Injuries

Molly E. Howard

CORE PRINCIPLES		CHAPTER CASES
PHOTOSENSITIVITY		
1	Ultraviolet radiation (UVR) exposure has been linked to many adverse effects, including malignant melanoma.	**Case 42-1 (Question 1, 2)**
2	Photoprotection encompasses all methods of UVR blocking, including sunscreens, protective clothing, and sunglasses. Sunscreens are widely used to prevent sunburn and reduce the incidence of premature aging and carcinogenesis, although clothing and avoiding direct sunlight offer greater protection.	**Case 42-1 (Question 3–8)**

3	UVA has been found to cause many of the same effects on the skins as UVB, including immunologic, degenerative, and neoplastic changes of skin.	**Case 42-2 (Question 1–3)**
4	Sunburn is a self-limiting condition, which is generally managed with symptomatic treatment including oral analgesics, topical analgesics, and topical anesthetics. Treatment beyond self-management is necessary if the sunburn is accompanied by constitutional symptoms, involves second- or third-degree burns, or is infected.	**Case 42-3 (Question 1)**
5	Phototoxicity and photoallergy are often drug- or chemical-induced reactions to UVR exposure and account for up to 8% of adverse drug reactions.	**Case 42-4 (Question 1–3)**

PHOTOAGING

1	Photodamaged skin is characterized as being wrinkled, yellowed, and sagging.	**Case 42-5 (Question 1)**
2	Topical retinoid therapy is most effective for patients ages 50 to 70 years with moderate-to-severe photoaging and for prophylactic use in patients undergoing the initial changes of photoaging.	**Case 42-5 (Question 2–5)**

BURN INJURIES

1	Most burn injuries are minor and can be managed in ambulatory settings.	**Case 42-6 (Question 1)**
2	Major second- or third-degree burns	**Case 42-6 (Question 1)**

	should be immediately triaged to a health system with a multidisciplinary team that can adequately manage all potential complications.	
3	Synthetic dressings and skin substitutes have expanded the options and the desired outcomes for recovery.	**Case 42-6 (Question 2)**

INTRODUCTION

Incidence, Prevalence, and Epidemiology of Ultraviolet Radiation Exposure

Changing lifestyles have considerably increased human exposure to sunlight, including more outdoor recreational activities, more emphasis on tanning, longer life spans, seasonal population shifts to the Sunbelt, and an emphasis on improving vitamin D deficiency. Epidemiologic evidence clearly implicates sunlight as a causative factor in many skin diseases, and public attitudes toward tanning and sun exposure have slowly begun to change. Skin cancer is the most common of all cancers and yet also one of the most preventable. Squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), which together account for more than half of all malignancies in the United States, are linked closely to exposure to ultraviolet radiation (UVR).[1] Melanoma incidence rates have increased annually from 2003 to 2016, with an average increase of around 78,000 diagnoses each year during that time period.[2] Without intervention, the annual cost of treating newly diagnosed melanomas is projected to triple by 2030, but the Centers for Disease Control and Prevention (CDC) estimates that a comprehensive national skin cancer prevention program could potentially avert 230,000 melanoma cases.[3] In July 2014, the acting surgeon general delivered “The Surgeon General’s Call to Action to Prevent Skin Cancer.” The purpose of the call was

to unite various sectors of the nation to address skin cancer as a major public health problem, increase awareness of skin cancer, and call for action to reduce risk.[4] Although melanoma diagnosis has continued to increase since 2014, mortality rates have decreased by ~5% per year, with approval of new treatments for advanced disease.[2]

Sunburn, photoaging, immunologic changes in the skin, cataracts, photodermatoses, phototoxicity, and photoallergy are other commonly encountered photosensitivity reactions that occur after UVR exposure. Phototoxicity and photoallergy are often drug- or chemical- induced reactions to UVR exposure and account for up to 8% of adverse drug reactions.[5] The appropriate use of sunscreens or other photoprotective behaviors can help mitigate the incidence of the adverse effects of UVR. Despite this fact, sunscreen use remains low, with recent survey-based estimates showing that fewer than 15% of males and 30% of females use sunscreen on both the face and the exposed skin as recommended. Forty-two percent of males reported never using sunscreen at all.[6]

Etiology

ULTRAVIOLET RADIATION SPECTRUM

UVR, the primary inducer of photosensitivity reactions in humans, is divided into ranges according to the effects of four primary wavelengths: UVA1 (ultraviolet A1) (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (200–290 nm) (**Fig. 42-1**; **Table 42-1**). UVA, with a wavelength of 320 to 400 nm, is closest in wavelength to visible light.[7] UVA is considerably less likely than a comparable dose of UVB to cause a similar degree of erythema.[8,9] However, UVA penetrates into the dermal layer and may cause harmful effects not caused by UVB.[6] About 10 to 100 times more UVA reaches the earth's surface than UVB. Consequently, UVA may contribute up to 15% of the erythemal response at midday.[7,10] UVB is the most erythemogenic and melanogenic of the three UVR bands.[7,11] Up to 90% of UVB is blocked by the earth's stratospheric

ozone layer, and it is absorbed completely by the epidermal layer of the skin.[12,13] In addition, UVB radiation can alter the immune system,[13] thereby increasing the incidence of certain cancers, including skin cancers. The only known beneficial effect of UVR in humans is exposure to small amounts of UVB, most commonly through sunlight, which converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3). Vitamin D enhances calcium homeostasis and has direct and indirect effects on cells involved with bone remodeling. As a result, vitamin D can decrease the risk of rickets in childhood and fractures and osteomalacia in adults.[14]

Figure 42-1 Ultraviolet radiation (UVR) spectrum. *Erythrogenic and melanogenic bands of UVR.

Table 42-1
Types of Ultraviolet Radiation and Characteristics

Radiation	Wavelength (nm)	Characteristics
UVA1 (long UVA; long-wave radiation)	340–400	Not absorbed by the ozone layer Passes through glass Produces some tanning, photoaging, and skin cancers Lower carcinogenic potential than UVA2, but harmful over long-term exposure Levels remain relatively constant throughout the day
UVA2 (short UVA)	320–340	Similar characteristics to UVA1, but greater carcinogenic potential with erythema production similar to UVB
UVB (sunburn range of radiation)	290–320	Partially absorbed by the ozone layer before reaching earth Does not pass through glass Causes erythema, sunburn, tanning, wrinkling, photoaging, skin cancers Daily and seasonal variation, with highest intensity at noon

UVA, ultraviolet A; UVB, ultraviolet B.

The UVC wavelengths are absorbed completely by the earth's stratospheric ozone layer. Artificial sources of UVC have been used in the sterilization and preservation of food and in minimizing bacterial growth in laboratories and hospital operating rooms by germicidal lamps, which can cause erythema or cataracts if mishandled.[7,11]

ENVIRONMENTAL EFFECTS ON ULTRAVIOLET RADIATION

Ozone and chlorofluorocarbons

The amount of UVR that reaches the earth's surface is influenced by many factors. Concern has been focused on the implications of depletion of the ozone layer caused by man-made pollutants, such as chlorofluorocarbons (CFCs), nitrous oxide, and other greenhouse gases (GHGs).[10,15] As GHGs contribute to ozone depletion, and because UVA is only slightly filtered by the ozone layer, any

decrease in the ozone layer would result in a disproportionate increase in UVB reaching the earth.

Time of day, cloud cover, and surface reflection

The time of day influences the amount of UVR reaching the earth's surface, with 75% of total daily UVR being received between 9 am and 3 pm. In general, whenever someone's shadow is shorter than his or her height, care should be taken; the shorter the shadow, the more likely a sunburn will occur. Cloud cover can decrease UV intensity and infrared radiation, but this can increase the risk of UVR overexposure, because less infrared radiation will be absorbed and turned into heat, resulting in less warning of overexposure to UVR. Reflection of UVR by substances (eg, sand, water, snow) is also important, with both sand and water reflecting significant amounts of harmful rays. Seasonal changes, geographic latitude, and altitude also influence the amount of UVR reaching the earth's surface.

Ultraviolet index

The UV Index/Global UV Index (http://www.epa.gov/sunwise/uvindex.html), developed by the Environmental Protection Agency (EPA), the National Weather Service, and the CDC, is a public health education service that is calculated on a next-day basis for every ZIP code across the United States and worldwide.[16] This index, with a scale ranging from 1 (low exposure) to 11+ (extremely high exposure), forecasts the probable intensity of skin-damaging UVR expected to reach the surface during the noon hour when the sun is highest in the sky. Theoretically, the UV Index can range from 0 (eg, during the night) to 15 or 16 (in the tropics at high elevations under clear skies). The higher the UV Index, the greater the dose received of skin- and eye-damaging UVR and the less time it takes before skin damage occurs.

The amount of UVR exposure needed to damage an individual's skin is affected by the elevation of the sun in the sky, the amount of ozone in the stratosphere, and the amount of clouds present. Clear skies transmit 100% of UVR to the earth's surface, with scattered

clouds transmitting 89%, broken clouds 73%, and overcast clouds 32%. The darker an individual's skin tone, the longer (or the more UVR) it takes to cause erythema.

Pathophysiology

ERYTHEMA, SUNBURN, AND TANNING

Erythema and oxygen free radicals

Excessive exposure of the epidermal and dermal layers of the skin to UVR can result in an inflammatory erythematous reaction. Excess UVA and UVB cause the release of vasodilatory mediators (eg, histamine, prostaglandins, cytokines), resulting in increased blood flow, erythema, tissue exudates, swelling, increased sensation of warmth, and a characteristic sunburn.[7,11] Severe UVR exposure, primarily UVB, can cause blister formation, desquamation, fever, chills, weakness, and shock. UVA-induced changes in the dermis are characterized by greater damage to the vasculature and dense cellular infiltrates that penetrate to deeper levels of the skin.[11] The dermis also may be damaged when endogenous components of the skin absorb UVR energy and subsequently interact with oxygen to form tissue-damaging oxygen free radicals.[12]

Immediate pigment darkening and delayed tanning

Tanning is an adaptive mechanism of the skin to UVR. Tanning occurs by two different mechanisms: immediate pigment darkening (Meirowsky phenomenon) and delayed tanning. The primary cell involved in tanning is the melanocyte, which produces the radiation-absorbing protein melanin.[7,10] Immediate pigment darkening begins during the actual exposure to UVA and certain bands of visible light,[7,10] and the oxidation of existing melanin in the epidermis transiently turns the skin grayish brown. The degree of immediate pigment darkening depends on the duration and intensity of exposure, the extent of previous tanning (or amount of preexisting melanin), and the skin type of the individual.[6] Immediate pigment darkening is not protective against UVB erythema.[10]

PHOTOCARCINOGENESIS

Squamous cell and basal cell carcinoma

The association between skin cancer in humans and UVR exposure is based primarily on clinical and epidemiologic evidence. Nonmelanoma skin cancers, such as SCC and BCC, occur most commonly on areas that are maximally exposed to sunlight (eg, the face, neck, arms, back of the forearms, hands).[7] The prevalence of nonmelanoma skin cancers is inversely related to geographic distance from the equator and to the melanin content of the skin, with SCC more strongly linked than BCC to UVR.[7],[17] Persons of skin types most sensitive to sunlight, as well as persons working outdoors, have higher incidences of nonmelanoma skin cancers.[6] A family history of SCC and BCC increases the risk at least twofold, depending on the histology, number of lesions, and degree of invasiveness.[18]

Cutaneous malignant melanoma

The development of cutaneous malignant melanoma (CMM) may also be linked to UVR exposure, specifically exposures that induce sunburn. A history of five or more severe sunburns during adolescence may more than doubles the risk of CMM.[17] Similar to nonmelanoma skin cancers, CMM demonstrates an inverse relationship to geographic distance from the equator and melanin content of the skin.[7] Unlike nonmelanoma skin cancers, however, CMM does not demonstrate a clear relationship to the cumulative dose of UVR, and it occurs on areas of the body exposed to the sun intermittently (eg, on the back in males and the lower legs in females). In addition, it occurs most commonly in the middle-aged population and in individuals who work indoors, as well as in those whose sun exposure is limited to weekends and vacations.[17] A family history of melanoma is a strong risk factor, as 8% to 12% of melanoma patients display a familial propensity for the disease.[19]

PHOTOEFFECTS ON THE EYE

Exposure to UVR can cause many types of ocular adverse effects, including cataracts, conjunctival degeneration and proliferation, and SCC of the cornea and conjunctiva.[20] Age-related opacification of the ocular lens, or senescent cataracts, has been attributed to a lifetime of exposure to sunlight. The incidence of cataracts increases steadily after age 50 years, reaching nearly 30% in individuals older than 74 years.[21] UVB is absorbed by the cornea and lens, which slowly results in protein oxidation and precipitation within the lens. UVA penetrates the ocular lens and can cause cumulative damage to deeper structures of the eye. Decreased transmittance and increased scattering of light by the opacified lens eventually result in blurred vision, rings or halos around lights, changes in color perception, and blindness.[20] In advanced cases, the only treatment is surgical removal of the cataract.

High exposure of the eye to UVR can cause conjunctivitis or photokeratitis, a painful inflammation of the cornea. Photokeratitis usually begins 30 minutes to 24 hours after the exposure, and time to onset depends on the intensity of the exposure.[22] Because the corneal epithelium has a great regenerative capacity, photokeratitis tends to be transient, with regression in 24 to 48 hours. Treatment consists of cool, wet compresses, and mild anti-inflammatory analgesics, such as ibuprofen, aspirin, or naproxen sodium.

PHOTOTOXICITY AND PHOTOALLERGY

The most common type of drug-induced photosensitivity reaction is phototoxicity, which is an immediate or delayed inflammatory reaction. When the offending agent is deposited on the skin surface, it is thought to act as a chromophore, absorbing UVR. When the chromophore reaches a sufficient concentration in or on the skin, and when the skin is exposed to the appropriate wavelength of UVR, energy is emitted and transferred to the surrounding molecules, which damages the adjacent tissue to cause a phototoxic reaction. The wavelength of radiation necessary to produce such a reaction depends on the absorption spectrum of the offending agent.[23–25]

Photoallergy results from a similar mechanism to phototoxicity, except that the immune system is involved. Most commonly, it is caused by polycyclic photosensitizers that react with UVA to form antigenic macromolecules, evoking a delayed hypersensitivity response. In photoallergic photosensitivity reactions, the suspected medication or chemical agent is altered in the presence of UVR to become antigenic or to become a hapten (ie, an incomplete antigen), which can combine with a tissue antigen. These antigen–antibody or immune-mediated processes differentiate photoallergic from phototoxic reactions. Photoallergic reactions do not occur on first exposure to the medication, but as with other allergic reactions, they require prior or prolonged exposure (sensitization period) to the offending agent.[23],[24] Once sensitization has occurred, subsequent exposure to even small amounts of the offending product will produce a photoallergic reaction.

Photoprotection

Photoprotection encompasses all methods of UVR blocking, including sunscreens, protective clothing, and sunglasses. Sunscreens are widely used to prevent sunburn and reduce the incidence of premature aging and carcinogenesis,[26–28] although clothing and avoiding direct sunlight offer greater protection. Sunburn preventive agents are those active ingredients that absorb >95% of UVB radiation and have the potential to prevent sunburn. Suntanning agents are those with active ingredients that absorb 85% to 95% of UVB radiation, thereby allowing suntanning without significant sunburn in the average individual. Chemical sunscreens include both aforementioned designations. Opaque sunblocks, or physical sunscreens, are those active ingredients that reflect or scatter all UVA, UVB, and visible light, thereby preventing or minimizing sunburn and suntanning.[29] The original formulations were developed to protect against the effects of UVB radiation before adverse effects of UVA were recognized. Because UVA plays a significant role in many of the adverse effects associated with UVR

exposure, broad-spectrum sunscreen products with absorption spectra in the UVA range have become commercially available, in combination with UVB absorbers. These broad-spectrum products provide additional benefit for patients with photosensitivity reactions caused by wavelengths not covered by single-ingredient sunscreens. **Table 42-2** lists the available sunscreen chemicals that have been judged to be both safe and effective.

Table 42-2
Sunscreens and UVR Absorption

Sunscreen	Absorption	UV Coverage
Anthranilates		
Meradimate (menthyl anthranilate)	260–380	Broad spectrum
Benzophenones		
Dioxybenzone	250–390	Broad spectrum
Oxybenzone (benzophenone-3)	270–350	Broad spectrum
Sulisobenzone (Eusolex 4360)	260–375	Broad spectrum
Cinnamates		
Cinoxate (diethanolamine *p*-methoxycinnamate)	280–310	UVB
Octocrylene	250–360	Broad spectrum
Octinoxate (octyl methoxycinnamate, Parsol® MCX)	290–320	UVB
Dibenzoylmethanes		
Avobenzone (butyl methoxydibenzoylmethane, Parsol® 1789 [DSM Nutritional Products, Lexington, MA])	320–400	UVA
Aminobenzoic Acid and Ester Derivatives		
Para-aminobenzoic acid (PABA)	260–313	UVB
Padimate O (octyl dimethyl PABA)	290–315	UVB
Salicylates		

Sunscreen	Absorption	UV Coverage
Homosalate	295–315	UVB
Octisalate (octyl salicylate)	280–320	UVB
Trolamine salicylate	260–320	UVB
Camphor Derivatives		
Ecamsule (terephthalylidene dicamphor sulfonic acid; Mexoryl)	290–400	Broad spectrum
Others		
Ensulizole (phenylbenzimidazole sulfonic acid)	290–340	Broad spectrum
Physical Sunscreens		
Titanium dioxide	290–700	Broad spectrum
Zinc oxide	290–700	Broad spectrum

UVA, ultraviolet A; UVB, ultraviolet B; UVR, ultraviolet radiation.

There is a clear association between UV exposure and the development of BCC and SCC,[30] and limiting UV exposure by starting sunscreen use during childhood is key to reduce the lifetime risk of nonmelanoma skin cancers.

Clinical Application of Photosensitivity

SKIN TYPES

CASE 42-1

QUESTION 1: R.J., a 26-year-old female, and her husband J.J., 28 years old, are spending a week in August vacationing on the Outer Banks of North Carolina with their two children, P.J., a 6-month-old girl, and L.J., an 18-month-old boy. They have plans for time at the beach, bicycling, and sailing. They come to your pharmacy to inquire about sunscreens for the trip. Mother R.J. has a light brown complexion with brown hair and brown eyes, and father J.J. has fair complexion with blonde hair and blue eyes. On first exposure to the sun with about an hour

of intense midday sunlight, J.J. almost always develops a deep red, painful sunburn, with only minimal subsequent tanning. He freckles easily when exposed to sunlight and remembers being severely sunburned on several occasions as a child. When R.J. is first exposed to the sun in the summer, she usually develops mild erythema, followed by moderate tanning. She cannot recall being severely sunburned as a child but does recall becoming moderately tanned each summer as a child and adolescent. R.J. is employed as a receptionist for an accounting firm, and J.J. is a lawyer for a local law firm. Both spend considerable amounts of time participating in outdoor activities.

Using subjective and objective data in this history, what are the skin types of R.J. and J.J. to guide you to a recommendation of a sunscreen product?

One of the most important pieces of information to include in the patient history is the patient's skin type.[31] Patients can be classified into six sun-reactive skin types based on their response to initial sun exposure, skin color, tendency to sunburn, ability to tan, and personal history of sunburn (**Table 42-3**). Father J.J.'s fair complexion, propensity to sunburn, and minimal tanning classify him as skin type II. Mother R.J.'s light brown complexion, minimal sunburn reaction, and moderate tanning classify her as skin type IV.

Table 42-3
Suggested SPF for Various Skin Types

Complexion	Skin Type	Skin Characteristics
Very fair	I	Always burns easily; never tans
Fair	II	Always burns easily; tans minimally
Light	III	Burns moderately; tans gradually
Medium	IV	Burns minimally; always tans well
Dark	V	Rarely burns; tans profusely
Very dark	VI	Never burns; deeply pigmented

SPF, sun protection factor.

Hair and eye colors also provide an indication to skin reactiveness to sunlight. People who have blonde, red, or light brown hair or blue or green eyes tend to have greater skin reactivity to sunlight than people with dark-colored hair or eyes. A history of severe sunburn

also can be associated with skin reactivity to sunlight, although self-reported patient histories of sunburn or tanning may not be consistently reliable and personal interviews may be a better indicator. Father J.J.'s propensity to freckle and his history of severe sunburns as a child may give an indication as to his skin's sun reactiveness. Other important information to consider in the patient before recommending a certain product is medication history, history of sun-reactive dermatoses, history of allergies (particularly contact hypersensitivities to cosmetics or other topical agents), and the intended activities during sunscreen use.

RISK FACTORS

Case 42-1, Question 2: R.J. and J.J. exhibit several risk factors that place them at risk for the long-term adverse effects of UVR. What are the risk factors for these long-term adverse effects of UVR?

The long-term effects of UVR include photocarcinogenesis and premature aging of the skin (photoaging). The associated risks for the development of these long-term effects are directly related to the congenital pigmentation of an individual (which includes skin type and hair and eye color) and intensity, duration, and frequency of exposure to UVR. With skin type II, father J.J. is at high risk for carcinogenesis and photoaging, whereas mother R.J., with skin type IV, may be at a lower risk. Excessive sun exposure, especially during early childhood, increases the risk of nonmelanoma and melanoma skin cancers. During the first 18 years of life, the average child receives three times the dose of UVB of the average adult; consequently, most sun exposure occurs during childhood.[32–34] A history of frequent sunburn or intermittent high-intensity exposures to UVR may be associated with the occurrence of malignant melanoma, whereas large cumulative doses of UVR during a lifetime may contribute to the incidence of nonmelanoma skin cancers. J.J.'s history of several severe sunburns as a child may more than double his risk of CMM.[34,35] Cumulative doses of UVR received

unintentionally from working outdoors or from participating in outdoor recreational activities also can contribute significantly to the risk of photocarcinogenesis and photoaging.[8] A large number of moles, congenital moles >1.5 cm wide, and abnormal moles also appear to be a risk factor for malignant melanoma.[17] Risk for skin cancer is increased among the first-degree relatives of patients with skin cancer[35] because frequent sunburns, suboptimal sunscreen use, and high rates of tanning bed use are common among children with a personal or family history of skin cancer.[36]

Photoprotection

Sun Protection Factor

Case 42-1, Question 3: Before deciding on the exact product for R.J., J.J., and their children, R.J. and J.J. want to know how to differentiate among products and how to interpret the sun protection factor (SPF) of a product. What type of sunscreen would be the best choice for them?

The effectiveness of a sunscreen formulation is based on its SPF and its substantivity.[37] SPF is a measure of how much solar energy (UVR) is required to produce sunburn on protected skin (ie, in the presence of sunscreen) relative to the amount of solar energy required to produce sunburn on unprotected skin. As the SPF value increases, sunburn protection increases. It is defined as the ratio of the minimal dose of UVR required to produce an erythemal response in sunscreen-protected skin compared with unprotected skin.[26] The SPF is based on tests of volunteers with skin types I to III, using either natural sunlight or a solar simulator that generates both UVB and UVA.[26,37] Because the SPF can be influenced by the composition, chemical properties, emollient properties, and pH of the vehicle, sunscreen formulations must be evaluated on an individual basis.[37] The concept of an SPF is commonly misunderstood and is also influenced by a variety of factors, including the amount applied to the skin, the time of initial application before UVR exposure, the frequency of application, and environmental factors, such as

photodegradation during UVR exposure; therefore, the SPF achieved during actual use can be significantly less than indicated on the label.[38–42] Consumers have been shown to routinely apply only one-fourth to one-half thickness of the layer of sunscreen used to determine the SPF before marketing.[43–46]

A popular misconception is that SPF relates to time of solar exposure. For example, many people believe that if they normally get sunburn in 1 hour, then an SPF 15 sunscreen allows them to stay in the sun for 15 hours (ie, 15 times longer) without getting sunburn. This is untrue because SPF is not directly related to time of solar exposure, but to the amount of solar exposure. Although solar energy amount is related to solar exposure time, other factors have an impact on the amount of solar energy, including time of day, geographic location, and cloud cover.

In February 2019, the Food and Drug Administration (FDA) issued a proposed rule to update the regulatory requirements for sunscreen products and ensure safety and efficacy.[47] The update is necessary because sunscreen products are used much more extensively and frequently than when the FDA made initial safety determinations on sunscreens.[47] Additional information is needed relating to chronic use, including systemic absorption, as there is a growing body of evidence that sunscreen products may be more systemically absorbed than initially thought.[48],[49] This rule would put into effect final monograph regulations for over-the-counter (OTC) sunscreen products as required by the Sunscreen Innovation Act, which provided a new process for the FDA review of the efficacy and safety of nonprescription sunscreen active ingredients in 2014.[50] An OTC monograph establishes conditions under which certain OTC drugs may be marketed without approved new drug applications, because they are generally recognized as safe and effective (GRASE) and not misbranded. The FDA has noted that changed conditions because the final rule “Sunscreen Products for Over the Counter Human Use”[51] in 1999 reflects a need for additional data on products to confirm that the products are GRASE.

The proposal identifies that of the 16 currently marketed active ingredients, zinc oxide and titanium dioxide were identified as

GRASE, because sufficient evidence currently exists regarding safety and efficacy of these ingredients. Para-aminobenzoic acid (PABA) and trolamine salicylate were not GRASE owing to safety concerns, specifically risk of allergic and photoallergic skin reactions and cross-sensitization with structurally similar compounds with PABA and the potential for adverse effects from the anticoagulation effects of salicylic acid and salicylate toxicity associated with trolamine salicylate use. The remaining 12 ingredients were identified as having insufficient data for GRASE determination, with the FDA requesting additional data to make that determination. The proposal identifies the following dosage forms as GRASE: lotions, creams, gels, oils, butters, pastes, ointments, and sticks. Sunscreens combined with insect repellents are not identified as GRASE.

The proposal requires sunscreens with an SPF value of 15 or higher to also provide broad-spectrum protection that, for the broad-spectrum products, as SPF increases, the magnitude of protection against UVA radiation also increases. Additional aspects of the proposal include raising the maximum proposed SPF value on sunscreen labels from SPF 50+ to SPF 60+, requiring new labeling that assists customers in more easily identifying key information and clarifies the FDA's expectations for testing and record keeping by entities that conduct sunscreen testing. The FDA sought public comment on the proposed rule in early 2019, but the final rule has not yet been enacted. A more detailed history related to the OTC sunscreen drug review and the FDA's regulation of OTC sunscreen drug products can be found within the proposed rule document in the Federal Register.[47],[52],[53]

Evaluation of Sunscreens

Substantivity is a measure of the sunscreen formulation's effectiveness. The substantivity of a sunscreen formulation is its ability to be absorbed by, or adhere to, the skin while swimming or perspiring. The substantivity of a product largely depends on the vehicle, as well as the active ingredient.[54] The affinity of a sunscreen

to the keratinaceous layer of the stratum corneum is directly related to the keratin or vehicle partition coefficient. The saturation of the active agent in keratin depends on the drug's lipophilicity, whereas its substantivity is independent of its lipophilicity. Sunscreen compounds with a high solubility in the product's vehicle penetrate the skin most easily. Classically, vehicles such as water-in-oil emulsions or ointments tend to have a higher degree of substantivity. Some of the newer products have improved substantivity with the addition of a polymer, such as polyacrylamide, to the formulation. Table 42-2 shows the 17 ingredients that act as sunscreens currently approved in the United States, along with their absorption spectrum.

CHEMICAL ORGANIC SUNSCREENS

Chemical organic sunscreens are compounds capable of absorbing UVR, thereby protecting the skin structures from the adverse effects of the selective wavelengths absorbed.[26] After application to the skin, these aromatic compounds convert the high UVR energy into harmless longer wave radiation, which may or may not be perceived as warmth.[26] Chemical organic sunscreens are usually nonopaque because they do not absorb the wavelengths of visible light.

Ultraviolet B filters

Aminobenzoates

Commonly used in the past and the first widely used UV filter, PABA absorbs UVR in the UVB range from 260 to 313 nm, with maximal absorption around 290 nm; its molar absorptivity is considered to be high.[37] PABA readily penetrates and binds to the stratum corneum, and, after several days of application, it may remain in the skin and provide protection even after water exposure, making it an ideal candidate for water-resistant sunscreens.[37] Its major disadvantage is the potential to cause contact or photocontact dermatitis, which has been reported to happen in ~4% of the population.[55] Responsible for more sensitivity reactions than any other sunscreen,[40] PABA can also cause cross-sensitivity reactions with benzocaine, thiazides, sulfonamides, paraphenylenediamine (a common ingredient in hair

dyes), and other PABA derivatives. These sensitivity reactions are why PABA was not identified as GRASE in the 2019 FDA's proposed rule discussed previously. The use of PABA in commercial sunscreens has decreased to the point where many of the newer sunscreens are promoted as being PABA free.

The PABA esters include octyl dimethyl PABA (Padimate O) and glyceryl PABA. These esters are incorporated easily into formulations, demonstrate good substantivity, and do not discolor clothing. Their absorption spectra are similar to those of PABA (Table 42-2). With a maximal absorption of 311 nm, Padimate O has the lowest likelihood of any PABA ester to cause cross-sensitivity reactions or contact and photocontact dermatitis.[56]

Cinnamates

Octinoxate (octyl methoxycinnamate), which has high molar absorptivity and a maximal absorption of 305 nm, is the most commonly used cinnamate and most potent UVB filter.[57] Cinnamates are related chemically to balsam of Peru, balsam of Tolu, coca leaves, cinnamic acid, cinnamic aldehyde, and cinnamic oil, ingredients that are used in perfumes, topical medications, cosmetics, and flavorings.[58] These agents do not bind well to the stratum corneum, leading to poor substantivity. Cinnamate-based sunscreens tend to be comedogenic because the vehicle may contain other occlusive ingredients that are added to improve the substantivity. Cinnamates are often used in combination with benzophenones, appear to be nonstaining, and rarely cause contact dermatitis.[57]

Salicylates

Salicylates are weak UVB absorbers often found in PABA-free products. Topical salicylates are considered among the safest sunscreens, even though they must be used in high concentrations to meet the SPF requirement.[59] Salicylates have low molar absorptivities, are incorporated easily into formulations, and are used to boost the SPF of combination products, particularly oxybenzone

and avobenzone.[60] Octisalate and homosalate are water insoluble, which leads to high substantivity. Sensitization to the salicylates is rare[59]; however, it has been reported with the use of octisalate.[61]

Octocrylene

Octocrylene has an absorption profile similar to the salicylates and cinnamates, with a peak absorption at 307 nm. It has low irritation potential and low substantivity; however, it has become increasingly popular because of its ability to photostabilize avobenzone.[62]

Ultraviolet A filters

Benzophenones

Benzophenones, such as oxybenzone and dioxybenzone, are UVB-absorbing sunscreens that have absorption spectra extending into the UVA range.[63] Benzophenones are also found in shampoos, soaps, hair sprays and dyes, paints, varnishes, and lacquers. The maximal absorption for each is about 290 nm, but both are limited because of poor substantivity and sensitization.[63] Photocontact dermatitis with oxybenzone and contact dermatitis with dioxybenzone occur commonly, with the latter usually occurring as a contact urticaria.[64] Systemic absorption has also been noted with oxybenzone, and it can be detected in the urine and bloodstream.[65]

Anthranilates

Anthranilates, such as Meradimate (L'oreal Usa Products, Inc., New York, NY, menthyl anthranilate), are weak UVB-absorbing sunscreens with an absorption spectrum extending into the UVA range. As with the salicylates, they have low molar absorptivity, with a maximal absorption of ~336 nm.[37] Meradimate has a low risk of sensitization and a desirable absorption spectrum, especially when it is used in combination with other sunscreens to give broad-spectrum protection.

Dibenzoylmethanes

As a prototype of the dibenzoylmethane class, avobenzone (butyl methoxydibenzoylmethane) has high molar absorptivity and absorption spectra exclusively in the UVA range, with maximal absorption of ~360 nm.[66] It is commonly formulated with UVB sunscreens to broaden UVR coverage. Avobenzone loses ~35% of its absorption capacity about 15 minutes after UVR exposure, because of the photoinstability of the compound, thereby reducing its UVA protection efficacy.[67] One molecule of avobenzone can absorb UVA radiation only once, making it inactive from that time forward as opposed to zinc oxide or titanium dioxide, which can reflect UVA radiation over and over again with minimal decay. All of the avobenzone applied to the skin is virtually rendered inactive after 5 hours of UVA exposure. Avobenzone is also not compatible with octinoxate, the most powerful UVB filter.[68] Photostability of avobenzone can be increased with the use of UV absorbers, as well as non-UV filters. Neutrogena has marketed this technology under the name of Helioplex, which initially stabilized avobenzone using oxybenzone and diethylhexyl 2,6-naphthalate (DEHN) but has now broadened to include additional technologies and ingredients.

Ecamsule

Ecamsule is a camphor derivative that protects against short UVA rays and is photostable and water resistant and has low systemic absorption.[69] The FDA has only approved ecamsule for use in certain formulations, with the FDA determining that more research was needed to evaluate the safety and efficacy of the ingredient in other concentrations.[50] Ecamsule provides protection within the short UVA range (320–340 nm), filling the gap between octocrylene and avobenzone capabilities (210–290 and 340–400 nm, respectively). Adverse events associated with its use are infrequent and include acne, dermatitis, xerosis, eczema, erythema, pruritus, skin discomfort, and sunburn.

INORGANIC SUNSCREENS

Inorganic sunscreens are opaque formulations made of particulate insoluble compounds, incorporated into a vehicle, which have been thought to scatter and absorb UV rays. However, recent evidence indicates that they protect primarily through absorption.[70] Both the size of the particles and thickness of the film determine the degree of protection.[71] Currently, there are only two inorganic sunscreens approved by the FDA: titanium dioxide and zinc oxide.[71],[72] Other inorganic sunscreens include magnesium oxide, red veterinarian petrolatum, iron oxides, kaolin, ichthammol, and talc. Iron oxides and talc continue to be found in commercially available sunscreen products and cosmetics, whereas kaolin and ichthammol may be found in products such as cleansers, moisturizers, and ointments. These compounds are often used in conjunction with chemical sunscreens to formulate products of higher SPF and as single-ingredient products. When used alone, they are usually placed in an ointment base designed specifically for vulnerable parts of the body, such as the nose, cheeks, lips, ears, and shoulders.[29] Inorganic sunscreens are important in individuals who are unusually sensitive to UVA and visible light, such as those with vitiligo, a skin condition with amelanotic lesions (white patches) surrounded by areas of normally pigmented skin. Appropriately colored formulations can be used to camouflage and protect these vulnerable amelanotic lesions.[29] Inorganic sunscreen agents are preferred for persons who need absolute UVR and visible light protection (eg, young children, persons with skin types I–IV who receive constant exposure, and persons with drug photosensitivity reactions, xeroderma pigmentosa, lupus erythematosus, and other photosensitive skin reactions).[29]

Despite some advantages, inorganic sunscreens are not widely accepted because they are visible to others, messy, and occlusive when applied to the skin. They have a higher substantivity, but may melt in the heat of the sun, limiting their protection to a few hours. Physical sunscreen products tend to be so occlusive that they may cause or worsen acne or obstruct sweat glands.[29] Substantial effort has been made to improve the shortcomings of these products by reducing the particle size to improve the cosmetic appearance. This has created a growing trend toward incorporating nanoparticles of

titanium dioxide and zinc oxide, which have been shown to have superior UV protection while maintaining cosmetic elegance. Concern about toxicity of these agents has been raised because of the potential for increased skin penetration and interaction with lower portions of the epidermis; however, this has been disproved in both in vivo and in vitro studies.[73-77] No current regulation in the United States exists regarding the testing and labeling of nanosized titanium or zinc oxides.

Antioxidants

The addition of botanical antioxidants and vitamins C and E to a broad-spectrum sunscreen may further decrease UV-induced damage compared with sunscreen alone because of neutralization of free radicals.[72],[78] Antioxidants have received increased attention for use as photoprotective agents, particularly because of the observation that vitamin C levels in the skin can be severely depleted after UVR exposure.[79] Vitamins C and E, either taken orally (po) or applied topically (incorporated into a commercially available sunscreen product), may provide additive protection against both UVA- and UVB-induced photodamage.[79],[80] Topically applied antioxidants do not have adequate diffusion into the epidermal layer, however, and are susceptible to chemical instability.[60] If recommended, they should only be used in conjunction with adequate sunscreen. Commercially available products can be found with combinations of antioxidants and broad-spectrum sunscreens, specifically those formulated for facial use.

Given their plans for the week of vacation and amount of UV exposure likely, R.J. and J.J. should consider a broad-spectrum product with high substantivity and a high degree of water resistance to offer the best protection. The next section further discusses appropriate choices relating to SPF.

CROSS-SENSITIVITY

Case 42-1, Question 4: According to your assessment of mother R.J. and father J.J., you determine that they have type IV skin and type II skin, respectively. On further inquiry, you learn that R.J. has no medication allergies; however, she has a history of contact dermatitis on her scalp and around her hairline on several occasions after dyeing her hair and using certain shampoos. As a teenager, J.J. suffered from frequent sinus infections and often was treated with trimethoprim–sulfamethoxazole (TMP-SMX) because of an allergy to penicillin. He remembers developing a severe sunburn after minimal exposure to the sun while taking the sulfa-containing antibiotic. He recently has been started on hydrochlorothiazide (HCTZ) 12.5 mg po daily, for hypertension. What considerations are important in recommending sunscreens for R.J. and J.J.?

The first consideration for recommending an appropriate sunscreen to R.J. and J.J. is their skin type. R.J. has skin type IV, suggesting that a sunscreen with an SPF of at least 15 would provide adequate protection for her (Table 42-3). J.J. has skin type II, suggesting that a sunscreen with an SPF of 30 to 50 would be required to provide adequate protection for him. Furthermore, the history of contact dermatitis and photosensitivity reaction exhibited by R.J. and J.J., respectively, is important when recommending use of a sunscreen.[81] The contact dermatitis that R.J. experienced from hair dyes and shampoos may have been caused by paraphenylenediamine, an ingredient of hair dyes,[82] or a benzophenone, which sometimes is included in products such as hair dyes and shampoos.[63]

Because cross-reactivity between paraphenylenediamine and PABA or its derivatives is possible, a sunscreen for R.J. that does not contain PABA or a benzophenone should be recommended. Cinnamates and anthranilates rarely cause contact dermatoses, which would be ideal for R.J.

Because both contain sulfa moieties, the photosensitivity reaction that J.J. experienced while taking TMP-SMX may indicate that he might be susceptible to a cross-sensitivity reaction with PABA or its derivatives. This reaction to TMP-SMX also indicates that J.J. may be susceptible to a photosensitivity reaction with HCTZ. If a photosensitivity reaction is likely, it is advisable to recommend an SPF of 30 or more. Because drug-induced photosensitivity reactions

are caused by UVA, a PABA-free, broad-spectrum sunscreen that absorbs UVA as well as UVB would be necessary to provide J.J. with adequate protection. Broad-spectrum chemical sunscreens commonly contain a benzophenone and a cinnamate. A broad-spectrum sunscreen containing both of these chemical classes would be an acceptable broad-spectrum product. Alternatively, because Padimate O is the least likely of the PABA ester derivatives to cause photocontact dermatitis,[56] a broad-spectrum combination product that contains Padimate O could be recommended for J.J. If the photosensitivity reaction is caused by visible light, it would also be necessary to recommend an inorganic physical sunscreen to block all sunlight or complete avoidance of the sun.[41] With all of these issues considered, it may be preferable to recommend an alternative antihypertensive medication for J.J. that would not place him at risk for a photosensitivity reaction.

PHOTOPROTECTION FOR CHILDREN

Case 42-1, Question 5: What photoprotective measures should be provided for 6-month-old daughter P.J. and 18-month-old son L.J.?

Sun protection during childhood is very important, considering that most of a person's lifetime of sun exposure occurs in childhood and that the harmful effects of UVR are cumulative.[83] However, infants and toddlers are at increased risk of overexposure to topical sunscreen products because of an increased body surface area (BSA) to body weight ratio compared to adults and a lower ability to metabolize absorbed drug.[84,85] It is, therefore, recommended that sunscreen should not be used for children younger than 6 months of age.[86] Daughter P.J. needs to be kept out of direct sunlight and, when outside, must be protected with proper clothing and shading.[86–90]

L.J. should be protected with a PABA-free, inorganic UV filter sunscreen, such as zinc oxide with an SPF of at least 15. Inorganic UV filters are preferred for children between the age of 6 months and

2 years because of the lack of systemic absorption.[84,85] Regular use of a sunscreen with an SPF of at least 15 for the first 18 years of life can reduce the lifetime incidence of nonmelanoma skin cancers by about three-fourths.[90] If son L.J. is in the sun during 6 hours of maximal exposure (ie, 10 am–4 pm), or otherwise for an extended period, he should wear protective clothing, covering as much of his body as possible.[89] Tightly woven clothing, long sleeves, and pants protect the skin from almost all UVR, whereas loosely woven clothing or wet T-shirts can allow up to 30% of UVR to pass through to the skin. Although not complete, water is thought to reduce UVR scattering, thus decreasing its transmission. An average-weight cotton T-shirt provides only an SPF of 7 or 8.[89]

The transmission of UVR through a fabric is measured using a spectrophotometer or spectroradiometer. The ultraviolet protection factor (UPF), rather than SPF, has been recommended as a measure of the sun-protective properties of fabrics.[91,92] It is calculated using a formula based on UV transmission through the fabric and the erythema responsible for human skin. For example, if a fabric has a UPF of 20, then only one-twentieth of the UVR at the surface of the fabric actually passes through it. Certain synthetic fabrics have UPF values that exceed 500, making them vastly superior to sunscreens.[89] **Table 42-4** compares the UPF with the amount of effective UVR transmitted and absorbed.

Table 42-4

Volume of Sunscreen Needed for Adequate Protection

Body Part	Recommended Minimum Amount of Sunscreen
Head	½ teaspoon
Neck	
Arms	
Anterior torso	1 teaspoon
Posterior torso	
Legs (each)	

No woven fabric provides complete coverage because the holes between the threads permit UVR transmission. A baseball cap shields little more than the upper central forehead. Broad-brimmed hats can protect the ears, neck, nose, and cheeks, but may provide inadequate protection against SCC of the head or neck.[93] The use of an UV-absorbing ingredient for fabric softeners (eg, bisoctrizole, Tinosorb M, BASF) is promoted to reduce transmission of excessive UVA and UVB radiation through fabrics to the skin, through absorption of UVR without impairing whiteness. This chemical absorption process has a high affinity for cotton fibers at various washing temperatures. Available as a laundry additive (eg, Sun Guard, Phoenix Brands), it works by binding to laundered fibers, and through accumulation, it increases the UV protection up to UPF 30 through up to 20 wash-and-rinse cycles.[94],[95]

Product selection

Inorganic physical sunscreens, such as zinc oxide or titanium dioxide, are generally recommended in children. However, if these options are not preferable or available, a broad-spectrum lotion of SPF 15 or higher can be utilized. A lotion is preferred for total body application versus an alcoholic lotion or gel because alcoholic preparations can cause stinging, burning, and irritation of the skin and eyes. Physical sunscreens are available in bright colors and are recommended for selected body areas, such as the nose, cheeks, and shoulders. PABA and its derivatives are considered potentially harmful to a child's tender skin. For adolescents with acne vulgaris, the use of an oil-free, noncomedogenic sunscreen formulation and a lip balm that contains a sunscreen of at least SPF 15 (eg, Blistex or ChapStick Sunblock [SPF 30]) would be appropriate.

Application

Case 42-1, Question 6: What instructions should you provide mother R.J. and father J.J. on how to apply the sunscreen that you have chosen for each of their family members?

Because R.J. and J.J. are planning to be active on the beach, sunscreens that are water resistant are recommended. Before complete application of the sunscreen to the body, because of the risk of cross-sensitivity reactions, patients can perform a patch test by applying a small quantity of the sunscreen to the inner aspect of the forearm and covering with a small bandage overnight.

Education on the appropriate volume of sunscreen to apply is vital. Most persons apply 20% to 60% of the required amount of sunscreen needed to achieve the SPF of their product.[39,42-45] Because of this, a method has been developed to determine an approximate volume of sunscreen product needed for adequate protection.[96] This rule states that you should use more than half a teaspoon on each of your head and neck area and arms and more than a teaspoonful on each of your anterior and posterior torso and your legs. This application size was determined based on the dose used in FDA sunscreen testing (**Table 42-5**).

Table 42-5

Relative Ultraviolet Protection Factor (UPF) of Fabrics by Ultraviolet Ray (UVR) Transmission and Absorption

UVR Absorbed (%)	UPF	Protection Category
90.0	10	Moderate protection
95.0	20	High protection
96.7	30	Very high protection
97.5	40	Extremely high protection
>98.0	50	Maximal protection

Studies of sunscreen application techniques have demonstrated inadequate application at all body sites.[43-45,97] The worst protected areas were the ears and top of the feet, and the back was poorly protected if sunscreen was self-applied. Patients should be reminded to apply sunscreen on those often-forgotten areas, such as the hands, cheeks, neck, ears, and dorsum of the feet. It is best to follow package directions, reapplying the sunscreen every 1 to 2 hours or

after sweating, swimming, or toweling off. There is evidence that early reapplication within 20 to 30 minutes be able to partly compensate for initial underapplication.[38,98-100]

Case 42-1, Question 7: Would father J.J. gain additional benefit from a product with an SPF >50?

Sunscreen formulations with SPF as high as 50 can be made using combinations of chemical and physical sunscreen agents.[7] Individuals who are extremely sensitive to the sun may benefit from formulations with higher SPF, but the average fair-skinned person gains adequate protection for sunbathing or for average daily exposure from a product with an SPF of 30.[39]

Protection from sunburn increases with higher SPF; however, it is important to remind J.J. that this protection does not correlate to the extent of skin damage from UVA rays. Studies have shown some benefit to higher SPF ratings.[101,102] However, in the FDA amendment that went into effect in 2012, SPF ratings were limited to a maximum of 50+ because of the lack of evidence for greater efficacy at higher SPF ratings.[103] Increasing this to a maximum of 60+ is included in the 2019 FDA's proposed rule, with increased evidence of additional benefit from higher SPF ratings.[47] J.J. should also be reminded that the SPF is only accurate if he correctly applies the sunscreen in the adequate amount.

PROTECTIVE EYEWEAR

Case 42-1, Question 8: What appropriate protective eyewear would you recommend for R.J. and J.J.'s family while they are on vacation?

R.J. and J.J. should wear sunglasses when outdoors to decrease their lifelong exposure to solar radiation and while at the beach to prevent high exposure of UVR and possible photokeratitis or conjunctivitis. Many manufacturers of sunglasses label their products according to three categories: cosmetic, general purpose, and

special purpose. Cosmetic sunglasses block at least 70% of UVB, at least 20% of UVA, and <60% of visible light and are appropriate for casual wear when high exposure to UVR is unlikely. General-purpose sunglasses block at least 95% of UVB, at least 60% of UVA, and 60% to 92% of visible light and are appropriate for most activities in sunny environments.[104] Special-purpose sunglasses block at least 99% of UVB, at least 60% of UVA, and at least 97% of visible light and are appropriate for very bright environments, such as ski slopes or tropical beaches.[104] Special- or general-purpose sunglasses are appropriate recommendations for R.J., J.J., and their children to wear while on vacation.

Tanning booths

CASE 42-2

Question 1: B.P., a 32-year-old female, is preparing for a business trip to Cancun. She is seeking advice about the use of a tanning bed to stimulate melanin for the prevention of sunburn while on her trip. B.P. has skin type III and light brown hair and green eyes. She recently heard, however, that a tan produced by artificial sunlight may not protect against sunburn and may even cause skin cancer.

What advice will you offer her?

Most tanning beds, booths, or salons use an artificial light source that emits about 95% UVA with minimal (ie, 1%–5%) UVB.[105],[106] It was originally thought that UVA is much less likely to produce photoaging and photocarcinogenic changes of the skin than UVB; however, UVA has now been found to cause many of the same effects on the skin as UVB, including immunologic, degenerative, and neoplastic changes, as well as damage to DNA and the formation of reactive oxygen species (ROS).[107] UVA also contributes to cataract formation and the activation of herpetic lesions.[21] The high doses of UVA received during a tanning session, as well as increasing cumulative UVA doses over time, raise great concern about the long-term effects of UVA.[108] In addition, UVA may augment

the photocarcinogenic effect of UVB,[67] and extensive evidence indicates a relationship between indoor tanning and melanoma.[109] Reduction of indoor tanning has been a national public health focus, including being a Healthy People 2020 goal, as part of the U.S. Department of Health and Human Services Office of Disease Prevention and Health Promotion program.[110],[111] In an attempt to combat the epidemic of use in young people, the FDA reclassified UV lamps to be class II medical devices in 2014 and include a box warning, indicating that they should not be used by minors ages 18 years or younger.[112] Although this act placed more regulation on tanning booths, concern has been raised that regulating tanning equipment as medical devices implies that they offer a therapeutic benefit and is not commensurate with other products that are known carcinogens with very little to no offered benefit.[113]

With a skin type III, B.P. may be able gradually to achieve a moderate tan with minimal burning, thus providing some protection from UVR because of increased melanization of the skin. This UVA-induced tan, however, may not be as protective as a tan achieved under normal sunlight conditions because UVA does not thicken the stratum corneum.[114] An artificially produced tan plus subsequent sun exposure has not been found to provide any net reduction in long-term damage to the skin when compared with the same amount of tan obtained by sunbathing alone.[114] For these reasons, B.P. should not use the tanning booth to obtain a protective tan, and she should use appropriate photoprotective measures during her trip.

Case 42-2, Question 2: What precautions would you recommend if she decides to visit a tanning salon?

If B.P. decides to artificially tan despite your recommendation, she should undertake some precautions. The FDA has recommended exposure schedules for first-time users based on skin type, which determines a person's minimal erythemal dose (MED) of UVR. The MED is determined by the amount of UV exposure necessary to produce any visible reddening of the skin 24 hours after exposure.

This policy suggests that exposure be limited to no >0.75 MED three times the first week, followed by a gradual increase to maintenance doses of a maximum of 4.0 MED delivered weekly or biweekly.[115] It is important to remember that MED is specific to an individual and, therefore, will be different depending on his or her skin type. Correlating the FDA's policy into time limits for an individual is, therefore, dependent on skin type as well as the amount of UV exposure provided by the tanning apparatus the individual will use. To minimize cataract development, B.P. should always wear protective eyewear that absorbs all UVA, UVB, and visible light up to 500 nm; simply closing her eyes or wearing regular sunglasses provides no protective effect against eye damage.

SUNLESS TANNING PRODUCTS

Case 42-2, Question 3: B.P. decides to accept your recommendations to avoid tanning beds; however, she would still like to have a tan before going to Cancun. Will the use of sunless tanning agents confer any photoprotection for B.P. against sunburn?

Sunless tanner is a commercial term that denotes a product that provides a tanned appearance without exposure to the sun or other sources of UVR. One commonly used ingredient in these products is dihydroxyacetone (DHA), a color additive that darkens the skin to orange brown by reacting with amino acids in the stratum corneum. The term *bronzer* is used to describe a variety of products intended to achieve a temporary tanned appearance. For example, among the products marketed as bronzers are tinted moisturizers and brush-on powders. These produce a temporary effect, similar to other types of makeup, and wash off over time. Some products are marketed with other ingredients in addition to DHA to provide a tanned appearance. Generally, neither sunless tanners nor bronzers provide any protective activity to UV exposure by themselves, unless specifically listed with an SPF rating.[116]

Treatment of sunburn

CASE 42-3

Question 1: G.B., a 31-year-old male with skin type IV, returned a few hours ago from an afternoon of activity in the sun. His shoulders, back, neck, and arms are bright red and are beginning to feel hot, stretched, and painful. G.B. has been otherwise healthy, has no significant medical history, and has no known allergies to medications.

What treatment recommendations would you give G.B. for his sunburn?

Sunburn is a self-limiting condition, and treatment is usually symptomatic.[117] Suggested treatments that G.B. can try for his first-degree burn are oral (eg, naproxen or ibuprofen) or topical (eg, camphor, menthol) analgesics, topical anti-inflammatory agents (eg, hydrocortisone cream or aloe vera gel), cooling compresses (tap water, saline, or aluminum acetate solution [Burow solution]) applied to the skin, or cool protectant baths (eg, colloidal oatmeal). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as naproxen or ibuprofen, may be preferred over acetaminophen because of blockade of the inflammatory prostaglandin-mediated sunburn process; however, although offering symptomatic relief, corticosteroids, NSAIDs, antioxidants, antihistamines, or emollients offer only mild improvement at decreasing the time to recovery.[117]

Topical anesthetics, such as benzocaine or lidocaine, provide only transient analgesia for up to 15 to 45 minutes. These topical agents should not be used in large quantities or applied more than three or four times a day. In addition, they should not be used on raw, blistered, or abraded skin. Benzocaine has minimal systemic toxicities but is commonly associated with contact sensitization.[118] In contrast, lidocaine is associated with a low incidence of contact sensitization.[119] Topical corticosteroids have been shown to provide minimal clinical benefit when applied after UV exposure.[120] If G.B. wants to try a topical agent, application or administration is recommended when the pain is particularly bothersome, such as at bedtime. Oral antihistamines may help control pruritus associated with sunburn, as well as aid with sleep, if taken at bedtime; however,

no definitive studies have shown benefit in reducing symptoms or benefit of one agent over another.

Treatment beyond self-management is generally unnecessary unless the sunburn is extensive with constitutional symptoms (ie, fever, chills, nausea, vomiting), involves second- or third-degree burns (particularly if on the eyes or genitalia), or becomes infected. In such cases, referral of the patient to his or her health care provider is indicated as a short course (ie, up to 3 days), or an oral corticosteroid may need to be given (eg, 1 mg/kg of prednisone or equivalent, given once daily).

Clinical Application of Phototoxicity or Photoallergy

Phototoxic photosensitivity reactions are dose dependent and occur in almost any person who takes or applies an adequate amount of the offending agent. The dose necessary to produce such a reaction varies from person to person and depends on factors such as complexion, hair and eye color, usual ability to tan, and the type and amount of UVR exposure. Phototoxic photosensitivity reactions are not immunologically mediated or true allergic reactions; they can occur on first exposure to the agent and generally show no cross-sensitivity to chemically related agents.

A phototoxic reaction usually has a rapid onset, often within several hours after UVR exposure, and presents as an exaggerated or intensified sunburn with erythema, pain, and prickling or burning. Blistering, desquamation, and hyperpigmentation can occur in severe cases.[23],[24] Symptoms generally peak 24 to 48 hours after the initial exposure and are usually limited to the areas of UVR-exposed skin. Because phototoxicity reactions do not involve the immune system, prior exposure to the photosensitizer is unnecessary for this reaction to occur. Common drug classes known to be phototoxic include fluoroquinolone, tetracycline, and sulfonamide antibiotics, diuretics, sulfonylureas, and nonsteroidal anti-inflammatory agents.

Clinically, photoallergy differs from phototoxicity in that it produces an intensely pruritic, eczematous form of dermatitis.[24] The rash is preceded by pruritus and may subside within an hour. In 5% to 10% of cases, persistent hypersensitivity to light occurs, even after the offending chemical has been eliminated.[23] Photoallergic reactions are not dose related, and eruptions can also be caused by chemically related agents via cross-sensitivity or cross-allergenicity. As a type of delayed hypersensitivity reaction, time is required to develop an immune response, and the onset of a photoallergic reaction is often delayed for 1 to 3 days. These reactions can present as macular, bullous, or purpuric lesions. Acute urticaria can occur within minutes after UVR exposure. Recovery is slower than from a phototoxic reaction, and it can persist after the offending product has been removed. These reactions may present with erythema and possible edema secondary to the inflammation, but are most commonly found to be eczematous, characterized by erythema; pruritus (possible severe); and papules or vesicles or both, with weeping, oozing, and crusting. Scaling, lichenification, and pigmentation may occur later.

CASE 42-4

Question 1: D.L., a 16-year-old, blond-haired, blue-eyed teenager with skin type II, presents with a severe sunburn. He states that he started a new summer job 2 days ago with typical sun exposure. He is surprised at the severity of this sunburn, which is worse than normal for the same amount of sun exposure.

What further information do you need to know before making treatment recommendations?

Because D.L. is reporting symptoms that differ from previous sun exposures, further questions should be asked regarding the history of the current scenario. Information that may be important from the history of the condition includes the temporal relationship between sun exposure and onset of symptoms; the nature and duration of symptoms; recent ingestion or topical application of medications; possible exposure to photosensitizers, chemical irritants, or plants

that can cause allergic contact dermatitis (eg, poison ivy); and the potential for arthropod bites. Information that may be important from the physical examination includes the distribution and morphology of the reaction, as well as areas of the body spared of the reaction.

A drug-induced photosensitivity reaction most commonly appears as a sunburn of greater severity than would normally be expected or as a rash in areas exposed to the sun or tanning apparatus. These reactions can be secondary to oral medications; however, it is important to remember that chemicals with photosensitization potential are found in cosmetics, shampoos, moisturizing lotions, hair dyes or tints, soaps, and other topically applied medications and agents.

Drug-induced photosensitivity reactions can be subdivided into phototoxic and photoallergic reactions. The same medication or agent may produce both phototoxic and photoallergic reactions, and it may at times be difficult to differentiate clinically between the two types of reactions.

Case 42-4, Question 2: On further questioning, you discover that D.L. first experienced painful erythema of the extensor surface of his hands and forearms, the anterior aspect of his neck, and parts of his face within hours of starting his new job at an outdoor garden and greenhouse. Besides painful erythema, the symptoms also included an immediate prickling and burning sensation. The symptoms continued to worsen until the following morning, about 24 hours after initial exposure to the sun. D.L. does not recall po ingesting or topically applying any medication or other preparation to his skin, nor does he recall exposure to any chemical irritants, or poison ivy or oak. The morphology of the skin lesions is that of an exaggerated sunburn. The skin lesions are patchy in distribution, with greater density on his forearms and hands than on his neck and face. The posterior aspect of his neck and covered areas of his body was spared completely. What are some possible causes of his exaggerated sunburn reaction?

The most likely explanation for D.L.'s exaggerated sunburn reaction is *phototoxicity,* secondary to contact with psoralen-like chemicals from the plants at his job at the outdoor garden and greenhouse. Photoallergy is another possible cause of D.L.'s symptoms. Although much less common than phototoxicity,

photoallergy requires prior or prolonged exposure to the photosensitizing compound.

Presumably, D.L. came into contact with psoralen-containing plants and simultaneous exposure to sunlight. With an unusual distribution of lesions on his hands, forearms, neck, and face and the lack of lesions on areas not contacted by the plants or sunlight, the temporal relationship between the exposure and onset of symptoms places phototoxicity higher in the differential diagnosis. D.L. is unlikely to have a photoallergic reaction because of the lack of a delayed temporal relationship between the onset of symptoms and combined exposure to a psoralen-containing plant and sunlight. Unlike phototoxicity reactions, photoallergic reactions can spread to areas that have not been exposed to sunlight; however, D.L.'s lesions were limited to areas of skin exposed to sunlight.

Case 42-4, Question 3: What nonprescription remedies might you recommend for D.L. at this time?

General recommendations for the management of phototoxicity and photoallergy reactions are focused on the removal of exposure to the potential photosensitizer and reduced exposure to the sun. Patients should be counseled not to take any medications, po or topically, without first consulting with their health care provider to minimize exposure to other photosensitizers. D.L. should try wearing long-sleeved shirts, pants, and gloves when working to limit exposure to plant photosensitizers. He may also try applying a broad-spectrum sunscreen to protect his skin from UVB and UVA radiation. If these measures do not prevent further photosensitivity reactions, D.L. should consider a different type of employment. His presenting symptoms should be managed in a manner similar to that for an exaggerated sunburn.

PHOTOAGING

Incidence, Prevalence, and Epidemiology

Photoaging, or premature aging of the skin, involves skin changes that differ from those associated with normal chronologic aging.[121],[122] Aside from advancing age, risk factors that have been associated with photoaging include fair skin, male gender, high sun exposure, and smoking.[123],[124] Because recognizing photoaging and photodamage may prevent the progression or development of skin cancer, it is important that they are recognized as real medical problems, not just cosmetic or aesthetic concerns.

Etiology

Normal aging of the skin involves fine wrinkling of the skin, atrophy of the dermis, and a decrease in the amount of subcutaneous adipose tissue, all of which lead to a state of hypocellularity of the skin.[122] Photoaging involves a chronic inflammatory state induced by long-term exposure to UVA radiation from ROS, leading to a hypermetabolic state of the skin.[125] Photodamaged skin is characterized histologically by an accumulation of excessive quantities of thickened, degenerated elastic connective tissue fibers (elastosis).[122]

Photodamaged skin is characterized as being wrinkled, yellowed, and sagging. Mildly affected skin becomes irregularly pigmented, rough, and dry, with mild wrinkles. Moderately affected skin becomes deeply wrinkled, sagging, thickened, and leathery, with vascular lesions.[122] Largely irreversible, severely affected skin can become deeply furrowed and permanently (and irregularly) pigmented and may manifest premalignant and malignant lesions.[122] Areas of the body most commonly affected are the face, back of the neck, back of the arms and hands, the V-line of the neck of females, and balding areas of the head of males.

Clinical Application of Photoaging

CASE 42-5

QUESTION 1: P.B. is a 38-year-old female who has enjoyed many outdoor activities over the years. She lives in a moderate climate, with hot, sunny summers and cold winters. She feels that she appears older than other females of her age because of wrinkling and color changes of her skin. Her facial color is somewhat yellowish in appearance, and the fine wrinkles at the corners of her eyes and mouth have become more obvious. She has noticed the formation of small brown spots mottling parts of her face, hands, and forearms. P.B. has skin type III, a clear complexion, and skin that is sensitive to soaps, heavy cosmetics, and perfumes.

What nonprescription recommendations can you provide P.B. for treatment of her photoaged skin?

Many nonprescription agents known as cosmeceuticals, products marketed as cosmetics that contain biologically active ingredients, are targeted at reducing visible signs of aged skin. These products include α-hydroxy acids, retinol, ascorbic acid, hyaluronic acid, and lipoic acid. One particular product class widely used is α-hydroxy acids and polyhydroxy acids. In normal concentrations (5%–17%), they are included in many products to lessen the appearance of damage; however, in high concentrations, they are used as facial skin peels because of their keratolytic properties. They have been shown in studies to reduce skin roughness and sallowness; however, minimal impact was seen on wrinkles.[122,126] Topical ascorbic acid and lipoic acid have also been shown to improve skin texture and wrinkles,[127-129] whereas a coenzyme Q_{10} derivative (idebenone) may reduce skin roughness and fine lines while increasing skin hydration.[130] In patients who choose to use these products, it should be strongly recommended that they wear at least SPF 15 to 30 because they allow for greater absorption of UVR. These agents are not regulated by the FDA and, therefore, do not have substantial evidence supporting their effectiveness and can be very costly. Emphasis should be placed on protection from the sun, using photoprotective strategies previously discussed.

CASE 42-5, QUESTION 2: Are there any prescription products that you would recommend to P.B. to discuss with her physician?

There are several topical retinoids currently available that are derivatives of vitamin A and are effective for the signs of photoaging (see Chapter 41, Psoriasis). Tretinoin (all-trans-retinoic acid) is available as a cream or gel, and tazarotene is available as a cream, foam, and a gel; they are the only two topical retinoids FDA approved for the treatment of photoaging. Although not approved by FDA for photoaging, adapalene is also utilized off label, especially in those with more sensitive skin. A 2018 randomized controlled trial showed adapalene 0.3% gel to have comparable efficacy to tretinoin 0.5% cream for cutaneous photoaging.[131] In 2016, adapalene 0.1% gel (Differin) became the first retinoid approved for OTC use for acne. These agents are effective in partially reversing some of the clinical and histologic changes of photoaging by lessening fine wrinkles, mottled pigmentation, and the tactile roughness associated with photoaged skin through mechanisms such as inhibition of metalloproteinase expression.[132-135] Additional benefits of retinoid therapy include the formation of new dermal collagen and vessels, reduction in the number and melanization of freckles, resorption of degenerated connective tissue fibers, and treatment of premalignant and malignant skin lesions.[136] In one of the initial trials, all subjects treated (100%) demonstrated global improvement in the signs of photoaging, with 53% showing moderate changes and the remainder having at least slight improvement. Of the clinical parameters assessed, the most impressive improvements were found with facial skin sallowness, with respondents developing a healthy, rosy glow.[133] These agents are more potent than the retinoids found in OTC products such as retinyl esters, retinol, and retinaldehyde and, therefore, produce more profound results.

Case 42-5, Question 3: Would P.B. be an appropriate candidate for therapy with a topical retinoid product (eg, tretinoin)?

Topical retinoid therapy is most effective for patients ages 50 to 70 years with moderate-to-severe photoaging and for prophylactic use

in patients undergoing the initial changes of photoaging.[132] Recently, P.B. has noticed some of the skin changes consistent with early photoaging and would be a good candidate for prophylactic therapy with topical tretinoin. Treatment may improve her sallow skin color and lessen the mottling on her face and forearms and fine wrinkles at the corners of her eyes and mouth, as well as prevent worsening of the photoaging process that she is experiencing.

Case 42-5, Question 4: P.B.'s physician calls you asking for dosing recommendations for tretinoin. What advice do you provide?

Because both the beneficial and adverse effects of topical retinoid therapy are dose dependent, the underlying goal is to provide the maximal benefit by using the highest concentration that causes minimal skin irritation. Considering P.B.'s skin sensitivity to soaps, cosmetics, and perfumes, her skin is likely to be irritated easily by topical therapy; therefore, it would be best to initiate therapy with the lowest strength (eg, tretinoin 0.025% cream or tazarotene 0.05% cream). These agents are usually applied every night at bedtime, but in some instances, they are applied initially on an every-other-night basis until the skin accommodates to the irritant effects. The likelihood of irritation depends on the type of vehicle more than the concentration of the agent.[136] The cream or the microsphere gel formulations cause the least skin irritation and would be preferred for initiating therapy for P.B. The microsphere gel formulation is preferred for patients with persistent acne or for those with focal actinic lesions. Younger patients often prefer the gel because it leaves no residue and is compatible with most cosmetics. The solution and gel may be better tolerated in older patients with oily, thick, pigmented skin.

Case 42-5, Question 5: You are now dispensing tretinoin cream 0.025% to P.B. What patient counseling should P.B. be given?

Before applying the cream to her face at bedtime, P.B. should wash her face gently, using her fingertips and mild soap, then pat her skin dry with a towel. If gentle washing with her fingers does not remove the dry, peeling skin, a washcloth can be used gently on the face. The treated stratum corneum is fragile, and erosions could occur if P.B. is not careful when washing. After waiting about 15 minutes, she should apply a pea-sized amount of cream to her forehead and spread the cream evenly over her entire face. Care should be exercised while applying the cream to the areas adjacent to the eyes and mouth because tretinoin can cause irritation and burning of mucous membranes.

Skin irritation can be expected to start in the first 3 to 5 days of therapy and, hopefully, will subside in 1 to 3 months. Irritation can manifest as erythema, peeling, burning, and stinging. If P.B. experiences excessive irritation, she can reinitiate the regimen on a slower timeline by applying the cream on an every-other-night or every-third-night basis for the first 2 weeks to reduce skin irritation, or she can also apply a topical corticosteroid product such as hydrocortisone 1% cream. Once she begins to tolerate the therapy, her frequency of applications and strength of cream should be titrated to cause mild scaling with only occasional mild erythema. A thicker film of cream can be applied to photodamaged areas. After 9 to 12 months of therapy, she can begin maintenance therapy, which consists of application two or three nights a week indefinitely.

Because these agents can dry the skin, P.B. should be counseled to use moisturizers during the day to help decrease the dryness and irritation of the skin. Nighttime application of moisturizers should be discouraged when topical tretinoin is being used because the moisturizers can cause a pH incompatibility with the cream and possibly dilute the concentration of tretinoin. With a thinning of the stratum corneum, P.B.'s skin may be more susceptible to the effects of UVR. For this reason, as well as to prevent further actinic damage, P.B. should begin prophylactic daytime application of a sunscreen. Considering her skin type (III) and early photoaging changes, a sunscreen with an SPF of at least 30 would be appropriate. P.B. should be counseled not to become discouraged by

any apparent lack of response; her skin damage is mild, her response to therapy will be gradual, and part of the goal of therapy is to prevent further damage. Her wrinkles may actually appear to worsen early in therapy owing to an initial buildup of the stratum corneum. P.B. should avoid facial saunas and irritating soaps and cosmetics. Retinoids are recognized as being teratogenic, and although risk is more highly associated with oral forms more commonly used for acne, the use of these should generally be avoided in any patients who are pregnant or those planning to become pregnant.[137]

BURN INJURIES

Incidence, Prevalence, and Epidemiology

Approximately 489,000 Americans are treated for burns annually.[138] With the development of multidisciplinary burn centers and a better understanding of the pathophysiology of the burn wound, survival of patients with second- and third-degree burns has improved by five to six times during the past three decades.[139] The majority of burn patients admitted to the hospital are males, with a mean age of 32 years. The two most commonly reported etiologies are fire/flame and scalds, accounting for almost 8 of 10 burn admissions. Seventy-three percent of the burn injuries, with known place of occurrence, occurred in the home.[140]

Burn injuries range from relatively minor, superficial injuries to severe, extensive skin loss resulting from contact with hot solids and liquids, steam, chemical agents, electricity, or other physical agents, such as UVR or infrared radiation. Teenagers and adults between the age of 17 and 30 years are most commonly involved in accidents with flammable liquids, but the mortality associated with clothing ignition continues to decrease as a result of the use of flame-retardant forms of fabric in clothing. Both income and income

disparity by country are associated with higher rates of burn-related deaths.[139]

Complications such as fluid and electrolyte imbalances, metabolic derangements, respiratory failure, sepsis, scarring, and functional impairment are the primary causes of hospitalization for these cases. Most burns, however, are minor and can be managed in an ambulatory environment, provided the burned patient is evaluated carefully, the severity of the burn is assessed accurately, and proper and continuous follow-up care is ensured.

Etiology

ZONES OF INJURY

The skin functions as a protective barrier of the underlying organ systems from trauma, temperature variations, harmful penetrations, moisture, humidity, radiation, and invasion by microorganisms (see Fig. 39-1 in Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders). It is also involved with carbohydrate, protein, fat, and vitamin D metabolism; produces secretions that lubricate the skin; is involved with the immune response; and provides the body with the sense of touch.

Burn wounds caused by thermal injury can be described by varying zones of injury.[141] The most peripheral area of injury is the *zone of hyperemia.* The tissue in this area is characterized by inflammatory changes with minimal tissue damage. The *zone of stasis* is the next area of injury, extending inward from the zone of hyperemia. This area involves ischemic, damaged tissue, with blood vessels only partially thrombosed. The damaged endothelial linings of blood vessels within this zone of injury may trigger further thrombosis, resulting in further ischemia, cell death, and deepening of the burn wound. This process of further injury can occur 24 to 48 hours after the initial injury. Drying of the burn wound or infection can cause deepening of the burn wound by preventing reestablishment of circulation to injured tissue. The central-most area, or the *zone of coagulation,* is characterized by thrombotic vessels and necrotic

tissue. This area absorbs the most thermal energy, resulting in the greatest tissue damage. Minor burns may involve only the most peripheral zones of injury, whereas severe burns encompass all three zones of injury.

EXTENT OF INJURY

Rule of nines

Total body surface area (TBSA) is used to assess the size of burns of the skin. The burned surface area is calculated as a percentage of TBSA to determine burn size. Burn severity is proportional to the percent of TBSA involvement and depth of the wound. The percent of TBSA for adults can be estimated by using the "rule of nines," in which each arm constitutes 9% of the TBSA, the head 9%, each leg 18%, the front and back of the torso 18% each, and the genitalia 1%.[142] For children younger than 10 years, the percent TBSA must be adjusted because their bodies have different proportions. Variations of the Lund and Browder chart have been used for this purpose.[143] At birth, the infant's head constitutes about 19% of the TBSA. For each additional year of age, the head decreases by about 1%, and the BSA of the legs increases by about 1% of the patient's TBSA, so a quick estimation of the size of a burn can be made.

Classification of wounds

Burn wounds are also classified according to the depth of tissue damage. Determining the depth of the burn wound can be difficult during the first 24 to 48 hours because of the presence of edema and continued tissue ischemia and infection, both of which can cause deepening of the wound. In addition, the depth of destruction can vary within the same burn, and skin surface characteristics may not match underlying tissue damage, making assessment of the burn wound difficult.[141]

First-Degree Burns (Superficial-Thickness Burn)

First-degree burns result from injury to the superficial cells of the epidermis; a common example is a mild sunburn. The burned skin does not form blisters, but it does become erythematous and mildly painful. This superficial-thickness burn heals within 3 to 4 days without scarring.

Second-Degree Burns (Partial-Thickness to Superficial Burn)

Second-degree burns may be superficial or deep, depending on the depth of dermal involvement. Superficial second-degree burns involve the epidermis and the upper layer of the dermis. The burn surface is often erythematous, blistered, weeping, painful, and very sensitive to stimuli. The erythema blanches with pressure, and the hair follicles, sweat, and sebaceous glands are spared. Superficial second-degree burns heal spontaneously within 3 weeks with little, if any, scarring. Deep second-degree burns involve the deeper elements of the dermis and may be difficult to distinguish from third-degree burns. The burn surface is pale, feels indurated or boggy, and does not blanch with pressure. This wound is less painful than more superficial wounds; some areas may be insensitive to stimuli. Healing occurs slowly over the course of about 35 days with eschar formation and possible severe scarring and permanent loss of hair follicles and sweat and sebaceous glands.

Third-Degree Burns (Partial-Thickness to Deep Burn)

Third-degree burns entail complete destruction of the full thickness of the skin, including all skin elements. The wound may appear pearly white, gray, or brown and is dry and inelastic. Pain is sensed only when deep pressure is applied. If the wound is small, healing over the course of several months can occur by epithelial migration from the margins of the injury, with scar and contracture formation. Third-degree burns are repaired by excision and grafting, or excision and primary closure to prevent contractures of the skin.[144]

Fourth-Degree Burns (Full-Thickness Burn)

Fourth-degree burns are similar to third-degree burns, except that devitalized tissue extends into the subcutaneous tissue, fascia, and bone. These burns are blackened in appearance; they are dry and generally painless because of destruction of nerve endings and are at high risk for infection.

COMPLICATIONS OF SEVERE BURN WOUNDS

Fluid loss

In severe burns, release of vasoactive mediators and capillary injury cause sequestration of large amounts of body fluid, plasma, and electrolytes in extravascular compartments, resulting in edema both locally and throughout the entire body. This redistribution of fluid, along with the loss of large amounts of fluid, electrolytes, and protein into the open wound, can cause shock, organ failure, and death if not adequately replaced.[145]

Infection

The most important threat to survival of the fully resuscitated patient is infection, with burn wound sepsis and pneumonia being the leading causes of death.[145] Impairment of the local mechanical defenses of the skin and respiratory tract and loss of circulation to the burn wound margins contribute to increased infection risk. Devitalized tissue and tissue exudates provide an ideal environment for the proliferation of bacteria. Colonization of gram-positive bacteria occurs if topical antimicrobial therapy is not initiated promptly, and gram-negative bacteria may predominate by the fifth day after injury.[145] Systemic antibiotics are of limited benefit in full-thickness burns and are used only to treat infections documented by wound biopsy.[146] Topical antimicrobials, local wound care, and strict infection control practices are the mainstays of controlling burn wound infections. Devitalized tissue initiates and perpetuates a sepsis-like state in the absence of an identifiable focus of infection.[145] For this reason, as well as for infection control, early excision of devitalized tissue and closure of the burn wound by skin grafting or substitutes have been adopted by many burn centers.

Inhalation injury

Burn injuries complicated by inhalation injury are associated with greatly increased mortality rates. Injury to the tracheobronchial mucosa is caused by inhalation of smoke or flames and may result in bronchospasm, ulceration of the mucous membranes, damage to cell membranes, edema, and impairment of bacterial ciliary clearance. The early symptoms of pulmonary injury (hoarseness, dyspnea, tachypnea, and wheezing) may not be evident for 24 to 48 hours, so patients with suspected inhalation injury (ie, facial burns or entrapment in a closed space) must be examined carefully. The diagnosis is established by bronchoscopy, and management may include endotracheal intubation and mechanical ventilation. Maintenance of the patient's fluid status is essential. Corticosteroids do not influence survival rates and should not be routinely administered to patients with inhalation injury. They can also increase morbidity and mortality associated with burns and inhalation injury by increasing the risk of infection.[145]

Clinical Management of Minor Burns

TRIAGE

CASE 42-6

Question 1: S.T., a 17-year-old, nonobese boy, has just burned the calf of his right leg on the muffler of his motorcycle. Immediately after being burned, S.T. was able to rinse his leg with cool water from a garden hose. The burn on his leg is about twice the size of the palm of his hand and appears erythematous and weeping. He sustained no other injury, but now he is in considerable pain. S.T. has no significant medical history.

Should S.T. be referred to a health care provider, or can he safely self-treat his burn? What patient information is necessary to consider in making this decision?

Before recommending treatment for a patient with a minor burn, it is important to accurately assess the patient to determine whether he or she can self-treat safely or whether referral or hospitalization is

necessary. The location and severity of the burn, the patient's age and state of health, and the cause of the burn injury all must be considered.

American Burn Association treatment categories

Three treatment categories for burn injuries are recommended by the American Burn Association: major burn injuries; moderate, uncomplicated burn injuries; and minor burn injuries.[147]

- *Major burn injuries* are second-degree burns with >25% TBSA involvement in adults (20% in children); all third-degree burns with 10% TBSA involvement; all burns involving the hands, face, eyes, ears, feet, and perineum that may result in functional or cosmetic impairment; high-voltage electrical injury; and burns complicated by inhalation injury, major trauma, or poor-risk patients (elderly patients and those with debilitating disease).
- *Moderate, uncomplicated burns* are second-degree burns with 15% to 25% TBSA involvement in adults (10%–20% in children); third-degree burns with 2% to 10% TBSA involvement; and burns not involving risk to areas of specialized function, such as the eyes, ears, face, hands, feet, or perineum.
- *Minor burn injuries* include second-degree burns with <15% TBSA involvement in adults (10% in children), third-degree burns with <2% TBSA, and burns not involving functional or cosmetic risk to areas of specialized function.

Patients with minor burn injuries may be treated on an outpatient basis if no other trauma is present; if circumferential burns of the neck, trunk, arms, or legs are not present; and if the patient is able to comply with therapy. After initial evaluation by a health care provider, patients may self-treat a second- or third-degree burn only if <1% BSA is involved.

Major or moderate, uncomplicated burns necessitate hospital admission, and surgical referral is recommended for patients of all ages who have deep second- or third-degree burns covering 3% of

the TBSA. Specific criteria exist to determine need for patient transfer to a burn center.[148]

Age- and disease-related recommendations

Children younger than 2 years and elderly patients with a burn injury should be referred for evaluation because these patients may not tolerate any trauma associated with the burn. Burn patients with any other medical condition, such as diabetes mellitus, cardiovascular disease, immunodeficiency disorders (eg, human immunodeficiency virus [HIV]–associated disease, patients receiving cancer chemotherapy), renal disease, obesity, or alcoholism, may be more susceptible to complications from the burn and may have compromised wound healing.

ETIOLOGY

The etiology of a burn should always be considered because this may provide some insight into the burn presentation and its management. Electrical burns can appear to be superficial because external injury may occur at only the entrance and exit sites of the current. These burns, however, can cause extensive damage to underlying nerve and muscle tissue that is not initially evident. Except for very minor electrical burns, these patients should be referred for further evaluation. S.T. has sustained a superficial second-degree burn over about 2% of his TBSA. Even though the burn wound on his leg was caused by thermal injury and is relatively minor, S.T. should be referred for further evaluation and treatment because it covers over 1% of his TBSA and is on his leg.

TREATMENT

Case 42-6, Question 2: How should S.T.'s burn be treated? What treatment alternatives may be used for S.T.? What immunization should S.T. be questioned about?

Goals of treatment and immediate care

Treatment goals for first- and second-degree burns are to relieve the pain associated with the burn, prevent desiccation and deepening of the wound and infection, and provide a protective environment for healing. Immediate care of the wound should be application of cold, wet compresses, or immersion in cool water.

S.T. may have prevented extension of the burn to deeper layers of tissue and alleviated some of his pain from the burn by immediately irrigating the wound with cool water. Next, the area should be cleansed with a mild hypoallergenic soap (eg, Basis, Purpose) and water. The sterile, nonadherent, fine-mesh gauze dressing impregnated with hydrophilic petrolatum (eg, Xeroflo, Kendall; 3% bismuth tribromophenate) should be placed over the wound. This type of dressing offers bacteriostatic activity and prevents the gauze from adhering to the wound and allows the burn exudate to flow freely through the dressing, thus preventing maceration.

A second layer of absorbent gauze should be placed over the petrolatum gauze, and a supportive layer of rolled gauze can be used to keep the dressing in place. The outer layer must not be too constricting, and the dressing should be replaced every 48 hours after recleaning the area and inspecting for signs of infection. If S.T.'s wound continues to weep, it may be beneficial to soak his wound or apply a towel saturated with water, normal saline, or Burow solution (diluted 1:20 or 1:40) for 15 to 30 minutes at least four times daily (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders). The use of butter, grease, or similar home remedies should be avoided in the treatment of burns because these measures tend to retain the thermal energy sustained in the burn and may increase the area of thermal injury. Because burn patients are susceptible to secondary tetanus infections, S.T. should receive a tetanus toxoid booster if he has not been immunized within the previous 10 years.

Skin substitutes and synthetic dressings

Advances in the development of skin substitutes are being used to achieve the elusive goal of finding a skin replacement to mimic completely the interaction and functions of dermis and epidermis. Although this goal has yet to be achieved, a growing number of synthetic and biologic products are available that can serve important roles in caring for burn patients.[148] Examples of some of the current modalities include human cadaver skin allografts, xenografts from porcine skin, and allodermal grafts.

Semisynthetic or Biosynthetic Dressings

Biosynthetic dressings can be used to facilitate healing while reducing the number of dressing changes. They are composed of semipermeable membranes, allowing the draining of exudate, but allowing blood or sera to clot and adhere to the dressing while epithelialization occurs. Examples of these dressings include Biobrane® (Smith & Nephew, Andover, MA), AWBAT® (Aubrey, TX) and AWBAT® Plus (Aubrey, TX), and Suprathel® (Wound Source, Atlantic Beach, FL).[149],[150]

For superficial- to partial-thickness burns, numerous agents are available OTC. DuoDerm® (ConvaTec, Bridgewater Township, NJ) is a hydrocolloid dressing, whereas OpSite (Smith & Nephew, Andover, MA) and Tegaderm (3M, St. Paul, MN) are elastomeric polyurethane films. Comfeel® (Coloplast, Minneapolis, MN) is a semipermeable polyurethane film coated with a flexible, cross-linked adhesive mass containing sodium carboxymethyl cellulose (NaCMC) as the principal absorbent and gel-forming agent.

Hyaluronic Acid

Produced by fibroblasts, this group of dermal matrices has a demonstrated positive impact on scar-free fetal wound healing and is also used commercially as a dermal filler. It can be obtained from *Streptococcus* fermentation or extracted from rooster combs. It is available as a scaffold for keratinocytes (Laserskin), an acellular dermal matrix (Hyalomatrix, Anika, Bedford, MA), and as a cellular dermal matrix (Hyalograft-3D).[151]

Alternatives in treating S.T.'s second-degree burn include the use of synthetic dressings and topical antimicrobial agents. Synthetic dressings serve as skin substitutes that are applied to fresh, clean, and moist burns. They are trimmed to about the size of the burn and left in place until the burn is healed or the dressing separates from the wound spontaneously. Indicated for superficial second-degree burns, biosynthetic dressings keep the wound warm and moist, allowing for a faster rate of healing. These dressings offer a significantly lower rate of infection, less frequent dressing changes, with less pain and electrolyte and albumin loss.

Tissue-Engineered Biologic Dressings

Tissue-engineered biologic dressings (eg, Dermagraft, Organogenesis; OASIS Wound Matrix, Smith & Nephew) have been used in the treatment of burns, chronic ulcers, surgical wounds, and other desquamating dermatologic conditions.[152],[153] Using an appropriate biologically active matrix to accelerate wound healing and achieving skin reconstruction is well established. Cellular components migrate to the wound from preexisting cell populations in adjacent tissue. Both circulating marrow-derived stem cells and preexisting organ-specific stem cells can contribute to tissue regeneration.[152]

Topical antimicrobial agents

Silver Sulfadiazine

Silver sulfadiazine 1% cream (Silvadene, generic; Aquacel® Ag [hydrofiber dressing with silver]; ConvaTec) is the usual agent of choice because it has broad-spectrum gram-positive and gram-negative antibacterial activity, provides reasonable eschar penetration, and is easy and painless to apply and wash off. The cream is a 1% suspension of silver sulfadiazine in a water-miscible base. As a consequence of poor water solubility, the active agent shows only limited diffusion into the eschar. Silver sulfadiazine cream is most effective when applied to burn wounds immediately after thermal injury to prevent bacterial colonization of the burn

wound surface as a prelude to intraeschar proliferation. This agent has the advantages of being painless when applied to the wound and being free from acid–base and electrolyte disturbances. The limitations of silver sulfadiazine cream include the potential for allergic reactions owing to its sulfadiazine moiety, silver staining of the treated burn wound, hyperosmolality, methemoglobinemia, and hemolysis as a result of a congenital lack of glucose-6-phosphate dehydrogenase.[154] Leukopenia, previously considered to be an adverse drug event associated with use of silver sulfadiazine, occurs when using other topical agents during burn care.[154] An evidence-based review of use of silver sulfadiazine in burns suggested that whereas there is evidence of antibacterial activity, no direct evidence is seen of improved healing or reduced infection compared with normal dressings.[155] In partial-thickness burns, the use of Aquacel Ag offers less treatment to reepithelialize burns 100% with less pain, as compared with silver sulfadiazine.[156] This agent should not be applied around the eyes or mouth in patients with hypersensitivity to sulfonamides or in pregnant or breastfeeding females.

Mafenide Acetate

Mafenide acetate (Sulfamylon®, UDL Labaratories, Rockford, IL) is an 11.1% cream formulation of mafenide acetate in a water-dispersible base, or a 5% powder for topical solution. An investigation in a pediatric burn population demonstrated the effectiveness of a 2.5% solution, without a change in the incidence of bacteremia or wound infection, and without experiencing adverse drug events.[157] As a water-soluble agent, mafenide diffuses freely to establish an effective antibacterial concentration throughout the eschar and at the interface of viable–nonviable tissue, where bacteria characteristically proliferate before invasion. Because of this characteristic, mafenide is the best agent for use if the patient to be treated has heavily contaminated burn wounds, if treatment is delayed for several days after the burn occurred, or if a dense bacterial population already exists on and within the eschar. Adverse effects include hypersensitivity reactions in 7% of patients (usually

responsive to antihistamines), pain or discomfort for 20 to 30 minutes when applied to partial-thickness burns (seldom a cause for discontinuation), and inhibition of carbonic anhydrase. The inhibition of carbonic anhydrase can produce both an early bicarbonate diuresis and an accentuation of postburn hyperventilation. The resulting overall reduction of serum bicarbonate levels renders such patients liable to a rapid shift from an alkalotic to an acidotic state. If acidosis should develop during use of mafenide, the frequency of application should be reduced to once daily, or it should be omitted for 24 to 48 hours, with buffering used as necessary and with efforts made to improve pulmonary function.

Either topical silver sulfadiazine or mafenide should be applied in a one-eighth-inch (0.31 cm) layer to the entire burn wound with a sterile gloved hand immediately after initial debridement and wound care. Twelve hours later, to ensure continuous topical treatment, a one-eighth-inch (0.31 cm) coat of cream should be reapplied to those areas of the burn wound from which it has been abraded by clothing. The topical cream should be cleansed gently once each day from all of the burn wound, and the wound should be inspected. Daily debridement should be carried out to a point of bleeding or pain without the use of general anesthesia. After debridement, the wound should be covered again by the topical cream.

In S.T.'s case, silver sulfadiazine cream could be chosen to treat his burn on an outpatient basis if an assessment determines that he is at particular risk of infection. The cream would be applied in a thin layer over the wound and covered with absorbent gauze and wrapped with rolled gauze. The dressing must be changed twice daily to maintain an application of cream that is biologically active. Topical bacitracin and the combination of polymyxin B and bacitracin are transparent formulations that also can be used, but, because of limited efficacy, may be desirable for use only on small, second-degree burns on the face.

Oral analgesics and topical protectants

S.T.'s burn pain can be treated with oral OTC analgesics, acetaminophen, naproxen, or ibuprofen. If these analgesics do not provide adequate relief, an oral opioid such as tramadol, codeine/acetaminophen, or hydrocodone/acetaminophen may be of additional benefit in extreme circumstances.[158] Topical protectants, such as allantoin, calamine, white petrolatum, or zinc oxide, are safe and effective in treating first-degree and minor second-degree burns. These agents protect the burn from mechanical irritation caused by friction and rubbing and prevent drying of the stratum corneum.

Postwound care

Postwound care is an essential part of total burn management to ensure adequate follow-up subsequent to wound healing, including psychological support. Good burn care that helps to alleviate physical discomfort, pain, and scarring and that promotes good wound healing will also provide psychological benefits for the patient. Healed wounds should be moisturized on a regular basis. Pruritus can be a major problem after burn injury. To reduce itching, moisturizers can be applied, and oral antihistamines may be necessary.[159] Protection from the sun will help prevent further thermal damage or pigmentation changes to the affected area. Patients in this population should avoid the sun after a burn injury whenever possible, with use of a sunscreen with an SPF of at least 50 recommended.[160] If surface changes occur (eg, skin becomes hypertrophic, or blisters or new wounds appear), the patient should be advised to return for evaluation.

Osteoarthritis

Dominick P. Trombetta and Christopher M. Herndon

CORE PRINCIPLES		CHAPTER CASES
1	Osteoarthritis (OA) is a chronic, progressive condition, primarily affecting females, that causes loss of articular cartilage in the hands, knees, hips, and cervical and lumbar spine. OA causes significant pain and functional disability and increases costs to our health care systems.	**Case 43-1 (Question 1)**
2	The evolving role of cytokines and the resultant imbalance between cartilage maintenance and destruction contribute to the pathophysiology of OA. There are no current disease-mitigating therapies.	**Case 43-1 (Questions 2, 3), Figure 43-1**
3	The typical presentation includes stiffness and pain unilaterally in one or more joints lasting <30 minutes after a	**Case 43-1 (Questions 1, 2)**

	period of immobility. This causes significant limitations in activities of daily living (ADLs) and overall quality of life.	
4	Conservative treatment strategies include weight loss, self-management, aerobic exercise, strength training, and physical and occupational therapies to best maintain optimal functional status.	**Case 43-1 (Question 4)**
5	Initial trials of routine dosing of acetaminophen, topical agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and intra-articular glucocorticoid injections represent initial pharmacologic interventions of OA.	**Case 43-1 (Questions 5, 6)** **Case 43-2 (Questions 1–4), Tables 43-1–43-3, Figure 43-2**
6	Intra-articular hyaluronan, tramadol, and duloxetine may be considered in those patients with insufficient relief of symptoms and worsening function after initial pharmacologic strategies have been attempted.	**Case 43-2 (Questions 1–6)**
7	A consistent and systematic approach to the management of chronic pain caused by OA can help identify patients with limitations in ADLs and prevent further disability. Then, the effectiveness of current therapies can be more appropriately evaluated, and the treatment plan can be updated.	**Case 43-1 (Questions 5, 7)** **Case 43-2 (Questions 1–6)** **Case 43-3 (Questions 1, 2)**

INTRODUCTION

Osteoarthritis (OA) is a chronic, progressive disorder characterized by changes to articular cartilage and bone primarily in the hands, knees, hips, and spine. The prevalence of OA was described between 2008 and 2014 as one out of seven adults, or ~32.5 million people in the United States.[1,2] Results from another study from 2013 to 2015 revealed that 59% (32.2 million people) age younger than 65 years had arthritis.[3] Females seem to carry the larger burden of the disease versus males (age-adjusted prevalence of 23.5% and 18.1%, respectively). The importance of these findings suggests that OA is not just a disease of the elderly but a chronic medical condition affecting those still working. Another study collaborated similar findings, describing 14 million people who had symptomatic OA, including 2 million people younger than age 45 and 6 million people ages 45 to 64 years.[4] Also, the ethnic minority population that was significantly younger than the White population has reported symptomatic knee OA, and this number is expected to increase.

Adults with OA may also have chronic conditions such as coronary disease, diabetes, or obesity. These conditions are known to be associated with lower levels of physical activity. Improving physical activities and reducing barriers may be particularly beneficial in these patient populations.[3]

ETIOLOGY

OA has been previously described as disease of cartilage that has undergone significant wear and tear. It is now known to be a more complex and dynamic process. Primary OA cannot be traced to any identifiable cause. In secondary OA, a known etiology or cause has been determined. We know that OA affects not only articular cartilage but also periarticular muscles, subchondral bone and ligaments, synovial membranes, and the entire joint capsule. The interplay of cellular, biochemical, and mechanical processes underlies the disease. Various risk factors have been identified and can be classified as modifiable and nonmodifiable. Modifiable risk

factors of OA include obesity and joint trauma. Increased body weight has been correlated with increased risk of OA of the knee, but not of the hip. Excess weight contributes to the biomechanical forces and stresses on the knee joints. The cascade of increased pain leading to decreased function and further worsening of obesity can be a difficult cycle to break. Weight loss and moderate amounts of activity improve symptoms of OA of the knee and improve overall health. Regular exercise and physical activity do not increase the risk of OA in normal joints and are necessary to maintain cartilage. Nonmodifiable risk factors are advancing age, sex, genetics, race, and joint location. Typically, the development of symptomatic OA occurs with increased age predominantly in the weight-bearing joints, although many females are affected by localized inflammation of the proximal and distal interphalangeal joints known as Bouchard and Heberden nodes, respectively.[5] The consequences of the biochemical and mechanical changes are articular cartilage that is less functional with structural abnormalities of cartilage, joint capsule, and subchondral bone (**Fig. 43-1**).[5]

Figure 43-1 Schematic representation of the convergence of modifiable and nonmodifiable risk factors and morphologic changes associated with osteoarthritis. PATHOGENESIS

In the early stages of OA, changes that appear to begin the complex abnormalities seen in the joint capsule, subchondral bone and ligaments, periarticular muscles, and synovial membranes occur.[5] Initial insult to the articular cartilage can result from repetitive damage with time. Either repetitive or traumatic injury to articular surfaces initiates the cascade, leading to the release of inflammatory cytokines (tumor necrosis factor [TNF], interleukin [IL-1]), nitric oxide, and enzymes that break down the extracellular matrix. The breakdown of the extracellular matrix results in cartilage that is less elastic, more vulnerable, and less able to support joint loads and stiffening of subchondral bone. The cartilage is less able to support forces, with diminished efficacy for providing joint lubrication and weight distribution across the joint. In early OA, chondrocytes attempt to repair joint damage by forming osteophytes, which try to stabilize the joint or alter the biochemical properties of cartilage. The formation of osteophytes may provide an increased surface area over which to distribute the forces across the joint. Cyst formation likely arises via synovial fluid pressure exerted on the fissures or other structural defects in subchondral bone.[5]

Early in the disease process, the water content of the cartilage is increased. However, this less viscous cartilage is structurally weaker than is normal cartilage. With disease progression, the proteoglycan concentrations diminish with shorter glycosaminoglycan side chains, resulting in decreases of net aggregate proteins. Eventually, the initial water swelling of the cartilage is replaced by cartilage with a reduced propensity to allow the bone to distribute the force and slide on bone.[5] Distinct alterations in cartilage matrix metabolism favor catabolism. Chondrocytes are unable to maintain the production of essential macromolecules necessary for healthy cartilage. However, the syntheses of those enzymes that break down the matrix are increased by the same chondrocytes. The enzymes that degrade proteoglycans and collagen are called aggrecanases and collagenases, respectively. The control of these enzymes is

complicated by enzymatic activation of latent proteins and inactivation by proteinase inhibitors. Ultimately, the imbalance between cartilage maintenance and degradation leads to erosion and eventual cartilage destruction.[5]

OVERVIEW OF DRUG THERAPY

The current treatment of OA is to provide analgesia, allowing performance of activities of daily living (ADLs), participation in exercise programs facilitating weight loss for obese or overweight individuals, recommend appropriate self-managed programs, and Tai chi. There are no disease-mitigating strategies that have demonstrated acceptable safety and efficacy in the treatment of OA. Current practice guidelines largely recommend or conditionally recommend topical nonsteroidal anti-inflammatory drugs (NSAIDs) as first-line treatment alternatives for OA of the hand and knee.[6,7] Acetaminophen is still conditionally recommended for those patients unable to tolerate topical or systemic NSAIDs. Although topical therapies include capsaicin creams, capsaicin gels, capsaicin liquids, capsaicin lotions, capsaicin topical patches, lidocaine topical patches, lidocaine topical creams, ointments, and gels, diclofenac topical gel, diclofenac topical patch, and diclofenac topical solution should each be evaluated individually based on its harm-to-benefit profile and supporting efficacy data. In patients presenting with effusions of the knee, aspiration of the affected joint and intra-articular (IA) injections of corticosteroids may be therapeutic once infectious etiologies have been ruled out.[7] The initial treatment for OA pain and stiffness is acetaminophen given on a routine basis for a 2- to 3-week trial in doses typically <4 g/day or <3 g/day in patients older than age 65 years, unless clinically contraindicated. Acetaminophen offers a considerable degree of safety over NSAIDs for mild-to-moderate OA disease. Unintentional liver injury may result from overuse of acetaminophen above recommended doses, in combination with over-the-counter (OTC) acetaminophen-containing

products, or the opioid–acetaminophen products available by prescription. A trial of a selective or nonselective NSAID would be a reasonable consideration in patients with inadequate response to acetaminophen or presenting with pain and inflammation. A careful risk and benefit analysis must be individualized for each patient starting an NSAID. Adverse events of gastrointestinal (GI) bleeding, diminishing renal function, liver toxicity, and cardiovascular risk of the specific medication considered need to be carefully assessed and a plan for therapeutic monitoring implemented. In addition, consideration of drug–drug interactions or drug–disease interactions is also warranted. In patients with inadequate relief in symptoms and worsening functions, there are few alternatives outside of surgical interventions. IA injections of hyaluronic acid derivatives are no longer recommended in the treatment of hip OA.[7] Tramadol may represent a useful option for many patients unless precluded because of seizures or opioid use disorder, or drug–drug interaction potential. There are currently no recommendations for the use of oral glucocorticoids in the treatment of OA. Glucosamine and chondroitin can be discussed with those patients interested in holistic therapies for hand OA; however, they are not recommended for OA of the knee or hip.[6,7] Recently, a small, randomized control trial suggests curcuma longa, a Chinese herbal medicine with pleiotropic properties, was of benefit for knee pain.[8] The chronic use of oral or transdermal opioids or opioid/acetaminophen combinations for pain management should be discouraged because of the limited evidence demonstrating benefit and the high potential for adverse drug reactions.

CLINICAL MANIFESTATIONS

Clinical Presentation of Osteoarthritis

CASE 43-1

QUESTION 1: R.T., a 64-year-old nonsmoking female, presents to her primary care physician reporting pain and stiffness in her right knee. The pain is usually worse in the morning and lasts for about 15 to 20 minutes and then subsides throughout the day. She reports some increased difficulty taking care of her grandchildren while her daughter is working. Her medical history is significant for hypothyroidism, hypertension, and hyperlipidemia. Social history is negative for tobacco and alcohol use. R.T. currently takes amlodipine 5 mg daily, levothyroxine 88 μg daily, and atorvastatin 20 mg daily. On physical examination, there is a varus misalignment of the knees. The right knee has no swelling or synovial effusions, and crepitus is noted on examination of passive motion. A radiograph shows right knee joint space narrowing with osteophyte formation at the joint margins.

Laboratory values and vital signs obtained at this visit include the following:

Blood pressure (BP), 130/78 mm Hg
Heart rate (HR), 80 beats/minute
Height, 64 inches (162.56 cm)
Weight, 205 pounds (92.99 kg)
Body mass index (BMI), 35.2 kg/m^2
Sodium, 140 mEq/L
Potassium, 4.5 mEq/L
Blood urea nitrogen (BUN), 10 mg/dL
Creatinine, 0.9 mg/dL
Estimated glomerular filtration rate (eGFR), 63 mL/minute
Thyrotropin (or thyroid-stimulating hormone [TSH]), 3.08 mIU/mL
White blood cells (WBCs), 5 × 10^3/μL
Red blood cells (RBCs), 4.7 × 10^6/μL
Hemoglobin, 12.7 g/dL
Hematocrit, 38.2%
Uric acid, 5 mg/dL
C-reactive protein (CRP), 0.9 mg/dL
Erythrocyte sedimentation rate (ESR), 18 mm/hour
Anticyclic citrullinated peptide (CCP) antibodies, negative
Total cholesterol, 160 mg/dL
High-density lipoprotein (HDL), 45 mg/dL

What signs and symptoms suggestive of OA are present in R.T.?

R.T. presents with unilateral right knee pain that is worse in the morning and subsides throughout the day. The OA diagnosis can be made by a good history and physical examination. Laboratory studies are not needed to confirm the diagnosis of OA, but a normal ESR rules out inflammatory conditions such as gout or septic

arthritis. Radiographs demonstrate joint space narrowing that is consistent with OA. However, radiographs do not reliably assess disease severity.

Case 43-1, Question 2: How do the subjective and objective findings of OA correlate with disease pathogenesis in R.T.?

The characteristic joint space narrowing as seen on radiograph without joint destruction is characteristic of OA. Osteophyte formation and bone rubbing against bone are most likely responsible for the pain, stiffness, and crepitus demonstrated on physical examination. Crepitus is an audible “crackling” sound that can be heard with passive or active movement of the joint. Instead of the opposing joint surfaces gliding past each other, the movement of the joint now creates the characteristic crunching or crackling sounds. In addition, the varus misalignment contributes to the stress on the knee joint and some of the functional impairments that R.T. reported to her primary care physician. A varus misalignment is described as the patient in a standing position with his/her knees appearing further apart (bow-legged), and valgus is when the knees are closer together. Both of these deformities can affect a patient’s functioning and quality of life.

The clinical presentation of OA is usually unilateral pain and stiffness of the knee, hip, or cervical or lumbar spine; the distal interphalangeal joints generally are not painful. More often than not, OA tends to affect more than one joint. There are some distribution associations described between knee and hand OA and knee and hip OA. Elbows, wrists, and shoulders tend not to be affected by OA. Patients usually present to their primary care provider reporting increased pain or stiffness lasting <30 minutes, usually in the morning or after periods of prolonged immobility. They usually will report decreases in their ADL, functional status, and overall health-related quality of life. Typically, household activities such as kneeling, stair climbing, and walking tend to be limited. The associated

decrease in activities, range of motion, and overall physical activity contribute to muscle weakness and unsteadiness.

Problems with sleep and depression can occur, compromising attempts to lose weight, increase activity, and participate in physical or occupational therapy or in Tai chi. Joint involvement can be characterized by swelling, easily recognized in the fingers and knees. Joints usually are tender when examined during active motion or application of pressure. Bursitis, tendonitis, muscle spasms, and torn meniscus can cause limitations in range of motion and need to be ruled out. Synovial effusions can be chronic but can also present during times of disease exacerbations. The patellar tap test or the wave test can elucidate joint effusions. Patients with advanced disease may present with not only the expected loss of cartilage but also deformities in surrounding bone and soft tissue, affecting the ligaments. Joint misalignment is common and contributes to joint unsteadiness. Fingers of patients with the characteristic Bouchard and Heberden nodes are misaligned. Muscle atrophy is demonstrated by simply measuring the circumference of the quadriceps muscles. The use of radiographs is usually not necessary for the diagnosis of OA, but rather is used to rule out conditions such as avascular necrosis, Paget disease of the bone, rheumatoid arthritis, or gouty arthropathies. However, radiographs can be useful to establish disease severity or monitor for disease progression. The clinical features described on radiographs that are characteristic of OA are joint space narrowing, osteophytes at the joint margins, and sclerosis of subchondral bone. As demonstrated in Case 43-1, Question 1, R.T.'s knee radiograph revealed joint space narrowing with osteophyte formation.

An ultrasound can be useful in detecting or confirming joint effusion, popliteal cysts, or other erosive inflammatory conditions. Laboratory assessments are usually unnecessary because the ESR and CRP are typically within reference ranges. Serum uric acid can help differentiate between similar inflammatory presentations. Synovial fluid aspiration is appropriate if septic or inflammatory arthritis is suspected. In the patient with OA, the WBC count is <2000 μL, synovial fluid is clear, and crystals are absent. There are

no relevant biomarkers of bone or cartilage remodeling that are used in the routine care of patients with OA. Magnetic resonance imaging (MRI) scans represent an exciting area of research for assessing cartilage, synovium, and bone, but are not routinely used in the diagnosis of OA.

Case 43-1, Question 3: Cytokines are involved in the pathophysiology of OA. Is it possible to modulate these cytokines and thereby slow or delay the disease process to benefit R.T. before her condition worsens?

The role of IL-1 and TNF in rheumatoid arthritis pathogenesis represented exciting discoveries that have led to highly effective disease remissions. However, in OA, the role of these cytokines in upregulating matrix metalloproteinase (MMP) and the exact mechanism that they play in the disease process have not been clearly elucidated and have not resulted in any effective disease-mitigating therapies.[7]

TREATMENT OF OSTEOARTHRITIS

Case 43-1, Question 4: What nonpharmacologic therapies should be recommended for R.T.?

Nonpharmacologic Management

Nonpharmacologic modalities are a primary strategy for OA treatment. As previously discussed, there are no interventions that effectively attenuate the disease process. Pharmacologic strategies have significant untoward effects and modest efficacy in the management of OA pain and disability. Patients typically have difficulty adhering to self-management, aerobic, or strength-training programs. Many times, nonpharmacologic strategies are not even

attempted until pharmacologic interventions have failed or side effects necessitate discontinuation of the offending agent.

Optimal pain management requires an individualized approach that supports increased functional status, and the social, economic, and emotional impacts of OA.[9] Shared decision-making helps determine the influences of culture, religion, preferences, and values. A general approach would include patient education and consideration of different strategies such as physical activities, orthotic devices, psychological and social interventions, good sleep maintenance, and weight management. Physical activities would include general exercise, aerobic and resistance training, Tai chi, yoga, Qigong, and whole-body vibration. Additional interventions such as acupuncture, balneotherapy, thermotherapy, manual therapy/joint stabilization, ultrasound/radiotherapy/diathermy, and cognitive-behavioral therapy have been highly effective for many people.[9] Patients can be referred to the Arthritis Foundation website (http://arthritis.org) for local resources or programs specific to their communities.

R.T. should be encouraged to lose weight and participate in either self-management or a structured exercise program that includes aerobic and strength-training exercises. In addition, R.T. should be encouraged to participate in mind–body activities such as Tai chi classes. Weight loss should be the primary goal in obese patients with OA of the knee. Exercise improves muscle strength and helps prevent falls. The use of knee bracing may offer some degree of support in patients with misalignments of the knee joints. See **Table 43-1** for recommendations for nonpharmacologic and pharmcologic treatments by osteoarthritis sites.

Table 43-1

Recommendations for Nonpharmacologic and Pharmacologic Treatments by Osteoarthritis Site

Site	Nonpharmacologic Recommendations	Pharmacologic Recommendations
Hand	Evaluate ability to perform ADLs.	Acetaminophen

	Instruct in joint protection techniques. Self-efficacy and self-management programs First CMC orthosis Provide assistance hand devices, as needed, to help patients perform ADLs. Case 43-1, Question 5: What is the initial pharmacologic treatment recommendation for R.T.?

Pharmacologic Management

A trial of acetaminophen 1000 mg orally (PO) three to four times a day should be attempted for 2 to 3 weeks. More aggressive medications are usually reserved for those patients who have failed acetaminophen. Medications such as NSAIDs can increase BP, cause GI ulceration, inhibit renal prostaglandins that are vasodilatory and, therefore, diminish renal function, and potentially increase cardiovascular risks. Given R.T.'s past medical history of peptic ulcer

disease and lack of knee inflammation on physical examination, the initial trial of acetaminophen is warranted.

ACETAMINOPHEN

Acetaminophen is conditionally recommended by the American College of Rheumatology (ACR) in those patients with a contraindication to systemic NSAIDs.[7] The role of acetaminophen in the treatment of hand, knee, and hip OA has been downgraded as single-agent therapy because of uncertain clinical benefits. Chronic acetaminophen use in patients who consume more than three alcoholic drinks per day can increase risk of GI bleeding and elevations of liver enzymes.[10] A 12-week randomized, controlled trial reported in 2007 that extended-release acetaminophen 3900 mg/day was safe, well tolerated, and more effective than was 1950 mg/day in patients with hip and knee OA.[11]

Case 43-1, Question 6: What is the role of topical agents in the treatment plan for R.T.?

TOPICAL THERAPY

Numerous prescription and nonprescription topical analgesics are available, containing capsaicin, diclofenac, lidocaine, or methyl salicylate. The ACR, European League Against Rheumatism (EULAR), and the Osteoarthritis Research Society International (OARSI) practice guidelines recommend topical NSAID therapy as a first-line therapy for knee OA.[7,9,12] Topical capsaicin cream is applied to the hands or knees three to four times daily. If used, R.T. should be counseled regarding proper application, initial burning and sensitivity reactions, and expectations of benefits that may take up to a few weeks. There are no systemic effects or drug interactions with topical capsaicin cream.[13]

Currently, three topical diclofenac products are commercially available in the United States, including a 1% gel, a 1.5% and 2% solution, and a 1.3% patch.[14] Diclofenac topical gel 1% has recently made the move to being available OTC. Topical diclofenac 1% gel,

alone or in combination with oral acetaminophen, represents another therapeutic option. Topical diclofenac 1% gel is indicated in the treatment of OA of the upper extremities such as the hands, elbows, and wrists, and the lower extremities such as ankles, feet, and knees. The gel is applied according to “dosing cards” in either 2- or 4-g measurements. The dose for the upper extremities is 2 g four times a day and 4 g four times daily for the lower extremities.

Diclofenac topical solution 1.5% and 2% w/w in dimethyl sulfoxide, USP (DMSO) 45.5% w/v represent another treatment option for the signs and symptoms of OA of the knee. In two 12-week, randomized, placebo-controlled trials, oral and topical diclofenac solution was equivocal for the outcome measures of pain and physical function.[15,16] Patients receiving the topical solution reported minor skin irritation, but fewer GI symptoms and abnormal liver function tests than did those patients receiving oral diclofenac.

The diclofenac 1.3% patch, although available, is indicated only for the treatment of acute pain due to musculoskeletal sprains and strains.

Case 43-1, Question 7: What monitoring parameters would be appropriate for R.T.?

Although improved tolerability and decreased toxicity profiles appear promising for topical NSAIDs, the warnings about typical NSAID-related adverse effects are similar for oral and topical agents.[17] Data are lacking for true upper GI bleed or cardiovascular event risk with topical versus oral administration. Outside of short-term efficacy trials, the risk of systemic complications with chronic therapy has not been investigated. In addition, limited comparative efficacy data exist comparing topical diclofenac with other oral NSAIDs or topical capsaicin. Oral and topical NSAIDs should not be used concomitantly unless potential benefit greatly outweighs the risk, following reports of increased incidence of rectal bleeding and abnormal laboratory findings when used together.[14] The combination of acetaminophen and topical diclofenac may be therapeutic for

some patients while avoiding other combinations with a higher degree of untoward effects. This combination, however, has yet to be evaluated in the rigor of randomized trials. In a 2010 systematic review, oral and topical NSAIDs were noted to have similar rates for discontinuation because of a high incidence of topical reactions with the latter.[18] It is unclear whether these skin reactions are caused by the type of formulation, vehicle, or other ingredients in the preparation.

R.T. does not have a history of liver disease or hepatitis C, so a short trial of acetaminophen does not require any monitoring for medication safety. However, it would be important to ask her to keep a daily pain log and complete a comfort assessment, besides a functional status questionnaire on her next visit. These tools are freely available online from multiple sources. This will engage the patient in her own care as well as provide the clinician with information regarding baseline data, medication efficacy, and the impact of medication on functional impairment. In addition, limitations or improvements in ADLs and instrumental activities of daily living (IADLs) can provide useful information in helping the clinician determine whether any changes in the plan of care need to occur.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND OTHER PHARMACOLOGIC TREATMENT

CASE 43-2

QUESTION 1: S.L., a 67-year-old female, presents to her primary care physician with increased pain and stiffness in her left knee. S.L. reports her left knee as "weak," and she has difficulty getting out of bed in the morning and after sitting on the recliner for some time. She has tried acetaminophen 1000 mg four times daily for 1 month without adequate relief. She also takes metoprolol succinate 50 mg daily, lisinopril 20 mg daily, and famotidine 10 mg twice daily. Her medical history includes hypertension, osteopenia, depression, gastroesophageal reflux disease, OA, and a right knee replacement 2 years ago. Her recent laboratory values and vital signs include the following:

BP, 135/80 mm Hg
HR, 76 beats/minute
Height, 66 inches (167.64 cm)

Weight, 190 pounds (86.18 kg)
BMI, 30.7 kg/m^2
Sodium, 145 mEq/L
Potassium, 4.8 mEq/L
BUN, 16 mg/dL
Creatinine, 1.2 mg/dL
eGFR, 48 mL/minute
WBC, 4.5 × 10^3/mL
RBC, 4.2 × 10^6/μL
Hemoglobin, 12.1 g/dL
Hematocrit, 36.6%

What medication do you recommend to provide adequate pain relief for S.L.?

In this patient who has failed an adequate trial of acetaminophen, therapeutic options include celecoxib, a nonselective NSAID, tramadol, or an opioid analgesic. There are no data to suggest that any particular NSAID is more effective than another.[19] S.L. does not have any known history of coronary heart disease or peptic ulcer disease. On the basis of the risk factors identified in **Table 43-2**, S.L. has one risk factor of age, placing her at moderate risk for GI ulceration. Data suggest that appropriate treatment of *Helicobacter pylori*, if present, reduces the risk of GI ulceration in patients taking NSAIDs chronically.[20] Therefore, if the decision is made to recommend a nonselective NSAID, then famotidine would need to be discontinued because of a lack of protection against gastric ulcers, and a proton-pump inhibitor (PPI) such as omeprazole should be initiated to prevent upper GI bleeding. Either option would represent a reasonable therapeutic recommendation.

Table 43-2
Recommendations for Nonsteroidal Anti-inflammatory Drug Selection Based on Gastrointestinal and Cardiovascular Risks

Risk Category	Low GI Risk	Moderate GI Risk	High GI Risk
	0 risk factors	1–2 risk factors	Multiple risk factors, history of previous ulcer events, or continued use of corticosteroids or anticoagulants
Low CV risk	NSAID alone	NSAID + PPI/ misoprostol	Alternative therapy or COX-2 + PPI/ misoprostol
High CV risk (low-dose aspirin required)	Naproxen + PPI/miso-prostol	Naproxen + PPI/ misoprostol	Alternative therapy recommended

COX-2, cyclooxygenase-2; CV, cardiovascular; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton-pump inhibitor.

Adapted with permission from Lanza FL, Chan FK, Quigley EM, et al. Guidelines for prevention of NSAID-related ulcer complications. *Am J Gastroenterol*. 2009;104(3):728–738. © 2009 The American College of Gastroenterology.

For those patients with insufficient pain relief from acetaminophen or topical agents, an oral NSAID should be considered. As with any decision regarding pharmacotherapy, the safety and efficacy of the chosen therapy needs to be evaluated in the context of a patient's specific case. The historical perspective and the knowledge of increased cardiovascular risk versus GI safety with cyclooxygenase (COX)-2 agents have had a tremendous impact on the use of these agents in clinical practice. Currently available NSAIDs have comparatively unique characteristics in terms of their ability to inhibit COX-1 (constitutive) and COX-2 (inducible). See **Table 43-3** for selectivity of COX-2 inhibition.

Table 43-3

Relative Selectivity of Cyclooxygenase Inhibitors

5- to 50-fold COX-2 Preferential	<5-fold COX-2 Preferential	COX-1 Preferential
Etodolac Meloxicam Celecoxib	Diclofenac Sulindac Meclofenamate Piroxicam Diflunisal	Fenoprofen Ibuprofen Tolmetin Naproxen Aspirin Indomethacin Ketoprofen Flurbiprofen Ketorolac

Based on log IC_{80} inhibition ratios COX-2 inhibitor/COX-1.

COX, cyclooxygenase.

Patients at increased risk for cardiovascular disease include those with unstable angina, a history of myocardial infarction (MI), coronary artery bypass surgery, ischemic stroke, or a high Framingham risk score.[21] Some clinicians have recommended the addition of low-dose aspirin 81 mg to attenuate the increased risk of cardiovascular disease; however, this practice has not been the primary focus of vigorous clinical trials. The addition of aspirin can potentially increase the risk of GI ulceration and compromise cardioprotection.[22] In addition, randomized controlled studies have not clearly demonstrated the efficacy and safety of this approach.[21,23] See **Figure 43-2** for overview of pharmacologic therapy treatment for the treatment of osteoarthritis.

Figure 43-2 Overview of pharmacologic therapy for the treatment of osteoarthritis.

All NSAIDs, including naproxen, carry the increased risk of cardiovascular events such as stroke or MI.[24] Cardiovascular safety of the nonselective NSAIDs naproxen and ibuprofen were prospectively compared to celecoxib in a randomized study of 24,081 patients. Celecoxib did not separate statistically from either naproxen or ibuprofen in the primary outcome measure of any cardiovascular event meeting the Antiplatelet Trialists Collaborative Criteria (APTC). However, celecoxib did exhibit statistically lower rates of clinically significant GI events than did naproxen (P = .01) or ibuprofen (P = .002).[25] In summary, for patients with low cardiovascular risk and moderate to higher risk of GI bleeding, a recommendation can be made for once-daily celecoxib or NSAID plus PPI or misoprostol. There is agreement that all NSAIDs may increase the risk of cardiovascular disease in those with or without risk factors. In the past, naproxen had been recommended in those patients, but the data have not been completely conclusive. In a non-Western population, Kang et al had found that all NSAIDs increase the risk of cardiovascular events and bleeding after MI, but meloxicam and celecoxib less so.[26] Until more data are available, physical modalities such as ice or heat or tramadol may be considered for patients at high risk for cardiovascular disease.

Case 43-2, Question 2: What monitoring parameters would be appropriate for this pharmacologic treatment recommendation for S.L.?

Many clinicians recommend checking a basic metabolic panel and complete blood count with differential 2 to 4 weeks after starting NSAIDs in older patients. Depending on the initial laboratory results, testing can occur every 3 to 4 months, thereafter for the next year. The risk of GI adverse events decreases after 1 month, but is always present, especially as age advances. Liver function should be checked regularly during the first year of treatment and periodically thereafter. Patients with significant comorbidities may need more

stringent follow-up and monitoring. Analgesic efficacy is best evaluated using a consistent systematic assessment approach. If S.L. is to remain on chronic NSAID therapy, then monitoring her liver and renal function every 3 months for the first year would be reasonable.

Case 43-2, Question 3: One week later after starting naproxen 500 mg twice daily, S.L. has been adherent to therapy and had a basic metabolic panel completed before this office visit. S.L. reported a decrease in pain since she had been started on naproxen. Laboratory values and vital signs obtained at this visit include the following:

BP, 135/78 mm Hg
HR, 88 beats/minute
Height, 66 inches (167.64 cm)
Weight, 194 pounds (87.99 kg)
BMI, 30.7 kg/m^2
Sodium, 135 mEq/L
Potassium, 5.5 mEq/L
BUN, 40 mg/dL
Creatinine, 2.2 mg/dL
RBC, 4.7 × 10^6/μL
Hemoglobin, 10.3 g/dL
Hematocrit, 33.8%

What changes, if any, need to be made with her OA therapy?

GI ulceration and bleeding are important considerations that require vigilance and concern with NSAID therapy in OA. The options to mitigate upper GI bleeding in patients taking NSAIDs are to add a PPI, use a COX-2 selective agent, or add misoprostol. A meta-analysis based on epidemiologic studies illustrates the safety of celecoxib with regard to risk of GI ulceration and bleeding. In addition, NSAIDs with long half-lives and slow-release formulations were found to demonstrate higher risks for GI events. Higher relative risk (RR) for GI bleeding (>5) was associated with naproxen, indomethacin, ketoprofen, ketorolac, and piroxicam, whereas a lower RR (<5) was found for ibuprofen, diclofenac, celecoxib, meloxicam, rofecoxib, and aceclofenac.[27] NSAIDs can also be associated with

abnormal liver function tests. Although possible with most NSAIDs, diclofenac has been associated with greater risk.[28]

In the week that has passed, there has been an increase in potassium, serum creatinine, and BUN. COX-2 preferential and nonselective inhibitors have the same potential to cause adverse renal effects. Naproxen should be discontinued, and additional monitoring should be ordered to ensure that laboratory values return to baseline. The drop in hemoglobin may also be concerning, and appropriate follow-up with either endoscopy or stool occult blood testing should be considered. High clinical suspicion of upper GI bleed would need to be accompanied by patient reports of coffee-ground emesis, black or tarry stools, abdominal cramping, and fatigue. Evaluation and treatment of possible upper GI perforation or ulceration secondary to NSAID therapy would necessitate endoscopic examination. Endoscopic assessment is necessary to determine the lesion size and location. Pharmacologic therapy with an intravenous (IV) PPI for 72 hours is recommended before initiating oral maintenance therapy for 12 weeks. Famotidine therapy would be discontinued if the patient had been initiated on maintenance therapy with a PPI.

TRAMADOL AND OPIOIDS

Case 43-2, Question 4: S.L. has seen commercials on television advertising "knee injections." What are the available therapeutic options?

In many patients with contraindications or subtherapeutic response to acetaminophen, NSAIDs, or COX-2 inhibitors, a trial of tramadol should be considered. Therapeutic alternatives for analgesia are now limited to opioids or tramadol for S.L. Tramadol is a centrally acting analgesic that binds to the μ-opioid receptor and also inhibits the uptake of norepinephrine and serotonin.[29] The ACR recommends tramadol in those patients who have failed or have contraindications to NSAIDs.[7] Tramadol should not be used in patients with a history of seizures or receiving medications with

serotonergic activity and requires dose adjustment with diminished renal function.[29] A trial of tramadol should be based on the shared decision-making trial with emphasis on safety, tolerability, and impact on functional status. Opioids or opioid/acetaminophen combinations are generally not recommended for the treatment of chronic OA knee pain.

The risks of opioid medication use include the side effects such as constipation, confusion, hallucinations, respiratory depression, tolerance, and addiction. A recent Cochrane Review evaluated the use of oral and transdermal non-tramadol opioids in the treatment of OA of the hip and knee.[30] Although the findings did conclude that opioids are effective, their modest benefits are outweighed by their side effect profiles and should thus be avoided. Randomized, placebo-controlled studies have pointed to the efficacy and tolerability of transdermal buprenorphine with or without concurrent acetaminophen in the treatment of hip or knee OA, although long-term safety cannot be concluded at this time.[31,32]

DULOXETINE

Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of chronic musculoskeletal pain, in addition to several other indications.[33] In a 13-week randomized, double-blind, placebo-controlled trial involving 231 patients, duloxetine demonstrated statistically significant reductions in osteoarthritic pain of the knee.[34] The magnitude of difference in average pain between duloxetine and placebo in the reported mean end points and the mean change from baseline was modest, yet the tolerability and adverse effect profile of this medication are preferable to other potential treatment modalities. S.L. should be initiated on duloxetine for treatment of OA-related pain, and she should be counseled on the risk of transient headaches, nausea, and, less frequently, diarrhea. The initial dose of duloxetine in the treatment of OA of the knee is 30 mg once daily for 1 week, and then, if tolerated, titrated to 60 mg once daily. Liver transaminases are also recommended for periodic monitoring. Specific education

regarding expected treatment results should also be provided because the onset of analgesia with duloxetine may be delayed following initiation. Given her concurrent diagnosis of depression, her mood should be reassessed frequently during the transition.

Intra-articular Therapy

Ultimately, many patients fail oral or topical therapies; and IA injections represent the last conservative efforts before surgical intervention for OA of the knee. Aspiration of synovial fluid and injections of glucocorticoids or viscosupplementation of hyaluronic acid are strategies that have been offered to patients with severe knee OA. Injections of triamcinolone or methylprednisolone with lidocaine 1% have been shown to be effective for ~4 to 8 weeks. Typically, IA glucocorticoids are given no more frequently than every 3 months. Side effects include a paradoxical localized inflammatory reaction.[35]

The role of IA hyaluronic acid injections in the treatment of knee and hip OA is controversial. There is agreement that hyaluronic injections are recommended against in hip OA.[7] Less clear is their use in symptomatic knee OA and the conditional recommendation against use in the 2019 guidelines. The evidence for benefit in knee OA had been reported in earlier trials; however, these trials had been subject to substantial bias. Shared patient decision-making of the benefits and risks of therapy should allow for more informed treatment strategies.

Case 43-2, Question 5: Two years have passed, and S.L. has now failed all conservative strategies including IA injections into her knee. After discussing all of her options with her physician, S.L. is referred to an orthopedic surgeon for elective left total knee replacement. She is awaiting discharge from the acute care hospital, pending transfer to a short-term rehabilitation facility to facilitate her return to home, and resumption of her previous level of function. S.L.'s current medications are metoprolol succinate 50 mg daily, lisinopril 20 mg daily, enoxaparin 30 mg subcutaneously twice daily, oxycodone controlled release (CR) 10 mg every 12 hours, senna/docusate one tablet twice daily, and oxycodone/acetaminophen 5 mg/325 mg one tablet every 4 hours as needed

for moderate pain and two tablets every 4 hours as needed for severe pain. S.L. asks you, as the counseling pharmacist, why she still needs "shots in the belly." What do you tell S.L.?

The American College of Chest Physicians (ACCP)'s highest level of evidence for elective knee arthroplasty recommends low-molecular-weight heparin, fondaparinux, dabigatran, apixaban, rivaroxaban, or warfarin (international normalized ratio [INR] goal of 2.5) for patients in whom a risk of significant bleeding does not exist. A minimal duration of therapy is for 10 days after surgery and up to 35 days for some patients.[36] It is important to educate S.L. about this information; providing the reason for enoxaparin is to prevent blood clots in her legs or lungs. In cases in which the creatinine clearance is <30 mL/minute, the appropriate dosage of enoxaparin would be 30 mg subcutaneously once daily.[37]

Case 43-2, Question 6: How long will S.L. need oxycodone CR and oxycodone/acetaminophen therapy?

Most patients return to their home environments, and the use of as-needed dosing of immediate-acting opioid/acetaminophen combinations may be necessary for the completion of the short-term rehabilitation process. However, the long-term use of opioids in the treatment of chronic pain should be discouraged.

Comorbid Conditions in the Elderly

CASE 43-3

Question 1: L.P. is a 76-year-old female who was recently admitted to the hospital for elective right total hip replacement. She had failed all previous conservative interventions. Her medical history is significant for type 2 diabetes, hypertension, dyslipidemia, OA left knee and right hip, a right knee replacement 2 years ago, coronary artery disease, and history of MI 1 year ago. Medications include metformin 850 mg twice daily, lisinopril 20 mg daily, atorvastatin 40 mg daily, metoprolol succinate 100 mg daily, rivaroxaban 10 mg once daily with dinner, aspirin 81 mg once daily, celecoxib 200 mg once daily, and

oxycodone/acetaminophen 5 mg/325 mg one tablet every 4 hours as needed for right hip pain.

What are L.P.'s risks associated with COX-2 inhibitor use?

The risks associated with nonselective NSAID or COX-2 inhibitor use in older adults with comorbid coronary artery disease include increased BP, heart failure, and worse cardiovascular outcomes. In addition, diminished renal function and GI bleeding risks are relevant and require careful follow-up and monitoring. The lowest effective nonselective NSAID or COX-2 inhibitor dose for the shortest duration would possibly be recommended in situations where continued therapy is clinically indicated.

Case 43-3, Question 2: What clinically significant drug-drug interactions may be present involving L.P.'s deep venous thrombosis prophylaxis after her hip replacement surgery?

Caution is encouraged when combining medications to rivaroxaban that may increase the risk of bleeding.[38] In this case, L.P. requires aspirin for cardiovascular protection after the MI. In addition, celecoxib was added for pain management following hip replacement surgery. The addition of antiplatelet agents and NSAIDs to oral anticoagulant therapy increases the risk of bleeding. A careful evaluation of the risks and benefits of combination therapy would suggest discontinuation of the COX-2 inhibitor.

Dietary Supplements

Dietary supplements offer patients an alternative to prescription medications. Some patients often either fail multiple prescription drugs or have intolerable side effects. Others confuse dietary supplements with natural products and consider them safer than traditional medications. In the case of OA, the role of glucosamine, chondroitin, and the combination products has represented such an alternative for many patients. As with any OTC dietary supplement, the vigor of product consistency and standardization are not equal to

U.S. Food and Drug Administration (FDA) requirements for legend drugs. Researchers have found in evaluating the use of glucosamine, chondroitin, and the combinations in OA of the knee that they were all ineffective in reducing pain. The ACR recommends against the use of glucosamine or glucosamine/chondroitin combination products in OA of the knee or hip. However, in OA of the hand, the ACR suggests consideration on a patient-to-patient basis as a low-risk intervention.[7] More recently, a small, randomized placebo-controlled trial of 70 patients followed over 12 weeks were given 1000 mg of curcuma longa daily to determine the benefits in symptomatic knee OA and effusion synovitis.[8] The trial data showed modest-to-moderate improvements in pain. Larger studies would be needed before generalizing the results for larger populations.

Rheumatoid Arthritis

Janet S. Cho and Ying Wang

CORE PRINCIPLES		CHAPTER CASES
1	Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder characterized by potentially deforming polyarthritis and a wide spectrum of extra-articular manifestations. Diagnosis of RA is based on joint involvement, serology, acute-phase reactants, and symptom duration.	**Case 44-1 (Questions 1, 2)**
2	Treatments for RA include nonpharmacologic (heat or cold therapy, range-of-motion [ROM] exercises, physical therapy, and occupational therapy) and pharmacologic options (nonsteroidal anti-inflammatory drugs [NSAIDs], synthetic [conventional and targeted] and biologic disease-modifying antirheumatic drugs [DMARDs], and	**Case 44-1 (Questions 3–5)** **Case 44-2 (Question 1)** **Case 44-3 (Questions 1–3)**

	corticosteroids). NSAIDs are for symptom management only and must be used cautiously, if at all, because of serious health risks, including gastrointestinal complications and thromboembolic cardiovascular events.	
3	Owing to the destructive nature of the disease, DMARDs should be initiated as soon as possible once diagnosis has been established. Methotrexate is the most common selection because of efficacy, safety, rapid onset, and cost-effectiveness. Other traditional DMARDs and combinations of traditional DMARDs may be selected based on disease severity, the presence of poor prognostic indicators, and patient preferences. Regardless of the DMARD chosen, all require diligent monitoring.	**Case 44-3 (Questions 4–7)** **Case 44-4 (Questions 1–7)** **Case 44-5 (Questions 1–4)**
4	Patients with RA who experience an inadequate response to traditional DMARD monotherapy or intolerable adverse effects should consider the addition of or switching to a biologic DMARD or targeted synthetic DMARD. Diligent monitoring is also critical with biologic and targeted synthetic agents owing to the risk of serious adverse effects such as infections and lymphoma.	**Case 44-5 (Questions 5–7)** **Case 44-6 (Question 1)** **Case 44-7 (Questions 1, 2)**
5	Corticosteroids, when used judiciously at the lowest effective doses and for limited duration, are very effective at	**Case 44-8 (Questions 1, 2)**

	quickly controlling inflammation while awaiting onset of DMARD therapy. Although systemic corticosteroids can be prescribed for short-term flares of RA disease activity, intra-articular corticosteroid injections are very effective at managing flares that are limited to a few joints and are not associated with the adverse effects of systemic therapy.	
6	Juvenile idiopathic arthritis (JIA) describes an assortment of arthritis conditions affecting children and adolescents. Symptoms of JIA, such as joint inflammation and ROM limitation, are present before age 16 years. As in RA, the diagnosis of JIA is based on clinical manifestations, and all infectious, traumatic, and other etiologies must be ruled out.	**Case 44-9 (Questions 1, 2)**
7	Many nonpharmacologic treatment options are also available to supplement JIA pharmacologic therapy, including healthy age-appropriate diet, exercise, massage, and physical and occupational therapies.	**Case 44-9 (Question 3)**
8	Pharmacologic treatment options for JIA include NSAIDs, synthetic DMARDs, biologic DMARDs, Janus Kinase (JAK) inhibitors, corticosteroids, and cyclosporine A.	**Case 44-9 (Questions 4, 5)** **Case 44-10 (Question 1)** **Case 44-11 (Questions 1, 2)**

INTRODUCTION

Arthritis refers to more than 100 different joint diseases causing swelling, pain, and damage to joints and connective tissue.[1] Rheumatoid arthritis (RA) is the most common chronic inflammatory arthritis and is characterized by potentially deforming polyarthritis and a wide spectrum of extra-articular manifestations resulting from abnormal systemic immune response. It has an estimated worldwide prevalence of 0.24%, although rates vary between geographic regions.[2,3] In the United States alone, RA afflicts 1.3 million adults, occurring approximately two to three times more often in females than in males.[3,4] RA most commonly affects females between ages 30 to 60 years.[1] RA-associated morbidity, mortality, and disability will rise in future years, especially as the United States' baby boomer generation ages.[4]

ETIOLOGY

The exact etiology of RA is unknown, but like many autoimmune diseases, it involves an interplay of multiple factors including genetic susceptibility, environmental influences, and effects of advancing age on somatic changes in the musculoskeletal and immune systems.[3] The onset of RA likely starts years before clinical symptoms develop with activation of specific genes, resulting in innate immunity activity leading the cascade of events.[3] It is suspected that genetics contribute 50% to 60% of the risk of developing RA. The genes with the strongest implication include the *HLA-DRB1* gene of the major histocompatibility complex (MHC) and chromosome 1's *PTPN22* gene. Cigarette smoking increases the production of rheumatoid factor (RF) and anti–cyclic citrullinated peptide antibody (anti-CCP), clinical markers associated with RA, and has been shown to double the risk of developing RA.[5,6] Female sex hormones may also play a role in RA development. In females,

peak incidence occurs at the fifth decade, a time when many enter menopause or perimenopause. Estrogen is known to stimulate the immune system; pregnant patients often experience a remission of RA symptoms, and females who take oral contraceptives appear to be somewhat protected against the development of RA.[2,5] Diets rich in fish, olive oil, and other omega-3 fatty acid sources are associated with a lower risk of developing RA.[5]

PATHOPHYSIOLOGY

Pharmacologic therapy for RA targets components of the inflammatory cascade, which lead to persistent inflammation of the synovial lining and ultimately cause joint destruction.[7] This normally thin membrane proliferates and transforms into the synovial pannus. The pannus, a highly erosive enzyme-laden inflammatory exudate, invades articular cartilage (leading to narrowing of joint spaces), erodes bone (resulting in osteoporosis), and destroys periarticular structures (ligaments, tendons), resulting in joint deformities (**Fig. 44-1**).[7,8]

Figure 44-1 Overview of joint changes in rheumatoid arthritis.

Under normal circumstances, the body can distinguish between self (ie, proteins found within the body) and nonself (ie, foreign substances such as bacteria and viruses). On occasion, immune cells (T or B lymphocytes) can react to a self-protein while developing in the thymus or bone marrow. These developing cells are usually killed or inactivated before release from their place of formation; sometimes, however, a self-targeted immune cell can escape destruction and become activated years later to initiate an autoimmune response. When the activation source (ie, the self-targeted immune cell) reaches the joint, complex cell–cell interactions take place, leading to the pathology associated with RA.

The initiating interaction for an autoimmune response takes place between antigen-presenting cells (APCs), which display complexes of class II MHC molecules, and CD4-lineage T-cell lymphocytes (**Fig. 44-2**). In addition, B cells can become activated, leading to antibody formation (including RF and anti-CCP), pro-inflammatory cytokine production, and accumulation of polymorphonuclear leukocytes that release cytotoxins and other substances destructive to the synovium and joint structures. B cells also act as APCs, leading to T-cell activation and acceleration of the inflammatory process.[7,8] T-cell activation requires two signals: (1) an antigen-specific signal occurring when a class II MHC antigen molecule on an APC binds to a T-cell receptor and (2) binding of CD39 on the T cell to either CD80 or CD86 on the APC. T-cell activation leads to activation of macrophages and secretion of cytokines, polypeptides that serve as important mediators of inflammation, and cytotoxins, which can directly destroy cells and tissues. Pro-inflammatory cytokines, such as interleukin (IL)-1 and tumor necrosis factor (TNF)-α, stimulate both synovial fibroblasts and chondrocytes in neighboring articular cartilage to secrete enzymes that cause degradation of proteoglycan and collagen tissues. In healthy individuals, the inflammatory process is regulated by balancing the ratios of pro-inflammatory cytokines (eg, IL-1, IL-6, and TNF-α) with anti-inflammatory cytokines—for example, IL-1 receptor antagonist (IL-1Ra), IL-4, IL-

10, and IL-11. In the synovium of patients with RA, however, this balance is heavily weighted toward the pro-inflammatory cytokines, which results in sustained inflammation and tissue destruction.

The Janus kinase (JAK)-signal transducer and activator of transcription (STAT) system are also involved in the pathogenesis of RA. JAKs are intracellular tyrosine kinases that bind and transmit signals from type 1 and type 2 cytokine receptors that eventually lead to cell formation, growth, and differentiation, and immune cell function. A variety of growth factors and cytokines (not including the TNF or IL-1 families) bind with type 1 and type 2 cytokine receptors, resulting in the phosphorylation of JAKs which activates STATs to translocate to the nucleus and modulate gene transcription. The JAK–STAT pathway facilitates cell signaling and plays a key role in immune-mediated inflammatory response.[9,10]

Clinical Presentation, Diagnosis, and Disease Course

CASE 44-1

Question 1: T.W., an otherwise healthy 42-year-old, 132.27-pound (60-kg) female, has been experiencing morning stiffness that persists for several hours, fatigue, and generalized muscle and joint pain for the past 4 months. In addition, she reports that her eyes seem red most of the time and are unusually dry. Her symptoms have been much worse during the past month and a half, causing her to limit her physical activities. She also can no longer wear her wedding ring because of swelling in her hand. Physical examination reveals bilaterally symmetrical swelling, tenderness, and warmth of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and the metatarsophalangeal (MTP) joints of the feet.

Pertinent laboratory findings include the following:

Erythrocyte sedimentation rate (ESR), 52 mm/hour (reference range: males 0–15 mm/hour, females 0–20 mm/hour)[11]
C-reactive protein (CRP), 2.1 mg/dL (reference range: 0–0.5 mg/dL)
Hemoglobin, 10.6 g/dL
Hematocrit, 33%
Platelets, 480,000/μL
Albumin, 3.8 g/dL
Serum iron, 40 μg/dL
Total iron-binding capacity, 275 mg/dL
Positive anti-CCP at 82 units (reference range: <20 units/mL)
Positive RF performed by latex fixation method in a dilution of 1:320 (reference range: <1:80)

Tests for antinuclear antibodies (ANAs) and tuberculin sensitivity are negative. Her uric acid level is normal. Radiographic films of the hands and feet show soft tissue swelling, narrowing of joint spaces, and marginal erosions of the second and third MCP and PIP joints bilaterally with no evidence of calcification. Other routine laboratory data and physical findings are normal.

What signs and symptoms of RA are manifested by T.W.?

More than 50% of RA cases, like that seen in T.W., will have slow onset of symptoms over weeks to months, although up to 15% of patients experience acute-onset RA, with rapid development of symptoms over several days. Onset of symptoms may be either articular or systemic, including nonspecific symptoms such as

fatigue, weakness, muscle pains, weight loss, and low-grade fever. Joint involvement is characterized by soft tissue swelling and warmth, decreased range of motion (ROM), and sometimes muscle atrophy around affected joints. The most common symptoms include pain and stiffness in multiple joints. Classically, as illustrated by T.W., the presentation is symmetrical involving wrists, PIP joints, and MCP joints, although asymmetrical joint involvement also occurs with symmetry developing later in the disease course. The peripheral joints of the hands, wrists, and feet are usually involved first. Reflective of joint inflammation, patients usually experience prolonged morning stiffness on awakening lasting at least 30 to 45 minutes, but it can be present all day with decreasing intensity after arising.[12,13] Morning stiffness lasting for >1 hour rarely occurs in other diseases outside of RA.[14]

Ultimately, any or all of the diarthrodial joints (elbows, knees, shoulders, ankles, hips, temporomandibular joints, sternoclavicular joints, and glenohumeral joints) can be involved (**Fig. 44-3**). Progressive disease is characterized by irreversible joint deformities, such as ulnar deviation of the fingers (**Fig. 44-4**), boutonniere deformities (hyperextension of the distal interphalangeal [DIP] joint and flexion of the PIP joint), or swan neck deformities (hyperextension of the PIP joint and flexion of the DIP joint) (**Fig. 44-5**). Similar irreversible deformities can also involve the feet. Patients with more aggressive disease (multiple joint involvement, positive RF) have a greater than 70% probability of developing joint damage or erosions within 2 years of disease onset.[15]

Temporomandibular 30%
Cervical spine 40%
Cricoarytenoid 10%
Acromioclavicular 50%
Shoulder 60%
Stemoclavicular 30%
Elbow 50%
Hip 50%
Wrist 80%
MCPs, PIPs 90%
Knee 80%

Case 44-1, Question 2: Which laboratory values in T.W. could be used to monitor her RA disease progression?

In 2010, the American College of Rheumatology (ACR) and European League against Rheumatism (EULAR) developed new classification criteria for RA. In comparison to criteria previously outlined in 1987, the intent of the new classification was to identify patients early in disease development so that therapeutic intervention can be initiated as soon as possible, ultimately decreasing disease progression and improving clinical outcomes.[16]

Diagnosis of RA is based on multiple clinical criteria. Individuals presenting with clinical synovitis (swelling) not explained by other differential diagnoses such as systemic lupus erythematosus, psoriatic arthritis, or gout, among others, should be tested for RA. RA criteria in the new classification system include quantifying joint involvement (higher scoring for small joints compared to large joints such as shoulders, elbows, hips, knees, and ankles) and symptom duration of 6 weeks or more. Other diagnostic criteria include the presence of autoantibodies (RF and/or anti-citrullinated peptide) and elevated acute-phase reactants (ESR or CRP).[13,16–18] Using a score-based algorithm based on these four categories, a summative score of 6 or more out of a total possible score of 10 suggests RA.[16]

Individually, each of the laboratory findings is characteristic for chronic systemic inflammatory disease with no test being specific for RA, although RF) and anti-CCP are more definitive than ESR or CRP.[11] Specifically, autoimmune diseases are frequently characterized by autoantibodies, with 50% to 80% of RA individuals having RF, anti-CCP, or both.[13,17,18]

RF, an IgM, or IgG autoantibody, abnormally reacts with the Fc portion of IgG to form an immune complex. It is found in 75% to 80% of patients with RA. It may also present in up to 5% of healthy individuals and in patients with diseases other than RA, including almost any condition associated with either immune complex formation or with hypergammaglobulinemia (eg, chronic infections, lymphoproliferative and hepatic diseases, systemic lupus erythematosus, and Sjogren syndrome). An RF titer of at least 1:160 is considered a positive test, and most patients with RA, such as T.W., typically have titers of at least 1:320.[11,19] Overall, RF is neither sensitive nor specific enough to independently diagnose RA, but it is found in the majority of patients and a higher titer early in disease generally correlates with increased disease severity and progression.[20]

Citrulline, a nonstandard amino acid, is also established as a key component of RA antigenicity and is more specific for RA than RF. Citrullinated proteins and anti-CCP antibodies are abundant in inflamed RA synovium. Anti-CCP antibodies can be detected in 50%

to 60% of patients with early RA, and the specificity of anti-CCP is very high at 90% to 95%.[11] Anti-CCP is present as early as 1.5 to 9 years before symptom presentation, suggesting a pathogenic role for these antibodies in RA.[21,22] A positive anti-CCP also correlates with an increased likelihood of a more erosive course of RA than either a negative anti-CCP or a positive RF. In summary, a positive anti-CCP antibody test is highly specific for RA, predictive of the development of RA, is a marker for an erosive disease course, and in combination with positive RF also correlates with 99.5% specificity for RA, making the likelihood of T.W. not having RA very minimal.[11,23]

The nonspecific markers for inflammation include ESR and CRP, but unfortunately, these acute-phase responses are also not disease-specific. T.W.'s hematologic findings are consistent with a mild anemia of chronic inflammation. Although her serum iron concentration is decreased, her normal iron-binding capacity makes a diagnosis of iron deficiency anemia unlikely. Her anemia probably results from a failure of iron release from the reticuloendothelial tissues and would not be expected to respond to iron therapy. The mild thrombocytosis is additional evidence of a systemic inflammatory response. The laboratory manifestations of inflammation should improve with effective drug therapy and, along with many of the clinical features of RA, are useful parameters for monitoring disease activity and response to therapy.

Finally, the negative test result for ANA rules out systemic lupus erythematosus in T.W. The ANA, however, can be positive in 10% to 70% of patients with RA.[16]

EXTRA-ARTICULAR MANIFESTATIONS AND COMPLICATIONS

The classic RA presentation involves joint findings; however, RA is a systemic disease reflected by accompanying extra-articular and organ system manifestations that, chronically, can occur in up to

46% of patients. These manifestations are also associated with higher disease activity,[24] and those with systemic involvement have higher mortality rates than those without, suggesting that early treatment may lower both the risk and severity of RA complications.[24,25]

Rheumatoid nodules occur in 15% to 20% of patients and are typically found on extensor surfaces, pressure points, and tendons. Pleuropulmonary manifestations include pulmonary nodules, fibrosis, and pleuritis; interstitial pneumonitis and arteritis of the pulmonary vasculature, although rare, can be potentially life-threatening. Vasculitis occurs infrequently, is more common in patients with long-standing and often severe disease. Complications include skin ulceration, peripheral neuropathy, and arteritis of organs.[12]

Some extra-articular manifestations occur as syndromes. Sjögren syndrome includes dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia), and connective tissue disease. T.W.'s eye symptoms may be an extra-articular manifestation of her RA. Felty syndrome is characterized by chronic arthritis, splenomegaly, and neutropenia; thrombocytopenia, anemia, and lymphadenopathy may also be present.[12]

Individuals with RA have a median life expectancy that is 3 to 10 years shorter than non-RA populations, with lower life expectancy associated with more severe disease.[5,26] The excess mortality has been attributed primarily to accelerated cardiovascular disease, responsible for one-third to one-half of deaths among adults compared with one-fourth to one-fifth of deaths among adults without RA. RA is associated with a twofold to threefold increased rate of myocardial infarction (MI), as well as lower MI survival. Management of cardiovascular risk includes annual cardiovascular risk evaluations for all patients, multiplying risk scores by 1.5 for patients with more than one marker of severe disease activity, use of statins and cardiovascular medications known to reduce cardiovascular risk, caution when prescribing nonsteroidal anti-inflammatory drugs (NSAIDs) owing to associated cardiovascular risk, and smoking cessation.[27] Lowering RA disease activity is also important to reduce

cardiovascular risk. Finally, pericarditis and myocarditis, although rare, may also occur.

Treatment

The treatment goals of RA are to maximize functional status through maintenance or improvement of symptoms (eg, joint pain and swelling), preserve joint function, and prevent deformity to ultimately improve quality of life and delay disability. Treatment to achieve low disease activity or remission (absence of disease activity) involves a combination of interventions. Early initiation of pharmacologic therapy starting at the point of diagnosis is critical to quality RA care.[28–30] Other supportive interventions include rest, exercise and physical therapy, occupational therapy, and emotional support. All patients with chronic diseases, such as RA, regardless of socially determined backgrounds should have equal access to treatment options in order to achieve optimal health outcomes.

Case 44-1, Question 3: What nonpharmacologic therapy should be included in the management of T.W.'s RA?

A balance of rest and physical activity can reduce inflammation and fatigue while improving muscle strengthening and flexibility. Restful and adequate sleep are particularly important in chronic, fatigue-inducing diseases such as RA. Therefore, T.W. should rest often especially when experiencing acute inflammation, but daytime rest periods should be limited to 30 to 60 minutes each as prolonged rest can also induce rapid losses in strength and endurance. Splinting of joints is typically prescribed throughout the day and night during periods of active inflammation, then only at night for several weeks after cessation of inflammation.[31]

Passive ROM exercises should be prescribed for T.W. because they minimize muscle atrophy and flexion contractures and maintain joint function without increasing inflammation or radiographic progression of the disease.[31,32] Regular low-impact aerobic

exercises, such as cycling, swimming, or walking, enhance muscle function and joint function.[33] Overall, physical and occupational therapies can provide valuable assistance to patients with compromised activities of daily living to maximize the potential for self-sufficiency. Some orthoses—medical devices secured to any part of a patient's body designed to support, immobilize, align, correct, or prevent deformity, or improve functioning—can reduce pain and inflammation or improve joint function in targeted joints for patients with RA.[34]

Finally, emotional support should be provided to all patients including T.W. As with all chronic debilitating diseases, the potential loss of independence, self-esteem, and employment, as well as altered interpersonal relationships with friends and family, can result in a twofold to threefold increase in depression.[35,36]

The expertise of different health care disciplines (eg, physical therapists, social workers, health educators, psychiatrists, clinical psychologists, podiatrists, vocational rehabilitation therapists, and pharmacists) should be consulted depending on T.W.'s needs. Pharmacists can monitor RA drug therapy for therapeutic and adverse effects under collaborative practice agreements with other practitioners and can counsel patients on proper medication use and clarify expectations.[37]

Cold treatments can be useful for acute pain and reduce inflammation; however, heat treatments can exacerbate pain and swelling and should be avoided during periods of active joint inflammation.[38]

Although symptoms of RA may be controlled by conservative management, more aggressive therapy is needed to prevent disease progression and disability. NSAIDs are often used to provide anti-inflammatory and analgesic effects. However, they do not prevent or slow joint destruction as compared to the disease-modifying antirheumatic drugs (DMARDs) and should be reserved for rapid symptomatic relief while awaiting DMARD onset of action. DMARDs alter long-term disease courses. As such, they are the mainstay of pharmacologic care and should be initiated in all patients as soon as they are diagnosed with RA.[28–30] Specific choice of treatment is

individualized based on joint function, degree of disease activity, patient age, sex, occupation, comorbidities, drug cost and coverage, prior therapies used, and patient preference. The two classes of DMARDs are synthetic compounds (sDMARDs) and biologic agents (bDMARDs). With the introduction of JAK inhibitors, EULAR has further subdivided sDMARDs into the conventional sDMARDs (csDMARDs) and targeted sDMARD (tsDMARD).[28,30]

The csDMARDs (eg, hydroxychloroquine [HCQ], sulfasalazine [SSZ], methotrexate [MTX], and leflunomide [LEF]) have demonstrated the ability to slow disease progression. These agents, alone or in combination, are considered as initial therapy for most patients and in the absence of any contraindications. MTX is the treatment of choice because of its strong efficacy and favorable safety profile. The tsDMARDs (eg, tofacitinib [TOF], baricitinib [BARI], and upadacitinib [UPA]) are considered for those with moderate-to-severe disease who have failed treatment with or are intolerant to TNF blockers.[39–41]

The bDMARDs target the physiologic pro-inflammatory and joint-damaging effects of inflammatory mediators, including TNF-α, IL-6, T cells, and B cells. Agents in this class include the TNF-α inhibitors (adalimumab [ADA], certolizumab pegol [CZP], etanercept [ETA], golimumab [GLM], and infliximab [IFX]), anti–B-cell therapy (rituximab [RXB]), IL-6 receptor antagonists (tocilizumab [TCZ] and sarilumab [SAR]), and the T-cell modulator (abatacept [ABT]). The bDMARDs are typically reserved for patients who fail to achieve an adequate response with csDMARD monotherapy.[30]

Corticosteroids are potent anti-inflammatory agents that slow the progression of joint damage in RA. However, long-term systemic use should be avoided because of serious adverse effects associated with chronic therapy. Short-term oral therapy may be reserved as bridge therapy in early RA with moderate-to-high disease activity while awaiting the onset of DMARD activity, brief periods of active disease, or with therapy failure.[30] Local intra-articular injections may be used for isolated joints experiencing disease flares.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Case 44-1, Question 4: T.W. will be treated with a DMARD and concurrent NSAID therapy initially to rapidly control inflammation and swelling. What is the role of NSAIDs in the treatment of T.W.'s RA and which is the NSAID of choice?

NSAIDs have a long history of use in RA treatment. They are effective for providing short-term pain and inflammation control but do not alter disease course.[42] In addition, NSAIDs are associated with side effects related to cyclooxygenase (COX) inhibition such as gastrointestinal (GI) intolerance, nephrotoxicity, and increased risk of bleeding and cardiovascular events. The cardiovascular risk associated with some agents is particularly concerning because patients with RA are at higher cardiovascular mortality risk. Therefore, given both the safety profile and the lack of long-term disease-modifying efficacy, NSAID use should be reserved only as an adjunct to DMARD therapy.[42,43]

CONVENTIONAL SYNTHETIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

With rare exception, every patient should receive csDMARD therapy soon after diagnosis to minimize loss of joint integrity, function, and risk of cardiovascular disease related to RA.[28,30] Although csDMARDs have the potential to cause serious toxicity, they can substantially reduce joint inflammation, reduce or prevent joint damage, maintain joint function and integrity, allow patients to remain productive, and ultimately reduce health care costs.[28–30] The onset of action of most csDMARDs is slow over 3 to 6 months; however, SSZ, MTX, and LEF can be beneficial within 1 to 2 months.[42] Several factors must be considered when selecting a csDMARD, including convenience of administration, monitoring requirements, medication and monitoring costs, time to therapeutic onset, and risk of severe adverse reactions.

MTX, a folate antimetabolite with immunomodulatory and anti-inflammatory properties, remains the mainstay first-line DMARD for

DMARD-naive patients with moderate-to-high disease activity because of its relatively rapid onset of action and excellent history of efficacy and safety.[28,30] LEF and SSZ are recommended if a contraindication to MTX is present, or if intolerance to MTX occurs. The primary metabolite of LEF, A77 1726 (M1), is responsible for nearly all of its pharmacologic activity. Although the exact mechanism of M1 is not completely understood, it is known that M1 inhibits dihydro-orotate dehydrogenase, an enzyme in cell mitochondria responsible for catalyzing an important step in de novo pyrimidine synthesis. SSZ appears to induce anti-inflammatory effects through one of its active metabolites, mesalamine, which is believed to inhibit both COX and lipooxygenase. HCQ may be considered for DMARD-naive patients with low disease activity, followed by SSZ, MTX, and LEF.[30] The mechanism of the anti-inflammatory effect of HCQ may be attributable to inhibition of migration of neutrophils and eosinophils, histamine and serotonin blockade, or inhibition of prostaglandin synthesis. Older csDMARDs such as azathioprine, cyclosporine, minocycline, and gold are no longer recommended because of the superior risk–benefit ratio of other csDMARDs, bDMARDs, and tsDMARDs.[29]

TARGETED SYNTHETIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Tofacitinib, baricitinib, and upadacitinib are Janus kinase (JAK) inhibitors, targeted molecules involved with inhibition of signal transduction pathways and are mechanistically different from the csDMARDs. These agents inhibit JAK enzymes that stimulate inflammatory cytokines; therefore, inhibition modulates leukocyte function and immune response. Because of increased safety concerns, they are only indicated for individuals with moderate-to-high disease activity who have had an inadequate response or intolerance to one or more TNF blockers.[30,39–41]

BIOLOGIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

In general, the bDMARDs are reserved for patients who have failed to respond to one or more csDMARDs alone or in combination. The ACR and EULAR guidelines recommend the use of bDMARDs in patients with moderate or high disease activity who are not at target taking maximally tolerated doses of MTX.[28,30] Since the late 1990s, more biologic agents have been approved for RA treatment. The earliest biologic agents targeted pro-inflammatory cytokines, such as TNF-α and IL-1, which play key roles in the immunopathogenesis of RA.[44] These cytokines are abundant in rheumatoid synovial tissues and fluid. Most cytokines can independently induce expression of the others, and IL-1 is capable of upregulating its own expression.[45] Excessive macrophage-produced cytokines (eg, TNF-α, IL-1, IL-6, and IL-8) correlate closely with RA disease activity and severity. Most importantly, RA improves when the physiologic action of TNF-α or several different ILs are suppressed. Newer agents have been developed to target additional key processes in RA, including T-cell costimulation, the depletion of $CD20^+$ B cells, and the inhibition of IL-6.[43]

The pro-inflammatory cytokine TNF-α is produced by activated macrophages and T cells in RA-affected joints. It also plays a role in keeping infections localized by increasing platelet activation and adhesion, resulting in local blood vessel occlusion and containment of infection. This action of TNF-α is responsible for its tumor necrosis properties, thus leading to the name. TNF-α exerts its physiologic effects by binding to two different cell-surface receptors known as p55 (ie, 55 kDa) and p75 (ie, 75 kDa) on inflammatory cells.[44] These receptors, with portions extending from within the cell cytoplasm to the cell exterior, are capable of binding TNF-α to the domains extending above the cell surface. Soluble forms of these receptors can be found in the serum and synovial fluid and seem to play a role in regulating TNF-α.

Two approaches have targeted the action of TNF-α: (1) the use of soluble TNF receptors with high TNF-binding affinity (ie, etanercept) and (2) antibodies against TNF-α (ie, infliximab, adalimumab, golimumab, and certolizumab pegol).[43] Etanercept is a recombinant TNF-receptor Fc fusion protein with the extracellular portion of two

p75 receptors fused to the Fc portion of human immunoglobulin G1 (IgG1).[46,47] Infliximab is a chimeric IgG monoclonal antibody directed against TNF-α, and adalimumab is a genetically engineered human IgG1 monoclonal antibody.[48,49] Certolizumab pegol is a polyethylene glycolated (PEG) Fab fragment of a humanized anti-TNF monoclonal antibody. Golimumab is a fully human anti-TNF-a IgG1 monoclonal antibody that targets and neutralizes both soluble and membrane-bound forms of TNF-α.[50,51] All five TNF-α inhibitors render TNF biologically unavailable and are highly effective in reducing RA disease activity. Currently, there is no conclusive evidence from well-controlled comparative trials that any one TNF-α inhibitor is superior to another with regard to efficacy and safety.[52] Comparative efficacy and safety will be discussed further in the section "Pharmacologic Treatment." TNF-α inhibitor selection may be driven by cost, insurance coverage, provider preference, and patient-specific factors.

There are also four non-TNF biologic agents recommended for patients with RA who are not at target taking at least one csDMARD, which include abatacept, rituximab, tocilizumab, and sarilumab.[30] These agents possess a novel mechanism of action targeting T cells, B cells, or IL-6. Abatacept, tocilizumab, and sarilumab may be considered first-line biologic DMARDs along with the TNF-α inhibitors. However, rituximab should only be considered as a first-line bDMARD in the presence of certain contraindications (ie, recent history of lymphoma, latent tuberculosis [LTB] with contraindications to treatment, or history of demyelinating disease) to the other bDMARDs.[28] There is also one final bDMARD, anakinra, which is seldom used because of lack of comparative efficacy. Anakinra is a recombinant human interleukin-1 (IL-1) receptor antagonist, which inhibits the binding of cytokines IL-1a and IL-1b to their receptor.[43] Anakinra has not shown comparable efficacy against other bDMARDs in meta-analyses and is infrequently used, although some individuals may still respond to this agent.[28,29] Anakinra is no longer recommended in the ACR guidelines owing to lack of any new data as well as infrequent use in RA.[29]

Abatacept is a selective costimulation modulator that inhibits T-cell activation.[53] For T cells to be fully activated, a CD80/CD86:CD28 costimulatory signal is required.[54] This costimulation is blocked by cytotoxic T-lymphocyte–associated antigen 4. Abatacept is a soluble fusion protein consisting of extracellular cytotoxic T-lymphocyte–associated antigen 4 attached to the Fc portion of IgG1, which inhibits T-cell activation by preventing the binding of CD80 and CD86 ligands on the surface of APCs to the CD28 receptor on the T cell.[54]

Rituximab is a chimeric monoclonal antibody that binds to the CD20 antigen on the surface of pre-B cells and mature B cells, resulting in the depletion of B cells from peripheral blood, lymph nodes, and bone marrow.[55] Stem cells, pro-B cells, and antibody-producing plasma cells do not express CD20 and are not affected by RXB. The exact role of B cells in RA pathogenesis is not known. However, studies have shown that B cells may contribute to the autoimmune and inflammatory processes by producing RF, acting as APCs, activating T cells, and producing pro-inflammatory cytokines.[55] Owing to its chimeric composition, RXB must be administered with MTX to reduce the risk of human anti-chimeric antibody (HACA) formation.[56,57] Inhibition of T-cell activation and depletion of pro-inflammatory B cells result in significant reductions in RA-related inflammation and joint destruction.

Tocilizumab and sarilumab are humanized anti–IL-6 receptor antibodies. The pleiotropic pro-inflammatory cytokine IL-6 is produced by a variety of cell types including lymphocytes, monocytes, and fibroblasts and is involved in multiple immunologic processes, including T-cell activation and B-cell proliferation.[58,59] When bound to the soluble IL-6 receptor, IL-6 activates chemokine production and upregulates the expression of adhesion molecules. This leads to the recruitment of leukocytes at inflammatory sites, thus implicating IL-6 as an important factor in RA.[60,61] High levels of IL-6 have been found in the serum and joints of patients with RA. Additionally, IL-6 has been shown to induce the proliferation of osteoclasts, which may be a component of the bone degradation seen in RA.[60,61] TCZ and SAR are humanized, monoclonal antibodies that can bind to both membranous and soluble IL-6

receptors. This blockade prevents the interaction of IL-6 with the IL-6 receptor, thus interrupting the inflammatory pathways that contribute to the disease processes in RA.[60,61]

Owing to their immunosuppressive nature, all bDMARDs and tsDMARDs should be avoided in patients with serious infections until the infection has been controlled. All carry boxed warnings for serious infections. Although these infections occurred primarily among patients with significant risk factors for infection (eg, poorly controlled diabetes, concurrent corticosteroid use, or concomitant csDMARD therapy), these agents should not be given to patients with active infection, and cautiously given to patients with a history of recurring infections or medical conditions predisposing them to infection.[62] It is recommended that all patients be screened for latent tuberculosis infection (LTBI) prior to initiation of a bDMARD or tsDMARD. If LTBI is identified, patients should receive at least 1 month of treatment prior to starting a bDMARD or tsDMARD. Patients with active TB should complete treatment prior to initiation of a bDMARD or tsDMARD. Patients should be monitored for active TB during treatment.[29]

It is recommended that patients receive the following vaccinations prior to the initiation of csDMARD, tsDMARD, or bDMARD therapy: pneumococcal, influenza, hepatitis B, human papillomavirus, COVID-19, and herpes zoster. However, if not completed prior to the initiation of therapy, these vaccinations may be given following the initiation of csDMARDs, tsDMARDs, or bDMARDs. Live vaccines should not be administered in patients receiving bDMARDs or tsDMARDs.[29]

CORTICOSTEROIDS

Corticosteroids can be used as needed at disease onset while awaiting response to DMARD therapy and intermittently during disease flare-ups or following failure of optimized treatment to control symptoms of pain and swelling. Corticosteroids have a long history of use in RA because of their potent anti-inflammatory and immunosuppressive effects and have been shown to enhance the

clinical, functional, and structural efficacy of baseline csDMARD or combination csDMARD and bDMARD therapies.[28] Corticosteroids administered orally at low dosages or through local injections are effective in rapidly reducing disease activity and relieving RA symptoms.

Corticosteroids are particularly beneficial when patients are awaiting the onset of DMARD action (known as “bridge therapy”) or during flares of active RA involving a small number of joints.[30,63] Oral corticosteroids seem to slow the rate of disease progression and have been shown to reduce radiographic changes for 1 to 2 years.[38,63,64] Use of corticosteroids in combination with DMARD therapy appears to improve clinical outcomes (signs and symptoms, functionality, radiologic damage) for patients with RA above the benefit of a DMARD used alone.[38,63,64] In addition, newer modified-release corticosteroids targeting nocturnal increases in inflammatory mediators, IL-6 and cortisol, have demonstrated a reduction in morning stiffness compared with older, standard immediate release agents.[65–67] Long-term use of corticosteroids, however, is associated with many serious adverse effects (eg, osteoporosis, weight gain, diabetes, cataract formation, adrenal suppression, hypertension, infections, and impaired wound healing).[68] As a result, oral corticosteroid dosing should be limited to daily doses of ≤10 mg of prednisone (or equivalent) and should be administered for as short a time as possible.[30] Frequent corticosteroid injections for an extended period have the potential to accelerate bone and cartilage deterioration; therefore, the same joint should not be injected more than once every 3 months.[68]

CLINICAL USE OF DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

DMARD treatment should be started as soon as possible following RA diagnosis with a treatment goal of low disease activity or remission. MTX remains the gold standard because of high response rate, mild side effect profile, low cost, and long sustained efficacy not just as monotherapy but also in combination with glucocorticoids,

other csDMARDs, bDMARDs, and tsDMARDs.[28–30] Furthermore, MTX therapy is associated with a reduction in cardiovascular morbidity and mortality in patients with RA, important given the strong association between RA and cardiovascular disease.[27] Optimization of MTX therapy also involves appropriate dose titration, adequate trial duration, and folate supplementation.

In the setting of moderate or high disease activity unresponsive to csDMARD monotherapy, ACR guidelines conditionally recommend the addition of bDMARD or tsDMARD over csDMARD combination therapy.[30] Combination csDMARD therapy may be considered based on patient preference as an alternative for patients who fail to reach treatment goals on a single csDMARD. Similarly, EULAR recommends when failure to achieve RA treatment target with the first csDMARD, in the setting of poor prognostic features (ie, functional limitation, extra-articular disease, positive RF or anti-CCP, and bony erosions), a bDMARD or tsDMARD should be added to the RA treatment regimen.[28] However in the absence of poor prognostic features, EULAR recommends the patient trial another csDMARD(s) (ie, LEF, SSZ, and/or MTX as mono- or combination therapy).

ACR and EULAR give no preference to any bDMARD or tsDMARD over another, except in certain clinical scenarios. Non-TNF inhibitor bDMARD or tsDMARD are conditionally recommended for patients with New York Heart Association (NYHA) class III or IV heart failure.[28–30] Rituximab may be considered as a first-line bDMARD in patients having certain contraindications to other bDMARDs such as recent lymphoma, because this agent is not associated with malignancy.[69–71] It is preferred that the bDMARDs be used in combination with either MTX or other csDMARDs rather than as monotherapy.[30] However, if a patient truly cannot be treated with csDMARDs, consideration may be given to monotherapy with etanercept, adalimumab, certolizumab pegol, abatacept, tocilizumab, or sarilumab.

If a patient has an inadequate response to the initial bDMARD or tsDMARD trial, switching to another from a different class is warranted. There is no preferred step-up bDMARD or tsDMARD and choice is dependent on patient-specific factors. Although the ACR

and EULAR guidelines do not currently provide recommendations for choosing between a bDMARD versus a tsDMARD (JAK inhibitors), recent safety data requiring a boxed warning in the prescribing information for tsDMARDs may favor the use of TNF inhibitors before tsDMARDs. Ultimately, shared decision-making is advised between a patient and their prescriber after reviewing the benefits and risks of JAK inhibitors, particularly in patients who cannot use or continue to use TNF inhibitors.[39–41]

QUANTIFYING RESPONSE TO DRUG THERAPY

RA low disease activity or remission is the highest aim of therapy and has become more realistic as medications capable of halting or slowing disease progression are now widely available and commonly used in clinical practice. Therefore, it is critical for all patients to have equal access to the medications available. The ACR and EULAR consider patients with RA in clinical trials to have achieved remission if either of the following occurs: (a) tender joint count, swollen joint count (of 28 joints), CRP in mg/dL, and patient global assessment scores (scale of 0–10) are all <1 (per Boolean-based definition) or (b) Simplified Disease Activity Index (SDAI) is ≤3.3.[38] If disease remission is unattainable, then minimizing disease activity to provide pain relief, maintain activities of daily living, maximize quality of life, and slow joint damage become primary targets.

In active disease, successful implementation of the treat to target approach requires reevaluation of pharmacologic therapy every 1 to 3 months. Therapy adjustment no later than 3 months into the treatment course is warranted because if there is no improvement by this time then it is unlikely that continuing the same course will achieve satisfactory results. Once treatment targets have been achieved, monitoring may occur less frequently. In patients with good response, glucocorticoids should be the first medications tapered and withdrawn, and if remission is sustained, then tapering and discontinuing DMARD therapy (all types) may be considered.[30] This is a conditional ACR recommendation; although the quality of evidence supporting this recommendation is low in terms of the risk

of disease exacerbation/recurrence, the long-term risk and cost of continuing therapy that is potentially unnecessary makes this a valid consideration.

Evaluating treatment response using validated clinical assessment tools yields a more accurate assessment of disease activity and improves the likelihood of attaining disease remission through modifications of drug therapy.[72,73] ACR has defined response criteria; however, these are designed for clinical research and may not be practical for clinical practice.[74] Although there is no single tool adopted as the standard of practice in the clinical setting, there are various other validated assessment tools that are advantageous for objectively evaluating disease activity and tracking disease progression.

- Disease Activity Score in 28 joints
- Simplified Disease Activity Index
- Clinical Disease Activity Index
- RA Disease Activity Index
- Patient Activity Scale (PAS) or PASII
- Routine Assessment Patient Index Data

These tools use various combinations of 28-tender joint count, acute-phase reactant measures, pain and function assessments, and patient and physician global assessments of disease activity to determine disease activity. For example, the Clinical Disease Activity Index (CDAI) and the SDAI scores are determined through a simple sum of swollen joint count, tender joint count, patient global disease activity, and evaluator global disease activity (both measured by a visual analog scale). However, the SDAI includes CRP in the summation, whereas the CDAI does not.[75] It is important to note that all of these tools have distinctly defined threshold scores corresponding to high disease activity, moderate disease activity, low disease activity, and remission, although there is little agreement among the tools in terms of classifying a patient's RA activity level. Choice of tool is typically practice-specific.

The scoring tools listed above should be used in conjunction with radiographic evaluation to determine RA course and treatment strategy. Conventional radiography was previously considered the gold standard, but imaging via computed tomography, ultrasound, and magnetic resonance imaging is now available and may offer some benefit in improved resolution compared with standard radiograph technology.[76] Radiographic changes occur in more than half of patients categorized in remission and tracking these can help clinicians objectively evaluate arthritis-related joint damage.[77]

Pharmacologic Treatment

NONSTEROIDAL ANTI-INFLAMMATORY DRUG THERAPY

T.W.'s clinical presentation clearly warrants DMARD therapy (see Case 44-3, Question 4, and Clinical Use of Disease-Modifying Antirheumatic Drugs section). The purpose of NSAID therapy, which has no disease-modifying activity, is to provide rapid pain relief and reduction of joint inflammation primarily as bridge therapy while awaiting the onset of DMARD activity, which could take weeks to months.[43] In general, there is no NSAID of choice for the treatment of RA.[15,78] There is no significant difference among the NSAIDs in efficacy, and it is difficult to predict a given patient's response to a particular agent. The selection of an NSAID is based primarily on patient preference, convenience, cost, and safety.[43,79] A 1- to 2-week trial of any NSAID at a moderate-to-high dose on a scheduled basis (ie, not as needed) is the best method of determining anti-inflammatory efficacy. The analgesic and antipyretic effects are relatively prompt in onset.

NSAIDs have important differentiating properties, and individualizing selection based on these characteristics is warranted in all patients such as T.W.[78] For example, several NSAIDs increase the risk of MI, with diclofenac, meloxicam, and indomethacin showing the highest risk of thrombosis, although celecoxib and ibuprofen at high doses also carry relatively high cardiovascular risk. Naproxen appears to have the best cardiovascular safety profile.[80,81]

Longer-acting NSAIDs such as piroxicam and ketorolac have been associated with a higher frequency of peptic ulcer disease and GI bleeding and should be avoided. Other NSAIDs, depending on their COX-2 selectivity, have varying GI toxicity profiles with naproxen conferring moderate risk and ibuprofen lower risk.[82,83] The selective COX-2 inhibitor celecoxib, at least with short-term use, is associated with a 20% lower risk of GI bleeding than traditional NSAIDs.[84] Because this agent does not interfere with COX-1—the isozyme responsible for production of the stomach's mucous lining and for reduced acid secretion—in theory COX-2 inhibitors reduce inflammation as effectively as nonselective NSAIDs while reducing the risk of GI toxicity. However, concurrent daily low-dose aspirin use appears to negate any benefit of COX-2 inhibitor therapy on lowering ulcer risk.[85]

Indomethacin penetrates the blood–brain barrier better than any other NSAID, achieving levels in the cerebrospinal fluid of up to 50% of serum levels. As a result, the incidence of central nervous system side effects of indomethacin such as dizziness often precludes the use of optimal anti-inflammatory doses, particularly in the elderly.[86]

A low-cost NSAID (eg, naproxen and ibuprofen) with a good safety profile is a good choice for T.W. because she is relatively young and does not have any concomitant illnesses. If convenience of administration is a more important consideration, a longer-acting NSAID (eg, naproxen) would be preferable. If the first agent chosen is ineffective or not well tolerated, other NSAIDs can be tried to identify the optimal one for this patient.

Case 44-1, Question 5: Naproxen 500 mg twice daily has been prescribed for T.W. If T.W. were to experience dyspepsia during therapy, should she be given antiulcer prophylaxis or a COX-2 selective NSAID at this time? What is the correlation between dyspepsia and gastroduodenal mucosal injury? What instructions regarding NSAID therapy should be provided to T.W., especially with regard to GI problems?

Patients should be informed that NSAID therapy is being prescribed to provide relief of pain and inflammation associated with

RA, but that it will not slow or stop the progression of the disease. It should be explained that the latter can only be accomplished by DMARD therapy. Patients should also understand that moderate-to-high daily doses of NSAIDs are required for anti-inflammatory activity, as opposed to analgesic and antipyretic effects which can be achieved with single and low doses.

About 5% to 15% of patients with RA discontinue NSAID therapy because of dyspepsia, and about 1.3% of patients taking NSAIDs for RA experience a serious GI complication. As expected, the rate is somewhat lower for patients using NSAIDs for osteoarthritis (0.7%) because these patients generally use analgesics only on an as-needed basis. Serious NSAID-induced GI complications account for >100,000 hospitalizations annually in the United States and ~16,500 NSAID-related deaths each year.[83,87] Although these figures warrant concern, most patients who experience NSAID-induced dyspepsia suffer only superficial and self-limiting injury. Nevertheless, prevention of NSAID-induced GI bleeding should be an important focus, particularly in high-risk patients.

Patients should be taught to recognize the signs and symptoms of GI bleeding (eg, nausea, vomiting, anorexia, and gastric pain) including melena (described to the patient as “dark, tarry stool”) and emesis of coagulated blood (described to the patient as “coughing or vomiting up what seems to be coffee grounds”). It should be emphasized that GI bleeding can occur without gastric pain. The patient should be instructed to contact their health care provider immediately for further instructions if any of these signs or symptoms occur.

Gastroduodenal mucosal damage induced by NSAIDs primarily results from inhibition of COX-1 in the mucosal lining.[87] This inhibition of COX-1 decreases bicarbonate secretion, mucosal blood flow, formation of protective mucus, proliferation of gastric epithelium, and the ability of the mucosa to resist injury. Topical damage to the GI mucosa can occur from NSAIDs, but direct injury plays a smaller role than COX-1 inhibition.

Dyspepsia can be managed by ingesting the NSAID with meals or a large glass of water; however, these measures usually are

ineffective in preventing GI ulcers. In addition, dyspepsia correlates poorly with endoscopically confirmed mucosal injury.[87–89] Histamine type 2 (H_2) receptor antagonists (eg, ranitidine, famotidine) significantly reduce dyspepsia among NSAID users; however, NSAID users with RA who take an H_2-receptor antagonist as needed might have a higher risk of developing serious GI complications compared with those who do not take these medications (odds ratio, 2.14; 95% confidence interval, 1.06–4.32).[90] The suppression of dyspepsia symptoms can give a false sense of security to the patient and physician, leading to higher doses of NSAIDs and increased risk of major gastropathy. Also, routine use of H_2-receptor antagonists is associated with tachyphylaxis.[91] Therefore, H_2-receptor antagonists are not recommended for routine use in asymptomatic patients receiving NSAIDs. Proton-pump inhibitors (PPIs; eg, lansoprazole, omeprazole) relieve dyspepsia better than H_2-receptor antagonists and prevent the development of NSAID-induced gastroduodenal ulcers.[90,92] They are safe and effective for the treatment of NSAID-induced dyspepsia and should be considered if symptoms develop in T.W.

Effective prevention options for reducing the risk of NSAID-induced ulcers and related complications include a PPI, double the dose of H_2-receptor antagonists, and misoprostol. PPIs are the most efficacious and best tolerated co-therapies with NSAIDs to reduce the risk of peptic ulcers and ulcer complications. Double doses of H_2-receptor antagonists have demonstrated a reduction in NSAID-induced endoscopic peptic ulcers; however, no study has demonstrated that double-dose H_2-receptor antagonists prevent ulcer complications and PPIs remain significantly more effective. Misoprostol, a prostaglandin E_1 analog, is most effective when given at the full dose of 200 µg four times daily; however, intolerable GI upset, particularly diarrhea and abdominal cramping, frequently leads to discontinuation of therapy at this dose. Lower doses are usually prescribed (200 µg two or three times daily) with better

tolerance but lower efficacy. Sucralfate or antacids are not effective in preventing NSAID-related GI injury.[92]

Routine concomitant antiulcer prophylactic therapy is not warranted for all patients taking NSAIDs; rather the risk for GI ulcer development must be assessed to determine the need for preventive measures. Established risk factors for NSAID-induced GI bleeding include advanced age (>65 years), history of ulcers and/or upper GI bleeding, concurrent use of antiplatelets, anticoagulants, corticosteroids and/or selective serotonin reuptake inhibitors, high-dose NSAID therapy, cigarette smoking, and/or alcohol consumption. Patients can be grouped into high, moderate, or low risk of NSAID-induced GI toxicity based on these risk factors. High-risk patients (>2 risk factors) should avoid NSAID therapy or take a COX-2 inhibitor instead along with either a PPI or a misoprostol. Moderate-risk patients (one or two risk factors) should take a PPI or misoprostol with an NSAID; naproxen is the preferred NSAID for high–cardiovascular-risk patients. Low-risk patients (no risk factors) do not need concurrent GI protective therapy and should receive a relatively less GI toxic NSAID at the lowest effective dose.[92] Without risk factors other than NSAID use, T.W. does not need concurrent ulcer prophylaxis or a COX-2–selective NSAID at this time, although a less toxic agent such as naproxen or ibuprofen should be chosen.

CASE 44-2

Question 1: R.Z. is a 28-year-old female who is planning a pregnancy and is concerned about the possible effects of NSAIDs on her baby.

What are the risks to the fetus with uninterrupted consumption of NSAIDs? What are maternal- and lactation-related effects of these medications?

Although NSAIDs, including aspirin, are not teratogenic, they must be used cautiously in females who are pregnant and who plan to breastfeed infants.[93] Fetal effects of NSAIDs include possible premature ductus arteriosus closure, increased cutaneous and intracranial bleeding, transient renal impairment, and a reduction in urine output. High doses of aspirin (>3 g/day) and NSAIDs can

inhibit uterine contractions, resulting in prolonged labor. The use of NSAIDs can also increase peripartum blood loss and anemia. Aspirin and nonaspirin NSAIDs should be used sparingly and at the lowest effective doses during pregnancy and discontinued at least 6 to 8 weeks before delivery to minimize adverse fetal and maternal effects.

Aspirin generally should be avoided for females who plan to nurse their baby because salicylate serum concentrations in breast-fed neonates raise concerns about the potential for metabolic acidosis, bleeding, and Reye syndrome. Nonaspirin NSAIDs are generally compatible with breast-feeding, with the best evidence supporting the use of ibuprofen, indomethacin, and naproxen.[94,95]

CASE 44-3

Question 1: T.Z., a 68-year-old male with heart failure previously managed with furosemide 40 mg/day, digoxin 0.125 mg/day, metoprolol 50 mg twice daily, and lisinopril 40 mg/day, returns for a prescription refill of ibuprofen 600 mg three times daily, which he takes for his RA. During the past 2 weeks, he has noted increased leg swelling, a weight gain of several pounds, exacerbated shortness of breath, and easy fatigability.

Why might these signs and symptoms be associated with ibuprofen use?

Mild fluid retention occurs in ~5% of NSAID users, and NSAID-induced kidney disease occurs in <1% of patients.[94,95] NSAID therapy should be avoided, if possible, in patients with preexisting heart failure, kidney disease, or cirrhosis.[96] If a patient with these conditions requires NSAID therapy, or patients are taking angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, serum creatinine should be checked soon after NSAID initiation. Inhibition of COX by NSAIDs within the kidney reduces prostaglandin concentrations and unopposed vasoconstriction. Consequently, urine output declines, serum blood urea nitrogen and serum creatinine levels rise, and fluid is retained. In addition, ibuprofen at higher doses is associated with an increased risk of MI, a concern for T.Z. because of his risk of thrombotic cardiovascular events.[80] The provider of T.Z.'s cardiovascular care should be

informed of his symptoms of fluid overload, and an alternative to NSAID therapy should be pursued.

Case 44-3, Question 2: If NSAID therapy is discontinued, what analgesic or anti-inflammatory alternatives are there for T.Z.? What other renal syndromes are associated with NSAID use?

Although celecoxib has been associated with a slightly lower risk of death and heart failure exacerbation when compared with traditional NSAIDs, it is not a reasonable initial option for T.Z. because celecoxib is also associated with an increased risk of MI and it may contribute to worsening of heart failure.[97]

NSAIDs should be used at their lowest effective doses for minimal periods for T.Z. High-dose NSAIDs should be avoided owing to increased MI risk. Although acetaminophen is not an anti-inflammatory agent, it can provide analgesic relief. Intra-articular corticosteroid injections can be useful if inflamed joints are limited in number, or a short course of oral corticosteroids can provide rapid control of inflammation while reducing the need for longer courses of NSAID therapy. If T.Z. is not yet being treated with a DMARD, initiation should be considered immediately because disease-modifying therapy can eventually preclude T.Z.'s need for an NSAID. If an NSAID or short course of systemic corticosteroid is used, close monitoring of renal function and fluid retention status is warranted.

In addition to acute renal failure, NSAIDs can induce various adverse renal effects (eg, nephrotic syndrome, interstitial nephritis, hyponatremia, abnormalities of water metabolism, and hyperkalemia).[98] The nephrotic syndrome, unlike NSAID-induced acute renal failure, can appear anytime (ie, from days to years) after initiation of therapy and can resolve as quickly as 1 month, or as long as 1 year, after discontinuation of the NSAID. Hematuria, pyuria, and proteinuria without prior renal disease differentiates nephrotic syndrome from other NSAID-induced renal problems. Histologically, NSAID-induced nephrotic syndrome is characterized by interstitial lymphocytic infiltrates, vacuolar degeneration of

proximal and distal tubules, and fusion of epithelial foot processes of glomeruli.

Prostaglandin-mediated inhibition of active chloride transport, regulation of medullary blood flow within the kidney, and antagonism of antidiuretic hormone can be suppressed by NSAIDs. As a result, urine is maximally concentrated, free water clearance is limited, and water retention that is disproportionate to sodium retention can occur. The resulting hyponatremia can be severe and could be potentiated by thiazide diuretics.[98] Local prostaglandin synthesis can also stimulate renin production within the kidney. NSAID therapy can critically attenuate this regulatory mechanism in some situations, resulting in reduced aldosterone-mediated potassium excretion and hyperkalemia.

Although the mechanism is poorly understood, some NSAIDs have been associated with sustained mean arterial pressure increases of 5 to 6 mm Hg,[99,100] presumably the result of COX-2 inhibition and sodium and water retention. Several studies suggest that only patients taking antihypertensive medications experienced NSAID-induced mean arterial pressure elevations, but it is now clear that even normotensive individuals can experience elevations in blood pressure from NSAID use.

Case 44-3, Question 3: How frequently should T.Z.'s renal and liver function be evaluated during his NSAID therapy?

Patients at high risk for NSAID-induced renal disease, like T.Z. (see Case 44-3, Questions 1 and 2), should have their serum creatinine levels checked regularly (eg, weekly) for several weeks after initiation of NSAID therapy because renal insufficiency more commonly occurs early in the course of therapy rather than later.[101] NSAID-induced nephrotic syndrome and allergic interstitial nephritis occur, on average, about 6.6 months and 15 days after NSAID initiation, respectively.[98]

In most cases, liver function testing (LFT) is unnecessary.[101] Although NSAIDs can elevate liver enzymes, severe hepatotoxicity is

rare. Abnormal LFTs without clinical symptoms have no impact on patient outcome and have not been associated with severe hepatotoxicity. Patients who seem to be at the greatest risk for hepatotoxicity are those with established or suspected intrinsic liver disease and those taking diclofenac. These patients should have LFTs performed no later than 8 weeks after initiation of therapy because liver toxicity manifests early in therapy, if at all.

Case 44-3, Question 4: T.Z. was diagnosed with RA 18 months ago, shortly after symptoms began to manifest. He exhibits no features of a poor prognosis and has low disease activity. Which traditional DMARD (csDMARD) therapies are most appropriate for him?

TRADITIONAL DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

According to ACR and EULAR, every patient with RA should receive DMARD therapy. Guidelines for DMARD selection were discussed previously (see Treatment section). Monotherapy with MTX is considered the preferred initial treatment for most patients with RA. A high and rapid response rate for all levels of RA severity, relatively low cost and toxicity, and radiographic evidence of slowing joint erosion (which is most rapid during the first several years of active disease) are reasons why MTX is preferred.[30] Other csDMARDs to consider are HCQ, SSZ, and LEF. Although most DMARDs are associated with potentially serious adverse effects, these generally are reversible and seldom lead to serious complications if the patient is monitored appropriately.

Safety and efficacy data, which reflect several years of DMARD therapy combined with biologic agents, have been excellent, and the combination is now commonly prescribed for patients who fail MTX monotherapy (see Case 44-5, Questions 9–11).[30] Combination DMARD therapy is indicated for more severe or more advanced patients with RA (see Case 44-5, Question 8).

Hydroxychloroquine dosing

Case 44-3, Question 5: Although MTX is considered the initial DMARD of choice for newly diagnosed RA with moderate-to-high disease activity, because T.Z. has low disease activity with no poor prognostic factors, treatment was initiated with HCQ. What dosages would be appropriate, and when should clinical improvement be expected?

Although the manufacturer's literature recommends an initial HCQ adult dose of 200 to 400 mg/day, dosages for HCQ should not exceed 5 mg/kg/day based on actual body weight.[102–104] About two-thirds of patients who tolerate HCQ respond favorably. Benefits usually are apparent within 2 to 4 months of therapy, but it can vary between 1 and 6 months. About 37% of patients discontinued HCQ within a year and 54% within 2 years, primarily owing to lack of efficacy.[101]

Risk of Retinopathy

Case 44-3, Question 6: When being counseled regarding HCQ, T.Z. was told that the drug can cause vision problems. How great is the risk of retinopathy from HCQ when used for the treatment of RA? What monitoring parameters are appropriate?

HCQ is usually well tolerated. The most serious toxicity, retinal damage and subsequent visual impairment, is rare.[30,101,103,104] With daily HCQ doses ≤5 mg/kg based on actual body weight, the risk of retinopathy is <2% from HCQ use of up to 10 years. Risk factors for retinopathy include high daily doses relative to body weight and cumulative doses, reduced renal function, concomitant use of tamoxifen (retinotoxic drug), and retinal disease. Patients should be instructed to stop therapy immediately and undergo an ophthalmologic evaluation if they are experiencing symptoms of HCQ-related retinopathy (eg, difficulty seeing faces or entire words, glare intolerance, poor night vision, and loss of peripheral vision).[102–104] The fully developed lesion of antimalarial retinopathy is seen on ophthalmoscopy as a pigmentary disturbance with a characteristic bull's-eye appearance in the macular region. The 4-amino-quinolines

bind to melanin, and as a result, concentrate in the uveal tract and retinal pigment epithelium. The retinopathy can be progressive even after discontinuation of the drug.

A baseline eye examination is recommended within the first few months of starting HCQ therapy, then annually after 5 years of treatment.[103–105] More frequent testing is recommended for patients with high-risk factors (noted above). Early changes of HCQ retinopathy are now detectable with optical coherence tomography (OCT), and early intervention with discontinuing HCQ may avoid serious visual loss.

Sulfasalazine

Case 44-3, Question 7: If SSZ were chosen as initial therapy for T.Z. instead of HCQ, when should therapeutic effects become apparent, and what adverse effects might be anticipated?

SSZ may be considered for treatment in patients with low disease activity before methotrexate and leflunomide. The onset of SSZ effect is generally more rapid than that of HCQ, usually providing benefits within 2 to 3 months.[105] Overall, SSZ adverse effects are relatively mild, although SSZ is considered to be slightly more toxic than HCQ. Adverse effects include nausea, abdominal discomfort, heartburn, dizziness, headaches, skin rashes, and, rarely, hematologic effects such as leukopenia (1%–3%) or thrombocytopenia. A complete blood count (CBC) is recommended every 2 to 4 weeks for the first 3 months of therapy, then every 3 months thereafter. Leukopenia, agranulocytosis, or hepatitis are rare, but serious side effects of SSZ usually manifest within the first 2 to 3 months of therapy. To minimize GI-related adverse effects, SSZ is initiated at 500 mg/day or 1 g/day, and the dosage is increased at weekly intervals by 500 mg until a dose of 1000 mg two or three times daily is reached.

CASE 44-4

Question 1: S.S., a 41-year-old Asian female diagnosed with RA, presents with inflammation in both hands (MCP and PIP joints), wrists, elbows, shoulders, knees, hips, ankles, and MTP joints. Objective test results include radiographic evidence of joint erosion in both hands and elbows, positive RF (dilution of 1:1280), positive anti-CCP at 102 units, and ESR of 78 mm/hour. Her SDAI score is 30. When she initially developed symptoms a year ago, she self-treated with ibuprofen 800 mg three times daily; however, pain and inflammation have progressively worsened. ROM testing reveals deficits in wrist flexion and extension (20° bilaterally for both motions; normal, 90° and 70°, respectively), elbow flexion (90° bilaterally with flexion contracture; normal, 160°), shoulder abduction (70° right, 90° left; normal, 180°), and plantar flexion of both ankles (20° bilaterally; normal, 45°). Three firm, pea-sized, nontender movable subcutaneous nodules are found on both elbows at the ulnar border, two on the right and one on the left. A decision is made to treat S.S. with MTX.

Why is MTX a good selection for her?

Methotrexate

MTX is recommended as initial DMARD therapy for all patients with RA.[30] S.S. has many indicators of severe disease (eg, an SDAI score indicating high disease activity, multiple joint involvement, extra-articular manifestations [ie, subcutaneous nodules], radiographic evidence of erosions, elevated ESR, positive anti-CCP, positive RF with a high titer of 1:1280 [high titers correlate with greater disease severity]). MTX is ideal because it has a rapid onset (usually 1–2 months before a plateau of effectiveness), a high efficacy rate at managing symptoms and slowing disease progression, low toxicity, and a long history of successful use.[30]

Dosing

Case 44-4, Question 2: How should MTX be dosed and administered to S.S.?

In general, MTX is administered orally at an initial dose of 7.5 to 10 mg once a week. The dose can also be divided over 24 hours for patients who are unable to tolerate adverse effects.[79] MTX dose should be titrated to at least 15 mg/week by week 4 to 6 of therapy

for increased efficacy. If inadequate response is seen at this time, then (a) the dose can be increased to the 20 to 30 mg/week based on tolerability, (b) the dose can be administered as a subcutaneous or IM injection to address concerns of adverse effects with higher doses, (c) the same dose can be continued for a longer time, or (d) another DMARD can be added to MTX or MTX can be substituted.[106,107]

Adverse Effects

Case 44-4, Question 3: What subjective and objective data should be evaluated for evidence of MTX adverse effects in S.S.?

S.S. should be monitored for nausea and other GI distress, malaise, dizziness, mucositis, and mild alopecia, which are commonly encountered adverse effects associated with low-dose MTX therapy.[101] More serious, but less common, adverse effects include myelosuppression, pneumonitis, and hepatic fibrosis and cirrhosis. A CBC, LFTs, and a serum creatinine concentration should be obtained for her at baseline, every 2 to 4 weeks for the first 3 months, every 8 to 12 weeks during months 3 to 6, and then every 12 weeks thereafter during MTX therapy. Renal dysfunction can result in accumulation of MTX and higher risk of myelosuppression. Interstitial pneumonitis, occurring in <1% of patients, has no known risk factors for development, although it may be more common in patients with a history of lung disease.[105] In addition, interstitial pneumonitis can occur at any time during therapy and at any MTX dosage. A baseline chest radiograph is recommended within the year before MTX initiation. If the patient is found to have preexisting lung disease, MTX treatment should be reconsidered because further pulmonary damage could be devastating to the patient. S.S. also should be monitored carefully for cough, dyspnea on exertion, and shortness of breath at each clinic visit.

MTX-induced liver disease is rare, but increased age, long duration of therapy, obesity, diabetes mellitus, ethanol consumption,

and a history of hepatitis B or C increase the risk of hepatotoxicity.[106] MTX should be prescribed with great caution, if at all, in patients with preexisting liver disease. The serum concentrations of liver enzymes commonly are modestly increased after administration for 1 to 2 days. However, MTX should be withheld if liver enzymes increase to three times the baseline value or if the liver enzyme serum concentrations remain elevated for sustained periods during therapy. Patients taking MTX should avoid alcohol and be instructed to report symptoms of jaundice or dark urine to their primary-care provider. Routine liver biopsies to monitor for MTX-induced hepatotoxicity are unnecessary (see Case 44-4, Question 4).

Liver Biopsy and Methotrexate

Case 44-4, Question 4: The following laboratory test results were obtained for S.S. before starting MTX:

Alanine transaminase (ALT), 28 IU/L
Aspartate aminotransferase (AST), 30 IU/L
Alkaline phosphatase, 100 IU/L
Albumin, 4.5 g/dL
Total bilirubin, 0.8 mg/dL

Should a baseline liver biopsy be performed before S.S. starts MTX?

Liver biopsy is only recommended at baseline for MTX patients who have a history of heavy alcohol consumption, persistently elevated liver function tests (defined as elevations above the upper limit of normal [ULN] in AST for five of nine tests within a 12-month period [or 6 of 12 if tests are performed every month] or a reduction in serum albumin below normal range), or chronic hepatitis B or C. During therapy, patients with persistently elevated liver functions tests or serum albumin below normal range should have a repeat liver biopsy. Otherwise, routine liver biopsy is unnecessary and not cost-effective.[106] Diligent LFT has proven to be highly effective at preventing liver injury.[108] When initiating or escalating methotrexate dosing, ALT with or without AST, creatinine and CBC should be

checked every 4 to 6 weeks until stable dosing is achieved, then testing should be repeated every 1 to 3 months thereafter along with screening for adverse effects and hepatotoxicity risk factors at every visit.

Because S.S.'s LFTs are normal and there is not a history of liver disease noted, there is no reason to consider a baseline liver biopsy.

Methotrexate and Folate or Folinic Acid

Case 44-4, Question 5: When should folate (or folinic acid) be administered to reduce the risk of MTX-related toxicity in S.S.?

Folate supplementation appears to reduce the incidence of several MTX-related adverse effects, including GI disturbances, mucositis (mouth or GI ulcerations), and LFT elevations.[108] The current consensus and evidence-based recommendation is at least 5 mg folic acid weekly. Although daily doses of folic acid as low as 1 mg are associated with protection against liver toxicity, GI disturbances are best prevented at doses above 5 mg weekly. Although folinic acid has also proven to be effective at lowering GI and hepatotoxicity, doses above 5 mg/week are associated with worsening of arthritis symptoms, consistent with the fact that MTX is a folate antagonist, and folinic acid supplementation could adversely impact efficacy.[105,108]

Methotrexate-Related Pulmonary Disorders

Case 44-4, Question 6: S.S. is treated with MTX 7.5 mg and with folic acid 7 mg orally once a week. Nine weeks later, she returns to the clinic with subjective and objective improvement in morning stiffness, fatigability, and joint tenderness and swelling. However, she has noted increased shortness of breath and dyspnea in the past week. Why might these symptoms be related to MTX?

Pneumonitis, a rare complication of MTX therapy, is characterized by a nonproductive cough, malaise, and fever, progressing to severe dyspnea.[109] Risk factors include older age (>60 years), previous use of DMARDs, low albumin, and diabetes. Recognition of this unusual reaction is important to ensure that MTX is discontinued before the pneumonitis progresses to respiratory failure. After discontinuation of MTX, pulmonary function improves. Corticosteroids can accelerate improvement in pulmonary symptoms associated with pneumonitis. S.S.'s dyspnea and shortness of breath might be related to MTX. If appropriate tests rule out other causes for her pulmonary symptoms, MTX-induced pulmonary toxicity should be considered and MTX treatment discontinued.

Methotrexate Interactions

Case 44-4, Question 7: What major MTX drug interactions need to be discussed with S.S. by her providers?

NSAIDs increase MTX serum concentrations and increase the risk of toxicity.[106] MTX doses should be adjusted cautiously if S.S. is taking NSAIDs concurrently to manage her RA pain. Trimethoprim, frequently used as part of the treatment for urinary tract infections, can increase the risk of MTX-induced bone marrow suppression. The concurrent use of MTX and LEF has been associated with major liver damage, including fatalities; as a result, this combination should be avoided. Because MTX is protein bound and renally excreted, other drugs (eg, salicylates, probenecid, penicillin, and ciprofloxacin) also might interact with MTX.

Leflunomide: place in therapy

CASE 44-5

Question 1: B.W. is a 36-year-old female who has severe, progressive RA and is unable to tolerate MTX therapy.

Would LEF be a reasonable consideration for her?

LEF, an oral csDMARD, seems to be similar in efficacy to MTX with regard to ACR-20, radiographic response, and work productivity.[29] The onset of benefit (as early as 4 weeks) and the percentage of patients who discontinue LEF therapy because of either lack of efficacy or toxicity are similar for LEF, MTX, and SSZ. The preferred initial csDMARD is MTX because of a long history of safety and efficacy, but LEF is a reasonable consideration as a replacement for MTX-intolerant patients, along with bDMARDs.

Case 44-5, Question 2: How should therapy with LEF be initiated in B.W. and how would you monitor B.W. for adverse effects?

Dosing and Monitoring

The active metabolite of LEF, A77 1726 (M1), is responsible for virtually all the pharmacologic activity of LEF.[106] The serum half-life of the M1 metabolite is ~2 weeks. As a result, LEF may be initiated with a loading dose of 100 mg orally once daily for 3 days to reduce time to steady state, followed by 20 mg once daily. If this dose is not tolerated, the dose should be reduced to 10 mg once daily.

Monitoring for Adverse Effects

Diarrhea (20%–30%), rash (10%), alopecia (10%–17%), and reversible liver enzyme elevations more than three times the ULN (2%–4%) are common adverse effects of LEF.[106] Routine laboratory testing includes a baseline ALT followed by monthly ALT testing for several months. When it is evident that ALT results are stable and within normal limits, testing can be performed less often according to the clinician's judgment. Because of the risk of liver toxicity and the need for activation by the liver to the M1 active metabolite, LEF is not recommended in patients with preexisting liver disease, including hepatitis B or C.

Potential hepatotoxicity is the greatest concern with LEF; however, the rate of LEF-induced liver enzyme elevation is not significantly different from MTX. Guidelines for managing potential hepatotoxicity include dosage reduction from 20 to 10 mg/day if ALT increases more than two times the ULN.[106] If ALT elevations remain steady between two and three times the ULN and treatment continuation is desired, a liver biopsy is recommended. If ALT elevations are persistently more than three times the ULN despite dosage reduction and cholestyramine administration to enhance elimination (see Case 44-5, Question 3), then the drug should be discontinued, and another course of cholestyramine elimination therapy should be given.

Enhancement of Elimination With Cholestyramine

Case 44-5, Question 3: After 2 months of therapy, B.W. does not respond to LEF and the treatment was discontinued, especially because she is beginning to consider starting a family. What precautions must be taken when discontinuing LEF? What are possible alternative treatments?

LEF is contraindicated in pregnancy because it greatly increases the risk of fetal death or teratogenicity in animals receiving as little as 1% of human equivalent doses.[106] After discontinuation of therapy, however, up to 2 years may be needed to elapse before plasma M1 metabolite levels of LEF are undetectable. As a result, cholestyramine is recommended for all females who discontinue LEF and who are hoping to become pregnant. After stopping the medication, cholestyramine 8 g three times daily is administered for 11 days (may be nonconsecutive). Plasma levels of the M1 metabolite are reduced by 40% to 65% in 24 to 48 hours and should become undetectable (<0.02 mg/L) at the end of therapy. B.W.'s blood should be evaluated at least 14 days apart to verify the absence of the metabolite. If plasma M1 levels remain >0.02 mg/L, more cholestyramine should be administered. Cholestyramine also can be used to enhance the elimination of LEF in patients who

experience hepatotoxicity or who overdose with this drug. Activated charcoal also can reduce plasma M1 levels by 50% after 48 hours and can be an effective alternative to cholestyramine when LEF overdosages need to be managed.

Both HCQ and SSZ appear to be safe in pregnancy, whereas MTX is not recommended in pregnancy because of the risk for embryo-fetal harm. However, because of B.W.'s high disease activity with poor prognostic factors, a bDMARD may be considered.

Traditional disease-modifying antirheumatic drug combination therapy

Case 44-5, Question 4: Is there evidence to support the early and safe use of csDMARDs in combination for B.W.?

Because most patients with RA develop joint erosions within the first 2 years of disease, the initiation of disease-modifying agents early in the course of therapy, and using them in combination, has been associated with improved patient outcomes. The rationale for combination therapy is based on the premise that a combination of drugs might improve outcomes because of different pharmacologic mechanisms of action or different sites of actions. A combination of drugs also may allow the use of lower doses of individual drugs, thereby reducing the risk of toxicity while maintaining or possibly increasing efficacy. However, the use of csDMARD combinations may increase patient burden of adhering to multiple medications.

Current ACR guidelines conditionally recommend bDMARD or tsDMARD over csDMARD combination therapy in patients with moderate-to-high RA disease activity. Combination csDMARD therapy may be considered based on patient preference as an alternative for patients who fail to reach treatment goals on a single csDMARD.[30]

In summary, every patient with RA, including B.W., should receive csDMARD therapy at or shortly after diagnosis, with MTX monotherapy as preferred initial treatment. Patients who experience

loss of efficacy or intolerable adverse effects from MTX can add one or two csDMARDs, or add or substitute a bDMARD or tsDMARD, which will be discussed in ensuing sections.

Biologic DMARD drug therapy

Case 44-5, Question 5: After 6 months of treatment with csDMARDs (LEF after intolerance to MTX), B.W.'s response is inadequate, her RA remains highly active, and she has signs of early joint damage. B.W.'s physician would like to try a TNF-α inhibitor. Is a TNF-α inhibitor an appropriate treatment option for B.W.?

According to the EULAR guidelines, bDMARDs or tsDMARDs should be considered for patients with moderate-to-high disease activity with poor prognostic factors, who do not reach treatment targets with the first csDMARD strategy (MTX alone or in combination with another csDMARD) within 6 months or without poor prognostic factors, who fail a second csDMARD strategy.[28] For patients not at treatment target with csDMARD monotherapy, the ACR guidelines conditionally recommend the addition of bDMARD or tsDMARD over csDMARD combination therapy.[30]

Given that B.W. has tried two different csDMARDs and continues to have highly active RA with poor prognostic factors, it is time to consider a bDMARD or tsDMARD. Out of the bDMARDs, TNF-α inhibitors have been available on the market for longer and thus have more robust long-term safety data, which may influence prescribers' confidence in these agents. A TNF-α inhibitor would be an appropriate choice in therapy for B.W. Her csDMARD therapy should be continued with the selected TNF-α inhibitor.

Case 44-5, Question 6: Which TNF-α inhibitor should be started in patient B.W.?

There are five TNF-α inhibitors available for the treatment of RA including etanercept, adalimumab, infliximab, certolizumab pegol,

and golimumab. Although there are multiple studies describing the efficacy and safety of these agents, there is no consensus on the preferred initial TNF-α inhibitor. The use of each of these medications as well as comparisons between them will be explored here.

TNF-α inhibitors: place in therapy and dosing

Etanercept (ETA) was the first biologic response modifier to be approved by the U.S. Food and Drug Administration (FDA) for reducing the signs and symptoms of moderate-to-severe active RA, either alone or in combination with MTX.[47] ETA is a soluble TNF receptor that competitively binds two TNF molecules, rendering both molecules inactive. It is self-administered once weekly by subcutaneous injection at a dose of 50 or 25 mg twice weekly.[47] ETA provides rapid and significant improvement in subjective and objective measures of RA, either alone or in combination with MTX.[46,110] The addition of ETA to MTX therapy has shown greater clinical efficacy when compared with MTX monotherapy.[111] ETA alone has also been shown to be superior to MTX as monotherapy in the reduction of RA symptoms and disease activity.[112,113] ETA has demonstrated decreased radiographic progression of RA as well as long-term safety and efficacy.[114,115] Etanercept is a reasonable choice for B.W. and should be used in combination with MTX for best results.

Adalimumab (ADA) is a genetically engineered, fully humanized IgG1 monoclonal antibody that has been shown to inhibit the structural damage of RA while reducing clinical signs and symptoms. The recommended dose is 40 mg administered by subcutaneous injection every other week. It is recommended to give ADA in combination with MTX.[48] Patients who cannot or choose not to take MTX may benefit from weekly dosing or 80 mg every other week.[48] When ADA 40 mg every other week was added to the treatment regimen of patients with RA receiving stable MTX doses, significantly more ADA-treated patients (67%) achieved an ACR-20 response than those receiving only MTX (14.5%, $P < .001$) after 24 weeks.[116]

Combination therapy with ADA and MTX was shown to be superior to either MTX or ADA monotherapy for RA symptoms and disease progression.[117] In radiographic data reflecting 1 or 2 years of treatment, ADA has been shown to slow the progression of joint damage. Data also support the long-term efficacy and safety of ADA.[118] ADA would also be an appropriate choice for B.W. and would require less frequent injections than ETA.

Infliximab (IFX) is a chimeric (mouse–human) IgG antibody directed against TNF. Specifically, IFX is approved in combination with MTX for the treatment of moderate-to-severe active RA. The recommended dose is 3 mg/kg via intravenous infusion at weeks 0, 2, and 6, then every 8 weeks thereafter. Some patients may benefit from an increase in dose up to 10 mg/kg or a decrease in treatment interval to as often as every 4 weeks.[49] IFX should be given with MTX therapy to prevent the formation of antibodies to infliximab. In a randomized, double-blind, multicenter, placebo-controlled trial of patients with active RA who failed to respond adequately to at least 12.5 mg/week of MTX, IFX 3 or 10 mg/kg or placebo was administered every 4 or 8 weeks along with MTX therapy. The signs and symptoms of RA were improved in the IFX groups versus MTX alone. This study was unblinded after 1 year because of radiographic evidence of disease modification in patients receiving IFX. Analysis of radiographic results after 2 years demonstrated that IFX significantly protected against joint erosion.[119] IFX would also be an appropriate bDMARD for B.W., particularly if she prefers less frequent intravenous infusions to self-administration of subcutaneous injections. Patient preferences are an important factor to consider when choosing between the anti-TNF agents.

Certolizumab pegol (CZP) consists of a Fab attached to a 40-kDa PEG moiety. The attachment to the PEG moiety increases the half-life of CZP to ~2 weeks, which allows dosing every 2 to 4 weeks.[120] The recommended dosing regimen is 400 mg initially and at weeks 2 and 4 followed by 200 mg every other week or 400 mg every 4 weeks by subcutaneous injection.[121] CZP's unique structure lacks an Fc region, so it may not induce complement- or antibody-dependent cell-mediated cytotoxicity, which has been observed in vitro with

adalimumab, etanercept, and infliximab.[122] The efficacy of CZP has been demonstrated in patients with moderate-to-severe active RA in combination with MTX and as monotherapy.[123–125] In a randomized, double-blind, placebo-controlled study in 619 patients with active RA, significantly more patients met ACR response rates with CZP plus MTX than patients treated with placebo plus MTX ($P < .001$).[124] Physical function, as evidenced by the mean change in the Health Assessment Questionnaire (HAQ) disability index (DI) score, DAS28 remission, and radiographic progression of RA were all improved in the CZP plus MTX group.[124] CZP has shown sustained efficacy and safety over 5 years in patients with active RA.[126]

To date, CZP is the only anti-TNF that has been studied specifically in pregnancy and lactation. Because of CZP's Fc region being replaced by PEG, it was considered to be less likely to cross the placenta while the large molecular size of CZP would limit transfer into breast milk. The CRIB study demonstrated no to minimal CZP drug transfer from mother to infant and no to minimal drug transfer into breast milk from the CRADLE study (Industry sponsored).[127,128] Thus, CZP is strongly recommended by ACR for use before conception, during pregnancy, and breast-feeding in 2020.[129] Patient B.W. would also be a candidate for CZP and CZP may be preferred if she still is family planning.

Golimumab (GLM) is a human IgG1 monoclonal antibody specific for human TNF-α. GLM binds to both the soluble and the transmembrane bioactive forms of human TNF. This binding prevents the binding of TNF-α to its receptors, thus inhibiting the biologic activity of TNF-α.[51] GLM shares common characteristics with both adalimumab and infliximab. Similar to adalimumab, GLM is a fully humanized bivalent immunoglobulin monoclonal antibody.[130] GLM is made up of light and heavy chains, which are identical to infliximab, but whereas infliximab is derived from both mice and humans, GLM is completely humanized. GLM is approved for the treatment of moderate-to-severe active RA in combination with MTX.[51] It can be administered by subcutaneous injection or intravenous infusion. The subcutaneous injection is a 50-mg injection dosed monthly.[51] The dose of the intravenous infusion is 2 mg/kg

over 30 minutes at weeks 0 and 4, then every 8 weeks thereafter.[131] Clinical trials have demonstrated GLM efficacy in patients with no previous MTX use and in patients with an inadequate response to MTX or a TNF-α inhibitor.[132–134] A randomized, placebo-controlled trial conducted in 444 patients examined the efficacy of GLM in patients with active RA despite concomitant MTX use.[135] Significantly more patients in the combined GLM plus MTX group achieved an ACR-20 response compared with the MTX plus placebo group (55.6% vs 33.1%, respectively, $P < .001$), and these results were sustained at 52 weeks.[135] In another study assessing the long-term safety and efficacy of GLM in patients with RA who discontinued previous TNF-α inhibitors, GLM treatment resulted in sustained efficacy and safety.[135] Given this information, GLM would also be an appropriate treatment option for B.W., and she would have the option of choosing between intravenous or subcutaneous dosing.

There are currently no definitive guidelines recommending one TNF-α inhibitor over another. Direct head-to-head comparisons between the anti-TNF agents are lacking; therefore, prescribers must depend on surveillance data, systematic reviews, and meta-analyses to make clinical decisions regarding comparative efficacy and safety.

Case 44-5, Question 7: What side effects will need to be monitored when starting B.W. on adalimumab?

TNF-α inhibitors: side effects and monitoring

The greatest concern with adalimumab therapy is the risk of immunosuppression and subsequent serious infections, including sepsis. TNF-α is a key mediator of inflammation and plays a major role in immune system regulation. Postmarketing reports of infections, such as TB, mycobacterial infections, fungal infections, and hepatitis B virus reactivation, further reinforce the strong recommendation against the initiation of adalimumab therapy in patients with sepsis or any chronic or localized active infection.[47] Mycobacterium tuberculosis testing and hepatitis B serologies should be undertaken before initiation of anti-TNF therapy. Therapy

should be postponed for patients identified as having active TB until appropriate antituberculosis therapy has been completed.[29] Patients being treated for latent TB infection may start anti-TNF therapy after the first month of latent TB treatment. Clinicians also must be cautious when prescribing adalimumab (or any bDMARD) to patients with a history of recurring infection or with underlying illnesses that predispose them to infection. B.W. should receive a TB test, hepatitis B serologies, and be warned of the potential adverse effects of adalimumab, particularly the risk of immunosuppression and subsequent infection. Any sign of infection must be reported to her health care provider.

TNF-α has been implicated in the pathophysiology of heart failure, and increased serum levels of TNF-α seem to be associated with worsening heart failure.[136] Proposed mechanisms contributing to the onset or worsening of heart failure include accelerated left ventricular remodeling, negative inotropic effects, and increased apoptosis of myocytes and endothelial cells. Clinical trials with anti-TNF therapy (which have included etanercept and infliximab) have shown an association between TNF-α and worsening heart failure; some have also shown increased cardiovascular risk.[136] As a result, anti-TNF therapy is not recommended for patients with RA with moderate-to-severe (NYHA class III and IV) heart failure. Anti-TNF therapy can be used with caution in patients with mild (NYHA class I and II) heart failure, but patients should be closely monitored for cardiac decompensation.[28]

Included in the labeling for all anti-TNF bDMARDs is a warning for increased risk of lymphoma and other malignancies. An increased incidence of lymphoma has been observed among patients with RA receiving any of the available anti-TNF agents; however, causation has not been established because both RA and MTX are associated with an increased rate of lymphoma. Additionally, the FDA has issued a warning following reports of hepatosplenic T-cell lymphoma, a rare cancer of the white blood cells, in patients being treated with TNF blockers, AZA, or mercaptopurine.[137] The majority of these cases were found in adolescents and young adults with Crohn disease or ulcerative colitis. Incidence was also more common in

patients on a combination of immunosuppressive agents. Although it is difficult to measure the added risk associated with anti-TNF agents, caution and monitoring is advised.[137] Other adverse effects, in order of decreasing frequency, include headache, rhinitis, dizziness, pharyngitis, cough, asthenia, abdominal pain, and rash.

With anti-TNF therapies, there have been rare reports of new onset or worsening demyelinating diseases, including multiple sclerosis, optic neuritis, and Guillain-Barré syndrome.[48] Patients should be screened for preexisting central nervous system and peripheral demyelinating conditions prior to initiating anti-TNF therapy.

CASE 44-6

Question 1: S.K., a 71-year-old female, was diagnosed with RA ~15 years ago. Her initial drug therapy included MTX, followed by the addition of SSZ and HCQ, which seemed to keep her RA in near-remission for 5 years. She then changed to etanercept in combination with MTX with good results until 1 year ago. In response to declining disease control, infliximab was substituted for etanercept with excellent results. Then last month, she experienced a flare in RA activity. At that time, her CRP was 5.1 mg/dL, ESR was 90 mm/hour, and anti-CCP was positive at 112 units. She also experienced morning stiffness lasting several hours and multiple joints with swelling (N = 26) and tenderness (N = 38). Of note, S.K. has a history of treated skin melanoma 2 years ago.

What are the reasonable treatment options for S.K. at this stage of her disease?

Non-TNF biologic DMARDs

Clinical studies have consistently demonstrated that bDMARDs improve the signs and symptoms of RA as well as slow the progression of structural damage. TNF-α inhibitors have long been considered first-line bDMARDs given the availability of long-term data and clinical experience compared to the non-TNF bDMARDs. However, ongoing registry and trial data suggest that the safety profiles of the non-TNF bDMARDs, abatacept, rituximab, tocilizumab, and sarilumab, are consistent with clinical trial results.[28] Some trials have shown superiority of some of these agents over

TNF-α inhibitors. TNF-α inhibitors also fail to produce an ACR-20 response in ~30% of patients, which is known as primary failure. Even more patients experience acquired resistance to treatment, known as secondary failure, which is defined as a loss of response with time and is illustrated by S.K.[138] Many patients who lose responsiveness to an initial trial of anti-TNF therapy can be successfully treated with an alternative anti-TNF agent.[139] However, studies have also shown that response rates with sequential anti-TNF therapy may be lower, and the reasons for initial anti-TNF failure (inefficacy or adverse effects) may be recurrent.[139,140] The ACR guideline conditionally recommends switching to a bDMARD or tsDMARD of a different class when not at target. Therefore, it is important to consider alternative options for the treatment of patients like S.K. with anti-TNF treatment failure.[139,140]

Abatacept (inhibitor of T-cell activation), rituximab (selectively depletes $CD20^+$ on B cells), tocilizumab, and sarilumab (anti–IL-6 receptor antibodies) have demonstrated excellent efficacy in patients with inadequate response to csDMARDs (eg, MTX) as well as to anti-TNF therapy.[28,30] Owing to their differing mechanisms of action, each of these agents possesses unique qualities with regard to efficacy and safety. (Detailed dosing information for the bDMARDs can be found in **Table 44-1**.)

Table 44-1

Biologic Disease-Modifying Antirheumatic Drug Dosing Information

Generic (Brand)	Mechanism of Action	Dosage Range	Administracion Schedule	Routes oF Administration	Can Be Self-Administered?
Infliximab (Remicade")	INF-u inhibitor	3 mg/kg'	Weeks 0, 2, and 6 and then every 8 weeks	IV	No
Etanercept (Enbrel®)	TNF-u inhibitor	50 mg	Weekly	5C	Vfes
Adalimumab (Humira*)	TNF-a Inhibitor	40 mg	Every 14 days	SC	Yes
Certolizumab pegol (Clmzia*)	TNF-a inhibitor	Initial: 400 mgSC on weeks 0, 2, 4 Subsequent: 200 mg every 2 weeks or 400 mg every 4 weeks	Weeks 0, 2, and 4 and then every 2 or 4 weeks	SC	Yes
Golimumab (Simponi*)	TNF-a inhibitor	50 mg	Every month	SC	Yes
Golimumab (Sim[x)ni Ana®)	TNF-a inhibitor	2 mg/kg infusion over 30 minutes	Weeks 0 and 4, then every 8 weeks	IV	No
Abatacept (Orencia®)	Costimulatlon modulator, T-cell activation inhibitor	Weight based: <60 kg, 500 mg 60–100 kg, 750 mg >100 kg, 1000 mg	Weeks 0, 2, and 4 and then every 4 weeks	IV	No
		Or			
		125 mg	Once weekly (may be initiated with or without IV loading dose)	SC	Vfes
RItuximab (Rituxan®)	CD20+ B-cell inhibitor	1000 mg IV infusion: Initial: 50 mg/hour, may Increase every 30 minutes to a maximum rate of 400 mg/hour Subsequent: 100 mg/hour, may increase every 30 minutes to maximum rate of 400 mg/hour®	Repeat in 14 days to complete course Repeat course every 24 weeks or based on clinlcal response, bot not sooner than every 16 weeks	IV	No
Tocilizumab (Actemra*)	IL-6 inhibitor	Initial: 4 mg/kg every 4 weeks Subsequent: Titrate to 8 mg/kg based on clinical response Max.: 800 mg/dose (8 mg/kg)	Every 4 weeks	IV	No
		Or			
		Weight-based SC dosing: <100 kg, 162 mg every other week, followed by an increase to every week based on clinic response ≥100 kg, 162 mg every week	Every 14 days or weekly	SC	Yes
Sarilumab (Kevzara*)	IL-6 Inhibitor	200 mg	Every 14 days	SC	Y?s

IL, interleukin; IV, intravenous; SC, subcutaneous; TNF, tumor necrosis factor.

[a]For incomplete response, may increase dose to 10 mg/kg or decrease dosing interval to every 4 weeks.

[b]Premedicate with corticosteroid, acetaminophen, and an antihistamine before each dose.

Abatacept

Abatacept (ABT) is a selective costimulation inhibitor of T-cell activation indicated for the treatment of moderate-to-severe active RA.[53] ABT may be prescribed as monotherapy or in combination with csDMARDs. It can be administered intravenously or subcutaneously. ABT intravenous dosing is based on body weight (500 mg for patients 132.27 pounds [<60 kg], 750 mg for patients 132.27–220.46 pounds [60–100 kg], and 1000 mg for patients >220.46 pounds [>100 kg]) and should be infused over 30 minutes at weeks 0, 2, and 4, and then every 4 weeks thereafter.[53] The dose for the subcutaneous injection is 125 mg weekly. The efficacy and safety profiles have been shown to be comparable between the two preparations.[141]

Abatacept has demonstrated efficacy in patients with an inadequate response to MTX as well as in patients with an inadequate response or adverse reactions to TNF-α inhibitors.[53] In a study comparing ABT plus MTX to placebo plus MTX, significantly more patients in the ABT plus MTX group attained ACR-20 response when compared with the placebo plus MTX group (73.1% vs 39.7%, respectively, $P < .001$) and had significant slowing of structural damage progression compared to the patients treated with placebo at 12-month follow-up.[54] ABT efficacy was maintained in the 5-year open-label extension of this trial.[142] Efficacy and safety data from 7 years of ABT therapy indicate that ABT maintains sustained improvements in disease activity and ACR-70 scores during this period, with no change in safety profile.[143] ABT has also demonstrated efficacy in patients with an inadequate response to one or more TNF-α inhibitors, such as S.K.[144,145]

Finally, ABT has also been compared head-to-head with the TNF-α inhibitor adalimumab. In a 2-year study in patients with RA with an inadequate response to MTX, ABT and ADA were found to be similar in both efficacy and safety. Overall, patients experienced similar improvement in clinical markers of disease control and progression.

Although rates of adverse events in both groups were similar, there were more discontinuations because of adverse events in the ADA group (9.5%) compared to the ABT group (3.8%) (95% CI −9.5 to −1.9).[146]

The side effects of greatest concern with ABT include serious infections such as pneumonia, cellulitis, urinary tract infection, bronchitis, diverticulitis, and acute pyelonephritis. Infections are significantly more common when ABT is combined with anti-TNF therapy; thus, this combination is not recommended.[53] Malignancies have also been associated with ABT, and patients with chronic obstructive pulmonary disease are noted to suffer from more respiratory-related and nonrespiratory-related adverse effects than patients with chronic obstructive pulmonary disease treated with placebo.[53]

Rituximab

Rituximab (RXB) is a chimeric monoclonal antibody that binds to the antigen CD20 on B cells. It is approved in combination with MTX for the treatment of moderate-to-severe active RA in patients who have had an inadequate response to one or more TNF antagonist medications.[55] However, according to the EULAR guidelines, rituximab may be considered as a first-line bDMARD in patients with contraindications to other bDMARDs, such as recent history of lymphoproliferative disorder, which RXB is indicated for, latent TB with contraindications to chemoprophylaxis, living in TB-endemic areas or a previous history of demyelinating disease.[28] RXB is administered as two 1000-mg IV infusions separated by 2 weeks, then every 6 months as needed.[55] RXB must be diluted to a final concentration of 1 to 4 mg/mL with either 0.9% sodium chloride or 5% dextrose in water. To reduce the incidence and severity of infusion-related adverse effects, premedication with IV methylprednisolone 100 mg, or its equivalent, 30 minutes before each infusion is strongly recommended; other premedications (eg, acetaminophen and antihistamine) may also be beneficial. Antihypertensive medications should be discontinued 12 hours

before RXB administration to avoid transient hypotension, which has been reported during RXB infusions. RXB must be given with MTX for maximal efficacy based on clinical trials and to help reduce the risk of developing HACA, which occurs in ~9% of patients receiving RXB. It is recommended that subsequent courses of RXB be given every 24 weeks. The dosing interval may be decreased on the basis of clinical evaluation, but must be no less than every 16 weeks.[55]

Rituximab has been shown to be effective in patients who have responded inadequately to MTX therapy as well as in patients who have responded inadequately to anti-TNF medications.[147] The REFLEX (Randomized Evaluation of Long-Term Efficacy of Rituximab in RA) trial evaluated the use of RXB plus MTX versus placebo plus MTX in 499 patients with active, long-standing RA who responded inadequately to one or more anti-TNF medications, such as S.K.[148] At 24-week follow-up, significantly more patients in the RXB group demonstrated an ACR-20 response than those in the placebo group (51% vs 18%, respectively). And in a 56-week follow-up report of the REFLEX trial, RXB significantly inhibited radiographic progression of joint damage.[149] In the 2-year extension of this trial, RXB showed significant and sustained inhibition of joint damage. These findings support the efficacy and appropriateness of RXB for patients with RA, such as S.K., who are refractory to anti-TNF therapy.

Serious and fatal infusion reactions can be caused by RXB. Severe reactions typically occur with the first infusion; thus, careful monitoring is warranted, and premedication with methylprednisolone 100 mg or its equivalent is recommended 30 minutes prior to each infusion. RXB should be discontinued if a serious reaction occurs. Severe mucocutaneous reactions and progressive multifocal leukoencephalopathy (PML) may also occur in patients receiving RXB. Finally, hepatitis B (HBV) reactivation may occur in patients receiving RXB. Therefore, all patients should be screened for HBV infection prior to initiation. The most common adverse reactions in patients with RA receiving RXB include upper respiratory tract infections, nasopharyngitis, urinary tract infections, and bronchitis.[55] RXB has not been associated with any increase in malignancy;

therefore, it is preferred over anti-TNF agents in patients with a recent history of cancer.[28]

Because S.K. failed two TNF-α inhibitors because of inefficacy, either ABT or RXB would be an appropriate choice. Given S.K.'s history of skin melanoma 2 years ago, RXB would be the preferred agent over ABT in this patient.

CASE 44-7

QUESTION 1: Q.O. is a 55-year-old female with highly active RA for the past year who cannot tolerate MTX therapy. Her provider would like to start a bDMARD as monotherapy.

Which medication would be best?

Tocilizumab

Tocilizumab is a humanized anti–IL-6 receptor antibody indicated for the treatment of adult patients with moderate-to-severe active RA, who have had an inadequate response to one or more csDMARDs.[58] TCZ may be administered intravenously or subcutaneously. For the intravenous infusion, the recommended dosage is 4 mg/kg, infused IV every 4 weeks with an increase to 8 mg/kg as needed based on clinical response. The dosing for the subcutaneous formulation is 162 mg per injection either weekly or every other week depending on patient weight and response.[58] The safety and efficacy of the intravenous and subcutaneous formulations have been studied and appear to be comparable. However, an increase in injection-site reactions in the subcutaneous TCZ group has been seen.[150] TCZ should not be initiated in patients with an absolute neutrophil count <2000 cells/μL, platelet count <100,000 platelets/μL, or in patients who have an ALT or AST value >1.5 times the ULN.[58] TCZ treatment should be interrupted if a patient experiences a serious infection; therapy may be resumed once the infection is controlled.[58]

TCZ has demonstrated efficacy in the treatment of RA as monotherapy, in combination with csDMARDs, and in patients who are refractory to anti-TNF medications.[151,152] In a systematic review of eight randomized controlled trials (RCTs), TCZ at a dose of 8

mg/kg in combination with MTX was shown to statistically significantly decrease disease activity and improve physical function when compared to MTX plus placebo.[153] TCZ has also shown decreased radiographic progression of RA compared to csDMARDs.[151,154] In the RADIATE trial, patients with an inadequate response to one or more TNF-α inhibitors were randomly assigned to receive 8 or 4 mg/kg of TCZ or placebo every 4 weeks for 24 weeks.[152] An ACR-20 response was achieved at 24 weeks by 50.0%, 30.4%, and 10.1% of patients in the TCZ 8 mg/kg, 4 mg/kg, and placebo arms, respectively ($P < .001$).[152] Given this information, TCZ would also be a reasonable option for patients who have failed one or more TNF inhibitors, like S.K. from Case 44-6.

According to the ACR and EULAR treatment guidelines, the standard of care indicates that patients should maintain MTX or csDMARD therapy when a bDMARD is added.[28,30] However, for up to 40% of patients, MTX therapy is discontinued because of intolerance or patient preference and as many as one-third of patients may be taking bDMARDs as monotherapy.[155] Three of the TNF inhibitors (etanercept, adalimumab, and certolizumab pegol) and three of the non-TNF bDMARDs (abatacept, tocilizumab, and sarilumab) are approved as monotherapy. In a study comparing ADA and TCZ monotherapy in patients who were either intolerant to MTX or MTX was not an appropriate treatment option, patients in the TCZ group were found to have significantly greater improvement in DAS28 as well as most clinical endpoints when compared to the ADA group.[155] Therefore, TCZ is a reasonable therapeutic option for Q.O. as monotherapy for RA and has demonstrated superiority over at least one anti-TNF agent.[152,154]

When starting TCZ, Q.O. should be monitored for potential side effects. The most serious side effects associated with TCZ therapy include severe infections, GI perforation, and laboratory abnormalities. As with the TNF-α inhibitors, TCZ has a boxed warning for increased risk of developing serious infections, especially those caused by opportunistic pathogens. The risk for infection is increased when TCZ is taken in combination with other immunosuppressant agents (eg, MTX and corticosteroids). As with

the anti-TNF agents, a TB skin test result and chest radiograph must be obtained before initiating treatment. In clinical studies, the overall rate of fatal serious infections was low at 0.13/100 patient-years.[58]

TCZ has also been associated with a number of blood chemistry changes, including neutropenia, thrombocytopenia, elevated LFTs, and lipid changes. Increases in lipids (total cholesterol, low-density lipoprotein, high-density lipoprotein, and triglycerides) have been shown in clinical trials. Increase in lipids may be caused in part by the decrease in inflammatory activity with TCZ use. Lipid elevations respond to lipid-lowering agents. Although clinical trials do not indicate an increase in cardiovascular risk, further studies are necessary to assess the effects of TCZ on cardiovascular risk factors.[156,157]

Sarilumab

Similar to TCZ, sarilumab is also a humanized IL-6 receptor antagonist that binds to soluble and membrane-bound IL-6 receptors to inhibit IL-6 signaling. It is approved as monotherapy or in combination with csDMARDs for the treatment of moderate-to-severe active RA in adults who have had an inadequate response or intolerance to one or more DMARDs.[59] Unlike TCZ, SAR is only administered subcutaneously with a recommended dosage of 200 mg every 2 weeks. SAR should not be initiated in patients with an absolute neutrophil count <2000 cells/μL, platelet count <150,000 platelets/μL, or in patients who have an ALT or AST value >1.5 times the ULN.[59] SAR could be another option for Q.O. if they are amenable to subcutaneous medication administration.

Three different phase III RCTs demonstrated that sarilumab improves signs and symptoms of RA, physical functioning, and radiographic progression for a wide range of patient subpopulations.[158] The efficacy of sarilumab has been demonstrated to be similar to TCZ, but SAR may be more effective in patients with RA who are anti-citrullinated protein antibody (ACPA)-positive, whereas studies for TCZ have not identified a relationship between ACPA and achievement of target endpoints. However, there were

also fewer ACPA-negative patients enrolled in the SAR studies, so the data may not be as reliable. Both SAR and TCZ studies have similar findings that IL-6 receptor inhibition had a greater effect in patients with high baseline CRP.[158]

A long-term safety study that included data from eight clinical trials found the overall incidence rates of adverse events were similar between combination SAR and csDMARD therapy and SAR monotherapy.[159] The monotherapy group reported neutropenia, injection-site erythema, and nasopharyngitis as the most common adverse effects, whereas the combination group reported neutropenia, injection-site erythema, and upper respiratory tract infections most frequently. Overall, the results of the study showed consistent safety findings of phase III trials and of IL-6 signaling inhibition. The same monitoring parameters for TCZ should apply to SAR; however, when comparing the data available thus far, SAR may have a slightly more favorable safety profile over TCZ.[159]

Targeted synthetic DMARDs: Janus kinase inhibitors

Tofacitinib, baricitinib, and upadacitinib are the three JAK inhibitors currently available in the United States for the treatment of RA. Although all three JAK inhibitors inhibit JAK1, tofacitinib also selectively inhibits JAK2 and JAK3, and baricitinib inhibits JAK2.[10,39–41] However, the importance of the specific JAK enzyme inhibition in relation to treatment effectiveness is yet to be fully understood. These tsDMARDs offer patients with RA a targeted oral treatment and an alternative route of administration compared to bDMARDs. In 2021, the FDA issued updated boxed warnings for all three JAK inhibitors, which includes the risk of major adverse cardiovascular events (MACEs), malignancies, thrombosis, and mortality. Because of these added warnings, the three JAK inhibitors are now indicated for the treatment of RA in patients with an inadequate or intolerant response to one or more TNF inhibitors.

Case 44-7, Question 2: Two years later, Q.O. remains not at target with moderate disease activity after failing adalimumab and tocilizumab. Would a

tsDMARD be an appropriate treatment option for Q.O.?

Tofacitinib

Tofacitinib (TOF) is the first JAK inhibitor FDA approved for the treatment of RA. TOF may be dosed as TOF 5 mg orally twice daily or TOF XR 11 mg orally once daily, with or without food. The TOF XR extended-release tablets should not be cut, crushed, or chewed. For patients with moderate and severe renal impairment or moderate hepatic impairment, a dose adjustment to TOF 5 mg once daily is recommended. TOF should not be initiated in patients with an absolute lymphocyte count <500 cells/μL, absolute neutrophil count <1000 cells/μL, or hemoglobin levels <9 g/dL.[39]

TOF was studied in six different trials and demonstrated improvement in signs and symptoms of moderate-to-severe RA. In the TOF Study RA-V, patients with RA and an inadequate response to TNF inhibitors were evaluated in a phase 3, double-blind, parallel-group study comparing TOF 5 mg twice daily plus MTX versus placebo plus MTX. The ACR20 response at 3 months was 41.7% in the TOF arm compared to 24% in placebo. TOF demonstrated a significant time to onset of ACR20 response at week 2 and achieved greater DAS28 rates and greater improvements in HAQ-DI compared to placebo.[160] TOF may be considered as a treatment option for Q.O. who has already failed a TNF inhibitor and non-TNF bDMARD.

Baricitinib

Baricitinib (BARI) is the second FDA-approved JAK inhibitor for RA. BARI is dosed 2 mg orally once daily and can be administered with or without food. Dose adjustment to BARI 1 mg once daily is recommended for moderate renal impairment (noted as estimated glomerular filtration rate [GFR] between 30 and 60 mL/minute/1.73 m^2). It is not recommended in severe renal impairment or severe hepatic impairment. BARI should not be initiated in patients with an absolute lymphocyte count <500 cells/μL, absolute neutrophil count <1000 cells/μL, or hemoglobin levels <8 g/dL.[40]

Two confirmatory studies demonstrated efficacy and safety of BARI for the treatment of RA. The RA-BEACON trial studied patients with RA and previous inadequate response or intolerance to one or more TNF inhibitors with or without other bDMARDs. In the phase 3, randomized, double-blind, placebo-controlled study, patients with RA were treated with BARI 4 mg daily, BARI 2 mg daily or placebo in addition to the current concomitant csDMARD therapy. The ACR20 response and DAS28-CRP at week 12 was higher in BARI treatment groups compared to placebo. ACR20 was achieved in 49% versus 27% for BARI 2 mg arm and placebo arm, respectively.[161] BARI is an alternative JAK inhibitor that may be considered for Q.O.'s RA.

Upadacitinib

Upadacitinib (UPA) is the most recently approved JAK inhibitor for RA and dosed 15 mg orally once daily, with or without food. Because of the extended-release formulation, it should not be cut, crushed, or chewed. It is not recommended to be used in patients with severe hepatic impairment. UPA should not be initiated in patients with an absolute lymphocyte count <500 cells/μL, absolute neutrophil count <1000 cells/μL, or hemoglobin levels <8 g/dL.[41]

UPA had five phase 3 studies to show efficacy and safety of UPA 15 mg daily for the treatment of moderate-to-severely active RA. The SELECT-BEYOND study evaluated patients with active RA and experienced inadequate response or intolerance to bDMARDs. Patients were randomized to receive UPA 15 mg, UPA 30 mg or placebo in addition to established csDMARDs. At week 12, ACR20 was 65% versus 28% for UPA 15 mg group and placebo, respectively ($P < .0001$). Additionally, DAS28-CRP was achieved in more patients in the UPA treatment groups.[162] Lastly, Q.O. may also consider UPA for the treatment of her RA after failure of two bDMARDs.

JAK inhibitors: side effects and monitoring

JAK inhibitors have several boxed warnings that should be reviewed and discussed with the patient prior to initiating therapy. In 2021, the

FDA issued the addition of increased risk for MACE, malignancies, thrombosis, and mortality for all three JAK inhibitors after results from the TOF postmarketing safety study. The ORAL Surveillance study examined TOF versus TNF-α inhibitors for the treatment of RA in patients 50 years and older with at least one additional cardiovascular risk factor. The incidences of MACE and malignancy were higher with TOF versus TNF inhibitor, with a hazard ratio 1.33 (95% CI, 0.91–1.95) for MACE and 1.48 (95% CI, 1.04–2.09) for malignancies.[163] Despite the study only including TOF, because of a similar mechanism of action between the three JAK inhibitors indicated for the treatment of RA, the FDA required all three medications to have prescribing information updates.

Prescribers should consider risk stratification prior to starting JAK inhibitor therapy for the treatment of RA after inadequate response or intolerance to TNF inhibitor. A previous history of MACE, thrombosis, and cancer as well as general risk factors including age older than 65 years and smoking should be first identified. Risk may be further evaluated for the presence of additional risk factors specific for thrombosis (severe obesity, varicose veins, hormones) and MACE (hypertension, dyslipidemia, and diabetes).[164] The type and number of risk factors present may facilitate the risk versus benefit discussion with the patient and ultimately the decision to initiate a JAK inhibitor or not.

As with the bDMARDs, JAK inhibitors have a boxed warning for increased risk of serious infections.[165] JAK inhibitors are not recommended to be used in combination with other JAK inhibitors, bDMARDs, or strong immunosuppressants. Patients should be screened for active and latent TB prior to initiating therapy.

Other serious side effects associated with JAK inhibitors include GI perforation and laboratory abnormalities. JAK inhibitors have been associated with lymphopenia, neutropenia, anemia, elevated LFTs, and lipid changes. Baseline labs as well as routine laboratory monitoring should be performed to ensure continued safe use of JAK inhibitors.[166]

Prior to initiating a JAK inhibitor for Q.O., the physician should stratify Q.O.'s risk for serious adverse events associated with JAK

inhibitors, review the risk versus benefits of treatment, and use shared decision-making with the patient. If the risk is low and the patient is agreeable, any of the three JAK inhibitors may be considered.

CORTICOSTEROIDS

CASE 44-8

Question 1: W.M., a 57-year-old male, has progressive RA that has not been responsive to SSZ. He is having difficulty working a full day and is seeking an alternative medication. After a discussion of therapeutic options, W.M. is willing to start MTX.

Would it be appropriate to initiate corticosteroids concurrently? And if so, at what dose?

Despite the potential for serious adverse effects with long-term therapy, the judicious use of low-dose corticosteroids represents an important component of treatment during the course of unremitting disease. In addition, low-dose corticosteroids may offer some disease-modifying properties, although this is controversial because of the long-term negative effects of corticosteroid use.[67] The benefit of low-dose glucocorticoid therapy is favorable as long as the course of therapy is short.[30] Considering that W.M.'s RA is sufficiently active to compromise his ability to earn an income, MTX is a much better DMARD selection. Regardless, concurrent initiation of a DMARD and an intermediate-acting corticosteroid (eg, prednisone in a daily or divided dose of 5–10 mg) is justified.[167] A Cochrane review showed that corticosteroid doses equivalent to ≤15 mg of prednisolone were superior to placebo and NSAIDs for joint tenderness and pain in RA.[168] In large cohort studies, prednisone doses >7.5 mg/day have been associated with a greater than twofold increased risk of cardiovascular events (MI, stroke, and heart failure), as well as the risk of developing hypertension with long-term use (at least 6–12 months).[169,170] Therefore, the lowest effective corticosteroid dose is preferred for the shortest duration of time

possible.[30] The onset of action of corticosteroids is relatively rapid, and their immediate benefits will allow W.M. to maintain his current employment and continue taking care of responsibilities at home. The corticosteroid dose can be decreased gradually and eventually discontinued as W.M. begins to respond to MTX therapy. An important goal of low-dose corticosteroid treatment is to provide bridge therapy until the DMARD therapy becomes effective, in hopes of then being able to taper and discontinue the corticosteroid.

Case 44-8, Question 2: Would intra-articular corticosteroid injections be a safe and effective treatment option for W.M.?

Intra-articular corticosteroids

Intra-articular corticosteroid injections are safe and effective for pain relief in patients with RA. This strategy is most sensible when flaring occurs in one or a few joints.[171] Systemic side effects are minimal when compared with oral corticosteroid therapy. Although the onset of action is virtually immediate, effects are often short-lived. W.M. could benefit from the use of intermittent intra-articular corticosteroid injections for the treatment of RA flares.

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) is a heterogeneous group of chronic arthritic conditions of unknown etiology, occurring before 16 years of age. It is one of the most common chronic diseases in the pediatric population worldwide and the most common chronic rheumatic disorder in childhood. In the United States, the incidence is estimated at more than 14 patients per 100,000 and the prevalence at 96 patients per 100,000.[172] JIA affects all races with a peak age of onset between 2 and 4 years. However, new cases are seen throughout childhood and often continue into adulthood, causing significant morbidity and physical disability.[173–178]

Clinical Presentation and Classification

By definition, symptoms of JIA (joint inflammation involving swelling, pain, limited ROM, warmth, and erythema) present before the age of 16 and must last for at least 6 weeks in at least one joint.[179] Morning stiffness and its duration is also a clear clinical symptom of JIA.

As with adult RA, JIA begins with synovial inflammation. Because children often cannot articulate, morning stiffness and joint pain may manifest as increased irritability, guarding of involved joints, or refusal to walk. Fatigue and low-grade fever, anorexia, weight loss, and failure to grow are other symptoms. Patients with JIA are categorized as having one of the following seven types of disease as established by the International League of Associations for Rheumatology (ILAR):[180]

1. Systemic
2. Oligoarthritis
3. Polyarthritis RF+
4. Polyarthritis RF−
5. Psoriatic
6. Enthesitis-related
7. Undifferentiated (patients who do not fulfill the criteria of other JIA subsets)

The most common type of JIA is oligoarthritis, which comprises about 50% of all JIA cases. This type of JIA typically presents before the age of 6 years, with most cases afflicting girls. Patients with oligoarthritis present with four or fewer affected joints, most commonly in the knee. Those who do not progress beyond four joints are categorized with persistent oligoarthritis, but 50% may eventually develop arthritis in additional joints after 6 months of disease, requiring a change in disease classification to extended oligoarthritis.[174,180]

JIA is classified as polyarthritis when the disease involves five or more joints during the first 6 months of the disease with few or no

systemic manifestations of the disease.180 Polyarthritis may be RF+ or RF− and accounts for up to 40% of all JIA disease, the majority of which is RF−.[181] Both types affect girls more often than boys. Disease onset is typically seen at age 8 or older and most often in adolescents. RF+ polyarthritis presents very similarly to adult-onset RA, involving aggressive, erosive, and symmetric joint inflammation, which may lead to general growth retardation, as well as fatigue, morning stiffness, and elevated inflammatory markers.[173,174]

Psoriatic JIA accounts for a small number of all JIA cases (about 1%) and is diagnosed if chronic arthritis and psoriasis are both evident. Children may also be diagnosed with psoriatic JIA if any two of the following are present: dactylitis (finger or toe inflammation), onycholysis, nail pitting, or family history of psoriasis.[173,180]

Enthesitis-related JIA is manifested as inflammation of the enthesis (the site of attachment of tendon to bone) along with arthritis, typically in the lower limbs, in boys older than 6 years old. Children with enthesitis-related JIA have at least two of the following in addition to arthritis or enthesitis: inflammatory lumbosacral or sacroiliac joint pain, HLA-B27 positivity, symptomatic anterior uveitis, or a family history of enthesitis-related JIA or ankylosing spondylitis (first-degree relative).[180,182]

CASE 44-9

Question 1: J.R., a 4-year-old girl, is brought to the hospital for high fever and arthritis. Several weeks before admission, J.R. had a daily fever ranging from 103°F (39.44 °C) to 106°F (41.11 °C). One week before admission, her knees became painful and swollen. J.R. is listless and irritable during her physical examination, and her rectal temperature measures 102.4°F (39.11 °C). She refuses to walk. The right hip is tender, and the right wrist and both knees are warm, red, and swollen. Minimal generalized lymphadenopathy and splenomegaly are present. The Westergren ESR is 82 mm/hour, the white blood cell count is 37,000 cells/μL with a mild left shift, and hematocrit is 33%. Cultures of the throat, urine, stool, and blood are negative. MD global assessment is 4. An intermediate-strength purified-protein derivative, antistreptolysin-O titer, ANA titer, and RF titer are normal, as are radiographs of the chest and involved joints. An electrocardiogram reveals only tachycardia. After withholding aspirin, an evanescent rash becomes apparent in conjunction with fever spikes.

What signs and symptoms of JIA does J.R. manifest?

The last category is systemic JIA, which is distinguished from other forms of the disease by the presence of hallmark systemic features including rash, lymphadenopathy, hepatomegaly or splenomegaly, serositis, and cyclical high-spiking fever. J.R. exhibits these distinguishing symptoms and, in addition, she experiences joint pain in her knees, with other commonly affected joints including the wrists and ankles. The pain often worsens when fever is elevated but may not be clinically evident at disease onset. Systemic JIA occurs equally in girls and boys, and although it makes up only 5-15% of all patients with JIA, it causes the highest mortality and morbidity of all JIA categories. Children presenting with this subtype of JIA may also have macrophage activation syndrome (MAS), which is characterized by fevers, increased ferritin, liver enzyme and triglyceride levels, cytopenias, and low fibrinogen.[177]

Prognosis

Case 44-9, Question 2: What is the expected prognosis for J.R.?

Features of poor prognosis for patients with JIA include:[176–177]

- Arthritis that involves the ankle, wrist, hip, or sacroiliac joint
- Involvement of temporomandibular joint (TMJ)
- Enthesitis
- Significant or prolonged elevation of ESR or other inflammatory markers
- Radiographic damage indicating erosive disease
- Delay in JIA diagnosis

Disease remission is qualified by lack of active arthritis in joints, absence of systemic symptoms (rash, fever, lymphadenopathy, etc.), symptomatic uveitis not present, normal ESR or CRP, and no disease activity measured on a physician's global assessment scale.

Although only 5% of patients achieve true remission, sustained periods of good control are becoming more common with treatment advances, and up to 35% to 50% of patients achieve clinical remission on medication therapy. Despite improvements in care, complete remission is still uncommon, and up to one-third of patients with JIA do experience long-term disability and decreased quality of life. Preservation of joint function is least promising in children with RF+ polyarthritis.[183–185] Although J.R. is exhibiting some poor prognostic indicators (hip and wrist involvement, elevated ESR), it is unclear whether these are long-term manifestations. Normal ANA and RF titers and the absence of radiographic damage are favorable for J.R.

Treatment

The goals of JIA treatment are to minimize joint inflammation and its destructive effects, control pain, preserve or restore ROM, facilitate an acceptable quality of life, and achieve long-term disease remission. Choice of medication therapy requires consideration of the type of JIA, current treatment, degree of disease progression, level of disease activity, and prognosis.[175–178]

NONPHARMACOLOGIC THERAPY

In addition to treatment with medication, many patients with JIA can benefit from nonpharmacologic efforts to help preserve joint flexibility, maintain ROM, and prevent disability in adulthood. Patients with JIA are often less physically active and more easily fatigued than their disease-free peers, and they may meet developmental milestones later than children of the same age.[186] Children with JIA are also more prone to decreased bone mineral density than their peers.

Case 44-9, Question 3: J.R.'s parents understand the need for medication therapy but also want to encourage lifestyle interventions as a way to promote health and combat disease complications. What recommendation can the physician give to J.R. and her family once her acute symptoms are stabilized?

A healthy, balanced, and age-appropriate diet should be recommended.[175] Heat and cold therapy, massage, and regular physical activity can all help reach disease treatment goals of minimizing joint inflammation, controlling pain, and improving quality of life. Regular physical activities, including muscle-strengthening, ROM activities, stretching, and endurance training, are safe and do not worsen arthritis. Weight-bearing exercise can help prevent bone loss, but it should be avoided when joints are acutely inflamed. At these times, low-impact sports such as swimming or bicycling can be enjoyed. Physical therapy and occupational therapy can also help pediatric patients hone gross and fine motor skills, balance, and coordination.[186,187] Once J.R.'s status improves, she should be encouraged to participate in regular exercise and organized therapy sessions to improve exercise capacity and preserve joint functioning.

PHARMACOLOGIC THERAPY AND TREATMENT CONSIDERATIONS

Whereas ILAR differentiates JIA into seven disease types, the 2019 and 2021 ACR guidelines classify treatment recommendations based on the clinical presentation of JIA and into the following eight treatment groups: (1) polyarthritis, (2) sacroiliitis, (3) enthesitis, (4) oligoarthritis, (5) TMJ, (6) systemic JIA without MAS, (7) systemic JIA with MAS, and (8) uveitis.[175–178]

(1) JIA and Active Polyarthritis

Patients with JIA and active polyarthritis should have MTX considered as first-line therapy. The role of NSAIDs was recommended as an adjunct therapy and is not appropriate for monotherapy as DMARD therapy is considered a cornerstone to slow disease progression. For specific DMARD selection, MTX is preferred over LEF and SSZ. Based on the presence of risk factors for more severe disease, refractory disease (positive anti-CCP, RF+, or presence of joint damage), and moderate-to-high disease activity, a bDMARD may be initiated or added to current DMARD therapy. The bDMARD therapy options include anti-TNF agents

(adalimumab, etanercept, infliximab, and golimumab) or non-TNF agents (abatacept and tocilizumab). Rituximab is considered the last-line bDMARD agent. In the setting of low disease activity, therapy can be escalated to include intra-articular glucocorticoid injection(s), increasing the DMARD, or bDMARD dose.[176]

Because the ACR 2019 JIA guidelines focused on polyarthritis, tofacitinib was FDA approved in 2020 for the treatment of polyarticular course JIA in patients 2 years and older who have failed or had an intolerance to one or more anti-TNF therapy.[39] Tofacitinib may be considered an alternative treatment option.

(2) JIA and Sacroiliitis

Patients with active sacroiliac arthritis may include individuals from any of the JIA disease categories, but the treatment group must be defined by both clinical and imaging evidence of the disease. NSAIDs are strongly recommended with step-up therapy to include the addition of a TNF-α inhibitor. MTX monotherapy is not recommended; however, it may be used as an adjunct therapy in some cases. Alternatively, SSZ may be considered for patients with contraindications to TNF-α inhibitors or failed multiple TNF-α inhibitors.[176]

(3) JIA and Enthesitis

Patients with active enthesitis may also include patients from any of the JIA disease categories. NSAIDs are strongly recommended as the first-line treatment. ACR conditionally recommends anti-TNF therapy over csDMARD (MTX or SSZ) in patients with active enthesitis despite treatment with NSAIDs. For patients with contraindications to TNF-α inhibitors or concomitant active peripheral polyarthritis, a trial of MTX or SSZ may be appropriate.[176]

Since the ACR 2019 JIA guidelines focused on enthesitis, secukinumab was FDA approved in 2021 for the treatment of active enthesitis-related arthritis (ERA) in patients 4 years and older and juvenile psoriatic arthritis (JPsA) in patients 2 years and older.[188] Secukinumab may be considered an alternative treatment option.

(4) JIA and Active Oligoarthritis

The history of arthritis of four or fewer joints treatment group includes ILAR disease-classified patients with extended oligoarthritis, RF− polyarthritis, RF+ polyarthritis, psoriatic arthritis, ERA, and undifferentiated arthritis, all have had no more than four affected joints in their disease course. Scheduled NSAIDs may be considered for initial therapy (now conditionally recommended); however, the use of intra-articular glucocorticoid injections is strongly recommended as part of initial treatment in JIA with active oligoarthritis. Step-up therapy includes csDMARD, followed by a bDMARD in those with poor response.[177] NSAIDs may be used as adjunctive therapy for any patient with JIA; however, the use as monotherapy should be limited to a short time frame due to limited efficacy and risks of drug side effects. Triamcinolone hexacetonide is the intra-articular glucocorticoid of choice and can provide clinical improvement for a minimum of 4 months; step-up to csDMARD therapy may be warranted if symptoms are not controlled within this period.[189,190] Among the csDMARDs, MTX is conditionally preferred over LEF, SSZ, and HCQ, and MTX may be initiated in those who fail initial therapy with NSAIDs and intra-articular injections or in those who have high disease activity and poor prognosis. Finally, in those who still lack response after a trial of NSAIDs, intra-articular glucocorticoid injections and at least one csDMARD, a bDMARD may be initiated. Based on the 2021 ACR guidelines, there is no preferred bDMARD of choice and may include anti-TNF agents (adalimumab, etanercept, infliximab, golimumab, and certolizumab pegol) or non-TNF inhibitors (abatacept and tocilizumab).

(5) Temporomandibular Joint Arthritis (TMJ)

JIA of the TMJ may develop without symptoms leading to a delay in diagnosis and treatment. Early evaluation and treatment are important to avoid dentofacial deformity, impairment in joint function, and poor quality of life.[191] Active TMJ arthritis therapy follows a similar treatment algorithm to JIA with oligoarthritis, with the exception that treatment should be promptly initiated and rapidly escalated to csDMARD (MTX over LEF) followed by bDMARD after an incomplete response to NSAIDs and/or intra-articular

glucocorticoids. Intra-articular glucocorticoids are less favored in patients with TMJ owing to TMJ-related side effects including heterotopic ossification and impaired bone growth.[177]

(6, 7) Systemic JIA (sJIA) with/without MAS and Systemic JIA with MAS

Systemic JIA is subdivided into two treatment categories based on the presence or absence of MAS. In those without MAS, biologic DMARDs (IL-1 and IL-6 inhibitors) are recommended as initial monotherapy. NSAIDs can also be used as monotherapy initially, but treatment should be escalated if a rapid and complete response does not occur.[177]

About 10% of pediatric patients with JIA develop MAS, a life-threatening complication characterized by fever, pancytopenia, liver insufficiency, and coagulopathy, among others, and if hospitalized, it is associated with a 6% mortality rate.[192] For those with MAS, initial treatment with IL-1 and IL-6 inhibitors is also recommended with the addition of glucocorticoids. Some patients will also require calcineurin inhibitors added to the treatment regimen to control MAS.

(8) JIA-Associated Uveitis

JIA-associated uveitis is the most common extra-articular manifestation and, if left untreated, may lead to sight-threatening complications.[178,193] Thus, routine screenings and prompt treatment are vital. Patients who are at high risk for developing uveitis include those with oligoarthritis, polyarthritis (RF−), psoriatic arthritis or undifferentiated JIA with positive ANA, JIA disease onset at age under 7 years old, and JIA disease duration of ≤4 years. These patients are recommended to have ophthalmic screening every 3 months. Initial treatment for chronic anterior uveitis begins with topical glucocorticoids, such as prednisolone acetate 1% drops for short-term control. If disease activity persists, systemic treatment with MTX and a monoclonal antibody anti-TNF biologic (adalimumab or infliximab) is recommended over MTX monotherapy.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Case 44-9, Question 4: Are NSAIDs an appropriate choice for initial drug therapy for the treatment of systemic JIA in patient J.R.?

NSAID therapy may be considered a first-line treatment for polyarthritis, sacroiliitis, enthesitis, oligoarthritis, TMJ, and systemic JIA without MAS, but was left out of the treatment guidelines for systemic JIA with MAS and uveitis. In the case of systemic JIA without MAS, as with patient J.R., NSAIDs may be considered as monotherapy; however, therapy should be quickly stepped up with continued disease activity.[177] NSAIDs can be useful in systemic JIA without MAS as they target joint inflammation as well as febrile episodes.[174,194] These medications work to control pain, fever, and inflammation by inhibiting prostaglandin synthesis and are usually fairly well tolerated by children. Analgesic effects usually occur first, and with continued use anti-inflammatory effects of NSAIDs will begin within a few weeks.

Many of the traditional NSAIDs as well as celecoxib have been used to treat JIA. The most commonly prescribed NSAIDs for JIA are naproxen and ibuprofen. Naproxen is approved for the treatment of JIA in children and adolescents at a dose of 10-15 mg/kg/day in two divided doses and is advantageous in school-age children because of the convenient dosing interval and availability in liquid or tablet formulations.[194] Ibuprofen is recommended at a dose of 30 to 40 mg/kg/day given in three or four divided doses. Ibuprofen is also available in tablet and liquid formulations.[195]

In most cases, at least two different NSAIDs should be tried before ruling out this group of medications owing to lack of efficacy or tolerability.[196] Failure to respond to an NSAID in a particular chemical class does not rule out the efficacy of others in the same class. As with adults, it is not possible to predict a pediatric patient's response to any one NSAID.

Given that J.R. has systemic JIA without MAS, a brief course of NSAIDs and/or initiating an IL-1 or IL-6 inhibitor would be the appropriate first-line agents for J.R.[177] For choice of NSAID, either ibuprofen or naproxen would be reasonable. Ibuprofen is available

over-the-counter in liquid and chewable forms, which is an important consideration for a 4-year-old. Naproxen is also available in an oral liquid suspension by prescription and can also be considered as initial therapy.

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Case 44-9, Question 5: J.R., who weighs 33 pounds (14.97 kg), was prescribed Naproxen 125 mg/5mL oral suspension at a dose of 75 mg bid. Her parents have given her the medication twice daily as directed for the past 2 weeks, but she continues to have disease activity with persistent fever. What should the next step in therapy be for J.R.?

Biologic Agents

There are several FDA-approved biologic agents available to treat forms of JIA: etanercept, adalimumab, abatacept, tocilizumab, tofacitinib, and secukinumab for JIA, and canakinumab and tocilizumab for systemic JIA. There are other bDMARDs that are not FDA approved for the treatment of JIA but are recommended in the ACR guidelines, including anakinra, rilonacept, rituximab, and the TNF-α inhibitors as a class.[176–178] Although the TNF-α inhibitors have demonstrated excellent efficacy in the treatment of adult RA as well as polyarticular JIA, they have not shown similar efficacy in the treatment of systemic JIA. The exact pathophysiology of systemic JIA remains unclear, but the pro-inflammatory cytokines IL-1 and IL-6 have been identified as targets of pharmacotherapy.[177,197–199] Thus, IL-1 inhibitors anakinra, canakinumab, and rilonacept as well as IL-6 inhibitor, tocilizumab, have demonstrated efficacy in the treatment of systemic JIA, and their use is addressed in the ACR treatment guidelines.[177]

IL-1 inhibitors, anakinra and canakinumab, are recommended for the treatment of systemic JIA, whereas rilonacept's place in therapy remains unclear. Anakinra blocks the action of IL-1α and IL-1β by inhibiting IL-1 binding to the interleukin-1 type receptor (IL-1R1). Although anakinra has shown suboptimal efficacy in the treatment of

adult RA, patients with systemic JIA have responded well to anakinra treatment. Case reports of good response to anakinra in patients who were refractory to other treatments for systemic JIA led to increased use of anakinra in patients with systemic JIA.[197,200,201] In a small randomized, controlled trial in patients with systemic JIA, 8 out of 12 patients in the anakinra group achieved the primary outcome (30% improvement in clinical status, resolution of fever, and 50% decrease or normalization of both CRP and ESR) versus 1 out of 12 patients in the control group. Furthermore, 10 of the patients in the control group were switched to anakinra after 1 month, and nine of these patients also responded to anakinra treatment.[201] Although anakinra is not FDA approved for systemic JIA, the dose that has been used in clinical trials is 1-2 mg/kg subcutaneously daily, with a maximum daily dose of 100 mg.[201] As with all of the bDMARDs, patients should be monitored for increased risk of infection when taking anakinra. Anakinra would be an appropriate treatment for J.R.

Canakinumab is a human monoclonal antibody, which binds IL-1β and blocks its interaction with IL-1 receptors. It is FDA approved for the treatment of systemic JIA in patients 2 years and older at a dose of 4 mg/kg subcutaneously every 4 weeks for patients with a body weight of ≥16.53 pounds (7.5 kg) (maximum dose 300 mg).[202] In a randomized, placebo-controlled trial evaluating canakinumab for the treatment of systemic JIA, 84% of subjects experienced a 30% clinical response in the canakinumab group compared to only 10% in the placebo group ($p < 0.001$) 15 days after one dose of canakinumab.[203] In another trial in patients receiving open-label canakinumab for 32 weeks, there was a significantly lower risk of flares in the canakinumab patients, and the average glucocorticoid dose was reduced in the canakinumab group.[203] Canakinumab, like other bDMARDs, has been associated with an increased risk of infections. It has also been associated with MAS. This association may be attributed to the severity of the disease in patients treated with canakinumab, and a causal relationship has not been established.[202–204] Canakinumab would also be an appropriate treatment option for J.R. The monthly dosing may be preferred over the daily dosing required with anakinra.

Rilonacept is an interleukin-1 inhibitor that binds IL-1β as well as IL-1α and IL-1 receptor antagonists with lesser affinity.[205] Although rilonacept has demonstrated efficacy for the treatment of systemic JIA, its place in therapy remains unclear.[206] It should not be used as first-line therapy, and its use was not included in the updated ACR guidelines for systemic JIA.[177]

Tocilizumab is a monoclonal antibody against the IL-6 receptor. It is recommended for patients with systemic JIA with active systemic disease and FDA approved for patients 2 years and older.[60,177] The TCZ dose for systemic JIA is 12 mg/kg for weight <66.14 pounds (<30 kg) or 8 mg/kg for weight ≥66.14 pounds (≥30 kg) given intravenously every 2 weeks.[60,207] Alternatively, TCZ subcutaneous dosing is 162 mg every 2 weeks for weight <66.14 pounds (<30 kg) or 162 mg every week for weight ≥66.14 pounds (>30 kg).[60] In a randomized trial of tocilizumab for systemic JIA, 71% of children who received TCZ experienced a 70% improvement in clinic status, compared to 8% of patients who received placebo.[208] Like canakinumab, there has been an association between TCZ and MAS. However, per ACR guidelines, IL-1 and IL-6 inhibitors may be recommended for the treatment of systemic JIA with MAS.[177,197]

Patient J.R. has tried an NSAID, but she continues to have active systemic RA. Anakinra, canakinumab, and tocilizumab would all be appropriate treatment options for J.R. Canakinumab has the most convenient dosing regimen of these three options and may be the best option for J.R.

CASE 44-10

Question 1: Seven-year-old C.E. has polyarthritis that consistently has not responded to NSAID or MTX therapy. Given the many potential side effects, C.E.'s parents are concerned about her taking steroids and refuse to let their daughter take them. They are worried about permanent joint damage and wish to try a biologic agent in hopes of finally suppressing disease activity. They have heard that biologic drugs are "safer than steroids."

Which agents are available to treat JIA in C.E.?

There are several FDA-approved biologic agents available to treat polyarticular JIA: etanercept, adalimumab, abatacept, tocilizumab, and tofacitinib. Secukinumab was most recently FDA-approved bDMARD for ERA and JPsA but would not be an appropriate choice for C.E.

Etanercept is a recombinant TNF-receptor Fc fusion protein indicated for patients 2 years of age or older with polyarticular JIA. ETA is recommended for patients with oligoarticular or polyarticular JIA, who continue to have active polyarticular JIA despite 3 months of treatment with MTX at the maximum tolerated dosage.[176] The recommended dose is 0.8 mg/kg (maximum 50 mg) subcutaneously weekly.[48] The safety of etanercept in children is comparable to adults, with the exception of significantly more abdominal pain (17% of patients with JIA vs. 5% of adult patients with RA) and vomiting (14.5% of patients with JIA vs. <3% of adult patients with RA). Patients with JIA should be up-to-date on their immunizations before initiation of etanercept therapy. Safety and efficacy data reflecting up to 10 years of treatment support the long-term use of etanercept for JIA.[209]

Adalimumab is a human monoclonal TNF-α antibody approved for use in patients age 2 years and older with moderately to severely active polyarticular JIA.[49] It is a weight-based dose—10 mg for patients 22.05 to <33.06 pounds (10 to <15 kg), 20 mg for patients 33.06 to <66.14 pounds (15 to <30 kg), 40 mg for patients ≥66.14 pounds (≥30 kg)—given as a subcutaneous injection every other week.[49] In a study involving 171 patients on adalimumab monotherapy and in combination with MTX, children taking combination therapy showed better disease improvement than patients on adalimumab monotherapy.[49] Concomitant NSAIDs or other analgesic agents may also be continued during adalimumab use.

Abatacept is an injectable biologic agent that inhibits T-cell activation. It is FDA approved for the treatment of moderate-to-severe active polyarticular JIA. Patients 6 years and older weighing <165.35 pounds (75 kg) receive a dose of 10 mg/kg via IV infusion for 30 minutes, whereas patients weighing 165.35 pounds (75 kg) or

more should receive the adult intravenous regimen, with a maximum dose of 1,000 mg.[55] All patients receive IV doses at 2 and 4 weeks after the first infusion and then every 4 weeks thereafter.[55] Alternatively, patients 2 years and older may administer weekly subcutaneous weight-based dosing without an IV loading dose—50 mg for patients 22.05 to <55.12 pounds (10 to <25 kg), 87.5 mg for patients 55.12 to <110.23 pounds (25 to <50 kg), 125 mg for patients >110.23 pounds (>50 kg). Unlike TNF-α agents, abatacept does not have an immediate onset and seems to exert its effect best after repeated doses over the course of several months.[196]

Tocilizumab, an IL-6 receptor blocker monoclonal antibody, is also indicated in patients 2 years and older with active polyarticular JIA. The dose differs from systemic JIA and may be 8 mg/kg for weight ≥66.14 pounds (≥30 kg) or 12 mg/kg for weight <66.14 pounds (<30 kg) given intravenously every 4 weeks.[60] The alternative subcutaneous dosing is 162 mg every 3 weeks for weight <66.14 pounds (<30 kg) or 162 mg every 2 weeks for weight >66.14 pounds (>30 kg).[60,176]

Tofacitinib is a targeted synthetic DMARD that inhibits JAK. It is FDA approved for active polyarticular course JIA in patients 2 years who have failed or had an intolerance to one or more anti-TNF. It is administered orally twice daily, dosed based on weight—3.2 mg for weight 22.05 to <44.09 pounds (10 to <20 kg), 4 mg for weight 44.09 to <88.18 pounds (20 to <40 kg), 5 mg for weight >88.18 pounds (>40 kg)—and available as a 5-mg tablet or oral solution.[39] Tofacitinib offers a different route of administration compared to biologic therapies.[176]

Other biologic agents, including the other TNF-α inhibitors, are not FDA approved for JIA but have been studied. Available data from clinical trials suggest that all of these treatments may be safe and effective for JIA, with no evidence of significant risk for serious adverse reactions. Owing to their mechanisms of action, all biologic agents share the side effect of lowered infection resistance, and patients must be monitored for signs of infection during treatment.

Of all FDA-approved bDMARDs, C.E. is a candidate for etanercept, adalimumab, abatacept, or tocilizumab therapy.

Tofacitinib is not indicated as C.E. has not tried an anti-TNF yet. Given that abatacept does not have an immediate onset, etanercept or adalimumab may be preferred. Adalimumab with its biweekly dosing schedule may be preferred compared to weekly dosing with etanercept. C.E. will also be able to continue her concurrent NSAID and MTX therapies during adalimumab treatment because it is possible she will experience enhanced clinical improvement on combination therapy versus adalimumab alone.

Conventional Synthetic Disease-Modifying Antirheumatic Drugs

Early csDMARD therapy should be considered for patients with a history of arthritis of four or fewer joints (eg, persistent oligoarthritis) as well as patients with a history of arthritis of five or more joints (eg, extended oligoarthritis and polyarthritis).[176–177,210]

CASE 44-11

Question 1: T.T. presents to rheumatology clinic on referral from her primary care provider. She is 9 years old and has been whining at home of her shoes hurting her feet and not being able to run with her classmates at school. On physical examination, it is noted she has multiple swollen, erythematous joints (tarsometatarsal and metatarsocuneiform joints bilaterally on the feet, knees bilaterally). Her CBC values are all normal, her ESR is normal, and her RF is negative. In addition to NSAID and steroid therapy, the rheumatologist would like to start a DMARD agent.

What DMARD options are available to treat T.T.'s JIA?

Patients with JIA and active polyarthritis should be considered for csDMARD as part of initial therapy. MTX is the csDMARD of choice for polyarthritic JIA.[208] The recommended dose of MTX for JIA treatment is 10 mg/m^2 orally or subcutaneously each week.[176] Food reduces the bioavailability of MTX, so MTX should be administered on an empty stomach. Radiologic evidence of improvement or slowing of joint damage has been demonstrated in patients with JIA who responded to MTX therapy during a 2-year period.[211] Other csDMARD options for JIA include leflunomide, sulfasalazine, or hydroxychloroquine. MTX is favored over these alternate

csDMARDs, and leflunomide is the preferred second-line csDMARD.[176]

Case 44-11 Question 2: What is the expected response to MTX treatment for T.T.?

Children tolerate MTX therapy well and generally experience few serious or troublesome adverse effects (eg, transient liver enzyme elevations, nausea, vomiting, and oral ulcerations).[212] These adverse effects are reduced with daily folic acid therapy (1 mg) or weekly folinic acid (the day after MTX dosing). CBC, renal function, and liver toxicity monitoring in JIA are the same as the guidelines recommended for MTX therapy in adult RA.[175] The combination therapy of MTX and other csDMARDs has not been fully evaluated in pediatric patients.

If complete disease remission is achieved, discontinuation of MTX may be attempted. The optimal time to discontinue MTX therapy remains unknown; however, it probably should not be stopped sooner than 1 year after disease remission, with slower withdrawal in patients at high risk for relapse.[212,213] Young age at diagnosis (<4.5 years) and oligoarthritis that progresses to polyarthritis seem to be the greatest risk factors for relapse.[213,214]

Systemic and Intra-articular Corticosteroid Therapy

Despite the potential for serious adverse effects associated with high-dose or long-term therapy, the use of low-dose corticosteroids is sometimes necessary to control disease flares or provide therapeutic relief during initiation or dose adjustment of DMARDs with slow onsets of action. Bridge therapy with systemic glucocorticoids may be considered as adjunctive therapy for JIA with active polyarthritis during initiation or escalation of therapy in patients with moderate or high disease activity, but not recommended in patients with low disease activity. They are also recommended as adjunctive therapy for JIA with active sacroiliitis or enthesitis during initiation or escalation of therapy in patients with high disease

activity, limited mobility, and/or significant symptoms. For patients with systemic JIA with MAS, systemic corticosteroids may be considered as part of the initial treatment. Once the patient's disease activity is inactive, the corticosteroid should be tapered and discontinued. For patients with JIA-associated uveitis, systemic corticosteroids may be used in order to taper topical corticosteroid treatment. Systemic corticosteroids are not preferred for oligoarthritis, TMJ arthritis, or systemic JIA without MAS.

It is preferable that patients take the lowest effective corticosteroid dose for the shortest duration possible to avoid long-term side effects. Common side effects of steroids include GI upset and damage to the GI mucosa, mood changes including depression or hyperactivity, and increases in blood pressure and blood sugar.[195] Corticosteroids may also cause impaired skin healing, osteoporosis (especially with long-term use), and vision problems such as cataracts and glaucoma. Oral corticosteroids are typically dosed once daily in the morning to best mimic physiologic cortisol release and minimize suppression of the hypothalamic–pituitary–adrenal axis.

Intra-articular corticosteroid therapy seems to be highly effective in some forms of JIA. They are strongly recommended for initial treatment of JIA with oligoarthritis as monotherapy or in combination with scheduled NSAIDs. Triamcinolone hexacetonide is the preferred agent but is not readily available in the United States. Alternatively, triamcinolone acetonide may be used. Intra-articular corticosteroids are also recommended for TMJ arthritis for initial therapy as monotherapy or in combination with scheduled NSAIDs. There is no preferred agent to use for TMJ arthritis. Side effects include local lipoatrophy or articular calcification, both of which do not present many issues clinically (**Table 44-2**).

Table 44-2

Classes of Commonly used Medications for JIA Treatment

Drug	Mechanism oF Action	Therapeutic Options	Adverse Event
Nonbiologic DMARDs			
MTX	■ MTX is a stiu r tural analog of foke acid that inhlblts dihydrofolate reductase and DNA synthesis ■ Acts in diFFeient pathway cy tokme production. arachidontc acid metabohsm. and celt apoptosis	■ Rolyarticulai IIA ■ Oligoarticulat JIA ■ JIA-related uveitis infractory to top-Icai treatment ■ HIA with predominam joint inflan mation and without active systemic symptoms ■ PsoiiaticJIA	■ Nausea ■ Oral ulceration ■ liifections (herpes zoster) ■ Severe complications in <11 of cases include ■ Grrhosls ■ Pneumomtis ■ leukopenia ■ Thfombocytopenia ■ Anemia
LEF	■ Inhibltion of T-cell prokferation by blocking pyrlmidine syntbesls	■ Patients witti polyarticular JIA wtio cannot tolerate MTX ■ Used rarely In pediatrlc patients be-cause of Its teratogeniclty and long half-life	■ Diarrhea ■ Rashes ■ Cytopenia ■ Abnormal liver funcrion test ■ Teratogeniclty
SSZ	■ Immune-suppressive effect not fully established	■ ERA with moderate activity, but noi m other types of JIA	■ Gastromtestinal toxinty ■ SulFonamide allergy ■ Neutopsychiatric complr:ations (headache. arixiety) ■ Pancytopenla ■ Pneumonitis ■ Myelosuppression ■ Hypogammaglobulinenna

Biologic DMARDs			
TNF inhibitors			
Adalimumab	■ Sutxutaneous recombinant human IgG I K monoclonal antibody ■ Neutralizes TNF-a by binding with soluble and membrane-bound TNF	■ JIApatientswithresistanceorintolerance to MTX ■ Polyarticular JIA ■ JIA with uveitis ■ ERA refractory to SSZ ■ Psoriatic JIA	■ Ø**sk of** reactivation **oT latent In**fections such as tuberculosis, and new infectlons caused by viruses, fungi, or bacterfa ■ Rare reports of ■ Lymphoma ■ **Jemydtnabngcem**ral nervous system disorders ■ Cardiac failure
Infliximab	■ Intravenous thimeric monoclonal antibody against TNF-ct a Binding with soluble and transmembrane TNF-a, that mediates compiement and antibody-dependent cytoioxicity of expressed TNF-acelis (macrophages and monocytes)	a Polyarticular JIA where there has been the use of MTX for at least 3months with poor response a Uveitis a Psoriatic JIA	a Opportunlstic Infeetions: nerpes, tuberculosis, pseudomonas pneumonia, reactivation of hepatitfs B, fungal infectlon
Etanercept	a Fusion piotein consisting of the extracellular dornain of the human p75 TNF-a receptor a Liriked to the Fc region of human IgG I, binds and inhibits soluble TNF-a	■ Polyarticulat JIA with reslstance or Intoleranee to MTX a ERA a Psoriatic JIA	a Central nervous system events (headache, neurltis) a Varicella infeetions a Rare a Mallgnancy
IL-1 inhibitors			
Anakinra	a Recombinant IL-T receptor antagonist binds to IL-1 receptors (IL-Tri) a Inhibits the binding ot IL-1a and IL-1P	a Refraaory sJIA with persistent systemie symptoms a MAS	a Vbmiting, nausea, diarrhea a Headache a Abdominal paln a Upper respiratory and urinary tract infectlons a Neutropenia
Canakinumab	■ Human monoclonal antibody a Selectively blcicks IL-1p	a sJIA parients with continued disease activity after tteatment with GC monotherapy and MTX or LEF, anakinra, or tocillzumab	a Thrombocytopema a Neutropenia a Upper respiratory tract infection a Cough a Abdominal pain a Gastroenteritis, vomiting, diarrhea a Pyrexia a Very rare a Pneumococcal sepsis
Rilonacept	a Fusion protein between the Fc portion of IgG and the IL-1 receptor ■ Blocks the interaction of IL-I with cell surface receptors preventing IL-1 signaling	a Active sJIA	a Infeetions a Oeveloped elevations in liver transaminases a High cholesterol or triglycerides a Abdominal paln a Gastroenteritis, nausea, diarrhea
T-cell Inhibitors			
Abatacept	a Inhibitor of naive T-cell activation a Soluble fusion protein of CTLA-4 with the Fc portion of IgG that binds to CD80/CD86 and blockades signal foilowing MHC peptide TCR engagement necessary for T-cell activation	a SeveresJIA a Polyarticular JIA patients with inadequate response to MTX and TNF blockers	a Bactenal and opportumstic infeetions a Rare a Acute lymphoblasiic leukemia

IL-6 inhibitors			
Tocilizumab	■ Humanized monoclonal antibody against the IL-6 ublquitous receptor (IL-6R) ■ Block IL-6 signaling pathway by binding to cell surface and soluble IL-6R	■ sJIA a Polyarticular JIA with resistance and continued dlsease activity after treatment with MTX and TNF blockers	a Headache ■ Upper resplratory tract infections (>10%) ■ Varicella, herpes zoster a Neutropenia ■ Elevation of aminotransferases
Anti-B-cells therapy			
Rituximab	■ Chimeric monoclonal antibody against B cells with mouse variable and human constant regions a Binds CD20 on the surface of B cells forming a cap that allow NK cells to destroy B cells a i.eads to B-ceil death and removal from circulation	a JIA refractory to anti-TNF agents and standard immunosuppressive therapy	■ Infusion reactions (headache, throat irritation, rash, itchiness, pyrexla) In one-third of patients ■ Bacterial infections a Flepatitis B reactivation a Rare a Cardiac arrest ■ Cytokine release syndrome a Vultifocal leukoencephalopathy a Pulmonary toxicity
Janus kinase (JAK) inhibitors			
Tofacitlnib	a Inhlbit JAKI and JAK3 a Interrupt the JAK-STAT signaling pathway, which Is responsible for the transmission of extracellular multiple pro-inflammatory cytokines, Including IL-6, into the nucleus, leading to changes in DNA transcriptome	a Refractory polyarticular JIA ■ sJIA refractory to other therapy	a Diarrhea a Headache a High blood pressure a Upper respiratory tract infections a Varicella zoster virus reactivation ■ Cytomegalovirus infection a Pulmonary embolism a Rare ■ Lymphoma or other malignancies
IL-17A inhibitor			
Seeuklnumab	■ Human monoclonal antibody that inhibits IL-17A a Blocks the release of pro inflammatory cytokines and chemokines	a Active JPsA a Active ERA	a Nasopharyngitis a Diarrhea a Upper resplratory tract Infections ■ Inflammatory bowel disease warning
Other medications			
Glucocorticoids (GC)	a Binding to gluaicortir nid receitors inhibits calcium and sodium cycle across plasma membranes, reducing activation and proliferation of immune cells ■ Posttranscriptional destabilization of messenger RNA resulting in reduced production of pro-inflammatory cytokines including IL-1 and IL-6	a V Systemic steroids for a sIIA with serious organ involvement (Including pericarditis and myocardltis) a Patients with features indicative of MAS a High disease activity In ollgo- and polyarticular JIA a Intra-articular steroids for oligo- and polyarticular JIA	a Infections a Myopathy a Neuropsychlatric symptoms a Osteoporosis a Obesity ■ Insulin resistance a Cushing syndrome a Gastric ulcer a Cataract a Glaucoma
Cyclosporine A	a A fungal cycllc polypeptide ■ Binds to the cellular protein cyclophllln, resulting in mhibition of the enzyme calclneurin a Specifically and reversibly inhibits CD4+ immunocompetent lymphocytes in the G0-G1 phase of the cell cycle a Then inhibits IL-2 production and release by T helpers	■ sJIA with indication of MAS	a Nausea a Headache ■ Renal complications ■ Neuronal complications (paresthesia) a Hepatotoxlcity

DMARDs, disease-modifying antirheumatic drugs; ERA, enthesitis-related arthritis; GC, glucocorticoids; IL, interleukin; JPsA, juvenile psoriatic arthritis; LEF, leflunomide; MAS, macrophage activation syndrome; MTX, methotrexate; NK,

natural killer; sJIA, systemic JIA; SSZ, sulfasalazine; TCR, T-cell receptor; TNF, tumor necrosis factor.

Gout and Hyperuricemia

Troy Lynn Lewis and Kimmy Nguyen

CORE PRINCIPLES		CHAPTER CASES
1	Gout is a disease that causes acute joint inflammation and pain secondary to the deposition of monosodium urate (MSU) crystals within the synovial fluid and lining. Clinically, acute gout presents as monoarticular inflammation in 90% of patients with the first metatarsophalangeal joint (great toe) typically affected; this is called podagra. Patients presenting with acute gout may or may not have hyperuricemia.	**Case 45-1 (Question 1)**
2	A definitive diagnosis of gout can be made if MSU crystals are present in a synovial fluid sample. However, the presence of hyperuricemia, clinical features, and imaging studies may be	**Case 45-2 (Questions 1–3)**

	useful if examination of synovial fluid is not possible.	
3	The primary goal of treating acute gout attacks is the relief of pain and inflammation. It is not necessary to lower the serum uric acid (SUA) immediately.	**Case 45-2 (Question 3), Table 45-2**
4	Acute episodes of gout are primarily treated with nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, or corticosteroids.	**Case 45-2 (Questions 4, 5)** **Case 45-3 (Question 1), Table 45-2**
5	Low-dose oral colchicine is as effective as and safer than traditional high-dose regimens, which are dosed to toxicity (diarrhea); avoid potential colchicine drug–drug interactions.	**Case 45-2 (Questions 4, 5) Case 45-3 (Questions 1, 5), Table 45-3**
6	Nonpharmacologic therapy for acute and chronic gout includes limiting daily alcoholic beverages, purine-rich meats, and fructose-containing beverages/foods. Specifically, beer and, to a smaller extent, spirits are associated with increased gout attacks; wine is less likely to be a risk factor. Increasing low-fat dairy protein has a favorable effect on SUA.	**Case 45-1 (Questions 3) Case 45-2 (Question 6) Case 45-1 (Question 2), Table 45-2**
7	Recent evidence has shown starting urate-lowering therapy (ULT) during a flare did not significantly worsen the flare, and guidelines now recommend initiating ULT during the flare, as opposed to after the flare has resolved.	**Case 45-3 (Questions 2, 3), Table 45-2**

	ULT should be initiated in patients with >1 subcutaneous tophi, frequent gout flares (>2 per year), and radiographic damage. Additionally, for patients experiencing their first flare and chronic kidney disease (CKD) stage >3, SUA >9 mg/dL, or urolithiasis, ULT may be initiated.	
8	Patients should be evaluated for drug-induced hyperuricemia before treatment.	**Case 45-3 (Question 3), Table 45-1**
9	The goal of ULT is to lower the SUA to <6 mg/dL. If this goal is achieved, most patients can be “cured” of acute gout attacks.	**Case 45-3 (Questions 3–5), Table 45-2**
10	The preferred first-line treatment of gout and hyperuricemia is xanthine oxidase (XO) inhibitors. Monitor for drug–drug interactions. Note that treatment of asymptomatic hyperuricemia with ULT is not recommended.	**Case 45-3 (Questions 4, 5) Case 45-4 (Question 1), Tables 45-2, 45-4**
11	Initiation of ULT can precipitate acute gout attacks, so prophylaxis with colchicine, NSAIDs, or prednisone/prednisolone is recommended, and the choice of specific anti-inflammatory prophylaxis should be based on patient factors. Prophylaxis should be continued for 3 to 6 months and continued as needed if the patient continues to experience flares.	**Case 45-3 (Question 5), Table 45-2**

INTRODUCTION

Gout is a form of arthritis characterized by recurrent episodes of acute joint pain and inflammation caused by the deposition of monosodium urate (MSU) crystals in joints and soft tissue. MSU crystals form as a result of elevated urate concentrations, and deposition in the urinary tract can cause urolithiasis and urinary obstruction.[1] Patients with gout may undergo asymptomatic periods or experience acute arthritis (gout flares) or chronic inflammation (gouty arthritis).[2] Hallmark characteristics of gout include the presence of tophi, which are hard nodules of MSU crystals that have been deposited in soft tissues. Tophi are most commonly found in the toes, fingers, and elbows. Although gout is often associated with hyperuricemia (defined as a serum urate level of ≥6.8 mg/dL),[3] elevated serum uric acid (SUA) does not always result in gout.[4] In a retrospective review of two studies on gout, 14% of patients presenting with acute symptoms had a normal SUA concentration <6 mg/dL, and 32% had an SUA concentration <8 mg/dL.[5] Another retrospective analysis that examined the cumulative incidence of gout using baseline SUA levels found that only about half of participants with SUA ≥10 mg/dL developed gout over 15 years.[6] Therefore, gout should be considered a clinical diagnosis, whereas hyperuricemia relies solely on an elevated laboratory value. These two terms are not synonymous and are not interchangeable.

Uric Acid Disposition

Uric acid is the end product of purine metabolism and serves no biologic function. Unlike animals, humans lack the enzyme uricase, which degrades uric acid into more soluble products for excretion. As a result, uric acid does not undergo metabolism, and the majority is renally excreted. Up to one-third of the daily uric acid produced is eliminated through the gastrointestinal (GI) tract.[7] Therefore, increased SUA concentrations arise from an increase in uric acid

production, a decrease in uric acid renal excretion, or a combination of the two.

OVERPRODUCTION

Overproduction of uric acid accounts for ~10% of gout cases[7] and can result from excessive de novo purine synthesis, which is primarily associated with rare genetic enzyme mutation defects, some neoplastic diseases, aggressive cytotoxic chemotherapy (causing tumor lysis syndrome), and certain myeloproliferative disorders. Overproduction of uric acid can also be the result of excessive dietary intake of purines from meat, seafood, high-fructose corn syrup (eg, soft drinks), beer, and other alcoholic beverages.[8–10] Interestingly, results from a meta-analysis suggest that dietary modifications yield minimal effect on SUA levels.[11] However, counseling and education on limiting purine and alcohol intake remain recommendations for gout management.

UNDEREXCRETION

A defect in the renal clearance of uric acid is the main cause of hyperuricemia and gout in about 90% of patients. Uric acid is filtered in the renal glomerulus and is almost completely (98%–100%) reabsorbed in the proximal tubule. Uric acid is then secreted distal to the proximal tubular reabsorption site, and most is reabsorbed again.[4] In healthy patients, homeostasis between reabsorption and secretion of urate is maintained. However, many factors (eg, renal impairment, certain drugs, excessive alcohol intake, metabolic syndrome, hypertension [HTN], coronary heart disease [CHD]) can cause this balance to fail, resulting in excess serum concentrations of uric acid and tissue deposition.[7,12]

ACUTE GOUT

Epidemiology

Global incidence and prevalence of gout vary, but higher prevalence has been observed in developed countries. Gout generally presents during middle age, and increasing age carries a strong association with a higher risk of hyperuricemia. Hyperuricemia increases the risk of gout in both males and females, but males are at an increased risk of elevated SUA levels.[13] Females have a lower prevalence of gout at all ages, whereas males experience a steady increase in gout risk with age. However, the risk of gout increases in females after menopause, and this is attributed to the uricosuric action of estrogen.[14,15]

Clinical Features

CASE 45-1

Question 1: M.D. is an obese 60-year-old female who has been referred to a medication management clinic by her primary care physician. She states that her past medical history includes HTN, type 2 diabetes, hyperlipidemia, and gout. M.D. states she was diagnosed with gout 3 months ago when she had a painful and swollen right big toe. When asked about that episode, M.D. related the following story: "One morning I just woke up and my big toe was swollen, red, and very painful. I couldn't even put weight on it. I had gone to my husband's 50th high school reunion the night before, and it was fine then because we danced all night. I did have a little too much to drink, though, so I thought maybe I had stubbed my toe without realizing it and broke it."

What signs and symptoms did M.D. exhibit that are typical of acute gout?

M.D.'s symptoms of severe, acute pain and an obviously inflamed joint are consistent with the usual presentation of gout. In addition, M.D.'s age is consistent with the epidemiologic data that are commonly associated with gout.

PAIN

The pain of gout rapidly reaches its maximum <24 hours of onset and is usually accompanied by erythema.[16] It is often so severe that patients cannot even tolerate a sheet lying on top of the affected area.

NUMBER AND TYPE OF JOINTS

M.D.'s report of a very painful big toe is typical. Approximately 90% of initial acute attacks are monoarticular, affecting a single joint. The first metatarsophalangeal joint (the great toe) is the most commonly affected joint, a condition referred to as podagra. The ankle and foot are also commonly affected joints.

Although initial gout attacks are primarily monoarticular, persistent hyperuricemia can lead to recurrent flares causing a polyarticular presentation overtime. Joints of the upper limbs can be affected. Generally, these recurrent attacks are more frequent and of longer duration than initial attacks.

Atypical presentations of gout can also occur. Elderly patients may initially present with polyarticular involvement. Multiple joints in the hands can be affected, which may be mistaken for rheumatoid arthritis or osteoarthritis in this population. This is more commonly seen in elderly females.[3,4]

NOCTURNAL OCCURRENCE

The onset of pain in M.D. during the night is typical of gout. The risk of gout attacks occurring during the night and through the early morning is approximately three times higher than during the daytime. Potential biologic mechanisms for this phenomenon include lower body temperature in the early morning, relative nocturnal arterial dehydration, or the nocturnal decrease in cortisol levels.[17]

PHYSICAL STRESS

Gout attacks also seem to be more common during episodes of increased physical activity. The acute episode of toe pain experienced by M.D. after a night of dancing is consistent with the appearance of gout after increased physical exercise or physical trauma.[18]

Risk Factors

Case 45-1, Question 2: What findings in M.D. place her at risk for gout?

The diagnoses of HTN, type 2 diabetes, hyperlipidemia, and obesity in M.D. have been associated with an increased risk of gout and hyperuricemia.

Common modifiable risk factors include alcohol consumption, the use of urate-elevating drugs, obesity, and diet. Certain conditions such as insulin resistance and other metabolic syndromes, chronic kidney disease (CKD), history of urolithiasis, CHD, organ transplant, and lead exposure are also associated with an increased risk of hyperuricemia and gout.[3,19]

URATE-ELEVATING MEDICATIONS

The consumption of urate-elevating medications is a potentially modifiable risk factor. Medications can increase blood uric acid levels through various mechanisms such as increased production, increased renal reabsorption, decreased excretion, decreased renal secretion, and decrease renal filtration. Medications that increase uric acid levels are highlighted in **Table 45-1**. Patients' medication lists should be surveyed for medications that can increase uric acid levels. A risk versus benefits assessment should be completed to determine if the offending medication can be discontinued and/or substituted with alternatives when possible. However, discontinuation of an offending medication may not always be possible. Patients taking these medications should be educated on the importance of maintaining adequate hydration. Regardless, routine monitoring of uric acid levels is recommended.[4,20]

Table 45-1

Urate-Elevating Medications

Angiotensin-converting enzyme inhibitors
Aspirin (low dose)
Cyclosporine
Diuretics
Ethambutol
Fructose

Niacin

Sources: Dalbeth N, Merriman TR, Stamp LK. Gout. *Lancet*. 2016;388(10055): 2039–2052; Salem CB, Slim R, Fathallah N, Hmouda H. Drug-induced hyperuricaemia and gout. *Rheumatology.* 2017;56(5):679–688.

DIETARY RISK FACTORS

Dietary factors may serve as triggers for flares. The risk of gout is increased with an increased intake of dietary purines from organ meats and seafood, as well as high-fructose corn syrup from soft drink and sugary beverages. Patients should be counseled to limit intake.[3,4,16,19]

OBESITY

Obesity has been associated with a higher risk of incident gout as observed in a large observational cohort study. In addition, the risk of recurrent gout flares was higher with an increase in body mass index (BMI) and lower with a decrease in BMI when compared with patients without a change in weight.[21]

Case 45-1, Question 3: During the medication management clinic visit, M.D. mentions that her doctor said her gout attack could have been caused by drinking too much beer, and she asks you whether this is really true. What do you tell her?

ETHANOL CONSUMPTION

Overindulgence in alcohol has been linked to acute gout attacks. Alcohol intake was examined in a prospective cohort of males with new diagnoses of gout from the Health Professionals Follow-Up Study and found that the risk of gout is 2.5-fold in patients who drink two or more beers per day.[22] Ethanol-induced gout or hyperuricemia has been attributed to several mechanisms. M.D.'s episode of

overindulgence in beer, possible dehydration from vigorous exercise, and lactic acidemia from muscle energy expenditure made the diagnosis of an acute gout attack the most likely cause of her toe pain and inflammation.

CORONARY HEART DISEASE AND IMPAIRED GLUCOSE UTILIZATION

Hyperuricemia is noted to be an independent risk factor for CHD, although it is unlikely to be a primary cause of the disease. Several observational studies have shown a link between hyperuricemia and an increase in CHD (eg, HTN, stroke, heart failure, and ischemic heart disease).[23–26] Researchers continue to study the causality and note that despite the apparent strong relationship, the subject remains controversial. Impaired glucose utilization also has a relationship with hyperuricemia. Because of these close linkages, patients who present with gout and/or hyperuricemia should be monitored closely for the development of CHD and diabetes.

RENAL DYSFUNCTION

CKD is an independent risk factor for gout. Uric acid is primarily excreted through the kidneys. Uric acid excretion is decreased in patients with renal dysfunction owing to decreased glomerular filtration, and, as a consequence, hyperuricemia occurs increasing the risk of gout.[27] Appropriate monitoring of renal function in M.D. by obtaining blood urea nitrogen (BUN), serum creatinine (SCr), and electrolytes is important for evaluating her risk factors as well as determining drug doses for treating gout.

ORGAN TRANSPLANT

The prevalence of gout is higher in renal transplant recipients. This can be because of impaired renal uric acid excretion because of poor graft function, proximal tubular dysfunction, and medication therapy such as diuretics for edema, as well as steroids and cyclosporine for immunosuppression.[28]

LEAD INTOXICATION

Both toxic and low levels of lead exposure are associated with hyperuricemia. In a large observational cohort study, blood lead levels considered acceptable by national standards were associated with a significantly increased risk of hyperuricemia and gout.[29]

Diagnosis

CASE 45-2

QUESTION 1: E.J. is a 52-year-old male school bus driver who reports to the emergency department with extreme pain in his right elbow. He reports playing several games of basketball yesterday followed by a few beers with friends. He awoke in the early hours of the morning with a sore, stiff elbow, which he self-medicated with acetaminophen before returning to sleep. However, the pain worsened, and he sought medical attention when he experienced difficulty moving the joint and was unable to apply pressure to the area. Pertinent medical history includes recently diagnosed HTN and obesity. His primary care provider prescribed hydrochlorothiazide 25 mg once daily 1 month ago. He is not on any other medications. He denies any known drug or food allergies and has not had any side effects from his antihypertensive medication. During that visit, he also received recommendations on lifestyle changes, including routine physical activity and a Mediterranean diet. On physical examination, the right elbow is tender, erythematous, and warm to the touch with moderate swelling. Vital signs are within normal limits.

What objective data would be of value in diagnosing E.J.'s elbow pain and inflammation?

CLASSIFICATION AND DIAGNOSTIC CRITERIA

The American College of Rheumatology (ACR) first suggested classification criteria for gout in 1977, which, until recently, have been commonly used for diagnosis.[30] However, the ACR released a statement in 2015 that elaborated on the distinction between classification and diagnostic criteria. Although classification criteria are used to ensure a well-defined set of patients for research studies, diagnostic criteria are a set of signs, symptoms, and tests that are needed to guide care. In collaboration with the European League Against Rheumatism (EULAR), the ACR created a set of

classification criteria in 2015.[31] Because of challenges related to creating a set of diagnostic criteria that consistently captures all presentations of a rheumatic condition, the ACR no longer funds or endorses diagnostic criteria.[32] In contrast, the EULAR published criteria for diagnosis in 2018.[16]

EULAR recommends a three-step approach to diagnose gout. The first step involves identifying MSU crystals in synovial fluid if feasible. If this is not possible, hyperuricemia and associated clinical features of gout are used to make a clinical diagnosis in step two. If the diagnosis remains uncertain and identifying MSU crystals is not possible, imaging is used to look for evidence of crystal deposition in step three.

JOINT FLUID ASPIRATION

A definitive diagnosis of gout is established through identification of MSU crystals in the affected joint by examining aspirated synovial fluid. However, the absence of MSU crystals in the synovial fluid does not rule out the diagnosis of gout. Although joint fluid aspiration is considered the gold standard for the diagnosis of acute gout, it is rarely done in clinical practice. If synovial fluid is aspirated from an inflamed joint, it should also be analyzed for bacteria, and a white blood cell (WBC) count should be obtained to aid in differential diagnosis. In gouty arthritis, the WBC count is likely to range from 5000 to 50,000/L, whereas a WBC > 50,000/L is suggestive of septic arthritis.[4] E.J.'s physician should consider fluid joint aspiration as a diagnostic measure.

LABORATORY TESTS

Because uric acid primarily is excreted renally, and renal impairment is a risk factor for gout, the serum concentrations of E.J.'s BUN and SCr should be measured along with an SUA concentration, especially in light of his recently initiated hydrochlorothiazide and new diagnosis of HTN. Although infection, in particular *septic arthritis*, could also present as sudden onset of joint pain and inflammation, it is not likely in this case. An elevated systemic WBC

count may be consistent with infection or gout. If joint infection is of genuine concern, synovial fluid aspiration could differentiate between infection and gout.

RADIOGRAPHY

Radiographic findings of the affected joint are nonspecific and generally characterized by asymmetric soft tissue swelling overlying the involved joint. When gout has been long-standing, bony changes can be noticed on a radiograph, along with calcium deposition and increased density in the areas of soft tissue swelling.[33,34] Ultrasound and computed tomography are also used for diagnosis with the latter showing early changes compared to traditional radiography. A radiograph of E.J.'s elbow may be obtained to detect tophi that may not be visible on clinical examination, but this is recommended if crystal identification is not possible and clinical diagnosis is uncertain.

PSEUDOGOUT

Deposition of microcrystals (ie, calcium pyrophosphate, calcium oxalate, calcium hydroxyapatite) into joints can cause acute or chronic arthritis in a manner similar to that caused by MSU deposition.[35] The role of these microcrystals in causing acute synovitis has been greater than previously expected because improved crystallographic technology (eg, electron microscopy, radiograph diffraction) can differentiate these diagnoses from that of acute gout. Crystal-induced diseases tend to occur in older patients as a result of prior joint disease, especially osteoarthritis, predisposing them to crystal deposition and acute episodes of joint inflammation. Older adults are also more prone to microcrystal-induced arthritis because these crystals generally accumulate for a long period and must attain a sufficient concentration and size before they precipitate into the synovial fluid and cause inflammation.[36]

CASE 45-2, QUESTION 2: Laboratory tests were ordered for E.J., and the results are as follows:

SUA, 10.1 mg/dL
BUN, 10 mg/dL
SCr, 1.0 mg/dL
WBC count, 10.2 × 10^3/μL

No MSU crystals were identified in aspirated synovial joint fluid. A radiograph of his elbow shows soft tissue swelling with no evidence of tophi. Does E.J. have gout?

Although E.J.'s clinical presentation is suggestive of gout, the absence of MSU crystals and lack of tophi through imaging studies do not support the diagnosis. E.J. appears to have hyperuricemia but not gout.

Management Guidelines

With the advances in urate-lowering medications on the market, gout is one of few rheumatologic diseases that can be treated successfully and even "cure" patients from debilitating attacks.[37] However, despite the availability of adequate and inexpensive pharmacologic interventions, gaps in care still exist including low medication adherence and dose escalation failure, inhibiting patients from achieving uric acid goals.[38] When compared to other common chronic medical conditions, gout was identified as the condition with the lowest adherence.[39] Although the prevalence of gout has increased, there has been no increase in urate-lowering therapy (ULT) utilization in recent years.[40] Because these common practices are contrary to current scientific data, the ACR Guidelines for Management of Gout were developed to provide evidence-based recommendations for treatment.[41,42] Since publication in 2012, numerous clinical trials have been completed necessitating an update published in 2020.[19] Other European guidelines include EULAR and British Society of Rheumatology and British Health Professionals in Rheumatology (BSR/BHPR) Guidelines for the Management of Gout.[33,34] A comparison of recommendations from these guidelines is found in **Table 45-2**. It is important to note that the guidelines mentioned were published in various years, and it can

be expected that the most up-to-date clinical trials are included in the most recently published guidelines.

Table 45-2

Comparison of American College of Rheumatology, European League Against Rheumatism, and British Society for Rheumatology/British Health Professionals Guidelines for Gout

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
Treatment of Acute Gout		
Treat an acute flare using oral colchicine, NSAIDs, or glucocorticoids (oral, intra-articular, or intramuscular) as soon as possible. Treatment selection should be driven by patient factors such as comorbidities, access, and past experiences as part of shared decision-making. Using topical ice as an adjuvant treatment is conditionally recommended.	Treat as soon as possible with colchicine, NSAIDs, oral corticosteroids, or articular aspiration and injection of corticosteroids. Medication choice should be based on the presence of contraindications, the patient's previous experience, time of initiation after flare onset, and the number and type of joint(s) involved.	Treat as soon as possible with NSAIDs or colchicine. Treatment selection should be determined by individual patient's preference and by renal function and comorbidities. Affected joints should be rested, elevated, and exposed to a cool environment.
NSAID dosing and duration should be guided by the severity of the flare.	NSAIDs should be utilized with proton-pump inhibitors if appropriate.	NSAIDs are effective at maximum doses; should be co-prescribed with a gastro-protective agent.

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
FDA-approved dosing of colchicine should be followed: 1.2 mg immediately followed by 0.6 mg an hour later, with ongoing anti-inflammatory therapy until the flare resolves.	Colchicine should be used within 12 hours of flare onset at a loading dose of 1 mg, followed 1 hour later by 0.5 mg on day 1.	Use colchicine at doses of 0.5 mg two to four times daily.
Injectable therapy is appropriate in certain circumstances to achieve pain relief as quickly as possible.	Oral corticosteroids at a dose of 30–35 mg/day of equivalent prednisolone for 3–5 days are recommended.	A short course of oral corticosteroids or a single injection of an intramuscular corticosteroid is an alternative in patients who are unable to tolerate NSAIDs or colchicine.
Treatment of Hyperuricemia to Prevent Recurrent Gout		
ULT is strongly recommended in patients with >1 subcutaneous tophi, frequent gout flares (>2 per year), and radiographic damage. ULT is conditionally recommended in patients experiencing their first flare and CKD stage >3, serum urate >9 mg/dL, or urolithiasis.	ULT is indicated in patients with recurrent flares, tophi, urate arthropathy, or renal stones. ULT is recommended close to the time of first diagnosis in patients older than 40 years or with a very high SUA level (>8.0 mg/dL; 480 mmol/L) and/or comorbidities (renal impairment, hypertension, ischemic heart disease, heart failure).	ULT is recommended in patients with recurring attacks (52 attacks in 12 months), tophi, chronic gouty arthritis, joint damage, renal impairment (eGFR < 60 mL/minute), a history of urolithiasis, diuretic therapy use, and primary gout starting at a young age.

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
A treat-to-target strategy is recommended with dose titration and subsequent dosing guided by SUA values to achieve an SUA target of <6 mg/dL. ULT should be started during the gout flare.	SUA goal is <6 mg/dL (360 mmol/L); SUA goal <5 mg/dL (300 mmol/L) is recommended for patients with severe gout (tophi, chronic arthropathy, frequent attacks) until total crystal dissolution and resolution of gout.	Plasma urate goal is <300 mmol/L (<5 mg/dL). Therapy should be delayed until inflammation has resolved.
Allopurinol at a dose <100 mg/day is recommended over all ULTs, including patients with CKD stage >3.	Allopurinol is recommended for first-line ULT, starting at a low dose (100 mg/day) and increasing by 100 mg increments every 2–4 weeks if required until target is reached. In patients with renal impairment, the allopurinol maximum dose should be adjusted based on creatinine clearance.	Allopurinol is the recommended first-line ULT, starting at 50–100 mg daily and increased in 100-mg increments approximately every 4 weeks until the SUA target has been achieved (maximum dose 900 mg). In patients with renal impairment, smaller increments (50 mg) should be used, and the maximum dose should be lower.

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
Febuxostat (<40 mg/day) is recommended as an alternative for patients who are not at SUA target and/or have continued frequent gout flares (>2 flares/year) or nonresolving subcutaneous tophi. It is recommended to switch to an alternative ALT for patients who are taking febuxostat with a history of CVD or a new CV event.	If the SUA target cannot be reached, allopurinol should be switched to febuxostat. Febuxostat is also indicated if allopurinol cannot be tolerated.	Febuxostat can be used as an alternative XOI if allopurinol is not tolerated or if renal impairment prevents sufficient doses to achieve target SUA levels. The recommended dosing for Febuxostat is 80 mg daily, increased after 4 weeks to 120 mg daily, to achieve therapeutic target.
The use of probenecid is conditionally recommended as an alternative agent starting at a low dose (500 mg once or twice daily) with dose titrations.	If the SUA target cannot be achieved at renally adjusted allopurinol doses, the patient should be switched to a uricosuric or combined with a uricosuric. Probenecid or benzbromarone can be alternatives to allopurinol if patients cannot tolerate allopurinol.	Uricosurics can be used in patients who are resistant to, or intolerant to XOI. Preferred uricosurics include sulfinpyrazone (200–800 mg/day) or probenecid (500–2000 mg/ day) in patients with normal or mildly impaired renal function, or benzbromarone (50–200 mg/day) in patients with mild-to-moderate renal insufficiency.

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
Concomitant anti-inflammatory prophylaxis with colchicine, NSAIDs, or prednisone/prednisolone is recommended. The choice of specific anti-inflammatory prophylaxis should be based on patient factors. Prophylaxis should be continued for 3–6 months and continued as needed if the patient continues to experience flares.	Prophylaxis is recommended during the first 6 months of ULT with colchicine, 0.5–1 mg/day and reduced in patients with renal impairment. If colchicine is not tolerated or is contraindicated, low-dose NSAIDs should be considered.	Colchicine 500 mg once or twice daily should be considered as prophylaxis and continued for up to 6 months. In patients who cannot tolerate colchicine, a low-dose NSAID or coxib, with gastroprotection, can be used as an alternative.
Adjunctive Therapy to Prevent Recurrent Gout		
Recommend limiting alcohol intake, purine intake, and high-fructose corn syrup. Weight loss is recommended for overweight/obese patients.	Patients should receive lifestyle education, including weight loss if appropriate, avoidance of alcohol (eg, beer and spirits), sugar-sweetened drinks, heavy meals, and excessive intake of meat and seafood; low-fat dairy products should be encouraged. Regular exercise should be advised.	In overweight patients, dietary modification to achieve a gradual reduction in body weight is encouraged. Patients should be educated on a well-balanced diet low in fat and added sugars, and high in vegetables and fiber; sugar-sweetened soft drinks containing fructose and excessive intake of alcoholic drinks and high purine foods should be avoided; skimmed milk and/or low-fat yogurt, soybeans and vegetable sources of protein, and cherries in the diet should be encouraged.

2020 ACR Guideline for the Management of Gout[19]	2016 EULAR Evidence-Based Recommendations for the Management of Gout[43]	2017 BSR/BHPR Guidelines for Management of Gout[44]
	Patients should be screened for associated comorbidities and CV risk factors, including renal impairment, CVD, heart failure, stroke, peripheral arterial disease, obesity, hyperlipidemia, HTN, diabetes, and smoking, and managed as an integral part of the management of gout.	CV risk factors and comorbid conditions such as cigarette smoking, hypertension, diabetes mellitus, dyslipidemia, obesity, and renal disease should be screened at least annually and managed appropriately.

CKD, chronic kidney disease; CV, cardiovascular; CVD, cardiovascular disease, eGFR, estimated glomerular filtration rate; FDA, U.S. Food and Drug Administration; HTN, hypertension; NSAID, nonsteroidal anti-inflammatory drug; SUA, serum uric acid; ULT, urate-lowering therapy; XOI, xanthine oxidase inhibitor.

Treatment of Acute Gout

GOALS OF THERAPY

Case 45-2, Question 3: What is the primary goal in the treatment of E.J.'s acute gout attack?

The primary goal in the treatment of an acute attack of gout for E.J. is to relieve his pain and inflammation. Treatment within 24 hours of symptom onset is recommended to rapidly improve patient symptoms. The immediate goal of therapy should not be aimed at decreasing the SUA concentration with ULT. Gout sufferers are most

likely to have been hyperuricemic for several months or years, and it is not necessary to treat the hyperuricemia immediately. Furthermore, a decrease in the SUA concentration at this time might mobilize urate stores and precipitate yet another acute gout attack. However, if the patient is already receiving ULT, it is not necessary to discontinue therapy during an acute attack.[19,43,44]

DRUG THERAPY OVERVIEW

Case 45-2, Question 4: What are the pharmacologic options for the treatment of E.J.'s acute pain?

Acute gouty arthritis can be effectively treated in most instances by using monotherapy with one of the following: nonsteroidal anti-inflammatory drug (NSAID), colchicine, or corticosteroids (oral, intra-articular, or intramuscular).[19,43,44] Each therapy has been proven efficacious when compared to placebo; however, to date, there are limited head-to-head comparisons between agents. As part of shared decision-making, treatment should be based on patient preference, previous response or experience with an agent, and patient-specific factors (eg, comorbidities, current medications, renal or hepatic impairment). Switching to an alternative agent or add-on therapy may be considered in refractory cases. Combination therapy is recommended in severe cases, especially those involving multiple joints. Treatment should be continued until the patient is asymptomatic (usually 7–10 days).

Nonsteroidal anti-inflammatory drugs

NSAIDs are the preferred first-line therapy for the treatment of acute gout according to the ACR, EULAR, and BSR/BHPR guidelines because of their effectiveness and tolerability.[19,43,44] Although only a few NSAIDs (ie, naproxen, indomethacin, sulindac) are U.S. Food and Drug Administration (FDA) approved for the treatment of pain associated with acute gout attacks, most have been studied, and experts consider them equally efficacious.[19,43] The choice of NSAID

should be determined based on patient-specific factors, and dosing should be consistent with the FDA-approved recommendations for the treatment of acute pain and/or acute gout. GI bleeding or ulceration and inhibition of platelet aggregation are two of the most common serious adverse effects of nonselective NSAIDs. Both compound the risk of bleeding when given concomitantly with anticoagulants (eg, warfarin). Among the nonselective NSAIDs, ibuprofen is the least likely to cause GI adverse effects and is perhaps the safest nonselective NSAID for use in patients at risk for GI bleeding, whereas piroxicam is the worst offenders.[45]

The selective cyclooxygenase-2 (COX-2) inhibitor NSAIDs are another option in patients at risk for GI bleeding or when taking chronic anticoagulants because they do not inhibit platelets at normal doses. Published data to support efficacy in acute gouty arthritis exist for etoricoxib and lumiracoxib (withdrawn in most countries because of hepatotoxicity), but these drugs are not available in the United States. Despite limited evidence for use, celecoxib and meloxicam are available in the United States with FDA-approved indications for the treatment of acute gout. A Cochrane systematic review compared nonselective NSAIDs to COX-2 inhibitors for the treatment of acute gout pain and found no significant differences in efficacy. However, the review demonstrated increased cardiovascular risk and GI adverse effects with nonselective NSAID use.[46]

The potential adverse cardiovascular effects of NSAIDs are of concern. Cardiovascular risk associated with NSAID therapy has been known for some time (eg, myocardial infarction, stroke); however, newer literature highlights the significance of this risk. Two separate cohort trials indicate an increased risk of cardiovascular morbidity and mortality in patients using NSAIDs after an acute myocardial infarction. This risk was increased in patients receiving antithrombotic therapy and was observed even with short-term use (0–3 days).[47] In patients with a history of myocardial infarction, proceed with caution when considering NSAID use. NSAIDs can also aggravate HTN, cause renal failure, inhibit diuretic-induced increases in renal sodium excretion, and decrease the hypotensive

effect of diuretics and other antihypertensive drugs.[47–52] Patients with CHD and renal insufficiency can be treated for a short duration with nonselective NSAIDs, albeit with much caution. The nonselective NSAIDs are safe for patients with stable, controlled HTN when given for only a few days and with close monitoring of blood pressure.

Colchicine

Colchicine has been successfully used to treat acute gout for more than 2000 years despite little published research supporting its efficacy.[53] By inhibiting microtubule polymerization, it decreases the action of inflammatory mediators such as cytokines and chemokines. Traditionally, colchicine has been dosed as one or two 0.5- to 0.6-mg tablets initially followed by 0.5 to 0.6 mg hourly or every other hour, until joint pain was relieved or GI effects (ie, diarrhea, nausea, vomiting) intervened. To minimize these significant adverse effects, BSR/BHPR guidelines,[44] recommend lower doses of 0.5 mg twice to four times daily. The AGREE trial,[54] multicenter, randomized, double-blind, placebo-controlled study, compared a lower-dose regimen (1.2 mg to start followed by 0.6 mg in 1 hour) with the traditional dosing and found significantly fewer adverse effects with the lower-dose regimen and similar efficacy. A 2014 systematic review, combining the AGREE trial with a separate randomized trial, found similar results.[55] Although colchicine has been marketed in the United States since 1961, it was never approved by the FDA as safe and effective. The AGREE trial was the basis of the FDA approval of a new registered colchicine product in the United States. The FDA granted brand exclusivity to this product after this, causing the cost to increase and the use of colchicine to decrease.[56] A generic form was eventually approved for use in 2015, increasing affordability.[57] The approved dosage is 1.2 mg to start followed by 0.6 mg in 1 hour for the treatment of acute gout and 0.6 mg once to twice daily for gout prophylaxis with a maximal dose of 1.2 mg/day for chronic dosing,[58] which is also consistent with the ACR recommendations.[19]

Colchicine should be used cautiously in patients with creatinine clearance (CrCl) <30 mL/minute and with hepatic impairment.[19,58]

Common adverse effects include nausea, vomiting, and diarrhea. Colchicine has a number of significant drug interactions that inhibit either cytochrome P-450 (CYP) 3A4 or P-glycoprotein (P-gp).[58,59] A thorough medication history is essential to assure safe prescribing. Some common medications that interact with colchicine include digoxin, fibric acids, statins, non-dihydropyridine calcium channel blockers, erythromycin, and antifungals. A table detailing significant colchicine drug interactions can be found in **Table 45-3**.

Table 45-3
Colchicine Drug Interaction

Interacting Drugs	Description
Conivaptan	May increase the serum concentration of CYP3A4 substrates. *Avoid combination.*
Cyanocobalamin	Colchicine may decrease the serum concentration of cyanocobalamin. *Monitor therapy.*
CYP3A4 inhibitors (moderate)	May increase the serum concentration of colchicine. Management: Reduce colchicine dose as directed when using with a moderate CYP3A4 inhibitor, and increase monitoring for colchicine-related iconicity. Use extra caution in patients with impaired renal and/or hepatic function. *Consider therapy modification.*
CYP3A4 inhibitors (strong)	May increase the serum concentration of colchicine. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are also receiving a strong CYP3A4 inhibitor. In those with normal renal and hepatic function, reduce colchicine dose as directed. *Consider therapy modification.*
Digoxin	May increase the serum concentration of colchicine. *Monitor therapy.*
Fibric acid derivatives	May enhance the myopathic (rhabdomyolysis) effect of colchicine. *Monitor therapy.*

Interacting Drugs	Description
Fosamprenavir	May increase the serum concentration of colchicine. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are receiving ritonavir-boosted fosamprenavir. In those with normal renal and hepatic function, reduce colchicine dose as directed. *Consider therapy modification.*
Grapefruit juice	Grapefruit juice may increase the serum concentration of colchicine. *Avoid combination*.
HMG-CoA reductase inhibitors	Colchicine may enhance the myopathic (rhabdomyolysis) effect of HMG-CoA reductase inhibitors. Colchicine may increase the serum concentration of HMG-CoA reductase inhibitors. *Consider therapy modification.*
Mifepristone	May increase the serum concentration of CYP3A4 substrates. Management: Minimize doses of CYP3A4 substrates and monitor for increased concentrations/toxicity during and 2 weeks following treatment with mifepristone. Avoid cyclosporine, dihydroergotamine, ergotamine, fentanyl, pinacide, quinidine, sirolimus, and tacrolimus. *Consider therapy modification.*
Multivitamins/fluoride (with ADE)	Colchicine may decrease the serum concentration of multivitamins/fluoride (with ADE). Specifically, colchicine may decrease absorption of cyanocobalamin (vitamin B_{12}). *Monitor therapy.*
Multivitamins/minerals (with ADEK, folate, iron)	Colchicine may decrease the serum concentration of multivitamins/minerals (with ADEK, folate, iron). Specifically, colchicine may decrease the serum concentration of cyanocobalamin. *Monitor therapy.*
Multivitamins/minerals (with AE, no iron)	Colchicine may decrease the serum concentration of multivitamins/minerals (with AE, no iron). Specifically, colchicine may decrease absorption of cyanocobalamin (vitamin B_{12}). *Monitor therapy.*

Interacting Drugs	Description
P-gp/ABCBI inducers	May decrease the serum concentration of P-gp/ABCBI substrates. P-gp inducers may also further limit the distribution of P-gp substrates to specific cells/tissues/organs where P-gp is present in large amounts (eg, brain, T lymphocytes, testes). *Monitor therapy.*
P-gp/ABCBI inhibitors	May increase the serum concentration of colchicine. Colchicine distribution into certain tissues (eg, brain) may also be increased. Management: Colchicine is contraindicated in patients with impaired renal or hepatic function who are also receiving a P-gp inhibitor. In those with normal renal and hepatic function, reduce colchicine dose as directed. *Consider therapy modification.*
Stiripentol	May increase the serum concentration of CYP3A4 substrates. Management: Use of stiripentol with CYP3A4 substrates that are considered to have a narrow therapeutic index should be avoided because of the increased risk for adverse effects and toxicity. Any CYP3A4 substrate used with stiripentol requires closer monitoring. *Consider therapy modification.*
Tacrolimus (systemic)	May increase the serum concentration of colchicine. *Monitor therapy.*
Tipranavir	May increase the serum concentration of colchicine. Management: Colchicine should not be used with tipranavir in patients with impaired renal or hepatic function. In those with normal renal and hepatic function, reduced colchicine doses (as directed) are required if used with tipranavir. *Consider therapy modification.*

Corticosteroids

Corticosteroids were previously considered to be second-line therapy because of the potential for adverse effects and adrenal

suppression when used long-term along with the risk of rebound pain when abruptly discontinued.[60] However, adverse effects (eg, osteoporosis, myopathy, peptic ulcer disease, central nervous system effects, HTN, predisposition to infections) are not likely with short courses of treatment for gout attacks. Glucose intolerance may occur with short-term therapy. Overall, corticosteroids are highly effective, rapid-acting anti-inflammatory agents with a favorable risk versus benefit profile.

Corticosteroid recommendations, including route of administration, depend on disease severity, number of joints involved, renal function, comorbidities, and patient preference. For example, corticosteroids may be particularly useful for elderly patients or those with renal disease or heart disease who cannot tolerate NSAIDs. Corticosteroids are recommended for the treatment of acute gout flares by the ACR,[19] EULAR,[43] and BSR/BHPR[44] guidelines.

Analgesics

When a patient requires more pain control, a dose or two of nonopioid or opioid analgesics can be a reasonable adjunctive therapy to blunt the pain of acute gouty arthritis while awaiting the apparent benefits of NSAIDs, colchicine, or corticosteroids. Most patients, however, generally experience benefits from NSAIDs, colchicine, and corticosteroids soon after a dose is administered.

Other agents

Alternative regimens include the use of adrenocorticotropic hormone (ACTH) and interleukin-1 (IL-1) inhibitors. The mechanism of action for ACTH in gout is not fully known, and more large-scale studies are needed before these agents should be considered for gout.[61] The ACR guidelines do not recommend the use of ACTH drugs, such as corticotropin, over first-line therapies.[19] For patients who cannot tolerate oral therapy (NPO), intramuscular, intravenous, or intra-articular corticosteroids remain preferred over ACTH and IL-1 agents.

IL-1 agents (eg, anakinra, rilonacept, canakinumab) have not been approved by the FDA for the treatment of acute gout. A systematic review comparing canakinumab to intramuscular triamcinolone indicated that canakinumab was more effective in pain reduction during an acute flare; however, it had significantly higher serious and nonserious adverse effects.[62,63] The EULAR guidelines recommend consideration of IL-1 blockers in patients with frequent flares who have contraindications to colchicine, NSAIDs, and corticosteroids.[43] As with the ACTH medications, the cost of IL-1 agents may prohibit use.

CHOICE OF AGENT

Case 45-2, Question 5: What therapeutic intervention would be most appropriate for E.J. at this time?

An NSAID would be an appropriate first-line therapy for the acute treatment of gout in E.J. because his renal function is normal. Assuming his blood pressure is adequately controlled, a short course of ibuprofen 800 mg now and every 8 hours until resolution of symptoms (usually 7–10 days) is appropriate. The ibuprofen should be prescribed on a scheduled basis rather than “as needed” to reduce inflammation and prevent breakthrough pain. The dose of 2400 mg/day does not exceed the maximum recommended dose of 3200 mg/day.

NONPHARMACOLOGIC INTERVENTIONS

Case 45-2, Question 6: What adjunctive therapies would be beneficial for E.J.?

The use of ice, reduction of alcohol consumption, and minor diet modification may be effective and can be considered for E.J.

Ice

The benefit of ice application to the affected joint in acute gouty arthritis should not be overlooked. Evidence from a systematic review indicates the application of ice to an affected joint for 30 minutes four times daily for 1 week reduced the pain of a gout attack when used in conjunction with oral steroids or colchicine.[64] In addition, a Cochrane systematic review of a randomized controlled trial showed that gouty attack pain was significantly improved from baseline, when topical ice therapy was added as an adjunct to standard treatments.[65] The use of ice as an adjuvant treatment during flares is recommended by both the ACR[19] and BSR/BHPR[44] guidelines.

Alcohol consumption

Excessive alcohol intake is known to be a risk factor for acute gout episodes. Beer was believed to be more problematic for gout than other alcoholic beverages because of its high purine content. The Health Professionals Follow-Up study[26] examined a cohort of patients with new diagnoses of gout over a 12-year time frame and found that when beer, spirits, and wine intake were examined, the greatest risk was with beer with a significant, but less, risk with spirits. Interestingly, wine, even more than two drinks/day, was not associated with an increased risk of gout. A smaller, independent study found that the quantity of alcohol consumed in the 24 hours before an acute attack is more important than the type of beverage consumed.[66] The current ACR,[19] EULAR,[43] and BSR/BHPR[44] guidelines recommend limiting and/or avoiding alcohol in all patients with gout regardless of disease activity.

Diet modification

Diet has a twofold effect on the epidemiology of gout. First, obese patients are at a greater risk of developing elevated SUA levels, and gout might, in part, be related to insulin resistance of obesity.[8] In a prospective, longitudinal study of male health professionals, weight gain was strongly associated with an increased risk of gout, and weight loss was associated with a decreased risk.[67]

Second, much of the uric acid produced daily comes from metabolism of food. The excessive dietary intake of purine-rich foods, without a concomitant increase in urinary excretion, can lead to elevated SUA concentrations.[8,68] However, the type of protein and purine-rich foods that are detrimental, as well as the true impact of these foods on the incidence of increased SUA and gout episodes are controversial issues because of the quality of evidence available.[11,69] Despite the lack of strong evidence, it is reasonable for clinicians to recommend patients limit certain foods (eg, organ meats, beef, lamb, pork shellfish, and products containing high-fructose corn syrup). Interestingly, low-fat or nonfat dairy products and coffee consumption have been associated with a decreased incidence of gout.[8,11] E.J. should be encouraged to limit or avoid purine-rich meats and fructose-containing beverages/foods and encouraged to increase consumption of low-fat dairy products.

CASE 45-3

QUESTION 1: V.D. is a 72-year-old female who was brought to the emergency department with shortness of breath and dizziness. On arrival, she is noted to have new-onset atrial fibrillation with a heart rate of 130 beats/minute and 2+ peripheral edema bilaterally to her knees. The latter is likely secondary to exacerbation of congestive heart failure caused by her rapid ventricular rate. In addition to administering diltiazem to control her heart rate, V.D. is given 40 mg of intravenous (IV) furosemide every 12 hours for three doses. The following day, she reports severe pain in her left great toe, and it is noted on examination to be erythematous and swollen. V.D.'s CrCl is 70 mL/minute, her SUA concentration is 7.5 mg/dL, and her blood pressure is 160/96 mm Hg.

What therapeutic option would be appropriate for V.D.?

The combination of V.D.'s advanced age, acute exacerbation of heart failure, and renal dysfunction is patient-specific parameters that are relative contraindications or precautions for the use of NSAIDs for the treatment of acute gout. Therefore, alternative treatments should be considered. Colchicine is the next drug to consider, but because she is now receiving diltiazem (a moderate CYP3A4 inhibitor), the dose of colchicine would need to be reduced. Because V.D.'s pain is monoarticular, intra-articular or oral

corticosteroids could be administered, but the latter would need to be tapered over the course of 10 to 21 days to avoid rebound gout symptoms. It is decided to give V.D. 1.2 mg of colchicine for one dose only, which is appropriate to avoid the diltiazem drug interaction.[59]

HYPERURICEMIA

Chronic Gout

Case 45-3, Question 2: V.D. is ready to be discharged 3 days later. Her toe is no longer inflamed, and her pain is gone. Should ULT be prescribed at discharge to prevent another gout attack?

ULT should be initiated in patients with >1 subcutaneous tophi, frequent gout flares (>2 per year), and radiographic damage.[19] Additionally, for patients experiencing their first flare and CKD stage >3, SUA >9 mg/dL, or urolithiasis, ULT may be initiated. If these indications are absent, ULT should not be prescribed. Long-term ULT should not be started for V.D. at this time because the criteria for therapy (see ACR, EULAR, and BSR/BHPR guidelines in Table 45-2)[19,43,44] are not met, and initiation of ULT during an acute episode can mobilize urate from tissues, worsening the problem.

DRUG-INDUCED HYPERURICEMIA

A patient's complete medication list should be reviewed to rule out drug-induced hyperuricemia before adding a medication to decrease SUA concentration. Common medications known to increase SUA can be found in Table 45-1. Perhaps, the only treatment needed would be to discontinue the offending agent. As mentioned, when discussing gout risk factors, the benefits versus the risks must be evaluated before discontinuing the offending agent.

GOAL OF URATE-LOWERING THERAPY

CASE 45-3, QUESTION 3: V.D. experienced another episode of acute gout 2 months later, which was treated successfully with colchicine. She is now on chronic warfarin to prevent stroke secondary to her atrial fibrillation and remains on diltiazem for heart rate control. Her blood pressure is 130/70 mm Hg, renal function is stable with a CrCl of 70 mL/minute, and SUA is 7.2 mg/dL. Would it be appropriate to initiate ULT at this time? If so, when would you initiate treatment?

The general goals for lowering SUA concentrations are the elimination of acute gout attacks and the mobilization of urate crystals from soft tissue. According to the ACR[19] and EULAR guidelines,[43] it is recommended to maintain SUA levels at a target <6 mg/dL for patients taking ULT. In addition, the EULAR[43] guidelines recommend a stricter goal of <5 mg/dL for patients with severe gout, which is defined as tophi, chronic arthropathy, and frequent attacks, until crystal dissolution. The EULAR guidelines state that they recommend these stricter goals for severe patients because of the fact that crystal dissolution is dependent on SUA levels. The BSR/BHPR[44] guidelines also recommend a more stringent goal of 5 mg/dL.

STARTING URATE-LOWERING THERAPY

The BSR/BHP[44] guidelines recommended to wait until the resolution of an acute attack and inflammation before starting ULT because of the risk of worsening the flare. However, based on recent evidence[70,71] that has shown starting ULT during a flare did not significantly worsen the flare, as well as evidence showing a decrease in time required to reach the target SUA,[72] the ACR[19] guidelines now recommend initiating ULT during the flare, as opposed to after the flare has resolved.

V.D. fits the criteria for initiating ULT (two attacks in <1 year); however, this should be preceded by a consideration of whether drug-induced hyperuricemia could be a contributing factor. V.D.'s initial episode of gout after aggressive diuresis with IV furosemide

was likely the cause of her first gout attack, but she is not currently on any drugs that cause hyperuricemia.

DRUG THERAPY OF HYPERURICEMIA

Xanthine oxidase inhibitors

Allopurinol

Clinical practice guidelines recommend allopurinol as a first-line agent for gout prevention.[19,43,44] It inhibits the production of uric acid and thereby decreases SUA concentrations. A 2014 systematic review of two clinical trials, with methodological limitations, shows that when compared to placebo allopurinol was superior at achieving target SUA concentrations, but failed to significantly reduce the frequency of acute gout attacks.[73] The ability of allopurinol to lower SUA concentrations is dose related. An allopurinol dose of 300 mg/day is typical maintenance dose, despite evidence to support that more than 50% of patients are unable to achieve target SUA at this dose or lower.[74,75]

The recommended initial dose of allopurinol is 50 to 100 mg once daily and then increased in 50- to 100-mg/day increments every 2 to 4 weeks until the SUA concentration is at target <6 mg/dL or until patient intolerance.[19,43,44] Starting at a low dose and titrating slowly hypothetically can reduce the risk for improved tolerance in renal impairment and hypersensitivity reactions. Allopurinol use has been associated with a rare (2%) but potentially life-threatening hypersensitivity reactions referred to as allopurinol hypersensitivity syndrome (AHS).[3] Symptoms may include erythematous rash, fever, hepatitis, eosinophilia, leukocytosis, and renal failure.[3,76] Symptoms usually begin within the first 8 weeks of therapy.[4] AHS does not have a cure; if a hypersensitivity reaction occurs, the medication should be stopped immediately and supportive measures must be taken.[76] Patients who recover should avoid future use of allopurinol. Although allopurinol desensitization can be attempted in patients with mild reactions, the risks are unknown with reactions that are more serious.[3] Risk factors for AHS include the presence of HLA-B*5801 genotype, renal impairment, and concomitant diuretic use, female

sex, and age. The relationship between allopurinol dose and AHS is unclear as studies[76,77] are contradictory to prove the association.[3,4,76] Regardless, lower initial doses are still recommended by the guidelines.

Allopurinol has several drug–drug interactions that can alter therapy and may warrant dose adjustment. Significant allopurinol drug interactions can be found in **Table 45-4**.

Table 45-4

Allopurinol Drug Interactions

Precipitant Drug	Object Drug		Description
Allopurinol	Ampicillin, amoxicillin	↑	The rate of skin reaction appears much higher with allopurinol coadministration than with either drug alone. *Monitor therapy.*
Allopurinol	Azathioprine	↑	Increase in active metabolites of azathioprine. Reduce azathioprine dose to one-third to one-quarter of the usual dose and monitor closely. *Consider therapy modification.*
Allopurinol	Carbamazepine	↑	Increase serum concentrations. *Monitor therapy.*
Allopurinol	Cyclophosphamide	↑	Myelosuppressive effects of cyclophosphamide may be enhanced increasing the risk of bone marrow suppression. *Monitor therapy.*
Allopurinol	Pegloticase	↑	Adverse effects/toxicity of pegloticase is enhanced with increased risk of anaphylaxis and infusion reactions. *Avoid combination.*
Allopurinol	Theophylline and derivatives	↑	Increased plasma theophylline levels and possible toxicity. *Monitor therapy.*
Allopurinol	Warfarin	↑	Enhanced anticoagulation effects; dose reductions in warfarin will likely be needed; monitor anticoagulation effects (eg, INR) with dose adjustments of allopurinol. *Consider therapy modification.*
ACE inhibitors	Allopurinol	↑	There is possibly a higher risk of hypersensitivity reaction to allopurinol when these agents are coadministered. *Monitor therapy.*
Loop and thiazide diuretics	Allopurinol	↑	Coadministration may increase serum concentrations and the incidence of hypersensitivity reactions to allopurinol. *Monitor therapy.*

↑, object drug increased; ↓, object drug decreased; INR, international normalized ratio.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

Febuxostat

Febuxostat, a nonpurine xanthine oxidase (XO) inhibitor, was approved by the FDA in February 2009 for chronic management of hyperuricemia in patients with gout.[79] Febuxostat is more selective

than allopurinol for XO and does not inhibit other enzymes involved in purine and pyrimidine metabolism. A 2012 Cochrane systematic review, with methodological limitations, evaluated six trials comparing febuxostat to allopurinol for clinical SUA-lowering effect and found febuxostat more effective than allopurinol 300 mg in achieving SUA of <6 mg/dL. An important consideration in evaluating the evidence is that although the studies allowed upward titration of febuxostat to achieve maximal SUA lowering, the allopurinol dosage was not titrated to >300 mg daily.[80] Because the urate-lowering effect with allopurinol is known to be dose related and some patients have required up to 900 mg/day to achieve a SUA <6 mg/dL, these results may not have allowed for an adequate comparison of efficacy between the two drugs. The same review revealed that compared to standard doses of allopurinol, higher doses of febuxostat, 120 and 240 mg daily, increased the risk of gout flares; however, long-term follow-up studies did not detect an increased risk of flares. The FDA-approved dose in the United States is 80 mg daily; however, doses of up to 240 mg daily are approved in other countries.

In addition, adverse effects were shown to be minor and similar between both drugs in comparative studies with increases in liver function tests, nausea, diarrhea, arthralgias, and rash being the most common adverse effects with >1% incidence.[74,79,81,82] However, a major concern with febuxostat was recently revealed in 2018 during the Cardiovascular Safety of Febuxostat or Allopurinol in Patients with Gout (CARES) Trial, a doubled-blind, randomized, multicenter trial.[83] Results from the CARES Trial demonstrated an increase in all-cause mortality and cardiovascular mortality compared to allopurinol in patients with gout and coexisting cardiovascular conditions. These findings resulted in updated FDA labeling with a black box warning in February 2019. The warning advises on the increased risk for cardiovascular death with the drug. The warning also states that febuxostat use should only be used by patients who do not respond to or cannot tolerate allopurinol.[79] The 2020 ACR guidelines[19] recommend switching to an alternative for patients who are taking febuxostat with a history of cardiovascular disease or a

new cardiovascular event after considering the most recent data and label changes.

The starting dose of febuxostat is 40 mg once daily with a recommended dose increase to 80 mg once daily if SUA concentration is not <6 mg/dL by 2 weeks of therapy. It does not require dose adjustments for CrCl > 30 mL/minute, and the labeling provides no recommendations for use in patients with more severe renal impairment.[79] Febuxostat is a substrate of urate transporter 1 (URAT1). Significant febuxostat drug interactions can be found in **Table 45-5**.[84]

Table 45-5
Febuxostat Drug Interactions

Precipitant Drug	Object Drug		Description
Febuxostat	Didanosine	↑	Systemic exposures of didanosine are increased during coadministration. *Avoid combination.*
Febuxostat	Pegloticase	↑	Adverse effects/toxicity of pegloticase is enhanced with increased risk of anaphylaxis and infusion reactions. *Avoid combination.*
Febuxostat	Xanthine oxidase substrate drugs (eg, azathioprine, mercaptopurine, theophylline); exception: dyphylline	↑	Febuxostat is a xanthine oxidase inhibitor. Inhibition of xanthine oxidase by febuxostat may cause increased plasma concentration of these drugs, leading to toxicity. *Monitor therapy.*

↑, object drug increased; ↓, object drug decreased.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

CHOICE OF AGENT

Case 45-3, Question 4: Because an XO inhibitor is first-line therapy to lower SUA concentration, which product should be chosen for V.D.?

Although febuxostat is clearly efficacious in lowering SUA concentrations, allopurinol is also effective when the dose is appropriately titrated to response and goal SUA concentration. Guidelines recommend allopurinol as first-line therapy.[19,43,44] In addition, V.D. also has an extensive cardiovascular history consistent with heart failure and atrial fibrillation. Given recent evidence and labeled warnings,[78,83] febuxostat should only be used by patients

who do not respond to or cannot tolerate allopurinol. V.D. does not have any contraindications to allopurinol therapy. She is on chronic warfarin, which may interact with allopurinol.[79] This warrants monitoring her international normalized ratio (INR) after allopurinol therapy is initiated and with any allopurinol dosage adjustments.

Uricosuric agents

Probenecid and lesinurad are the only uricosuric agents available in the United States. Clinical practice guidelines recommend uricosurics as add-on therapy for patients who experience a partial response to XO inhibitors.[19] Uricosurics may also be considered in patients who are intolerant of XO inhibitors because of intolerability, contraindications, or significant drug interactions.[43] Overall, high fluid intake to maintain urine flow of at least 2 L/day also minimizes renal stone formation when using a uricosuric. This gradual approach to the initiation of ULT also decreases the likelihood of precipitating an acute attack of gout.

Probenecid is well absorbed orally, and plasma concentrations peak within 2 to 4 hours. Its biologic half-life is 6 to 12 hours, and its active metabolites extend the duration of action. The usual initial dose of probenecid (250 mg twice daily for the first week of therapy) can be increased to 500 mg twice a day. If necessary, the dose can be increased further to 2 to 3 g/day. Therapy should begin with small doses because the excretion of large amounts of uric acid increases the risk of urate stone formation in the kidney. Probenecid should not be administered to patients with impaired renal function or urolithiasis.

Probenecid inhibits secretion of penicillins into the renal tubule, and thereby prolongs the serum half-life of penicillin and increases penicillin serum concentrations. Probenecid can also compete with salicylates for renal tubular transport, but its interactions with salicylates involve several mechanisms.[85] Low-dose aspirin for cardioprotection is unlikely to interfere with probenecid therapy. Interestingly, high-dose aspirin (eg, >1 g) has uricosuric activity of its own.[86]

In 2015, lesinurad, a uricosuric that works as an URAT1 inhibitor, was approved as ULT in gout. However, lesinurad is only indicated in combination with an XO inhibitor because of the risk of increased renal toxicity when taken monotherapy.[87] Randomized controlled trials found that lesinurad in combination with XO inhibitors lowered SUA levels more than XO inhibitors alone.[88,89] Major cardiovascular events have been noted with lesinurad, although a causal relationship is unclear. Of note, lesinurad was discontinued by the manufacturer in late 2018 because of business reasons and not related to any efficacy, safety, or clinical concerns.[90]

Recombinant urate oxidase drugs (uricase)

Uricase, an enzyme endogenous in many animal species other than humans, converts uric acid to allantoin, which is much more soluble than uric acid and, therefore, more readily excreted into urine. Recently, two recombinant urate oxidase drugs have been developed for the treatment of hyperuricemia and gout. However, the high incidence of serious adverse reactions (23%–24%) as well as cost prohibit routine use. Rather, they should be considered as alternatives when all other ULTs have failed.[91]

Rasburicase

Rasburicase is a recombinant uricase drug that was initially approved by the FDA for the management of hyperuricemia in children who are receiving cytotoxic chemotherapy likely to result in tumor lysis syndrome and later received approval for the same indication in adults. Rasburicase does not currently carry an indication for gout. A comparative short-term study in patients with renal impairment found rasburicase was significantly more effective than allopurinol in lowering SUA concentrations at the end of 7 days of therapy.[92]

Rasburicase is administered as a short IV infusion of 0.2 mg/kg daily for up to 5 days.[93] Although lower-quality studies show significant reductions in SUA, rasburicase is not indicated for the treatment of hyperuricemia in patients with gout because of its short

half-life and immunogenicity.[94] Until further studies confirm safety and longer-term efficacy in nonchemotherapy-related hyperuricemia, rasburicase should be reserved for patients with hyperuricemia who are at risk for tumor lysis syndrome.

Pegloticase

Pegloticase, another recombinant uricase drug, has been shown to be effective in reducing SUA concentrations in patients who were refractory to conventional treatment. In clinical trials, pegloticase demonstrated lower SUA levels, decreased frequency of flares, reduction in tophi, and improved quality of life.[95–97] Pegloticase is administered IV for two hours as a dose of 8 mg every 2 weeks.[98] It has a significant risk of anaphylaxis and infusion site reactions, so each dose must be preceded by prophylaxis with an antihistamine and corticosteroid.[98] It is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, and the usual gout flare prophylaxis is recommended for the first 6 months after initiation. Finally, pegloticase antibodies occurred in the majority of patients studied, and this can ameliorate the SUA-lowering effects by decreasing the half-life of pegloticase. The full implication of this remains unknown.

However, pegloticase is not recommended as first-line therapy given significant warnings and precautions, high cost, and the need for twice monthly infusions.[19] Instead, pegloticase is reserved for patients with refractory disease, especially those in whom use of XO inhibitors, uricosurics, and other interventions have failed to lower SUA to target levels and who have frequent gout flares or persistent subcutaneous tophi.

Other agents

Some medications (eg, ascorbic acid, antihypertensive agents, and fenofibrates) used to treat conditions commonly seen in conjunction with gout have been proven to have uricosuric properties. However, current available data on these agents have significant limitations, and uric acid lowering is oftentimes minimal. It is also important to

note that to date no trials evaluating their effectiveness on clinically relevant outcomes (eg, gout attacks) have been published. If future randomized trials show promise, some patients with hyperuricemia might be better managed by selecting drugs to manage comorbid conditions rather than requiring the use of the more traditional ULT.

Ascorbic Acid

Vitamin C has a urate-lowering effect that is believed to be mediated by competition with urate for renal tubular reabsorption.[99] A meta-analysis found that vitamin C supplementation lowered SUA levels in patients without gout.[100] A prospective cohort study found an association between vitamin C and a lower risk of gout.[101] However, there is a lack of high-quality evidence to support routine use for the prevention of gout attacks.[102,103]

Antihypertensive Agents

In cases where gout occurs in patients using loop or thiazide diuretics, losartan or calcium channel blockers should be considered as substitutions for antihypertensive control. A large epidemiologic study found a lower relative risk of gout incident in patients on calcium channel blockers or losartan.[104] Based on several studies, losartan appears to be the only ARB that consistently demonstrates a reduction in SUA levels, and this does not seem to be a class effect.[105,106] Other antihypertensive agents (eg, β-blockers, diuretics, angiotensin-converting enzyme inhibitors, and non-losartan angiotensin II–receptor blockers) were also studied and were found to have increased risk of gout. In patients with hyperuricemia and HTN, losartan and calcium channel blockers may be a viable option depending on individual patient variables.

Fenofibrate

Fenofibrates have been shown to decrease SUA concentrations by increasing renal urate excretion.[107] In addition to therapeutic lifestyle changes, fibrates (ie, gemfibrozil, fenofibrate) are commonly used for

the treatment of hypertriglyceridemia. However, the use of fenofibrate remains controversial. Although fenofibrate is a reasonable option for patients with hyperlipidemia,[43,44] the 2020 ACR guidelines recommend against adding or switching to fenofibrates based on an inadequate risk versus benefit ratio.[19] However, the selection of a medication to manage hyperlipidemia should also involve other clinical variables.[108,109]

FLARE PROPHYLAXIS

Case 45-3, Question 5: V.D. is started on allopurinol 100 mg orally once daily for initial ULT. Her SUA concentration will be checked, and her allopurinol will be increased by 50 to 100 mg/day in 2 to 4 weeks if needed until she reaches the goal of ≤6 mg/dL. What other drug therapy should also be considered when starting ULT?

Paradoxically, initiation of ULT can precipitate acute gout attacks. Guidelines recommend prophylaxis with anti-inflammatory agents for all patients when ULT is initiated.[19,43,44] Prophylactic medication include colchicine, NSAIDs, or prednisone/prednisolone is recommended. The choice of agent should be based on patient-specific factors.[19] Upon initiation of ULT, anti-inflammatory therapy should be continued for at least 3 to 6 months and continued as needed if the patient continues to experience flares. V.D. would be a candidate for flare prophylaxis. As stated above, V.D.'s advanced age, acute exacerbation of heart failure, and renal dysfunction are patient-specific parameters that are relative contraindications or precautions for the use of long-term NSAID therapy for flare prophylaxis. Colchicine would be a reasonable option because it is considered first line and she tolerated colchicine during acute attacks. The colchicine dose for flare prophylaxis is 0.6 mg once or twice daily for 6 weeks. V.D. should be monitored for adverse drug reactions.

MONITORING AND FOLLOW-UP

In addition to monitoring for subjective and objective evidence of drug-related adverse effects, SUA concentrations should be monitored monthly until at goal, then every 6 to 12 months, thereafter. The optimal duration of ULT is unclear. Patients with mild gout may go years without experiencing repeat attacks after discontinuation of ULT. Lower SUA concentrations during treatment correlate with a longer interval between acute attacks or before tophi reappear. The majority of patients on long-term ULT are likely to experience recurrent acute attacks, tophi, or both if treatment is stopped.[110] Data suggest that patients with average SUA levels <7.0 mg/dL for at least 5 years can discontinue ULT and remain symptom-free for a prolonged period. The decision when to discontinue ULT should be made based primarily on patient preference after a shared-informed discussion.

Asymptomatic Hyperuricemia

CASE 45-4

Question 1: T.K. is a 50-year-old male who presents to his primary care provider for an annual wellness check. His physical examination is unremarkable, and his laboratory evaluations are all within normal limits except for an SUA concentration of 9.7 mg/dL. He denies any problems.

Should his hyperuricemia be treated?

Individuals with high SUA concentrations are more likely to develop acute gouty arthritis than individuals with normal SUA levels. A large percentage of patients with hyperuricemia never experience an acute gout attack.[3] Therefore, it is not recommended to treat asymptomatic hyperuricemia with uric acid–lowering medications to prevent acute gout flares. If a gout attack occurs, it can be quickly and easily treated.

The key issue in the treatment of hyperuricemia concerns the effect of uric acid on renal function. Data suggest that hyperuricemia may play a role in the progression of CKD.[111] More recent prospective cohorts have shown that hyperuricemia may cause renal

failure.[112] Despite this, the consensus remains against treating hyperuricemia with pharmacologic therapy.

PHARMACIST'S ROLE

Pharmacists have an important role in the treatment and management of gout. As noted several times in this chapter, there are significant drug–drug interactions associated with the majority of agents used to treat both acute and chronic gout. A 2008 retrospective cohort study showed that 28% of patients did not meet with a provider prior to initiation of ULT, and 56% of patients were nonadherent with ULT.[113] Additionally, adherence rates in gout vary from 20% to 70%.[114] Patient education about the roles of medication, including the importance of adherence and how to monitor for and manage adverse drug reactions in the treatment of gout, is an essential part of therapy. In cases where a provider visit did not occur prior to starting ULT, a pharmacist could serve as a resource for education and counseling. Pharmacists are equipped with the knowledge and skills to identify drug–drug interactions, monitor and encourage medication adherence, and provide general counseling on gout and lifestyle recommendations. Open communication with the patient's other health care professionals has the potential to improve gout management.

Connective Tissue Disorders

Steven S. Kheloussi, Julie L. Olenak, and Jonathan D. Ference

CORE PRINCIPLES		CHAPTER CASES
1	Systemic sclerosis (SSc) can be classified into localized and diffuse forms, with the major differentiation point being the dermatologic areas affected.	**Case 46-1 (Question 1)**
2	Ninety-five percent of patients affected by SSc also have signs and symptoms consistent with Raynaud phenomenon, which may be treated with nifedipine, prazosin, losartan, or phosphodiesterase-5 inhibitors.	**Case 46-1 (Question 2)**
3	SSc may involve dermatologic, pulmonary, gastrointestinal (GI), cardiac, and renal manifestations. Although treatment options exist for individual	**Case 46-1 (Questions 2, 3)**

	complications, no therapies exist to target the underlying disease.	
4	Many authorities believe polymyalgia rheumatica and temporal arteritis are manifestations of the same underlying process occurring at different times during the clinical course. However, they each have characteristic symptoms and are treated differently.	**Case 46-2 (Questions 1, 2), Table 46-4**
5	Reactive arthritis is secondary to certain genitourinary, GI, or respiratory infections. Patients with the *HLA-B27* gene are more susceptible to developing spondyloarthritis.	**Case 46-3 (Question 1), Table 46-5**
6	Nonsteroidal anti-inflammatories are appropriate initial therapy for reactive arthritis to control pain and inflammation.	**Case 46-3 (Question 2)**
7	Patients with documented active infections, and their partners when caused by a sexually transmitted disease, should be offered antibiotics. However, efficacy of prolonged antibiotics as a treatment of reactive arthritis is conflicting.	**Case 46-4 (Question 1)**
8	In severe or prolonged cases of reactive arthritis, corticosteroids, disease-modifying antirheumatic drugs, and biologicals may be considered.	**Case 46-4 (Question 2)**
9	Polymyositis and dermatomyositis should initially be treated with high-dose	**Case 46-5 (Questions 1, 2)**

corticosteroids. Immunosuppressive agents are recommended if the disease is not controlled with corticosteroids alone, if the response is positive but corticosteroid-sparing effects are desired, or if the condition presents initially with extramuscular complications.

INTRODUCTION

Connective tissue diseases (CTDs) are a complex group of conditions that are inflammatory in nature and are related to dysfunction of the immune system. It often takes years to properly diagnose CTDs, given heterogeneous patient presentations, nonspecific symptoms, complex etiologies, and overlapping syndromes.[1,2] Patients may present with findings consistent with more than one CTD, and symptoms generally do not all appear simultaneously. It has been reported that as many as half of patients who have a diagnosed CTD had been identified as having undifferentiated CTD.[3] Mixed CTD is an overlap of autoimmune disease features that can include myositis, scleroderma, and lupus.[1,3] Beyond the select CTDs covered in this chapter, the reader is also referred to Chapter 33 (Systemic Lupus Erythematosus).

Systemic Sclerosis (Scleroderma)

Systemic sclerosis (SSc), or systemic scleroderma, is a CTD associated with autoimmunity characterized by excessive extracellular matrix deposition and vascular injury to the skin and other visceral organs.[4] SSc can be classified into distinct clinical subsets based on the patterns of skin and internal organ involvement, autoantibody production, and patient survival.[4] The

most common subsets include limited cutaneous (~60% of patients) and diffuse cutaneous (~35% of patients).[4] Overlap syndrome occurs in up to 20% of patients and is the term used to define SSc features that are common in one or more of the other CTDs.[5] The limited cutaneous subset is diagnosed when skin thickening is limited to areas distal to the elbows and knees. Another form of the disease, localized scleroderma, presents with no systemic involvement and is usually benign and self-limiting.[6] This section will focus on SSc.

The prevalence of SSc is estimated at 276 cases/million adults in the United States.[7] More females than males suffer from SSc (female-to-male ratio, 3:1), although it appears the ratio is higher in younger patients (ages 15–44 years) compared to those older than age 45 years.[7] Onset of SSc generally begins in adults between ages 40 and 50 years.[8] African American patients are twice as likely as non–African American patients to have diffuse disease.[7,9] Additional risk factors for development of SSc are shown in **Table 46-1**.

Table 46-1

Risk Factors for the Development of Systemic Sclerosis

Female sex
Age (onset typically between 40 and 50 years)
African American race
Environmental exposure to silica dust (eg, coal miners)
Chemotherapeutic agents (gemcitabine, taxanes)
Presence of a connective tissue growth factor polymorphism

The underlying pathophysiologic changes that lead to systemic scleroderma remain unknown, but many believe that it results from a lymphocyte-mediated autoimmune reaction with endothelial cells, activated immune cells, and fibroblasts playing a key role in the process.[10,11] T-cell and B-cell abnormalities cause the production of autoantibodies that are seen in over 95% of patients.[11,12]

CASE 46-1

QUESTION 1: F.G. is a 47-year-old African American female with recently diagnosed diffuse cutaneous scleroderma. She presents with pain, tingling, and tricolor discoloration in her fingers. F.G. reports that she was previously diagnosed with Raynaud phenomenon and has experienced these symptoms for the previous 2 years, but they have recently worsened. Additionally, she presents with skin thickening and pruritus extending from the hands to the shoulders. It is determined upon testing that F.G.'s antinuclear antibodies are elevated, specifically anti-centromere and anti-topoisomerase I. She has a 32-year pack smoking history but has no other pertinent past medical history and does not take any medications. She also notes that she has recently gone through a divorce and has been smoking more because of the stress.

Which symptoms of SSc is F.G. experiencing that support a diagnosis of diffuse SSc?

The presentation of SSc is heterogeneous; however, several key clinical signs aid in pinpointing this condition. Diagnostic criteria for SSc rely on a scoring system that takes into account the presence and location of sclerosis (proximal or distal to the metacarpophalangeal joint), fingertip lesions, telangiectasia, abnormal nailfold capillaries, pulmonary involvement, Raynaud phenomenon, and SSc-specific autoantibodies.[10] Autoantibodies specific to SSc, including anti- centromere, anti-topoisomerase I, and anti-RNA polymerase III, are helpful in the diagnosis and differentiation of classification of the disease, but alone offer limited predictive and prognostic value.[13,14]

The major differentiation point between diffuse and localized scleroderma includes the dermatologic areas affected. Individuals, like F.G., who experience dermatologic involvement proximal to the elbows and knees are considered to have diffuse disease, whereas

those with localized SSc have distal involvement only.[4] Historically, the CREST acronym (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia) was used to describe limited cutaneous SSc, although this has recently fallen out of favor because these symptoms may be present in different subtypes of the disease.[15]

Case 46-1, Question 2: What are possible complications of Raynaud phenomenon and an appropriate treatment approach for this patient?

Raynaud phenomenon is the most universal sign of SSc, occurring in more than 95% of patients.[12] Patients may experience moderate-to-severe discoloration of affected areas, including fingers and toes, secondary to cold exposure or emotional stress.[4] Tricolor discoloration, such as that experienced by F.G., may occur, resulting in white, red, or blue phalanges or digits secondary to paroxysmal ischemia, stasis, and reactive hyperperfusion, respectively.[4,13] Vascular and tissue complications may occur and can result in digital pitting, digital ulceration, and autoamputation.[4,13] Efforts should be made to identify causative factors and reduce exposure. In F.G.'s case, stress reduction techniques and smoking cessation should be advised.

Pharmacologic therapy can also be considered for the treatment of Raynaud phenomenon. Clinical practice guidelines exist, which may assist in determining treatment for SSc complications, including Raynaud phenomenon.[16] Compared with placebo, nifedipine and prazosin modestly reduced the severity and frequency of Raynaud ischemic attacks.[17,18] When losartan was compared with low-dose nifedipine in a nonblinded, randomized, controlled trial, losartan users experienced a decrease in severity and frequency of Raynaud symptoms in a 12-week period.[19] This should not be considered as definitive evidence that losartan is superior as the lack of blinding may have resulted in an overestimation of losartan's benefit. Phosphodiesterase-5-inhibitors, including sildenafil and tadalafil, appear to be modestly effective as add-on therapy, but may also be

considered as monotherapy in patients who do not tolerate first-line therapy with a calcium channel blocker.[16,20–22] Notably, botulinum toxin was not found to increase blood flow to the hands of patients with scleroderma-related Raynaud phenomenon in one small double-blind, randomized, controlled trial.[23] In this case, F.G. is a candidate for standard first-line therapy with low-dose nifedipine, and a phosphodiesterase-5-inhibitor, such as sildenafil, may be considered if nifedipine monotherapy is ineffective.

Case 46-1, Question 3: Beyond Raynaud phenomenon, which complications of SSc is F.G. at risk for developing? What is an evidence-based treatment approach for each?

Those affected by diffuse SSc are more likely to develop organ complications compared to patients with localized disease, including an increased risk of skin, pulmonary, gastrointestinal (GI), cardiac, and renal complications.[13,24] Treatment complications are managed individually, as there are no available therapies to treat SSc.

Pulmonary disease, including pulmonary arterial hypertension and interstitial lung disease, occurs in up to 80% of individuals with SSc and represents the most common cause of death in patients with SSc.[4,5] Those with diffuse SSc tend to develop pulmonary disease sooner than those with limited skin involvement.[24] Interstitial lung disease is more prevalent in the diffuse SSc population, whereas pulmonary arterial hypertension is more common in patients with localized disease.[4]

Treatment for interstitial lung disease includes the respiratory tyrosine kinase inhibitor, nintedanib, which is approved for use in SSc-associated interstitial lung disease based on its demonstrated ability to slow the worsening of lung function in this population.[25] Tocilizumab, an interleukin-6 receptor antagonist, has also been shown to preserve lung function in SSc-associated interstitial lung disease and received approval for this indication in 2021.[26] Phase 2 data for pirfenidone, an antifibrotic agent, has shown promise, though this agent has not yet been approved for use for this

indication in the United States.[27] Additionally, cyclophosphamide, an antineoplastic agent, may be considered as it has been shown to improve forced vital capacity in these patients; however, it does not improve mortality.[28] In a single-center, retrospective study, mycophenolate mofetil showed promise for SSc-associated interstitial lung disease by leading to similar outcomes as cyclophosphamide.[29]

For patients who develop pulmonary hypertension, treatment with endothelin receptor antagonists (bosentan, macitentan, ambrisentan), phosphodiesterase-5 inhibitors (sildenafil, tadalafil), or riociguat may be considered as they have all been shown to improve functional capacity.[16] Less data support the prostanoids, iloprost and treprostinil, although these agents may still be considered. Although epoprostenol is effective, given that it must be administered through a permanent indwelling central venous catheter, it should be reserved for more severe, treatment-resistant disease.[16]

Digital ulceration may occur as a complication of prolonged ischemia in Raynaud phenomenon. Guideline-recommended therapies available for use in the United States include phosphodiesterase-5 inhibitors (sildenafil and tadalafil) and bosentan.[16] Sildenafil and tadalafil have both been shown to reduce healing time, whereas tadalafil and bosentan have been shown to reduce new digital ulcer formation.[16] Atorvastatin 40 mg daily has also been shown to reduce the number of new digital ulcers in patients with Raynaud phenomenon and SSc over a 4-month period.[30]

GI complications tend to be common in patients with SSc and may include reflux, diarrhea, constipation, dysphagia, bloating, and early satiety.[5,24] These sequelae may be managed similarly to non-SSc patients who present with these disorders, despite limited evidence. This includes proton pump inhibitors, histamine-2 receptor antagonists, and the prokinetic agent, metoclopramide.[5,16] Weight loss and malnutrition can lead to morbidity in patients with SSc, and parenteral or enteral nutrition should be considered to ameliorate these conditions.[5]

Finally, in diffuse disease, extensive skin involvement may require treatment. Methotrexate may be effective for improving skin symptoms and is recommended by guidelines.[16] Despite a variety of uses for methotrexate, it lacks efficacy on other organ manifestations of SSc. Cyclophosphamide, mycophenolate mofetil, and rituximab have also been shown to improve dermatologic symptoms.[5,31,32] Tocilizumab was found to be ineffective for improving skin involvement.[26]

Polymyalgia Rheumatica and Temporal Arteritis (Giant Cell Arteritis)

Polymyalgia rheumatica (PMR) and temporal arteritis, also known as giant cell arteritis (GCA), are closely related clinical syndromes that many authorities believe to be different phases of the same underlying disease process. PMR is two to three times more common than GCA. However, about 27% to 53% of persons with GCA also have PMR, and 18% to 26% of those with PMR also have GCA.[33] Inflammation is the hallmark of both conditions. PMR is characterized by aching and morning stiffness in the cervical region and shoulder and pelvic girdles and may result in disability.[34] Inflammation as a result of GCA most commonly involves the temporal artery, but arteries in other parts of the body can also be affected.[35] Despite certain similarities, PMR and GCA have distinct symptoms, corticosteroid requirements for treatment, and prognoses.

The incidence of PMR and GCA increases in patients after age 50 years and peaks in those ages 70 to 80 years.[34] GCA can lead to blindness if not diagnosed and treated in a timely manner. Likewise, patients with PMR are at an increased risk of peripheral arterial disease. The primary risk factor for both conditions is age, and both occur more frequently in females than in males. The incidence of PMR is 5.9/10,000/year in the United States, with an overall prevalence of about 740/100,000.[36] The incidence of GCA is 0.17

new cases annually per 1000 persons older than age 50 years with a prevalence of 2/1000 persons.[37]

Although the exact pathogeneses of PMR and GCA are yet to be determined, they are both thought to arise from an autoimmune or inflammatory dysfunction involving similar cellular immune responses from T cells, antigen-presenting cells, macrophage-derived inflammatory cytokines, genetic human leukocyte antigen molecules, and macrophages.[34,38]

CASE 46-2

Question 1: D.C. is an 85-year-old White male presenting to the emergency department with new-onset morning aching pain and stiffness in his shoulders and upper arms. He states his symptoms developed 3 weeks ago and have progressed to the point where his pain and limited range of motion are keeping him from performing activities of daily living. D.C. denies headaches or vision disturbances, but reports overall malaise, fatigue, and anorexia. He has a past medical history significant for hyperlipidemia, type-2 diabetes mellitus, and hypertension. He has been taking his current medications for the past 2 years, which are adequately controlling his hyperlipidemia, diabetes, and hypertension. His current medications include simvastatin 40 mg daily, metformin 1000 mg twice daily, lisinopril/hydrochlorothiazide 40/25 mg daily, and aspirin 81 mg daily. His physical examination was negative for decreased muscle strength. Limited range of shoulder and upper arm motion is noted along with tenderness of these areas on palpation. Routine baseline laboratory values are within normal limits, with an erythrocyte sedimentation rate (ESR) of 75 mm/hour. D.C. was admitted to a general medical ward with a diagnosis of PMR and was started on prednisone.

What signs and symptoms present in this case differentiate PMR from GCA?

No conclusive laboratory test for PMR or GCA exists, and nonspecific clinical features and the absence of physical signs often complicate diagnosis. Appropriate diagnosis requires a thorough history and physical examination. Distinguishing between the two disorders is of importance, as GCA can lead to blindness and requires higher doses of treatment medications. The typical onset of PMR is acute in nature. However, as is the case with D.C., most who present for a medical evaluation describe their symptoms as occurring for 1 month or longer.[35] D.C. is also exhibiting symptoms

associated with PMR, which include aching pain and morning stiffness in the shoulders and upper arms, hips and thighs, or neck and torso. The shoulders are affected in 95% of cases. New-onset GCA often manifests as a new headache or a headache that is described as different from previous headaches and has been occurring for 2 to 3 months. Constitutional symptoms such as fatigue, anorexia, and weight loss in an older patient often accompany headaches seen in GCA.[33] The absence of headache in D.C. further supports the diagnosis of PMR. Common findings associated with both conditions are presented in **Table 46-2**.[35] An elevated ESR is a common diagnostic finding for both PMR and GCA.[35] At least three different sets of diagnostic criteria are in use for PMR.[39] Patients with suspected GCA should be referred to a specialist for diagnostic work-up where clinical diagnosis is often confirmed by imaging or histology.[40] The 2020 British Society for Rheumatology guidelines recommend patients with suspected GCA should have a confirmatory diagnostic test. This test could be either a temporal artery biopsy or an ultrasound of the temporal and axillary arteries, or both.[41]

Table 46-2

Common Findings Associated With Polymyalgia Rheumatica and Giant Cell Arteritis

Polymyalgia Rheumatica	Giant Cell Arteritis
Age ≥ 50 years	Age ≥ 50 years
ESR > 50 mm/hour	ESR > 50 mm/hour
Anemia (mild, normochromic, normocytic)	Anemia
Aching, pain, and morning stiffness in the shoulders and upper arms, hips and thighs, or neck and torso	Headache: temporal with temporal artery involvement or occipital with occipital artery involvement
Symptoms of systemic inflammation	Visual symptoms or jaw claudication
	Fever, weight loss, depression, fatigue
	Arthralgias

ESR, erythrocyte sedimentation rate.

Case 46-2, Question 2: What is the preferred initial treatment approach for PMR in D.C.? What are the difference(s) in this approach as compared with those for GCA?

Owing to its anti-inflammatory properties, corticosteroids are considered first-line therapy for either PMR or GCA. Early visual loss may occur in up to 20% of GCA patients and rarely improves once present. Therefore, initiation of corticosteroid treatment should not be delayed pending temporal artery biopsy results.[33] When PMR and GCA occur simultaneously, higher corticosteroid doses (indicated for the treatment of GCA) are required to prevent significant complications. For the treatment of PMR, European League Against Rheumatism/American College of Rheumatology (EULAR/ACR) guidelines recommend the use of corticosteroids (equivalent to prednisone 12.5–25 mg daily) in place of nonsteroidal anti-inflammatory drugs, except for short-term use for analgesia.[39] Clinicians should consider initiating treatment with the minimum effective corticosteroid dose. A higher dose may be preferred if the patient is at elevated risk of relapse and minimal risk of adverse events, whereas a lower dose may be preferred if the patient has comorbidities (eg, diabetes, osteoporosis, or glaucoma) and risk factors for corticosteroid-related adverse events. Beginning low-dose prednisone (owing to his diabetes) may improve D.C.'s PMR symptoms within days, but optimal results could take several weeks to achieve, and most patients can expect to receive therapy for 1 to 2 years. Treatment should be tailored to patient symptoms and inflammatory markers should be followed. Attempts to taper the dose to avoid long-term adverse drug events (eg, osteoporosis, hypothalamus–pituitary–adrenal axis suppression) should be made once acute relief has been achieved. Initially, the dose should be reduced to the equivalent of prednisone 10 mg daily within 4 to 8

weeks.[39] If the patient relapses, the dose should be increased back to the pre-relapse dose. Once remission is achieved, the corticosteroid dose should be tapered by 1 mg every 4 weeks. Addition of methotrexate to corticosteroid therapy may be considered in patients with comorbid conditions, those requiring prolonged treatment, and those who do not respond to therapy.[35]

GCA is a medical emergency requiring immediate treatment. As opposed to PMR, treatment for uncomplicated (no jaw or tongue claudication or visual changes) GCA should begin with high-dose corticosteroids, equivalent to prednisolone 40 to 60 mg/day.[41] Complicated GCA (evolving visual loss or history of amaurosis fugax) should be treated with intravenous methylprednisolone 250 mg to 1 g/day for 3 days, followed by oral prednisolone 60 mg/day.[41] A corticosteroid taper can be initiated after 4 weeks of treatment, resolution of symptoms, and normalization of ESR/C-reactive protein. High-quality evidence comparing different corticosteroid taper schedules is not available. Clinical practice guidelines provide examples of different schedules.[41] Use of immunosuppressants as adjunctive therapy may be recommenced in patients with refractory or relapsing GCA, and in patients with or at an increased risk of corticosteroid-related side effects.[41] In such cases, tocilizumab 162 mg/week is recommended and methotrexate, at a minimum dose of 15 mg/week, may be considered as an alternative.[40]

All patients on long-term corticosteroids should be offered calcium (1200 mg/day) and vitamin D (800 international units/day) for the prevention of osteoporosis and be monitored for other complications of corticosteroid therapy. Patients at risk for gastritis should receive prophylactic protection with a proton pump inhibitor.

Patients being treated for PMR or GCA should be monitored closely for response to treatment and disease progression. It is recommended that the first follow-up visit should take place 1 to 3 weeks after the start of corticosteroids.[38] Subsequent visits should occur at 6 weeks as well as 3, 6, 9, and 12 months, or on an as-needed basis if relapses or adverse events occur. At each visit, patients should be assessed for specific symptom improvement, and routine blood work should include ESR, C-reactive protein, a

complete blood count, and a comprehensive metabolic panel. Bone mineral density testing every 2 years may be considered in patients receiving long-term corticosteroids.

Reactive Arthritis

Reactive arthritis is defined as peripheral arthritis often accompanied by one or more extra-articular manifestations that appear after certain genitourinary (GU), GI, or respiratory infections. **Table 46-3** lists bacterial pathogens associated with the development of reactive arthritis.[42–44] In addition, it shares features with other forms of spondyloarthropathies, which is the grouping it falls under. The term "Reiter syndrome" was previously used to describe the unique combination of arthritis, urethritis, and conjunctivitis.[42] The majority of the patients do not present with all three symptoms in the triad.[42,45] The presentation of arthritis is usually a large joint monoarthritis or oligoarthritis in the lower extremities and/or enthesitis, which is an inflammation of the site where the tendon or ligament attaches to the bone.[42] Typically, reactive arthritis would occur 1 to 6 weeks after the infection.[42] The clinical course of reactive arthritis is variable and usually runs a self-limited course of 3 to 12 months.[43] Although mortality from reactive arthritis is not common, it may result from rare cardiac complications. Approximately 20% of patients may continue to have chronic, destructive, and disabling arthritis or enthesitis and some may progress to ankylosing spondylitis.[43,45]

Reactive arthritis. *Infect Dis Clin N Am.* 2017:31(2):265–277.

The annual incidence of reactive arthritis in the United States varies between 3.5 and 5/100,000/year.[42] Reactive arthritis most frequently occurs in patients between 20 and 40 years old, but it can occur at any age. In general, it occurs more frequently in males than in females following GU infection. Following bowel infections, the prevalence is equal.[42]

Reactive arthritis is considered a sterile inflammatory response to a remote infection. Genetics has been identified as a likely risk factor, playing a role in the pathogenesis of spondyloarthropathies. Between 30% and 50% of patients are surface antigen *HLA-B27* positive, which presents antigenic peptides to T cells.[44] Some sources present this as high as 80% among families.[43] These patients are susceptible to a more severe and prolonged disease.[42,43,45]

Onset of symptoms typically occurs 1 to 6 weeks after infection and may present in an insidious or acute manner. Patients usually present with joint pain and stiffness, myalgia, and low back pain that is worse with rest. Initial symptoms of the infection may no longer be present.[43] **Table 46-4** describes the clinical manifestations of reactive arthritis. It may present as arthritic in nature or as dysfunctions of the ocular, skin, GU, mucocutaneous lesions, or cardiac systems.

Urethritis, cystitis, prostatitis, mild dysuria, and a mucopurulent urethra are the most common symptoms that occur in males. Females may have dysuria, vaginal discharge, and purulent cervicitis or vaginitis. Arthritic symptoms are usually asymmetrical, involving the lower extremities, and are associated with the appearance of a "sausage finger" digit.[43–45]

Table 46-4
Clinical Signs of Reactive Arthritis

Musculoskeletal System
Arthritis affecting one to four joints of typically large, lower limb
Entheses
Low back pain (sacroiliitis)
Skin/Mucosal Manifestations
Keratoderma blennorrhagica on soles and/or palms
Mucosal ulcers
Circinate balanitis on penile gland
Genitourinary
Cervicitis
Urethritis
Ocular Manifestations
Conjunctivitis
Uveitis

CASE 46-3

Question 1: E.O. is a 47-year-old male who had a stool sample–confirmed GI infection with *Salmonella Typhimurium enteritidis*. E.O. was able to manage the infection at home. Approximately 2 weeks after the diarrhea, fever, and abdominal cramps subsided, E.O. presented with two swollen, stiff, and erythemic joints (ie, right knee and left ankle). He also is experiencing tendonitis presenting as heel pain. He has no significant medical or family history and takes a multivitamin tablet daily.

Based on the history of symptoms present in this case, what supports a diagnosis of reactive arthritis?

E.O. had an infection known to be associated with reactive arthritis. Symptoms also began within a few weeks of the infection. Lower limb joints are most frequently impacted in reactive arthritis. Additionally, tendonitis is an example of endothesis. The asymmetric presentation of joint pain and swelling is typical.[43–45]

Case 46-3, Question 2: What is an appropriate initial treatment strategy for E.O.?

First-line therapy with a nonsteroidal anti-inflammatory drug would be appropriate for symptom relief. Nonsteroidal drugs offer analgesic and anti-inflammatory properties. For example, naproxen 500 mg twice daily could be initiated.[42–44]

CASE 46-4

Question 1: C.S. is a 27-year-old female who was diagnosed with *Chlamydia trachomatis* and was properly treated with antibiotics. One month later, she presented with a new painful right knee effusion; a left "sausage finger"; cervicitis; vaginal discharge; and red, irritated eyes. The effusion was drained, and no bacteria or crystals were identified. She has no cardiac or dermatologic abnormalities on physical exam. She reports no current medical conditions and a family history of a father with psoriatic arthritis. She was started on ibuprofen 800 mg three times daily and has been taking it for 6 weeks. She presents for a follow-up and reports that all of her symptoms are gone except the joint pain. She rates her pain as a 6 out of 10 and indicates that her joint pain is interfering with her activities of daily living. She has tested positive for the *HLA-B27* gene, her rheumatoid factor was negative, and her ESR was elevated at 35 mm/hour.

The laboratory confirmed that her test was now negative for *Chlamydia trachomatis*.

What additional therapies may be recommended for C.S.?

C.S. developed reactive arthritis following her chlamydia infection. It is important to confirm that any sexual partners were also treated for chlamydia at the time of her diagnosis. She is presenting with the classic triad of symptoms, including arthritis, urethritis, and conjunctivitis.[42,43] C.S. is still experiencing an active inflammatory response as evidenced by the elevated sedimentation rate. A family history of psoriatic arthritis, which is also classified as a spondyloarthropathy, and testing positive for the *HLA-B27* gene are risk factors for severe or chronic reactive arthritis.[42]

Because C.S. is still experiencing pain in her joints, an intra-articular corticosteroid injection may be considered if one joint is predominantly causing her pain or oral corticosteroids if more joints are affected. Joint pain is typically present in a limited number of joints (ie, one to six joints), and some experts prefer to use injections to avoid systemic adverse effects. However, oral corticosteroids may be helpful for the treatment of pain and swelling.[44] An example oral corticosteroid dose would be 20 to 40 mg of prednisone daily.[42] Reactive arthritis will spontaneously resolve in approximately half of cases, even without treatment.[42,43,46] Physical therapy and ice modalities may be an integral part of management to improve mobility and strength and to prevent stiffness and deformities if needed.[42,46]

Case 46-4, Question 2: What additional treatment options are available if C.S. does not respond to corticosteroid therapy or develops chronic reactive arthritis?

For those who suffer from a persistence of acute reactive arthritis, a disease-modifying antirheumatic drug (DMARD) may be used. One example is sulfasalazine, which is well tolerated and possibly effective at a dose of 1 g twice or three times daily.[42] Consideration may be given to start a nonbiologic DMARD therapy earlier in the

course of the disease if a patient is refractory to first- and second-line treatments, has a recurrence of reactive arthritis, or is *HLA-B27* positive.[42] Given its use in other rheumatologic conditions, methotrexate has been used by some as a nonbiologic DMARD despite a lack of strong evidence. Aggressive and unremitting reactive arthritis may be treated with immunosuppressants if it is confirmed the initial infection is cleared.[46] In severe cases, where patients fail to achieve adequate relief with prior therapies, antitumor necrosis factor-α treatment may be considered.[47] Tumor necrosis factor has been found to be elevated in synovial samples of patients with reactive arthritis.[42,47] Additional large-scale studies are needed to evaluate the role of these agents for routine use because most current evidence is based on case reports and small studies.[46,47]

Prolonged antibiotic use is not known to improve symptoms once the initial infection is cleared with the possible exception of chronic reactive arthritis, defined by a duration of >6 months, from an active chlamydia infection. It was noted that heterogeneity of studies potentially limits results. A small, randomized trial of 42 patients who took a 6-month course of antibiotics in chlamydia-induced reactive arthritis, including rifampin combined with doxycycline or azithromycin, improved symptoms in 63% of treated patients compared to 20% of placebo-treated patients.[42,43,48,49] GI side effects are frequently reported with prolonged antibiotic use.[42,43,48,49] Most cases of chronic reactive arthritis resolve within 1 year.[42,43]

Polymyositis and Dermatomyositis

Polymyositis (PM) and dermatomyositis (DM) are idiopathic autoimmune and inflammatory disorders of unknown etiology involving a number of voluntary skeletal muscles simultaneously. PM and DM are characterized by the presence of inflammatory myopathies. In addition, DM involves specific skin manifestations, whereas PM does not.[50,51] Dermatomyositis is also associated with an increased risk of malignancies. Twenty-five percent of patients diagnosed with DM will develop a malignancy in the future, typically

within 5 years. For PM, the risk is lower with between 10% and 15% developing a malignancy within 5 years.[50] A patient may also have a preexisting malignancy they are unaware of and when diagnosed with DM should have age-appropriate screenings (eg, mammogram, colonoscopy, pelvic exams, prostate tests, imaging of chest).[51]

In addition to maintaining functions of daily activities and improving quality of life, therapy is aimed at reducing the risk of respiratory failure, renal failure, and cardiomyopathy as potential complications of either disorder.[50] A proportion of patients will meet the diagnostic criteria for other CTDs. This overlap syndrome with myositis and other CTDs (eg, systemic lupus erythematosus, scleroderma, rheumatoid arthritis) is thought to occur in about 20% of adult patients.[50]

Polymyositis typically presents in older adults over age 50 years and is rarely seen in children. Dermatomyositis exhibits a bimodal distribution and affects middle-aged adults (ages 30–50), as well as a peak in children age 7. These disorders occur in females more than males (~2:1).[51] Additionally, unlike other myopathies PM has not been associated with any specific antibodies. Ruling out other conditions is important as PM has become a diagnosis of exclusion.[52] The estimated prevalence of idiopathic inflammatory myopathies is between 50 and 100 cases/million.[50] Of those diagnosed with myositis, DM occurs in about 35% to 50% of cases and PM in ~30% to 45%.[50]

There is no clear cause of either disorder, and both are thought to involve immune-mediated processes triggered by viruses, cancer, other autoimmune CTDs, environmental factors (ultraviolet radiation in DM), or drugs in genetically susceptible individuals.[50] Dermatomyositis is thought to be a complement-mediated microangiopathy in which inflammatory infiltrates arise owing to ischemic phenomena. In patients with PM, muscle fibers may be damaged by T-cell mediated immune response. Infectious agents implicated as causative factors include coxsackievirus, group A *Streptococcus*, influenza virus, retroviruses, cytomegalovirus, parvovirus, and Epstein-Barr virus.[50]

Symptom onset for both PM and DM are insidious, and patients initially report muscle weakness of the trunk, shoulders, hips, upper arms, thighs, neck, and pharynx. These patients usually report increasing difficulties in everyday tasks requiring the use of proximal muscles, such as getting up from a chair, climbing stairs, stepping onto a curb, and combing hair. Frequent falls, fatigue, malaise, weight loss, shortness of breath, and low-grade fever are also often present. Classification of PM and DM can be accomplished by assessing the presence or absence of certain characteristics unique to the condition. Specifically, they are largely separated by the involvement of cutaneous changes and calcinosis in DM.[50,51] Specific manifestations seen in DM are described in **Table 46-5**.[53] The recently published EULAR/ACR classification criteria are helpful in using uniform definitions in clinical trials and looking at the probability of an idiopathic inflammatory myopathy.[54] Specific autoantibodies are helpful for diagnosing DM but have not been identified for PM.[52]

Table 46-5

Cutaneous Manifestations of Dermatomyositis

Pathognomonic Skin Lesions of Dermatomyositis
1. Gottron papules: papules having a violaceous hue overlying the dorsal lateral aspect of interphalangeal and/or metacarpophalangeal joints. When fully formed, these papules become slightly depressed at the center, which can assume a white, anthropic appearance. Associated telangiectasia can be present 2. Gottron signs: symmetric macular violaceous erythema with or without edema overlying the dorsal aspect of the interphalangeal/metacarpophalangeal joints, olecranon processes, patellae, and medial malleoli
Highly Characteristic Skin Lesions of Dermatomyositis
1. Periorbital violaceous (heliotrope) erythema with or without associated edema of the eyelids and periorbital tissue 2. Grossly visible periungual telangiectasia with or without dystrophic cuticles 3. Symmetric macular violaceous erythema overlying the dorsal aspect of the hands and fingers (where it can track the extensor tendon sheaths), extensor aspects of the arms and forearms, deltoids, posterior shoulders, and neck (the shawl sign), V-area of anterior neck and upper chest, central aspect of the face and forehead

Compatible Skin Lesions of Dermatomyositis
1. Poikiloderma vasculare atrophicans (poikilodermatomyositis) circumscribed violaceous erythema with associated telangiectasia, hypopigmentation, hyperpigmentation, and superficial atrophy most commonly found over the posterior shoulders, back, buttocks, and V-area of the anterior neck and chest
2. Calcinosis cutis

CASE 46-5

Question 1: C.F. is a 55-year-old female who presents with a diagnosis of PM. Other CTDs and myopathies have been ruled out. She has no dermatologic abnormalities or other organ involvement. Her primary symptoms include fatigue and moderate symmetric muscle weakness. Activities she finds particularly difficult include rising from a seated position, climbing stairs, and performing activities that require her arms to be raised.

What is a first-line pharmacotherapeutic option to recommend that may provide C.F. with symptom relief?

The initial and long-term goals of therapy are to improve muscle weakness, thereby improving the activities of daily living. The clinical course of both PM and DM varies in severity from mild to more severe progressive disease. Those with mild forms of the disease usually have a rapid response to therapy, whereas those with more severe or slowly progressive forms of the disease are more likely to not respond to treatment. This is a marker for a poor prognosis.

An appropriate first-line therapy is a corticosteroid at a dose of up to 80 mg of prednisone or the equivalent for 2 to 4 weeks.[50] Weight-based dosing of 1 mg/kg may be considered.[52,55] A slow taper is recommended to avoid a flare of PM symptoms. An example taper could include reducing the dose by 10 mg every 2 weeks until 30 mg/day is achieved; then by 5 mg every 2 weeks until 20 mg/day is achieved; finally, by 2.5 mg every 2 weeks until the prednisone is discontinued.[50] Alternatively, taper approaches may involve a switch to alternate day dosing during the taper or a 10% reduction in dose every 2 weeks.

Depending on her response to the corticosteroids and the taper, C.F. may be offered methotrexate, azathioprine, or mycophenolate mofetil, as recommended immunosuppressants and corticosteroid-sparing agents if the disease is not controlled with corticosteroids alone, is rapidly progressive, or presents with extramuscular involvement. Intravenous immune globulin can be given over 2 to 5 days, depending on the dose, for severe or refractory cases. In severe cases, it may be preferred to begin with intravenous corticosteroid therapy with methylprednisolone 1000 mg for 3 to 5 days. If the complication of interstitial lung disease is present in patients with PM or DM, mycophenolate mofetil or tacrolimus may be considered as well as intravenous cyclophosphamide or rituximab, for which there is emerging data.[50,52,55,56] Ongoing trials will evaluate the potential use of other immune-modulating therapies.[52,55]

Case 46-5, Question 2: What preventive health measures may be offered to C.F. to augment her pharmacotherapeutic treatment regimen?

Supportive therapies such as physiotherapy, rest, and moist heat applications to the affected areas can improve muscle stiffness. If oral lesions are present, irrigation of these lesions with warm saline solution is helpful. Preventive health measures for those experiencing either disorder include cancer screenings, osteoporosis prevention, a review of immunization records, minimizing aspiration risk in patients with esophageal dysmotility, and physical therapy or customized exercise in patients with muscle weakness.[51,55] Patients with DM should routinely use sunscreen. Although there have been previous concerns to not further damage muscle, appropriate exercises including passive range of motion exercises and aerobic and resistance exercises have shown benefit.[55] Female patients placed on teratogenic immunosuppressants should discuss contraception, when appropriate.

Contraception

Shareen El-Ibiary

CORE PRINCIPLES		CHAPTER CASES
1	Contraceptive choice is based on several factors that include preferred formulation, hormone content, effectiveness, side effect profile, cost, accessibility, past medical history, medication use, privacy of use, prevention of sexually transmitted infections (STIs), and return to fertility time.	**Case 47-1 (Question 1)**
2	Combined hormonal contraceptive (CHC) agents are a combination of estrogen and progestin. They are available in a variety of formulations that include a combination of estrogen and progestin (oral tablet, vaginal ring, and transdermal patch). CHCs may be classified by estrogen content into high	**Case 47-1 (Questions 3–5, 7), Table 47-3**

	dose (50 µg of ethinyl estradiol), low dose (30–35 µg of ethinyl estradiol), and very low dose (10–25 µg of ethinyl estradiol), and can vary in cycle length (eg, 21, 24, or 84 days of active hormone). Combined oral contraceptives (COCs) can be further classified by hormone content into monophasic, biphasic, triphasic, and quadriphasic.	
3	CHCs have benefits, aside from pregnancy prevention, that include treatment of acne, hirsutism, premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD), and endometrial cancer; menstrual cycle regulation and bleeding; endometriosis, and prevention of ovarian cancer and functional ovarian cysts.	**Case 47-2 (Questions 1–3)**
4	Breakthrough bleeding, nausea, acne, and weight gain are among the most commonly reported side effects in females taking hormonal contraceptives. Risks and side effects may be linked to estrogenic, progestogenic, or androgenic properties of hormonal contraceptives.	**Case 47-2 (Questions 4–8) Case 47-3 (Question 1), Table 47-4**
5	There are risks associated with CHCs and contraindications for use in some females. Estrogen-containing contraceptives should be avoided in females who are age 35 years or older	**Case 47-1 (Question 2)**

	and smoke >15 cigarettes/day and who have uncontrolled hypertension, history of gallbladder disease, stroke, migraines with aura, cardiovascular disease, and history of thromboembolic events.	
6	Progestin-only contraceptives are alternative agents for females with contraindications to CHCs. Progestin-only contraceptives vary in formulations that include oral tablet, depot and subcutaneous injection, and subdermal implant. Common side effects include weight gain, acne, mood changes, and irregular menses.	**Case 47-3 (Questions 2–6)**
7	Effectiveness of hormonal contraceptives is in part based on proper use and counseling. Patients need to understand how to use the contraceptive, what to do for mishaps (eg, missed dose, vaginal ring falls out, transdermal patch falls off), and when to use a backup method. Directions for missed doses of progestin-only contraceptives vary from those for COCs.	**Case 47-1 (Questions 6, 7) Case 47-3 (Questions 2–6)**
8	Concomitant use of certain drugs may increase or decrease the levels of hormonal contraceptive agents. In particular, antibiotics and hepatic inducers may decrease the effectiveness of CHCs. Progestin-only contraceptives or nonhormonal contraceptives including backup	**Case 47-1 (Question 8), Table 47-5**

	methods may be alternatives in these cases.	
9	Intrauterine devices (IUDs) or intrauterine systems (IUSs) are available in two formulations (copper IUD and levonorgestrel IUS) and are best for long-term pregnancy prevention. To avoid the risk of pelvic inflammatory disease, the products should be used in females involved in a monogamous relationship.	**Case 47-3 (Question 7)**
10	Some nonhormonal contraceptives include diaphragms, condoms, and spermicides. Male and female condoms are the only contraceptive products that also provide protection against STIs.	**Case 47-4 (Questions 1, 2)**
11	Timing is a key for emergency contraception (EC) to be effective. It is best taken as soon as possible after unprotected sexual intercourse but may be effective up to 120 hours after coitus. EC can be in the form of high-dose progestin pills, high-dose estrogen and progestin pills (known as the Yuzpe method), selective progesterone receptor modulator (SPRM), or copper IUD.	**Case 47-4 (Question 3)**
12	Medical abortion generally consists of mifepristone or methotrexate (to stop development of the pregnancy), or both, in combination with misoprostol (to	**Case 47-4 (Question 4)**

induce uterine contractions and expel the pregnancy).

INTRODUCTION

Contraception is currently an issue worldwide. Preventing unintended pregnancy is an important goal of contraceptive use, particularly in countries where population control is a goal. Economic implications play a role as well. Data from 2008 to 2011 show that an estimated 45% of pregnancies in the United States were unintended, and of these, 42% resulted in abortions.[1] Proper use and understanding of contraceptives is important for preventing unintended pregnancies.

HORMONAL CONTRACEPTION BACKGROUND AND PHARMACOLOGY

Hormonal contraceptives include combinations of estrogens and progestins known as *combination hormonal contraceptives (CHCs)* or *progestin-only contraceptives*. Estrogens prevent the development of the dominant follicle by suppressing follicle-stimulating hormone (FSH) secretion and stabilize the endometrial lining to minimize breakthrough bleeding (see Chapter 50, Disorders Related to the Menstrual Cycle, for more information about the menstrual cycle).[2] Progestins (synthetic progesterone) prevent ovulation by suppressing luteinizing hormone (LH) secretion. They may work in combination with estrogen in CHCs, such as combined oral contraceptives (COCs), the contraceptive patch, and the contraceptive ring, or alone in formulations such as a progestin-only pill (POP), depot intramuscular (IM) or subcutaneous injection, subdermal implant, and as part of intrauterine systems (IUSs).

Progestin-only contraceptives hamper the transport of sperm through the cervical canal by thickening cervical mucus and causing alterations in the endometrial lining (so that it is not favorable for implantation) and in the fallopian tubes (affecting ovum transport).

COMBINATION HORMONAL CONTRACEPTIVES

Patient Evaluation

CASE 47-1

QUESTION 1: S.F., a healthy 33-year-old female, presents to the clinic stating she is getting married soon and would like birth control pills as a method of contraception. She does not have children but would like to start a family in a year or two. Her past medical history is noncontributory other than occasional headaches for which she takes ibuprofen 200 mg by mouth (PO) as needed.

Vital signs: weight, 128 pounds (58.06 kg); height, 64 inches (162.56 cm)
Blood pressure, 122/72 mm Hg
Heart rate, 85 beats/minute
Temperature, 98.6 °F (37 °C)
Social history: smokes one pack/day, denies alcohol
Family history: sister gestational diabetes, mother hypertension, father unknown

Which factors are important in the selection of a contraceptive agent for S.F.?

There are several factors that affect selection of a contraceptive. Among them is effectiveness in preventing pregnancy. It is important to determine the importance of pregnancy prevention for S.F. and choose a method based on this information. For example, patients taking teratogenic medications or those with underlying medical conditions in which pregnancy may not be desired will require a highly effective birth control method or multiple methods. Others may not desire a pregnancy, but, for a variety of reasons, an unintended pregnancy may be more acceptable.

The effectiveness of contraceptive methods depends on the mechanism of action, availability (eg, prescription required), patients' concurrent medications, past medical history, and acceptability (eg, side effects, ease of use, adherence, cost, and religious and social beliefs). Any or all of these factors can account for the discrepancy between the lowest failure rate observed for 1 year in clinical trials (perfect-use failure rate) and the actual failure rate in users (typical-use failure rate) and should be taken into account when selecting a method of contraception (**Table 47-1**).[2] Return to fertility time is also an important factor to consider. Some contraceptive methods allow a patient to conceive shortly after discontinuation, whereas others may delay fertility longer. S.F. indicated that she would like to have children in the near future. Given her age of 33 (fertility starts to decrease after age 32) and desire for future pregnancy, it would be best to select a product with a faster return to fertility.[3] However, other factors to consider when selecting a contraceptive agent for S.F. include contraindications and risks for her that may indicate one method over another. A combined hormonal contraceptive (CHC) is used commonly in females and may be appropriate for S.F. once all factors are considered.

[a]Among *typical* couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, fertility awareness–based methods, the diaphragm, the male condom, the oral contraceptive pill, and Depo-Provera® are taken from the 1995 National Survey of Family Growth corrected for underreporting of abortion; see the source for the derivation of estimates for the other methods.

[b]Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for

any other reason. See the table source for the derivation of estimates for the other methods.

[c]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

[d]The percentages becoming pregnant in the first year are based on data from populations in which contraception is not used and from females who cease using contraception to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentages who would become pregnant within 1 year among females now relying on reversible methods of contraception if they abandoned contraception altogether.

[e]The ovulation method and the TwoDay Method® are based on evaluation of cervical mucus. The Standard Days Method® avoids intercourse on cycle days 8 through 19. The symptothermal method is a double-check method based on evaluation of cervical mucus to determine the first fertile day and evaluation of cervical mucus and temperature to determine the last fertile day.

[f]Foams, creams, gels, vaginal suppositories, and vaginal film.

[g]With spermicidal cream or jelly.

[h]Without spermicides.

[i]ella® (ulipristal acetated) is labeled for 120 hours after unprotected intercourse. Plan B One-Step®, Next Choice One Dose®, MyWay®, Take Action®, Aftera®, EContra® Ez, EContra One-Step®, Fallback Solo™, My Choice®, New Day®, Opcicon One-Step®, and React® are levonorgestrel products specifically marketed for emergency contraception. The labeling for these products says to take the pill within 72 hours of unprotected intercourse. Research has shown that all of the brands listed here are effective when used within 120 hours of unprotected sex.

[j]However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breast-feeding is reduced, bottle feeds are introduced, or the baby reaches 6 months of age.

[k]$ up to $10/item, $$ up to $50/unit, $$$ up to $80/unit, $$$$ more than $80/unit. (These are approximate costs and may vary based on location of purchase and patient insurance.)

[l]Administration or clinic costs not included. Initial cost of product reported but over time similar to $$ cost (eg, injectable MPA 150 mg/mL suspension one syringe ~$100, but works for 3 months, making its monthly cost similar to combined oral contraceptives (COCs) or progestin-only pill (POPs), which range from $20 to $45/pack generic, and copper IUD and levonorgestrel IUS may cost more initially but will work for up to 10 and 5 years, respectively).

[m]Initial cost for procedure but over time may be more cost-effective than are other products used frequently (eg, monthly contraceptives, condoms, or spermicides).

Ayers Publishing Company, Inc; 2018:100, Table 3–2; includes additional information from www.goodrx.com; http://americanpregnancy.org/preventing-pregnancy/diaphragm/; https://www.plannedparenthood.org/learn/birth-control/cervical-cap

Choosing a Piil

• The World Health Organization and the Food and Drug Administration both recommend using the lowest dose pill that is effective. All combined pills with less than 50 pg of estrogen are considered "low dose" and are effective and safe.

• There are no studies demonstrating a decreased risk for deep vein thrombosis (DVT) in females on 20-ug pills. Data on higher dose pills have demonstrated that the less the estrogen dose, the lower the risk for DVT.

• All COCs lower free testosterone. Class labeling In Canada for all combined pills states that use of pills may improve acne.

• To minimize discontinuation due to spotting and breakthrough bleeding, wam females in advance, reassure that spotting and breakthrough bleeding become better over time.

"The package insert for females on Yasmin® and Yaz® states [Berlex-2001]: "Yasmin is different from other birth control pills because it contalns the progestin drospirenone. Drospirenone may increase potassium. Therefore, you should not take Yasmin if you have kidney, liver or adrenal disease, because this could cause serious heart and health problems. Other drugs may also increase potassium. If you are currently on daily, long-term treatment for a chronic condition with any of the medications below, you should consult your healthcare provider about whether Yasmin is right for you, and during the first month that you take Yasmin, you should have a blood test to check your potassium level: NSAIDs (ibuprofen [Motrin®, Advit®], naproxen [Naprosyn®, Aleve®, and others] when taken long-term and daily for treatment of arthritis or other problems]; potassium-sparing diuretics (spironolactone and others); potassium supplementation; ACE inhibitors (Capoten®, Vasotec®, Zestril®, and others); Angiotensin-II receptor antagonists (Cozaar®, Diovan®, Avapro®, and others); heparin."

hThese are conditions that receive a US MEC:3 or MEC:4 (based on Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. medical eligibility criteria for contraceptive use. 2016. *MMWR Recomm Rep* 2016;65(No. RR-3):1–104. Category 3—A condition in whlch theoretical or proven rlsks usually outweigh the benefit of contraceptive method use. Category 4—A condition that represents an unacceptable health risk if contraceptive method is used).

Figure 47-1 Choosing a pill. ACE, angiotensin-converting enzyme; COC, combined oral contraceptive; IUD, intrauterine device; NSAIDs, nonsteroidal anti-inflammatory drugs; PE, pulmonary embolism. (Adapted from Hatcher RA, Zieman M, Lathrop E, Haddad L, Allen AZ. *Managing Contraception 2019–2020*. 15th ed. Bridging the Gap Foundation; 2019. Figure 24.1. Reprinted with permission from ManagingContraception.com)

Contraindications to Combined Hormonal Contraceptive Use

Case 47-1, Question 2: Are CHCs an appropriate form of contraception for S.F.? What contraindications to CHC therapy must be considered?

To determine whether any contraindications or precautions exist, the clinician should first obtain baseline health information from S.F. such as past medical history, social history, and family history (**Fig. 47-1**).[4] The World Health Organization (WHO) has developed medical eligibility criteria to identify appropriate contraception for patients with specific conditions. In 2010, the U.S. Centers for Disease Control and Prevention (CDC) adopted those guidelines for recommendations in the United States and updated them in 2016 (see http://who.int/reproductivehealth/publications/family_planning/MEC-5/en/) for the WHO Medical Eligibility Criteria and CDC link.[5,6] Most data regarding contraindications are based on COCs, but the conclusions are applied to all CHCs (eg, vaginal ring and transdermal patch).

CIGARETTE SMOKING AND USE OF COMBINED HORMONAL CONTRACEPTIVES

S.F. should be strongly encouraged to stop smoking (see Chapter 91, Tobacco Use and Dependence). Females who are age 35 years or older and smoke ≥15 cigarettes per day should not use CHCs as

a method of contraception. Although S.F. is not yet 35, she is smoking one pack per day (20 cigarettes). In her case, many clinicians would not prescribe CHCs. Although S.F. currently does not have any medical problems that would preclude her from using CHCs, she should be informed that CHCs should not be prescribed for her in 2 years if she continues to smoke. In addition, S.F. should be informed that smoking may decrease fertility and has adverse effects on birth outcomes, which is important given her plans to start a family in the near future.

CARDIOVASCULAR DISEASE

An increased risk of cardiovascular death in females who use COCs has been reported in multiple studies.[7–19] One study reported that in females who do not smoke or use COCs, the risk of cardiovascular death is 0.59/100,000 females younger than age 35 years and 3.18/100,000 females at least age 35 years. Among nonsmokers, using COCs increased the risk to 0.65/100,000 and 6.21/100,000 in females younger than age 35 years or at least age 35 years, respectively. For COC users who smoke, the risk is 3.3/100,000 in females younger than age 35 years and 29.4/100,000 in females at least age 35 years.[10] The increase in mortality is concentrated in smokers age 35 years and older.

Several studies have focused on the effect of COCs on serum lipoprotein concentrations because of the association between lipoproteins and atherosclerotic cardiovascular disease.[11–13] High levels of total cholesterol (TC), triglycerides (TGs), low-density lipoprotein (LDL) cholesterol, and very low-density lipoprotein (VLDL) cholesterol serum concentrations are associated with the risk of developing atherosclerotic circulatory diseases, whereas high-density lipoprotein (HDL) cholesterol has an inverse relationship. Apolipoprotein levels also affect atherosclerotic risk (eg, elevations in apolipoprotein increase risk).

Patients taking COCs may be more likely to experience a myocardial infarction (MI) than do nonusers.[14] The risk is higher with higher doses of estrogen and especially if the patient is a smoker or

has hypertension. It is not clear whether certain types of progestin are more likely to cause MI than do others.[8,15] COC users may also be at a slightly higher risk of stroke, but some data are conflicting.[14,16] Those at highest risk of stroke are smokers, patients with hypertension, and patients older than 35 years.

S.F. and her fiancé should understand that the risk of adverse cardiovascular effects may be increased with CHC use, but the absolute risk is still very low no matter which product is used. S.F.'s cigarette smoking, however, is a much more significant risk factor for MI in combination with a CHC product.

MIGRAINES AND STROKE

Ischemic stroke is more likely to occur in CHC users with a history of migraines and is thought to be caused by the estrogen component. The risk is further elevated in females who have migraines with aura up to sixfold in one study or among those who smoke.[2,17,18] One study did not indicate a higher risk of ischemic stroke in females experiencing migraines without aura; however, females experiencing migraines without aura should use CHCs with caution or avoid use if they smoke and are at least age 35 years.[6,18,19] Clinical experience indicates that females who have increasing migraine attacks with CHCs are not likely to improve when the product is changed to one with a different hormone balance. Headaches or migraines may start with initiation of CHCs (see Case 47-2, Question 6); however, if a patient experiences a migraine with aura while taking CHCs, she should discontinue the product and switch to a nonestrogen method.[17–19] Evidence does not show an increased stroke risk with progestin-only contraceptives, and these agents may be used in females with risk factors for stroke.[19]

S.F. does have a history of occasional headaches, but does not have a history of migraines with aura. Therefore, she is still a candidate for CHCs but should be informed of the increased risk of stroke from cigarette smoking.

THROMBOEMBOLIC EVENTS

CHCs contribute to thromboembolic events by several mechanisms. Estrogens increase coagulability and thereby increase the possibility of clot formation. Although they have been shown to significantly increase some clotting factors, other studies have shown no changes or decreases in prothrombotic factors.[11,13] Long-term COC use is associated with an increased platelet count and increased platelet aggregation similar to that seen late in pregnancy; this is generally thought to be caused by the estrogen component. Other data show increased thrombosis rates in users of third-generation progestins (desogestrel and gestodene [not available in the United States]), suggesting that progestin may also have a role in thromboembolism risk.[20]

The baseline risk of venous thromboembolism (VTE) in females is low, at 5 to 10 cases/10,000 person-years, but increases to 8 to 10 cases with COC use.[21] The best studies looking at thromboembolism in COC users found that most users have a two- to sixfold increased risk of having superficial or deep venous thrombosis or pulmonary embolism (PE).[20] Patients requiring emergency major surgery while taking COCs are more prone to VTE than are nonusers. The risk of venous thrombosis does not seem to be associated with duration of COC use or past COC use. A greater risk is associated with ethinyl estradiol (EE) doses >35 µg.[20]

Females with a mutation in clotting factor V (also called factor V Leiden) or a deficiency in protein C, protein S, or antithrombin are more likely to experience a VTE with COCs than do females without a hereditary prothrombotic defect.[22] Females with factor V Leiden using COCs have a 30-fold increase in VTE compared with females without the mutation.[22]

The minimal risk of thrombosis associated with CHCs in the general population does not justify the cost of routine screening for deficiencies and mutations in the coagulation system; however, if a patient has a family history of thrombosis, then measurement of antithrombin III, protein C, activated protein C resistance ratio, protein S, anticardiolipin antibodies, prothrombin G mutation, factor V Leiden, and homocysteine levels should be considered.[4]

Whether third- or fourth-generation progestins (desogestrel, dienogest, drospirenone, or gestodene) are associated with a higher risk of VTE relative to other progestins is controversial.[20,21] It was believed that the risk of thrombosis with third-generation progestins would be lower than that with other progestins because they have more beneficial effects on HDL. A recent meta-analysis, however, reported that COCs containing <50 µg of EE in combination with desogestrel, dienogest, or drospirenone had an increased VTE risk of 1.5 to 2 times that of products containing levonorgestrel, but noted that the difference was not statistically significant for dienogest and that COCs containing norgestimate did not show an increased risk.[21] The finding was similar when the analysis was limited to monophasic products containing 30 µg of EE and the respective progestins, indicating that progestins may have a role in clot development, although their role is not well understood.[21] Of note, in April 2012, the U.S. Food and Drug Administration (FDA) published a safety communication regarding a possible increased risk of thrombosis with drospirenone-containing products.[23] Although the risk may be increased, the overall rate of thrombosis is still low. All patients using CHCs should be counseled about the VTE warning signs (**Table 47-2**).[4]

Table 47-2
CHC Early Danger Signs: ACHES

Signals	Possible Problem
Abdominal pain (severe)	Gallbladder disease, hepatic adenoma, blood clot, pancreatitis
Chest pain (severe), shortness of breath, or coughing up blood	Blood clot in lungs or myocardial infarction
Headaches (severe)	Stroke, hypertension, or migraine headache
Eye problems: blurred vision, flashing lights, or blindness	Stroke, hypertension, or temporary vascular problem
Severe leg pain (calf or thigh)	Blood clot in legs

CHC, combined hormonal contraceptive.

From Hatcher RA, Kowal D, Nelson AL, et al. *Contraceptive Technology*. 21st ed. Ayers Publishing Company, Inc; 2018. Reprinted with permission from Managing Contraception LLC.

S.F. does not have a history of clotting disorders or previous clots. Therefore, she is still a candidate for CHCs. Her smoking status, however, puts her at higher risk for VTE. If she experiences a VTE while taking CHCs, a progestin-only method or nonhormonal contraceptive method should be recommended and the CHC discontinued.

HYPERTENSION

CHCs appear to increase blood pressure. Small studies have found systolic blood pressure to increase by about 8 mm Hg and diastolic blood pressure to increase by 6 mm Hg in normotensive or mildly hypertensive females.[24] Other studies have shown differing results on whether females with hypertension who use COCs are more likely to suffer an MI than do nonusers.[5,25] A small study of adolescent females showed similar systolic and diastolic blood pressures in users versus nonusers.[26]

The underlying mechanisms for CHC-induced hypertension may be sodium and water retention and increased renin activity.[27,28] Hypertension secondary to COCs may develop slowly during 3 to 36 months and may not decline for 3 to 6 months after COC discontinuation.[29] Females with controlled hypertension may attempt a trial of CHCs with blood pressure monitoring; however, progestin-only contraceptives have not been shown to increase blood pressure and may be preferable for females with uncontrolled hypertension.[24]

S.F.'s blood pressure is not elevated at 122/72 mm Hg. Therefore, she is still a candidate for CHCs. If her blood pressure were >140/90 mm Hg, a nonhormonal method or a progestin-only contraceptive would be a preferred form of contraception.

HEPATOTOXICITY

COCs have been associated with benign liver tumors, hepatic adenomas, and liver cancer.[2,30] The risk of liver cancer is low, and

COCs are thought to cause only a modest increase in risk.[30,31] A European study found a small, statistically significant increase in the risk of liver cancer in females without cirrhosis and without hepatitis B or C, with an increased the risk of liver cancer by 1 case/1.5 million woman-years.[31] A meta-analysis of observational studies concluded that oral contraceptives (OCs) were not positively associated with liver cancer risk.[32] S.F. should be reassured that it is very unlikely for her to develop benign or malignant liver tumors associated with COC use.

DIABETES

Generally, low-dose COCs do not alter glucose tolerance.[13,33] Females with a history of gestational diabetes such as S.F.'s sister and those with a strong family history of diabetes in parents or siblings are at greater risk for COC-induced glucose intolerance.[24] COCs have complex effects on carbohydrate metabolism. Progestins decrease and estrogens increase the number of insulin receptors on the cell membrane. Progestins also may alter insulin receptor affinity. The different progestins in CHCs have different propensities to induce glucose intolerance. Desogestrel seems to have the best glucose values compared with other progestins, but insulin results are not consistent.[33]

For females with diabetes, the WHO recommends avoiding COCs and depot medroxyprogesterone acetate (DMPA) if they have been diabetic for >20 years or they have end-organ damage such as retinopathy, neuropathy, or nephropathy.[5]

S.F.'s sister having a history of gestational diabetes does not preclude S.F. from using a CHC at this time. Preferably, S.F. should start on a low-dose CHC.

GALLBLADDER DISEASE

The incidence of gallstones has been reported to increase with COC use; however, conflicting data exist. Estrogens and progestins may contribute to bile stasis and gallstones by reducing cholesterol clearance and altering bile acid composition.[34] The incidence of

gallbladder disease has been reported to increase during the first year of use, but then to decline steadily to a rate lower than that of control females.[35] Conversely, a meta-analysis study concluded that it is unlikely that COCs cause gallbladder disease.[36]

Females who are obese, young, or long-term users of COCs may be the most likely to develop gallstones. At this time, this is not a concern for S.F. in starting COCs.

Combined Oral Contraceptives

Case 47-1, Question 3: S.F. has decided to quit smoking. Based on her past medical history, she is a candidate for CHCs and indicates she wants to start a COC. Which COC should be selected for her?

Selecting a COC for S.F. can be confusing because of the multitude of products available, the lack of studies directly comparing products, and health insurance medication formulary restrictions. The failure rate of COCs ranges from 0.3% with perfect use to 7% with typical use (see Table 47-1).[2]

The COCs are available in varying strengths of estrogens and progestins. **Table 47-3**[37,38] lists the brand-name and generic COCs in the United States. Almost all COCs available in the United States contain the synthetic estrogen, EE. Doses of EE generally range from 10 to 50 µg, with 10- to 25-µg formulations considered very low dose; 30- to 35-µg formulations, low dose; and 50-µg formulations, high dose. Mestranol, another estrogen available in the United States and used internationally, is an inactive prodrug that is hepatically metabolized to EE. Mestranol 50 µg has approximately the same activity as EE 35 µg.[2] Estradiol valerate is a third estrogen available in one oral formulation. The formulation of estradiol valerate 2 to 3 mg with 2 to 3 mg of dienogest was compared against EE 20 µg with levonorgestrel 100 µg in clinical trials.[39,40]

Table 47-3

Oral Contraceptives and Relative Progestin, Endometrial, and

Androgen Activities

Combination Oral Contraceptives: Estimated Relative Progestin/Endometrial/Androgen Activity[30]						
Ingredients		**Example Trade Names**	**Progestin Activity**	**Endometrial Activity**	**Androgen Activity**	**Unique Properties**
Monophasic	Desogestrel 0.15 mg/ ethinyl estradiol 30 µg	Apri®, Cyred®, Cyred EQ®, Emoquette®, Enskyce®, Isibloom®, Juleber™, Kalliga®, Reclipsen™	High	Intermediate	Low	
	Drospirenone 3 mg/ethinyl estradiol 20 µg	Beyaz®,[a] Gianvi®, Jasmiel™, Loryna™, Lo-Zumandimine™, Nikki™, Rajani™,[a] Yaz®			None	Antimineralocorticoid properties, FDA-approved use for treatment of acne and PMDD, only 4 days of placebos Beyaz® and Rajani™ provide folate supplementation, 24 active pills and 4 days of 0.451 mg of levomefolate calcium instead of placebos.
	Drospirenone 3 mg/ethinyl estradiol 30 µg	Ocella®, Safyral®,[a] Syeda®, Tydemy®,[a] Yasmin-28®, Zarah®, Zumandimine™				Antimineralocorticoid properties Safyral® and Tydemy® provide folate supplementation, 21 active pills, and 7 days of 0.451 mg of levomefolate calcium instead of placebos.
	Ethynodiol diacetate 1 mg/ ethinyl estradiol 35 µg	Kelnor® 1/35, Zovia® 1/35E	High	Low	Low	
	Ethynodiol diacetate 1 mg/ ethinyl estradiol 50 µg	Kelnor® 1/50		Intermediate		
	Levonorgestrel 0.1 mg/ ethinyl estradiol 20 µg	Afirmelle®, Aubra®, Aubra EQ®, Aviane®, Balcoltra®,[b] Delyla®, FaLessa®,[a] Falmina®, Larissia®, Lessina®, Lutera®, Orsythia®, Sronyx®, Vienva®	Low	Low		Balcoltra® contains 21 active pills and 7 pills that contain ferrous bisglycinate 36.5 mg.
	Levonorgestrel 0.15 mg/ ethinyl estradiol 30 µg (28 days)	Altavera™, Ayuna™, Chateal®, Chateal EQ®, Kurvelo™, Levora® 0.15/30, Lillow®, Marlissa®, Portia-28®	Intermediate	Intermediate	Intermediate	
	Levonorgestrel 0.15 mg/ ethinyl estradiol 30 µg (91 days)	Jolessa®, Quasense®, Setlakin™		Low		Jolessa®, Quasense®, and Setlakin™ contain 84 active pills and 7 placebo pills.
	Levonorgestrel 0.09 mg/ ethinyl estradiol 20 µg (1-year continuous formulation available in packs of 28 active pills)	Amethyst®	Intermediate/ high		Intermediate/ high	Amethyst® is a 1-year continuous formulation available in packs of 28 active pills.

Norethindrone O 4 mg/ ethinyl estradiol 35 pg	Balziva", Briellyn*. Phillth", Vyfemla'*. Wymzya Fe'*.[1]	Low	Intermediare	low	Wymzyax Fe"' is a chewable focrnulation and comains 7 pllls of 75-mg ferrous lumarate instead of placebos.

Essential Medical Information Systems; 2014; Slynd. Package insert. Exeltis USA, Inc; June 2019.

The COCs also contain one of the following progestins: ethynodiol diacetate, desogestrel, dienogest, drospirenone, levonorgestrel, norethindrone, norethindrone acetate, norgestimate, and norgestrel (a mixture of dextronorgestrel and levonorgestrel; dextronorgestrel appears to be progestationally inert compared with levonorgestrel).[2] Progestins differ significantly in their progestational potency and in the extent of their metabolism to estrogenic substances. Progestins have both estrogenic and antiestrogenic effects. Because the progestins have a chemical structure similar to that of testosterone, they also have varying degrees of androgenic activity (Table 47-3).[38] Minor structural changes in all of the progestins may lead to significant changes in their progestational, estrogenic, antiestrogenic, and androgenic activities, which may affect patients differently (**Table 47-4**).[2] Drospirenone is a unique progestin because it has antiandrogenic and antimineralocorticoid properties. Drospirenone is chemically similar to the potassium-sparing diuretic spironolactone, and, therefore, may increase potassium levels. Drospirenone should be used with caution in patients using medications that can increase potassium levels (eg, high-dose nonsteroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting enzyme [ACE] inhibitors, heparin, potassium-sparing diuretics, aldosterone antagonists, and angiotensin II blockers).[37]

Essential Medical Information Systems; 2014.

Because no COC has been shown to be superior to the others, any COC with <50 µg of EE can be used for patients who are COC candidates.[41] The information in Figure 47-1 may be used to select an initial COC for most patients and to change formulations when side effects necessitate an alternative choice.[4,5] Concerns of decreased COC effectiveness in obese and overweight females has been debated; however, there are no contraindications for COC use.[24] Various reviews of literature found conflicting and lower quality studies addressing the issue.[42,43] Most studies reviewed did not include females with body mass indexes (BMIs) of >35 kg/m^2.[44] Pharmacokinetic studies have also provided conflicting data, with some showing a longer time to steady state in obesity and others showing no difference. It has been suggested that continuous OC use or using formulations with higher doses of EE (30–35 µg) may be more effective in females with obesity.[24] If S.F. were heavier, a COC with a higher dose of EE (eg, 35 µg) or perhaps a continuous-use OC could be a better option. Any pill containing <50 µg EE, however, can be used for S.F. because she is healthy and without medical complications or active medications.

LENGTH OF ACTIVE HORMONE: 21, 24, OR 28 DAY

The COCs are available in a variety of cycle lengths. The most common is the 28-day pack that contains 21 days of active pills (pills that contain estrogen and progestin) followed by 7 days of placebo pills. Some newer products contain 24 days of active pills followed by 4 days of placebo. CHCs with 4 days of placebo may shorten menses and minimize the hormonal withdrawal side effects (eg, headaches, mood changes) that some females experience during the placebo week.[45] It is also possible that efficacy is improved; however, this has not been proved in clinical trials.

The 21-day pill packs contain only the active pills. Most patients are instructed to take one pill daily for 21 days and then take nothing for 1 week. Many clinicians prefer the use of 28-day pill packs to minimize confusion; the patient takes one pill daily regardless of whether it is an active or a placebo pill. After taking the last pill of a 28-day pack, the patient should begin a new pack the next day. However, when continuous ovarian suppression is indicated to treat estrogen-dependent disorders such as endometriosis, the 21-day cycle products are preferred to facilitate taking active pills continuously. Alternatively, the placebo pills could be removed from 28-day cycle packs. S.F. will not be taking COCs continuously, so a 24- or 28-day pack is recommended.

MULTIPHASIC ORAL CONTRACEPTIVES

Case 47-1, Question 4: Should S.F. start a monophasic or multiphasic COC? What are the advantages and disadvantages of the monophasic versus multiphasic COC?

COCs have varying amounts of hormones in the active pills, which can be divided into phases that include monophasic, biphasic, triphasic, or quadriphasic (see Table 47-3).

Monophasic COCs contain the same dose of estrogen and progestin in each active pill throughout the pill pack, whereas multiphasic COCs have varying amounts of hormones. Because of metabolic and physiologic effects related to the progestin component of COCs, multiphasic products were initially formulated to contain less progestin overall. Some products, however, are now marketed with varying amounts of estrogen to reduce the overall exposure to estrogen or to minimize estrogen withdrawal side effects (eg, norethindrone/EE [Tri-Legest 21® and Tri-Legest® Fe 28]).

A biphasic formulation usually contains a certain amount of progestin and estrogen for the first half of the cycle, then a different amount for the second half, and then a week of placebos. Triphasic formulations have a different amount of hormones for each of the 3

weeks of active pills. No studies, however, show a superiority of one triphasic over another or compared with monophasics. The reduced progestin content is desirable for females with progestin-associated side effects (eg, increased appetite, acne, weight gain) or females with cardiovascular disease or metabolic abnormalities.[2] Females with side effects related to progestin deficiency (eg, late-cycle bleeding) or conditions necessitating progestin dominance (eg, benign breast disease) may do better with monophasics. Recently, a quadriphasic COC (Natazia®) became available, and it contains four different amounts of hormones throughout the pill pack.[39] Advantages of the product remain to be seen, but it may help decrease hormone withdrawal side effects and intermenstrual bleeding.

One drawback associated with triphasic and quadriphasic COC use is the confusion caused by the different-colored pills in each of the three different phases, making the missed-dose instructions more complicated. Monophasics are preferred for females who will be taking COCs continuously (ie, skipping the placebo pills) because of the same weekly hormone content.

Other unique formulations include Mircette® (see Table 47-3 for generic names), which is classified more appropriately as monophasic because the hormone content is consistent throughout the 21-day cycle similar to other monophasic formulations, but sometimes referred to as *biphasic* because it does not contain 7 days of placebos. It provides a unique regimen containing 21 days of 0.15 mg of desogestrel plus 20 µg of EE, then only 2 days of placebo, followed by 5 days of 10 µg of EE alone.[46] The patient does not need to take the missed 10-µg EE doses or use a backup method when those specific pills are missed. Adding low-dose estrogen for 5 days during the typical placebo week helps minimize breakthrough bleeding with this product and may be useful for patients who have estrogen-deficiency symptoms such as headaches during the hormone-free week. Because S.F. has not been on a CHC before and does not have a history of side effects associated with COCs, she may be started on any of the COC formulations.

EXTENDED CYCLE

Case 47-1, Question 5: S.F. has heard that she can skip the placebos from her pill pack to have fewer menses each year. She is interested in this approach. Is this a reasonable option for S.F.?

Continuous- or extended-cycle COC regimens (ie, skipping the placebo pills and taking no break between pill packs, thus having no menses) are often prescribed in females with underlying conditions including anemia, dysmenorrhea (less cramps with fewer menstrual cycles), menorrhagia (heavy menstrual bleeding), and endometriosis (to decrease hormone fluctuations that affect endometrial tissues).[4] In addition, for convenience and lifestyle reasons, many females prefer to take COCs continuously to minimize the number of menstrual periods. Regardless of the reason, any patient who is a candidate for CHCs can use them continuously.

Any CHC (eg, pill, patch, vaginal ring) may be used continuously; however, from the COCs, monophasic pills are recommended because of the consistent hormone content throughout the cycle. Any duration of continuous pill use is acceptable, but many providers recommend that patients take the active pills for 3 to 4 months (3–4 pill packs) and then stop COCs for 2 to 7 days. Alternatively, providers may prescribe COCs that are specifically packaged for continuous use (eg, Amethyst®, Camrese® Lo; see others in Table 47-3). Patients should be informed that continuous COC use usually results in more breakthrough bleeding or spotting than do traditional COC dosing regimens, with up to 41% of females experiencing some form of irregular bleeding in the first few months of the 1-year regimen.[47]

Concerns raised with extended-use regimens include harmful effects on the endometrium; however, one study showed no harmful changes to the endometrium with extended cycles.[48] Long-term side effects of the extended regimens are still being studied. If breakthrough bleeding continues beyond 6 months of continuous COC use, a pelvic examination may be considered. If S.F. is willing

to tolerate more irregular bleeding during the first 6 months of continuous COC use, then the extended-cycle regimen may work for her.

Patient Instructions

Case 47-1, Question 6: What instructions should be given to S.F. about her COC?

WHEN TO START ORAL CONTRACEPTIVES

S.F. should start the first cycle of COCs according to the manufacturer's package instructions or according to one of the following recommendations[2]:

1. Quick start: Take the first COC tablet as soon as possible regardless of cycle day.[49]
2. Day 1 start: Take the first tablet in the COC pack on the first day of menses.
3. Sunday start: Take the first tablet in the COC pack on the first Sunday after the beginning of menstruation. If menses begins on Sunday, start that day.

The quick start method is not described in COC package inserts; however, this method is used by family planning providers.[6,49] The method can minimize the confusion that many patients have about when to start their first pack and can increase adherence. Also, the quick start method provides contraceptive protection sooner and would, therefore, likely lower the risk of unintended pregnancy. More research on and awareness about this method are needed for it to be used routinely by all health care providers.

WHEN TO USE A BACKUP METHOD OF CONTRACEPTION

Some clinicians recommend that a patient use an alternative method of contraception for the entire first COC cycle. Others, including the 2016 CDC Selected Practice Recommendations for Contraceptive

Use, suggest that alternative methods of contraception are unnecessary if the COC is started on or before the fifth day of the menstrual cycle.[50] Most COC package inserts, with the exception of Natazia® (estradiol valerate/dienogest), state that a backup method of contraception (eg, male or female condoms, spermicides, diaphragms) is not necessary if patients use the day 1 start method.[3] If patients use the Sunday start or quick start method, backup contraception should be used for the first week of the COC cycle. A backup method is also recommended when doses are missed, as described in the following section. S.F. has decided to use the quick start method, so she will need to use another method of contraception for her first week of COC use.

COMBINED ORAL CONTRACEPTIVE ADMINISTRATION AND MISSED-DOSE INSTRUCTIONS

S.F. should take her COC at the same time each day. Nausea may be prevented or alleviated by taking the dose at bedtime or with food. The best time to take COCs depends on the patient. The optimal time for S.F. is the time when she will have the fewest problems in remembering to take her pill each day.

If a patient forgets to take one pill, she must take it as soon as she remembers and refer to the patient instructions in the package insert for further information.[2] Some unique formulations such as estradiol valerate/dienogest (Natazia®) have more specific recommendations based on the cycle day missed. If she is taking Natazia® (Bayer Healthcare Pharmaceutical Inc., Whippany, NJ)., she should be referred to the package insert for information (see http://www.natazia.com), because the advice varies from that listed subsequently.

For the majority of COCs, most manufacturers recommend that if she forgets to take one pill, she should take two pills on the day she remembers (eg, if she forgets her pill on Monday, she should take two pills on Tuesday). Then she should take the remaining pills as usual. A backup method of contraception is not necessary. If she misses two pills in a row in week 1 or 2 of her pack, she must take

two pills on the day she remembers and two pills the next day. She should use an alternative method of contraception for 7 days after missing the pills and may consider emergency contraception (EC).

If a patient misses two pills in a row during the third week (for day 1 starters), she must discard the rest of the pack, start a new pack on that same day, and use an alternative contraceptive method for 7 days. For a Sunday starter, she should keep taking one pill every day until Sunday, and then start a new pack on Sunday. She must use an alternative method of contraception for 7 days after missing the pills and may consider EC. She may miss her menstrual period this month.

If a patient misses three or more pills in a row during the first 3 weeks (for a day 1 starter), she must discard the rest of her pack, start a new pack that same day, and use an alternative method of contraception for 7 days; Sunday starters should keep taking one pill every day until Sunday, start a new pack on Sunday, and use an alternative method of contraception for 7 days after missing the pills, and they may consider EC. Females may not have a menstrual period this month. If two pills are missed from a low-dose COC (less than EE 30 µg), some references suggest following the instructions as if three pills were missed.[2] Other references and organizations may cite different recommendations. The recommendations described here are recommended by manufacturers.

CONTRACEPTIVE PATCH AND RING

Case 47-1, Question 7: S.F. returns to the clinic 3 months later and is very concerned about getting pregnant because she has trouble remembering to take her pill each day. She wants an effective contraceptive method but is wondering whether other dosage formulations are available. She also indicates concern about high doses of estrogen because she has heard that such doses can lead to blood clots. She wants the lowest possible dose. What do you tell her?

Contraceptive Patch

The contraceptive patch has an estimated failure rate of 0.3% with perfect use and 7% with typical use (see Table 47-1). There are two contraceptive patches approved by the FDA, Xulane® (Mylan Pharmaceuticals, Morgantown, WV) and Twirla® (Agile Therapeutics, Princeton, NJ). The first contraceptive patch was originally marketed as Ortho Evra® and is now known as Xulane®. It delivers 150 µg of norelgestromin and 35 µg of EE daily into the systemic circulation.[51] Twirla® was approved in 2020. It delivers 120 µg of levonorgestrel and 30 µg of EE daily.[52] Both patches are thin and beige, Xulane® is a 1.75-inch square with rounded corners, whereas Twirla® is a 28 cm^2 circular patch.

For both products, one patch is applied each week for 3 consecutive weeks for a total of three patches used, followed by 1 week with no patch. The day of the week the patch is applied is called the *patch change day*. Then this cycle is repeated. Menses should begin during the patch-free week. If a patient wants to avoid menses, the patch-free week may be skipped by applying a new patch on week 4 for an extended-use regimen.

A contraceptive patch may be worn on the buttock, abdomen, upper torso, or upper outer arm.[51,52] The patch should not be applied to the breasts to prevent direct administration of estradiol to the breast tissue. To minimize irritation from the adhesive, S.F. should rotate the patch application sites and not apply the patch to the same location within each month. When applying the patch, S.F. should select the application site and be sure it is clean and dry. She should press firmly on the patch for 10 seconds and trace her finger around the edge of the patch to be sure it adheres securely to the skin. The patch should stay attached during usual activities, including exercising, swimming, and bathing, although prolonged exposure to water could cause detachment. Patch adherence should be checked after prolonged water exposure. If the patch falls off and is off <24 hours, she should reapply it or apply a new one as soon as possible, and her patch change day will stay the same. No backup contraception is needed. If the patch is off for >24 hours, she should

start a new cycle of patches, and she will have a new patch change day.[51,52] She should use backup contraception for 1 week.

The patch may be started using the quick, Sunday, or day 1 start method, and the recommendations for backup contraception are the same as described earlier with CHCs.[51,52] If S.F. forgets to start the first patch of a new cycle, she should apply it as soon as she remembers. This day will become her new patch change day, and she should use backup contraception for 1 week. If she forgets to change the patch for 1 or 2 days during week 2 or 3, she should apply a new patch as soon as she remembers. This becomes her new patch change day. No backup contraception is needed. If she forgets to wear the patch for >2 days, she should start a new cycle as soon as she remembers. She will need to use backup contraception for 1 week and will have a new patch change day.

The effectiveness of the patches are reduced in patients weighing >198.42 pounds (90 kg) and should not be used alone for prevention of pregnancy in these females.[51,52] S.F. does not weigh >198.42 pounds (90 kg), which does not preclude her from using this method.

The most common side effects reported with the patch are breast tenderness, headache, application site reaction, and nausea. Most risks and benefits with the contraceptive patch are thought to be similar to that with COCs. One notable difference is the rate of VTE. A small pharmacokinetic trial found that overall monthly serum levels of EE are significantly higher in patch (EE/norelgestromin) users compared with vaginal ring (EE/etonorgestrel) or COC users.[53] With the patch, the peak levels of estrogen are lower, but the steady-state concentrations are higher. It has been noted that the EE/norelgestromin patch provides 60% more EE than does an oral 35-μg tablet.[51] This raised concern that the patch may have a higher incidence of VTE than do the other methods; however, it is controversial. A systematic review had conflicting results, with two studies finding a doubling of VTE risk in patch users compared with COC users, one with an elevated risk that did not meet statistical significance, and four with no difference in risk.[54] The EE/levonorgestrel patch has a lower amount of EE and theoretically may have a lower risk of VTE, although more data are needed for

confirmation. Future studies may find that there are other differences in certain risks or benefits between the patch and the pill. Given the controversy surrounding VTE with the transdermal patch, this may not be the most appropriate method for S.F. based on her concerns of VTE associated with COC use.

Contraceptive Ring

There are contraceptive vaginal rings available, NuvaRing® (Merck, Whitehouse Station, NJ) and Annovera™ (TherapeuticsMD, Boca Raton, FL). NuvaRing® and EluRyng® (Amneal Pharmaceuticals, Bridgewater, NJ) delivers 120 µg of etonogestrel and 15 µg of EE and Annovera™ delivers about 150 µg of segesterone acetate and 13 µg of EE daily through the vaginal mucosa.[37,55,56] The failure rate of a contraceptive ring is 0.3% with perfect use and 7% with typical use (Table 47-1).[2] NuvaRing®, EluRyng®, and Annovera™ are inserted vaginally and kept in place for 3 weeks in a row. After 3 weeks, the ring is removed for 1 week, and then a new ring is inserted (see https://www.nuvaring.com/ and https://www.annovera.com/pi.pdf). For extended use, the ring-free week may be skipped by inserting a new ring on week 4. Each NuvaRing® and EluRyng® is formulated for 3 weeks of use, and then discarded; after a 7-day ring-free interval, a new ring is used. Annovera™ is formulated to work for 21 days, with a 7-day ring-free interval and can be used again for a total of 13 cycles. It is not discarded after use unless the patient has used the ring for 13 cycles.

The ring may be placed anywhere in the vagina, so S.F. does not need to worry about its exact position.[55,56] To insert the ring, she should compress it so that the opposite sides of the ring are touching, and gently insert it into the vagina.

If she feels discomfort with the ring, it has probably not been inserted into the vagina far enough. Most females do not feel the ring once it is in place. To remove the ring, S.F. should grasp the ring between two fingers or hook one finger inside the ring and pull it out. Menses will usually begin within 3 days of removing the ring. If the

ring slips out, it should be rinsed with lukewarm water and reinserted. If the NuvaRing® or EluRyng® is out for <3 hours or the Annovera™ is out <2 hours, backup contraception is not needed. If the NuvaRing® or EluRyng® is out for >3 hours or the Annovera™ is out for >2 hours continuously or 2 hours cumulatively over the 21 days, backup contraception should be used for 1 week. According to the manufacturers, if the NuvaRing® has been left in the vagina for >3 weeks but no more than 4 weeks, S.F. should remove it, wait 1 week, then reinsert a new ring. The NuvaRing® is formulated to contain ~35 days of medication, but should not be promoted for use beyond 21 days.[55] If it has been in place for >4 weeks, she should remove it, confirm that she is not pregnant, reinsert a new one, and use backup contraception for 1 week. If the Annovera® ring is left in place >3 weeks, it should be removed for 7 days and then reinserted for 21 days resuming the 21-day/7-day ring-free interval as before (assuming the product has not been used for >12 cycles).[56]

Both contraceptive vaginal rings should be inserted anytime during the first 5 days of the menstrual cycle or inserted using the quick start method.[2,55,56] Backup contraception should be used for the first week with the NuvaRing® and EluRyng®. When changing from the COC, S.F. should insert the ring within 7 days of the last active pill and no backup contraception is needed.

The rings are believed to have the same contraindications and precautions as that of COCs. The most common side effects with the ring are vaginal infections, irritation, and discharge; headache; weight gain; dysmenorrhea; and nausea. Unlike the patch, the ring has not been shown to have reduced efficacy in obese females.[55,56] There are conflicting data regarding increased risk of VTE with the contraceptive ring. The ring provides the least amount of EE exposure when compared with other CHCs.[53] However, despite the lower levels of EE provided, one study has shown an increased risk of VTE with the use of the contraceptive vaginal ring when compared with levonorgestrel-containing contraceptives, although two others showed no increased risk.[54] Although one study indicated a possible increase in VTE with the vaginal ring, the FDA has not required any labeling changes or communicated any safety issues with the

vaginal rings. Given the good adherence rates and lower EE levels, the vaginal ring may be appropriate for S.F. if she is comfortable with the dosage form.

Case 47-1, Question 8: S.F. returns to the clinic 2 months later for a sore throat. She indicates that she is using the NuvaRing®.

Current vitals at clinic: weight, 132 pounds (59.87 kg); height, 64 inches (162.56 cm)
Blood pressure, 125/78 mm Hg
Heart rate, 97 beats/minute
Respiratory rate, 16 breaths/minute
Temperature, 101.1 °F (38.39 °C)
Physical examination: head, eyes, ear, nose, and throat: tonsils 2+, bright red, soft palate erythematous
Laboratory test results: rapid streptococcal antigen test, positive

S.F.'s primary care physician prescribes Augmentin® 875 mg/125 mg (amoxicillin/clavulanate) twice daily PO for 10 days. Could this medication affect her contraception? What advice should be provided to S.F.? What other drug interactions are of concern with CHCs?

Drug Interactions

A variety of drugs may alter the levels of CHCs and in turn affect their efficacy (**Table 47-5**).[6,57] Currently, most data available regarding drug interactions are with COCs. However, as a precaution, the potential drug–drug interactions observed with COCs are also applied to the other CHC dosage formulations (eg, vaginal ring and transdermal patch).

Table 47-5
Common Combined Oral Contraceptive Drug[a] Interactions

Drugs That Increase Effect of CHCs or Side Effects of CHCs	Drugs/Herbals That Decrease the Effect of CHCs	Drugs That May Decrease the Effect of CHCs (Controversial)	Metabolism or Clearance Altered by CHCs (Levels of Drug Listed May Either Increase or Decrease Oepending on Patient)
Acetaminophen	Amprenavir	Amoxiclllin	Acetaminophen
Ascorbic acid	Aprepitant	Ampicillin	Amprenavir
Atazanavir	Barbiturates	Oprofloxacin	Antidepressants, tricycllc
Arorvastatin	Bexarotene	Clarithromycin	Benzodiazepines
Glnseng	Bosentan	Colesevelam	[Blockers
Indinavir	Carbamazeplne	Doxycycline	Caffeine
Red clover"	Darunavlr	Erythromycln	Clofibrlc acid
Rosuvastatin	Efavirenz	Fluconazole	Corticosteroids
Tranexamic acid	Felbamate	Itraconazole	Cyclosporine
Voriconazole	Griseofulvin	Ketoconazoie	Lamotrigine
	Isotretinoin	Metronidazole	Levothyroxine
	Lopinavir	Minocycline	Morphine
	Modafinil	Renicillins	Paciltaxel
	Mycophenolate mofetil	Phenylbutazone	Sallcyllc acid
	Neifinavir	Ofloxacin	Selegllline
	Mevirapine	Tetracyclines	Tacrine
	Oxcarbazepine	Topiramate	Tacrollmus
	Phenobarbital		Theophytlines
	PhenytoirVFosphenytoin		Tizanidlne
	Piogllltazone		Vatproic acid
	Primidone		Voriconazole
	Red clover[b]		Warfarin[1]
	Rifamycins

ANTIBACTERIALS

The antibacterials rifampin and griseofulvin are known to cause contraceptive failure, because these products increase the

metabolism of estrogen. For other antibacterials, the possible interaction is more complicated.

EE is conjugated in the liver, excreted in the bile, hydrolyzed by intestinal bacteria, and reabsorbed as active drug.[58] Antibacterials, by reducing the population of intestinal bacteria, interrupt the enterohepatic circulation of the estrogen, resulting in a decreased concentration of circulating estrogen. Theoretically, any antimicrobial with significant effects on intestinal bacterial flora could affect COC efficacy. Numerous reports of changes in bleeding patterns and contraceptive failure have been documented.[58] Cases of pregnancy in COC users taking antibiotics have been reported.[58–60] About 30 case reports of contraceptive failure with concomitant COC and antibiotic use have been published.[58] The antibacterials in the case reports include rifampin, ampicillin, penicillin G, tetracycline, and minocycline. In addition, surveys conducted on patients in clinics have revealed about 20 other cases of COC failure.[58] A major limitation of survey data is that they rely on patient reporting, which is often unreliable. A systematic review of 29 studies concluded that the probability of a clinically significant drug interaction between COCs and antibacterials is low and the CDC US Medical Eligibility Criteria does not recommend a need for alternative birth control methods while taking broad-spectrum antibiotics that do not affect hepatic enzymes.[6,60–62]

Numerous factors may affect the likelihood of an interaction: the hormonal content of the COC relative to the patient's requirements, the dosage and duration of use of the interacting drug, variation in the patient's response to bacterial flora alteration, and the fertility of the couple.[58] The number and complexity of these variables make prediction of outcome in a specific patient exceedingly difficult. Even if a drug produces a several-fold increase in unintended pregnancies in females taking COCs, the likelihood of pregnancy in a given patient still will be low. For patients who require long-term, low-dose tetracycline use for acne therapy (eg, tetracycline 250 mg PO daily), it is unlikely to interfere with COC efficacy.[61,62] Alternatively, topical antibacterials often can control acne and are viable alternatives to oral medications.

A practical approach to managing patients taking COCs and antibacterials is to educate them about the available data. To be conservative, S.F. should be advised to use backup contraception while taking the amoxicillin/clavulanate and to continue the backup method until her next menses occurs, although this is controversial and the CDC Medical Eligibility Criteria does not call for it.[6] For other antibiotics that affect hepatic enzymes such as rifampin, isoniazid, and griseofulvin, backup contraception should be used while taking the medication and for 4 weeks after discontinuation of the antibiotics.[6]

HEPATIC ENZYME INDUCTION

EE is a substrate of cytochrome P-450 3A4 (CYP3A4), so drugs that induce CYP3A4 activity may decrease COC efficacy. In earlier years, COC efficacy was not decreased significantly by other drugs because of their high hormone content. Because the estrogen and progestin concentrations of COCs have gradually been decreasing, reports of menstrual irregularities (eg, spotting) and unintended pregnancies attributable to drug interactions have been increasing.

Anticonvulsants such as carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, and topiramate are CYP3A4 inducers and are known to cause increased metabolism of COCs (see Chapter 60, Seizure Disorders).[63,64] Some studies have shown that another inducer of COC metabolism is St. John's wort.[65] Although drugs can influence COC efficacy, COCs also can affect the activity of other drugs. For example, COCs have been reported to decrease serum levels of lamotrigine and can affect seizure control; increased levels of lamotrigine have also been reported after COC discontinuation.[63,64] Other drugs may increase the hormone levels of COCs (see Table 47-5), increasing the risk of COC side effects (see Table 47-4).

Unlike many drug classes that are carefully dosed to maintain a therapeutic range of monitored blood levels, contraceptive estrogen and progestin blood levels are obtained only in clinical drug studies. Therefore, patients are managed by monitoring side effects and by

changes in menstrual patterns. Some prescribers suggest using a 50-μg EE COC in patients taking interacting drugs, although others might recommend using an alternative method of contraception if drug interactions are an issue.

Noncontraceptive Benefits of Combined Hormonal Contraceptives

ACNE

CASE 47-2

Question 1: D.S., a 20-year-old patient, presents to her primary care physician for a yearly pelvic examination and reports moderate acne flares. She has tried a variety of treatments without resolution and is currently using only topical medications. She heard birth control pills can help acne, especially if it occurs right before her period. She also reports fatigue most days of the month and mood changes, cravings, cramps, and bloating near the time of her period.

Vitals: weight, 118 pounds (53.52 kg); height, 63 inches (160.02 cm)
Blood pressure, 118/75 mm Hg
Heart rate, 86 beats/minute
Respiratory rate, 13 breaths/minute
Temperature, 98.6 °F (37 °C)
Past medical history: acne (since age 16)
Social history: denies tobacco and alcohol use, not sexually active
Family history: older sister cervical dysplasia grade 2 (age 26), maternal grandmother breast (at age 61) and ovarian cancer (at age 68)
Allergies: no known drug allergies
Current medications: benzoyl peroxide 5% cream, apply topically twice daily
Benzoyl peroxide 2.5% wash, wash affected area twice daily
Retin-A Micro® 0.1%, apply topically twice a week as tolerated
Multivitamin with iron PO daily
Past medications: doxycycline 100 mg PO twice daily for acne, stopped because of vaginal yeast infections
Physical examination: unremarkable with the exception of moderate facial acne
Laboratory test results: white blood cells, 6.0×10^3/μL
Red blood cells, 3.9×10^6/μL
Hemoglobin, 10.8 g/dL
Hematocrit, 32%
Mean cell volume, 79 μL

Mean corpuscular hemoglobin concentration, 31 g/dL
Red blood cell diameter width, 15%

What effect, if any, would CHCs have on her acne? Does D.S. qualify for CHC treatment of acne, and, if so, which COC would you recommend for D.S.?

Depending on the patient, a CHC may cause acne to appear, disappear, or significantly improve.[3] D.S. is interested in COCs. Four COC products, including their generic brands (norethindrone acetate/EE [Tri-Legest® 21 and Tri-Legest® Fe 28], norgestimate/EE [Ortho Tri-Cyclen® (discontinued, but generics available)], and drospirenone/EE [YAZ®, Beyaz®]) are U.S. Food and Drug Administration (FDA) approved for the treatment of moderate acne vulgaris in females at least 15 years old (at least 14 years old for Beyaz® and YAZ®), who have no known contraindications to CHCs, reached menarche, desire contraception, and have failed topical acne treatments (Tri-Legest® 21, Tri-Legest® Fe 28, and Ortho Tri-Cyclen®). Most CHCs, however, improve acne mainly as a result of the estrogen component. Higher doses of estrogen may decrease acne by suppressing the activity of sebaceous glands, decreasing the production of androgens, and increasing the synthesis of sex hormone–binding globulin (SHBG). The SHBG binds androgens and thereby diminishes their effects.[66] Progestins with higher androgenic activity may be more likely to increase acne because they stimulate sebaceous glands to produce more sebum. Both desogestrel- and norgestimate-containing OCs are less androgenic, whereas drospirenone has antiandrogenic properties, thereby decreasing acne associated with androgenic activity.[67] D.S. is 20 years old, has reached menarche, and has not responded to different acne treatments, and she therefore is a candidate for COC therapy. Her acne appears to be hormonally mediated, particularly because it appears around the time of her menses. It is likely that D.S.'s acne should improve with COC use, particularly if she uses a formulation with higher estrogenic activity and low androgenic activity (eg, Beyaz®, Safyral®, YAZ®, Yasmin®, Tri-Sprintec®, Tri-Sprintec Lo®, Mircette®, Tri-Legest 21®; see Table 47-3 for others).

MENSTRUAL CYCLE BENEFITS

Case 47-2, Question 2: D.S. has iron deficiency anemia, likely attributed to heavy menses. Will a COC help reduce her menstrual bleeding or menstrual cramps?

COCs help regulate menstrual cycles and reduce monthly blood loss.[25] This may reflect the progressive thinning of the endometrium of COC users and the lack of irregular bleeding. Bleeding may be decreased the most by COCs that have a high ratio of progestin to estrogen because endometrial thinning is maximized.[38] The formulation of EE/dienogest (Natazia™) has FDA labeling for the treatment of menstrual bleeding.[39] Some COCs have iron pills instead of placebos, often denoted with "Fe" in the name (eg, Tri-Legest® Fe 28, Femcon® Fe, Loestrin® Fe, Lo Loestrin® Fe; see Table 47-3 for others). Others have folic acid (eg, Beyaz®, Safyral®, see Table 47-3 for others), but D.S. would likely benefit more from the formulations with iron. Another option would be to have D.S. take COCs continuously so she has fewer menses.

Dysmenorrhea, or painful menstruation, may be of unknown origin or may be attributable to endometriosis or uterine fibroids. Data suggest menstrual pain might decrease by 60% after the initiation of a COC.[2] A COC with decreased estrogenic and increased progestational activity may be the best at relieving dysmenorrhea (see Chapter 50, Disorders Related to the Menstrual Cycle).

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Case 47-2, Question 3: D.S. also reports PMS symptoms such as bloating and mood changes. What treatment approaches are appropriate? What other noncontraceptive benefits do CHCs have?

Premenstrual syndrome (PMS) is a cyclic occurrence of one or more symptoms before the onset of menses. Most females report at

least one PMS symptom, which includes irritability, bloating, and depressed mood.[68] Premenstrual dysphoric disorder (PMDD) is a more severe form of PMS and has diagnostic criteria by the American Psychiatric Association. Premenstrual tension has been reported to be reduced in COC users, and other premenstrual symptoms seem to improve as well. Nevertheless, the effect of COCs on PMS symptoms is inconsistent and unpredictable, probably because PMS symptoms are neither consistent nor predictable.[69]

There may be augmentation of depression and mood swings by the progestational component, although the probability of this effect is low with a low-dose product (see Chapter 50, Disorders Related to the Menstrual Cycle, for further discussion of PMS). Some patients may also notice depressed mood during the hormone-free period, in which case a continuous-use COC may be helpful.

Two products, drospirenone/EE (YAZ®, Beyaz® and their generics), have the FDA-approved indication for treatment of symptoms of PMDD. Drospirenone/EE has been studied most extensively in patients with PMDD.[69] D.S. may try any CHC to help with her PMS symptoms; however, because YAZ® and Beyaz® have more data to show that they are effective for PMDD and acne, one of them may be the preferred initial product for her. In addition, both products are 24-day formulations, which may help minimize her menstrual bleeding and help her iron deficiency anemia.

ENDOMETRIAL CANCER

Clinical data suggest that COCs protect against endometrial cancer. This effect continues for 20 years after the last pill.[69] The protection is directly related to duration of use and may persist for many years after discontinuation of the COC.[3] A meta-analysis of 11 studies showed a 56%, 67%, and 72% reduction in endometrial cancer risk after 4, 8, and 12 years of COC use, respectively.[70] Another prospective study found risk reductions in endometrial cancer strengthened with longer use.[71]

OVARIAN CANCER AND FUNCTIONAL OVARIAN CYSTS

The risk of developing functional ovarian cysts is decreased, preexisting cysts are more rapidly resolved, and surgery rates for ovarian masses are reduced in females taking COCs.[72,73] This is likely attributable to reducing ovulation, suppressing androgen production, or increasing progesterone levels.

Each year of COC use decreases the relative risk of developing ovarian cancer by 7% to 9%.[73] The risk reduction continues to be seen in females using COCs for >15 years and persists after discontinuation.[69] D.S. should be reassured that COC use may decrease her risk of ovarian cancer given that she has a positive family history.

Combined Hormonal Contraceptive Risks and Adverse Effects

Some patients may not be candidates for CHCs because of the risks and adverse effects associated with their use. Other patients may experience minor side effects with CHCs that may be managed by changing to a CHC with different types or doses of estrogen or progestin. All patients should be counseled on the most serious side effects, which include PE or VTE, hepatotoxicity, or visual disturbances (could be a sign of retinal and corneal changes in the eye) and stroke. A helpful acronym to remember when counseling is "ACHES" (see Table 47-2),[2] which can be used to increase a patient's awareness of serious potential adverse effects that warrant immediate medical attention.

Other less severe adverse effects are listed in Table 47-4.[38] Most side effects resolve within 3 months of use. If a patient experiences adverse effects other than those described in "ACHES" (Table 47-2), she should be encouraged to continue the CHC for at least 3 months before switching to a different contraceptive.

BREAKTHROUGH BLEEDING, SPOTTING, AND AMENORRHEA

Case 47-2, Question 4: D.S. comes to the family planning clinic after taking EE 20/30/35 μg/norethindrone acetate1 mg (Tri-Legest Fe®) for 2 months. She had been started on Tri-Legest® to help with her acne. She feels her acne has improved, but reports irregular menstrual bleeding during her last two menstrual cycles, which occurs around the fifth pill of the pack and requires a pad. What action should be taken to correct D.S.'s bleeding pattern?

Intermenstrual bleeding is a bleeding that occurs at times other than the regular menses timing. Intermenstrual bleeding that requires a pad or tampon is designated breakthrough bleeding, whereas a lesser amount of intermenstrual bleeding is called spotting. Intermenstrual bleeding is experienced by many females in the first months of starting COCs (30%–50%).[2] Intermenstrual bleeding may also occur if a patient is not adherent to her COCs or taking medications that decrease COC effectiveness (Table 47-5).

Most clinicians will recommend that patients continue the same COC for at least 3 months if breakthrough bleeding or spotting is the only problem, because this complication usually resolves within 3 months.[2] Early-cycle intermenstrual bleeding, which usually starts before the 14th day of the menstrual cycle (or never ceases completely after menses), is usually caused by insufficient estrogen. Late-cycle intermenstrual bleeding, occurring after day 14, is usually attributable to insufficient progestational support of the endometrium. Another cause of intermenstrual bleeding is drug interactions (see Case 47-1, Question 8, for more information about drug interactions).

The balance between estrogen and progestin components in COCs determines its endometrial activity and, therefore, the likelihood of intermenstrual bleeding problems. It may be helpful to envision the estrogen component as the basic building blocks or "bricks" of the endometrium and the progestational component providing the mortar that holds the bricks together. The estrogenic activity of the progestin component increases the number of bricks, whereas its antiestrogenic activity decreases their numbers. If there are not enough bricks or mortar or if they are present in the wrong

proportions, the wall will crumble, and bleeding will occur (Table 47-3).

If D.S.'s intermenstrual bleeding continues early in her cycle after 3 months, another COC with the same progestin activity, more endometrial activity, and low androgen activity should be prescribed. Drospirenone 3 mg/EE 30 µg (eg, Ocella®, Safyral®, Syeda®, Tydemy®, Yasmin®, Zarah®, Zumandimine™) or Drospirenone 3 mg/EE 20 µg (eg, Beyaz®, Gianvi®, Jasmiel™, Loryna™, Lo-Zumandimine™, Nikki™, Rajani™, Yaz®) would be a good choice because endometrial activity would be increased and endometrial activity would be maintained with no androgenic activity (Table 47-3). For D.S., products with low or no androgenic activity should be selected because of her acne.

Intermenstrual bleeding may also be the sign of other health conditions such as cervical or uterine cancer. If a patient presents with intermenstrual bleeding and has not had a recent pelvic examination, a health care provider may perform an examination to rule out other possible causes of intermenstrual bleeding. D.S. recently had a normal pelvic examination 2 months ago. Given the timing of when she began her COCs, it is likely her intermenstrual bleeding is caused by her COCs.

Some patients experience amenorrhea (no menstrual bleeding) with CHCs. If this occurs, pregnancy should first be ruled out. If the patient is not pregnant and amenorrhea is acceptable to the patient, then the CHC need not be changed. But this does make it difficult for the patient to recognize whether she may become pregnant in the future.

Case 47-2, Question 5: During the same visit, D.S. states she is gaining weight and feels "bloated on and off" since starting the new birth control pill. What might be happening, and how should the clinician respond?

WEIGHT GAIN

Weight gain associated with CHC use is another common concern for females. A Cochrane review of three trials concluded that

available evidence was insufficient to determine an association between COCs and weight gain and also stated that no large effect was seen.[74] If weight gain is a concern, a low-dose estrogen and low-dose progestin products should be considered. Cyclic weight gain is generally caused by the mineralocorticoid effects of EE-stimulating aldosterone receptors to retain sodium, causing water retention and bloating. Too much progestin may cause an increased appetite and noncyclic weight gain. Drospirenone with antimineralocorticoid properties opposes EE effects, resulting in less water retention and weight gain, and increases in appetite may not be as apparent. The clinician should explain that weight gain is a potential side effect associated with COC use and is likely related to the estrogen component. It is reasonable to consider an alternative COC because she is having breakthrough bleeding and weight gain. A possible choice for D.S. is drosperinone 3 mg/EE 30 µg, which may help decrease the cyclic weight gain and still help control her acne. In addition, drospirenone 3 mg/EE 30 µg has the same progestational activity and higher endometrial activity to address D.S.'s previous breakthrough bleeding and has nonandrogenic activity that will likely help her acne.

NAUSEA

Case 47-2, Question 6: D.S. continues to have intermenstrual bleeding early in her cycle after 3 months of use along with feeling bloated and is placed on a new COC. Five days after starting drospirenone 3 mg/EE 30 µg, D.S. calls with reports of nausea. What counseling should the clinician provide to D.S.?

Nausea from COCs can generally be attributed to the estrogen component. To help alleviate nausea, D.S. can take her pill at bedtime rather than in the morning. Another alternative may be to take it with food or to try another COC with a lower estrogen strength. Yasmin® has a higher amount of EE as compared with the start of Tri-Legest Fe® (30 vs 20 µg of EE), which may be causing nausea to D.S. She should be advised that nausea generally resolves within 3 months of use.

HEADACHE

Case 47-2, Question 7: Three months later, D.S. returns to the clinic for follow-up and states that she has daily headaches during her placebo week but not when she is taking active pills. How should she be managed?

Headache is common in females taking CHCs or COCs, as is the case with D.S. Females may notice headaches while taking active pills, which may be related to sensitivity of estrogen. Others may experience headaches during the placebo week as a result of the withdrawal of estrogen.[2] Females with migraines may find that their headaches either improve or worsen when CHCs are initiated.

Mild headaches may improve with time, or if the patient is changed to a pill with less estrogen or progestin. Headaches that occur during the placebo week can be managed by trying desogestrel 0.15 mg/EE 10 to 20 µg (eg, Azurette®, Bekyree®, Kariva®, Pimtrea®, Mircette®, Simliya®, Viorele®, Volnea®), which minimizes the estrogen withdrawal by having only 2 days of placebos, or by taking CHCs continuously (ie, skipping placebo pills or the hormone-free week). Patients with severe headaches should discontinue CHCs and should be evaluated by their health care provider (see section on Contraindications). D.S. is experiencing headaches during the placebo week, indicating withdrawal of estrogen as the cause. Skipping the placebo pills and using an extended-cycle regimen may help decrease D.S.'s headaches.

BREAST CANCER, CERVICAL DYSPLASIA, AND CERVICAL CANCER

Case 47-2, Question 8: The medical history and physical examination of D.S. return negative findings for breast and cervical diseases, except for a history of breast cancer in her maternal grandmother and a history of cervical dysplasia in her sister. D.S. asks, "How COC use will affect her risk of breast cancer and cervical cancer?"

There are conflicting data regarding the association of COC use and breast cancer. The reported overall lifetime risk of breast cancer in American females is 12% to 13%.[75] Mørch et al cited several studies, including their own, that indicate a possible link between COC use and breast cancer showing an increased risk of breast cancer that increased with longer duration of use.[76] The study noted that absolute risk increases were small, whereas another study found the increased risk of breast cancer disappeared after 5 years of stopping contraception.[76,77] Other studies suggest that COC use does not increase breast cancer risk even with long-term use (eg, 10 years).[78,79] In addition, other studies concluded that breast cancer rates in high-risk females with *BRCA* 1 and 2 mutations or strong family history of breast cancer did not increase with COC use.[71,80,81]

COCs would not be expected to increase the risk of breast cancer in D.S. She should be instructed to perform monthly breast self-examinations and to return annually for a physical examination by her primary care physician.

With regard to D.S.'s concern of cervical cancer, it is important to educate D.S. about the incidence of cervical cancer and its relation to COC use. The American Cancer Society estimates that >14,100 cases of invasive cervical cancer will be diagnosed in 2022 and more than 4280 females will die of it.[82]

Females at highest risk for cancer are those whose test results are positive for certain subtypes of human papillomavirus (HPV), who have certain sexual behaviors, who are immunosuppressed, or who smoke.[2] Sexual behaviors associated with cervical cancer include beginning sexual activity at a young age, having multiple male sexual partners, and having a male sexual partner who has had multiple partners. Females at low risk for cancer are those who have two or fewer partners, whose partners use condoms, and who do not smoke.

Pooled data on cervical cancer risk from eight case–control studies found that OC users whose test results were positive for HPV were more likely to develop cervical cancer.[83] Females who had ever used OCs and those who had used OCs for >5 years were 1.5 and 3.4 times, respectively, more likely to develop cervical cancer.

This is consistent with other studies that suggest that OC users have an increased risk of developing cervical cancer, although one study suggests that the risk disappears 10 years after discontinuation of COCs.[76]

Epidemiologic comparisons of the prevalence of cervical cancer in OC users versus nonusers often are difficult to interpret because yearly medical examinations and regular Papanicolaou (Pap) smears of COC users result in early detection and treatment of precancerous lesions. Three vaccines for HPV are available and recommended for females ages 9 to 26 years. Because D.S. is 20 years old, she may be a candidate for the HPV vaccine (see Chapter 64, Vaccinations). D.S. may use COCs, should be encouraged to have regular Pap smears, and should be counseled on the behaviors that put her at risk for cervical cancer and the risks and benefits of the HPV vaccine.

USE DURING PREGNANCY AND BREAST-FEEDING

CASE 47-3

QUESTION 1: P.K., a 35-year-old female, comes to clinic stating that she recently took a home pregnancy test that reported a positive result. Her last menstrual period (LMP) was 9 weeks ago. She would like to confirm the results and discuss the effects of her current medications on the fetus.

Vitals: weight, 143 pounds (64.86 kg); height, 66 inches (167.64 cm)
Blood pressure, 128/82 mm Hg
Heart rate, 97 beats/minute
Respiratory rate, 16 breaths/minute
Temperature, 98.6 °F (37 °C)
Past medical history: history of abnormal menses, initiated on COC therapy to help regulate
Medications: desogestrel 0.15 mg/EE 30 µg (Reclipsen™)
Laboratory test results: blood test, qualitative human chorionic gonadotropin >25 mIU/mL

P.K. was started on desogestrel 0.15 mg/EE 30 µg (Reclipsen™) extended regimen 3 months ago because of a history of abnormal menstrual periods. Unknowingly, she became pregnant in the first month, continued her COC for two cycles, and is now 8 weeks pregnant.

What can you tell P.K. about the possible effects of CHC use on the fetus?

Although older, poorly designed studies found an association between COC use and cardiac or limb anomalies, newer data suggest that CHC use does not substantially increase the risk of anomalies over that expected in other uneventful pregnancies.[3]

Although a CHC should not be started in a patient who might possibly be pregnant, P.K. should be instructed to stop using her COC and be reassured that the risks to her fetus from the use of a low-dose CHC during the first trimester are likely minimal, while also informing her that no drug is without risk and that she should follow up with her obstetrician.

Case 47-3, Question 2: P.K. plans to breast-feed her infant and begin some type of contraception after her discharge from the hospital. Her past experience with condoms and concurrent spermicidal foams or gels resulted in itching and burning. She indicates she would like a contraceptive that would be suitable for long-term use while breast-feeding. What contraceptives are best for her while she is breast-feeding?

P.K. may use CHCs 4 to 6 weeks after delivery depending on her risk factors for VTE, even if she is breast-feeding, although it is preferable for her to use a progestin-only method (oral tablets, injectable, or subdermal implant).[6,24] In females with VTE risk factors, waiting at least 6 weeks before starting any estrogen-containing contraceptive regardless of breast-feeding status is recommended. By this time, the increased risk of thrombosis that occurs during pregnancy should be reduced to baseline. For non-breast-feeding females, a progestin-only contraceptive may be used immediately postpartum and for breast-feeding females, after the onset of lactogenesis, generally, in the first 48 to 72 hours postpartum.[24] COCs have been reported to decrease milk quantity and quality, although data are sparse.[24] Therefore, many providers suggest avoiding CHCs in females who are exclusively breast-feeding. If P.K. is planning to breast-feed, a progestin-only contraceptive is probably

best, which will inhibit ovulation, thicken the cervical mucus, and suppress endometrial growth, making them effective contraceptives.

PROGESTIN-ONLY CONTRACEPTIVES

Progestin-Only Pill

ADVANTAGES

Case 47-3, Question 3: What advantages and disadvantages of the POP should you discuss with P.K.?

There are two types of POPs available, norethindrone known as the *minipill* (Camila®, Deblitane®, Errin®, Heather®, Incassia™, Jencycla™, Lyza®, Nora-BE®, Norlyroc™, Ortho Micronor®, Sharobel™, Tulana™) and drospirenone (Slynd®). Slynd® (Exeltis USA, Inc., Florham Park, NJ) is a relatively new POP.

Norethindrone and drospirenone are devoid of some of the nuisance side effects (see Table 47-4) caused by estrogen (eg, headaches, chloasma).[2] More importantly, estrogen-mediated hypertension and clotting factor changes will be avoided with norethindrone; however, clotting is still a concern with drospirenone. Possible bone loss and hyperkalemia need monitoring with drospirenone.[84] Confusion with pill taking is minimized with norethindrone because there is no placebo week and all 28 tablets in each pack are the same. Therefore, the missed-dose directions are the same whenever any tablet is missed. Drospirenone has 24 active and 4 inactive tablets. Females may choose them because they are not estrogen containing and fertility returns rapidly after discontinuation.[2]

Theoretically, progestin use in the early postpartum period may decrease milk production because milk production is triggered by the decline in progesterone that occurs after delivery. However, no data have consistently shown this to be a problem in postpartum

females.[24] Once breast-feeding has been established, progestins have not been shown to interfere with the quantity or quality of milk produced by a nursing mother. Thus, a contraceptive method that is nonhormonal or only contains progestin is preferred for a patient who plans to breast-feed her infant.

DISADVANTAGES

Norethindrone with a failure rate of 0.3% to 7% and drospirenone with a 4% failure rate (in clinical trials) are similar in effectiveness to the COCs in preventing pregnancies (see Table 47-1).[2] Minipills (norethindrone), however, must be taken even more regularly than are COCs, and, therefore, are not used often in females who are not breast-feeding (see section on Patient Instructions). Some females on minipills ovulate regularly, and some shift back and forth between ovulatory and anovulatory (no ovulation occurring) menstrual cycles. Females who consistently have menses on the minipill may be ovulating and should consider using a backup contraception or changing to a different method.

Irregular menses, decreased duration, and amount of menstrual flow, spotting, or amenorrhea commonly occur in females taking the minipill.[2] Because of this, patients often are concerned that they may be pregnant. Females who are exclusively breast-feeding will usually have amenorrhea. The high incidence of irregular menses associated with the minipill may mask underlying disease such as uterine fibroids or uterine cancer causing irregular bleeding. Other side effects reported with minipills include headaches, breast tenderness, mood changes, and nausea.

Minipills should be avoided if there is a personal history of breast cancer or unexplained vaginal bleeding. Caution should be exercised when using minipills in females with hepatic disease, multiple risk factors for cardiovascular diseases, ischemic heart disease, a current deep venous thrombosis or PE, or complicated diabetes (eg, diabetes with nephropathy, neuropathy, retinopathy), or those taking medications that may interact with COCs such as hepatic inducers that include St. John's wort and bosentan (Table 47-5).[85,86]

PATIENT INSTRUCTIONS FOR THE PROGESTIN-ONLY PILL

CASE 47-3, QUESTION 4: What instructions should P.K. receive regarding the use of a POP?

P.K. may begin taking the minipill or drospirenone on the first day of her menses.[2] Because she is breast-feeding and recently postpartum, she is less likely to have a menses. She could begin taking norethindrone immediately postpartum if she were not breast-feeding. Because she is breast-feeding, it is recommended that she wait until lactogenesis occurs about 48 to 72 hours postpartum.[24] Drospirenone does not enter breast milk and is not thought to affect lactation. It does carry a risk of thromboembolism, and, therefore, it may be best to wait 4 to 6 weeks postpartum based on the patient's VTE risk factors.[84] If at 6 weeks' postpartum, P.K. started a POP on the first day of her menses, a backup contraception is not needed with the day 1 start. Alternatively, P.K. can use the quick start method, starting any day of her cycle and using a backup method for 48 hours with norethindrone and 7 days with drospirenone.[2,84]

P.K. should be instructed to take the POP at the exact same time each day. If she is more than 3 hours late taking a norethindrone tablet, she should take the tablet as soon as she remembers and should use backup contraception for 48 hours.[85] This is quite different from the directions for COCs, so this point should be stressed with patients. If one active drospirenone tablet is missed, another should be taken as soon as possible, and she should finish the pill pack. If two active tablets are missed, she should take the last missed tablet as soon as possible and continue to take one tablet a day as instructed while using an additional backup method for 7 days.[84]

Injectable Medroxyprogesterone Acetate

Progestin-only contraceptives are available in two different injectable formulations of medroxyprogesterone acetate (MPA). Depo-Provera®

(Pharmacia & Upjohn Co., Pfizer Inc, New York, NY) is given as a 150-mg IM injection in the deltoid or gluteus maximus every 11 to 13 weeks.[2,87] More recently, Depo-subQ provera 104® (Pharmacia & Upjohn Co., Pfizer Inc, New York, NY) was approved. This product also contains MPA; however, it is given subcutaneously as a 104-mg dose every 12 to 14 weeks.[87] Package inserts instruct the patient to begin the injectable MPA methods in the first 5 days of her menses and then no backup is required; however, P.K. may also begin any other time and use backup for 1 week.[2,87]

Case 47-3, Question 5: P.K. decided to receive injectable MPA. She is now lactating and returns to the gynecology clinic for her second IM injection of MPA. She was given her first injection 3 months ago, immediately postpartum. She is experiencing prolonged intermenstrual bleeding and a 3- to 5-pound (1.36- to 2.27-kg) weight gain. Is this to be expected? What are the advantages and disadvantages of injectable MPA? How are the side effects managed?

ADVANTAGES

Injectable MPA is a reasonable contraceptive choice for P.K. because she is breast-feeding and indicated that she needed a long-term contraceptive. Among its benefits are a low failure rate of 0.3% to 4% (see Table 47-1), ease of use, lack of estrogenic side effects, decreased dysmenorrhea and monthly blood loss, and a reduced risk of endometrial cancer.[2,24] Other noncontraceptive benefits may include a reduction in seizure frequency in patients with epilepsy and a possible reduction in ovarian cancer.[3,24] Furthermore, contraceptive effectiveness is not reduced by the concurrent use of anticonvulsants or certain antibacterials as seen with COCs.[5,6] Depo-subQ provera 104® is also indicated for pain caused by endometriosis.[88]

DISADVANTAGES

Patients with breast cancer should not use injectable MPA owing to concerns that breast cancers are hormonally sensitive and the prognosis may worsen for some females.[5,6] Injectable MPA should be used with caution in females with unexplained vaginal bleeding

(MPA may cause irregular bleeding and may mask conditions resulting in vaginal bleeding such as cervical or uterine cancer), multiple risk factors for cardiovascular diseases, ischemic heart disease or multiple risk factors for cerebrovascular disease, or a current VTE or PE (for medical eligibility, see https://www.cdc.gov/mmwr/volumes/65/rr/rr6503a1.htm?s_cid=rr6503a1_w).[6] Because clotting factors have not been shown to be clinically affected by injectable MPA, some experts disagree with the manufacturer's labeling for the injectable MPA products, which lists a history of prior thromboembolism as a contraindication.[4–6,87,88] Some clinicians also begin injectable MPA immediately postpartum rather than waiting 6 weeks postpartum, as directed by the package insert.[6]

Estrogen production declines in females using injectable MPA, so P.K. should be told that injectable MPA may decrease bone mineral density (BMD).[87] Loss of BMD may be of particular concern in adolescent patients. Numerous studies have found that females receiving injectable MPA have lower BMD compared with nonusers.[89] Although there have been reports of stress fractures in injectable MPA users, no studies to date have documented an increased rate of hip or vertebral fractures in injectable MPA users.[90] Also, BMD has been shown to recover after discontinuation of the injections.[3] The manufacturer of both products recommends that patients do not use injectable MPA >2 years unless they are unwilling or unable to use other methods.[87]

P.K. must understand that injectable MPA frequently causes irregular bleeding or spotting during the first few months or more of use because estrogen is insufficient to maintain the endometrium. After 1 and 2 years of Depo-Provera® use, 55% and 68% of females experience amenorrhea, respectively.[87] With Depo-subQ provera 104®, 56.5% of patients experienced amenorrhea after 1 year.[88] In addition, during the postpartum period, irregular bleeding may occur as well. Although not harmful, amenorrhea leads to discontinuation of injectable MPA in 13% of patients.[87] All patients beginning injectable MPA should be informed that during the first year of use they might have menstrual changes. If unusually heavy or

continuous bleeding occurs, P.K. should be evaluated. P.K. should be counseled and reassured that her intermenstrual bleeding probably will resolve in the next few months. If the bleeding is bothersome, a 4- to 21-day course of oral estrogen (eg, conjugated estrogen 0.625–2.5 mg/day) or a COC with 20 µg of EE will minimize or eliminate the bleeding.[7] However, the bleeding may recur after discontinuation of the estrogen. Low-dose estrogen may be continued if bleeding recurs.

Weight gain is another concern with injectable MPA. The mean weight gain after 1 year of therapy with injectable MPA was about 5 pounds (2.27 kg) in two-thirds of users.[87] Depo-Provera® users typically gain a total of about 8 pounds (3.63 kg) in 2 years, nearly 14 pounds (6.35 kg) in 4 years, and 16.5 pounds (7.48 kg) in 6 years. Depo-subQ provera® users gain a little less weight, 3.5 pounds (1.58 kg) in the first year of use and 7.5 pounds (3.40 kg) after 2 years.[88] Other side effects include mood changes, hair loss, and headaches. P.K. should be counseled on the weight gain associated with injectable MPA. P.K. has already reported an increase in weight since she gave birth 3 months ago, which may be caused by injectable MPA, or possibly her weight is fluctuating because of her recent delivery.

The long return to fertility time is another disadvantage of injectable MPA. After the last injection of 150 mg of MPA, median time to conception has been reported to be by 9 to 10 months, which has been reported similarly for the 104-mg dose.[2,88] It is recommended to discontinue MPA about 12 to 18 months before the desire of pregnancy. Because P.K. is 35 years old, she should be counseled on the return to fertility time with injectable MPA use in case she desired to have children in the near future. She has indicated that she is not interested in having any more children; however, the long return to fertility time with injectable MPA should be explained to all females, especially those older than age 35 years.

Subdermal Implant

Case 47-3, Question 6: P.K. returns to the clinic 7 months postpartum for her third MPA injection. She started menstruating today after missing two appointments; she is now 1 month late for her MPA dose. She states that her busy family life and work schedule make it difficult to attend appointments. She also does not like the weight gain and the prolonged intermenstrual bleeding that has occurred during the past few months. She read that an implant is available, and she would like to know whether this might be a better option for her. What information should you give P.K.?

The contraceptive implant (Nexplanon®) contains 68 mg of etonogestrel in a single, thin, radiopaque, rod.[91] The rod is inserted subdermally in the upper inner arm using a needle and a local anesthetic. Once inserted, the implant is effective for up to 3 years. Nexplanon® (Organon Global Inc., Jersey City, NJ) should be inserted during the first 5 days of menses, and no backup contraception is required. A small incision is required to remove the implant. The etonogestrel implant has the same mechanism of action as injectable MPA. The radiopaque property of Nexplanon® is preferred for ease of removal.

ADVANTAGES

The contraceptive implant is a relatively newer product, so information on its protection against cancers or effects on other diseases such as cardiovascular disease is limited. Females using the implant reported amenorrhea, decreased menstrual cramping, and less anemia than did nonusers.[2] Also, decreases in BMD have not been shown with this product. Fertility returns quickly after the removal of the implant, and this will be a benefit to P.K. if she decides to have another child, given her age.

DISADVANTAGES

As with the injectables, irregular bleeding is likely and is the most common cause of discontinuation. Side effects reported with the implant are headaches, mood changes, and acne. Nexplanon® is not recommended for patients on medications that induce hepatic enzymes (eg, anticonvulsants) because they may decrease

contraceptive efficacy. Weight gain is also common, with users gaining 2.8 pounds (1.27 kg) after 1 year and 3.7 pounds (1.68 kg) after 2 years.[91] So P.K. may still experience weight gain with this product. The implant is not recommended for patients with a current VTE; however, it may be used in patients with a personal or family history of VTE.[5,6] The effectiveness of the implant has not been that well studied in females who are 130% of their ideal body weight, which could be an issue for overweight or obese females.[91]

INTRAUTERINE DEVICE AND INTRAUTERINE SYSTEM

Case 47-3, Question 7: P.K. is concerned about weight gain and is not interested in a subdermal implant. What other long-term, reversible contraceptive methods might work for her? Is P.K. a candidate for an intrauterine device (IUD) or IUS, and, if so, what information would you provide her?

Background and Mechanism of Action

Despite concerns (increased risk of pelvic inflammatory disease [PID], tubal scarring, and infertility) with early IUDs, also known as intrauterine contraceptives (IUCs), the current devices offer a safe and effective method of contraception.[2] Currently, there are four products on the market that include the ParaGard T 380A® (copper) IUD (CooperSurgical, Trumbull, CT) and the Mirena® (Bayer Healthcare Pharmaceuticals Inc., Whippany, NJ), Skyla® (Bayer Healthcare Pharmaceuticals Inc., Whippany, NJ), Kyleena® (Bayer Healthcare Pharmaceuticals Inc., Whippany, NJ), and Liletta® (Odyssea Pharma, SPRL, Belgium, distributed by Allergan USA, Inc., Irvine, CA) (levonorgestrel) IUSs. Although the IUDs and IUSs available today are a safe and effective method of contraception, they are still not as popular in the United States (1%–6% of females

are users) as they are worldwide (12% of married females of reproductive age are users).[92,93]

The copper IUD has a polyethylene body that is wound with copper wire. Once inserted, the copper IUD may be left in place for 10 years.[94] The Mirena®, Skyla®, Kyleena®, and Liletta® IUSs also have polyethylene bodies, with levonorgestrel reservoirs in the vertical stem of the T that provide levonorgestrel daily. Mirena® is effective in preventing pregnancy for up to 7 years and helps with heavy periods for up to 5 years. Kyleena® is effective for 5 years, whereas Liletta® is effective for 6 years. Mirena® and Kyleena® provide 20 and 17.5 μg of levonorgestrel daily, respectively.[95,96] Liletta® provides 20 μg of levonorgestrel daily and progressively declines to about 8.6 μg/day after 6 years.[97] Skyla® is slightly smaller in size and provides 14 μg of levonorgestrel daily after 24 days and is effective for up to 3 years.[98]

Failure rate of the copper IUD is 0.6% to 0.8% for the first year compared with 0.1% to 0.4% for the levonorgestrel IUS (Table 47-1). Both IUDs and IUSs are inserted by a health care provider in the office. The procedure usually takes only a few minutes and does not require sedation. Many providers will recommend that patients take a dose of an NSAID before the insertion visit.

Possible mechanisms of action for copper IUDs include prevention of fertilization and implantation and the copper interfering with sperm transport, viability, or number.[94] The levonorgestrel IUS is believed to work by thickening the cervical mucus, preventing sperm from entering the uterus, altering the endometrial lining, preventing ovulation, and altering sperm activity.[92]

Advantages

Both the copper IUD and the levonorgestrel IUS are very effective, reversible, long-term methods that are easy to comply with.[2] The copper IUD is a particularly beneficial option for females who desire a nonhormonal method of contraception. The levonorgestrel IUS has

the advantages of reducing menstrual bleeding and cramping as a result of the progestin.

Although the initial cost of inserting an IUD or IUS is high (around $500 for the device plus insertion costs), there are no ongoing monthly costs to P.K. as there are with other methods. Therefore, the IUD or IUS becomes more cost-effective when used for >1 year.

Disadvantages

Menstrual changes are the most common side effect of IUDs and IUSs.[2] Copper IUD users are more likely to have heavier menstrual bleeding and cramping. Levonorgestrel users should expect to have irregular bleeding and spotting during the first 3 months after insertion. After 3 months, however, levonorgestrel IUS users report lighter menses and reduced cramping.

Both IUDs and IUSs are contraindicated in females with certain anatomic abnormalities of the uterus (eg, distortion of the uterus, cervical stenosis, or cervical lacerations), unexplained vaginal bleeding, cervical cancer, and PID or other active genital infections. They should be used with caution in females who are immunosuppressed (for medical eligibility, see https://www.cdc.gov/mmwr/volumes/65/rr/rr6503a1.htm?s_cid=rr6503a1_w) and may be used in females at high risk for human immunodeficiency virus (HIV) (https://www.cdc.gov/mmwr/volumes/69/wr/mm6914a3.htm?s_cid=mm6914a3_w#T1_down).[6,98] The levonorgestrel IUSs should be used with caution in females with a current VTE or PE. Although the serum levels of levonorgestrel are low, the manufacturers currently do not recommend that females with active or past breast cancer use the device.

It has been reported that the greatest risk of PID occurs shortly after insertion; however, more recent studies also show that there is a low risk of getting PID and no risk at initial insertion.[2,99,100] To aid in infection prevention, all patients should be tested for gonorrhea and chlamydia before IUD or IUS insertion and evaluated for risk factors

of contracting sexually transmitted infections (STIs; eg, multiple partners, unprotected intercourse). Females whose test results are positive for an STI should consider an alternative form of contraception until the infection has resolved. Alternatively, once treatment is provided, an IUD or IUS may be initiated and the patient counseled on ways to prevent STIs.[5,6]

If an IUD or IUS user becomes pregnant, the likelihood that the pregnancy is ectopic is higher (ie, the ratio of ectopic to uterine pregnancies is higher in IUD or IUS users).[94,95] Common problems with IUD use include excessive uterine bleeding, spotting, or pain. The device may be removed as a result of these issues. Spontaneous expulsion of the copper IUD occurs in about 3% to 10% and 3% to 6% of females within the first year with the IUS.[2] Rarely, an IUD or IUS may become embedded in the endometrium or partially or totally perforate the uterine wall. P.K. should be instructed to look for the warning signs of a possible complication with IUD or IUS use, such as abdominal pain or abnormal vaginal discharge.

OTHER NONHORMONAL CONTRACEPTION

CASE 47-4

Question 1: C.J. is a 22-year-old HIV-positive female presenting to the clinic for routine checkup and DMPA injection. She is currently using DMPA IM injection every 12 weeks and taking Atripla™ (efavirenz 600 mg/tenofovir 300 mg/emtricitabine 200 mg) 1 tablet PO daily.

Vitals today: height, 66 inches (167.64 cm); weight, 116 pounds (52.62 kg)
Blood pressure, 124/81 mm Hg
Heart rate, 89 beats/minute
Respiratory rate, 12 breaths/minute
Temperature, 96.8 °F (36 °C)
Laboratory test results: CD4, 581
HIV-1 RNA, <75 copies/mL (undetectable)

C.J. wants to make sure she does not get pregnant and is recommended to use a barrier method in addition to DMPA. C.J. mentions that she is concerned about STIs and, more specifically, transmission of HIV.

What barrier methods are available, and which one is best to recommend for C.J.?

Diaphragm and Cervical Cap

The diaphragm is a soft latex or silicone rubber cap with a metal spring reinforcing the rim.[2] The device is inserted vaginally and placed over the cervical os to mechanically block access of sperm to the cervix. The diaphragm is held in place by the spring tension of the rim, vaginal muscle tone, and the pubic bone.

A cervical cap marketed as FemCap™ (FemCap Inc., Del Mar, CA) is made of silicone.[101] The FemCap™ is kept in place by suction formed between the cervix and the device. Because all of these devices do not fit tightly enough to be a complete barrier to sperm, spermicidal gel must be applied to each device before it is inserted.

The first-year failure rate with diaphragms is 16% to 17% (Table 47-1).[2] C.J. should be counseled that diaphragms are less effective than are other available methods. Because breast-feeding offers some protection against pregnancy, breast-feeding females may be the best candidates for the diaphragm. Failure rates of cervical caps range about 14% in nulliparous females and 29% in parous females.[2]

TYPES AND FITTING

Diaphragms must be properly fitted to be effective. They are available in different sizes (50–95 mm in diameter) and different styles of construction of the circular rim. The goal of fitting a diaphragm is to select the largest rim size that is comfortable for the patient.[2] A diaphragm that is too small may become dislodged during intercourse because vaginal depth increases during sexual arousal. Conversely, a diaphragm that is too large may cause vaginal pressure, abdominal pain or cramping, vaginal ulceration, or recurrent urinary tract infections. Proper size is estimated during

bimanual examination, and several diaphragm sizes may need to be tried by the health care provider to find the right size for the patient. Caya® (HPSRx Enterprises, Salem, VA) is a marketed diaphragm that is contoured with one size and made of silicone and nylon spring that allows it to be used with varying vaginal and cervical sizes (see https://www.caya.us.com/).[2,102] Contraindications for use include <6 weeks postpartum, if a diaphragm sized <60 mm or >85 mm was previously used, or the patient has severe pelvic floor or uterine prolapse; it should also not be used with a silicone-based lubricant.[102] If C.J. gains or loses 10 (4.54) to 20 pounds (9.07 kg), has a pregnancy, or has abdominal or pelvic surgery, depending on the diaphragm used, it may need to be refitted.

The FemCap™ is shaped like a sailor's hat[102] (see http://www.femcap.com/). It is available in three sizes, and size selection depends on the patient's pregnancy history; the 22-mm FemCap™ is for patients who have never been pregnant, the 26-mm one is for females who have miscarried or had a cesarean section, and the 30-mm size is for females who have vaginally delivered a full-term infant.

C.J. would likely be able to tolerate the diaphragm or cervical cap. Fitting will depend on the device that she selects. These barrier methods, however, do not protect against STIs, which is important to C.J. when selecting her barrier method, and therefore, are not the best choice.

PATIENT INSTRUCTIONS, ADVANTAGES, AND DISADVANTAGES

The diaphragm and cervical cap offer pregnancy prevention without the use of hormones, and females only need to use the devices when they are sexually active.[2,101] All of these devices are available only by prescription, should not be used during menstruation, may be difficult to insert and remove for some patients, and are not as effective as the hormonal methods or IUD. All devices should be inspected for holes or puckering (small areas of wrinkle) before use.

The diaphragm should not remain in the vagina for >24 hours.[4,102] Toxic shock syndrome (TSS) has been associated with diaphragm use, and females should be alert to its symptoms, which include fever, diarrhea, vomiting, muscle aches, and a sunburn-like rash. Allergic reactions to the latex or spermicides also have been reported.

The diaphragm should always be inserted before intercourse; it can be inserted as long as 6 hours before intercourse, if desired.[2] The diaphragm should not be removed for at least 6 hours after intercourse. One teaspoon of spermicidal gel should be placed into the dome of the diaphragm before insertion or the Caya contraceptive gel® if using Caya®.[102] If intercourse is repeated, a new application of spermicide should be inserted vaginally without removal of the diaphragm.

To use the FemCap™, first apply about one-fourth teaspoon of spermicide inside the bowl and one-half teaspoon on the other side that will face the vagina (between the brim and the dome).[101] Insert the FemCap™ with the long brim side first and the dome side up. Push until the cap is in contact with the cervix. More spermicide should be applied if intercourse is repeated. The FemCap™ should be inserted at least 15 minutes before sexual arousal and can be left in for up to 48 hours. The FemCap™ must be left in place for a minimum of 6 hours after intercourse.

Both devices should be washed with mild soap and water, rinsed and dried, and stored in the accompanying container. Oil-based products also may decompose the latex of a diaphragm and should not be used. These devices should be replaced every year or sooner if there are signs of wear or holes.

Vaginal Sponge

The vaginal sponge is another barrier method. The sponge contains a polyurethane foam and 1 g of nonoxynol-9 (spermicide). The sponge is inserted into the vagina and placed against the cervix. It may be worn up to 24 hours. After intercourse, the sponge should

remain in place for 6 hours. The sponge works in three ways: It acts as a spermicide, is a mechanical barrier, and absorbs semen. The failure rate reported is 14% for nulliparous females and 27% for parous females (see Table 47-1).[2] Irritation or ulceration of the cervix and vaginal mucosa may occur. If the sponge is not removed within 24 hours or if particles remain after removal, TSS could be an issue. Because the sponge may cause irritation and does not provide protection against STIs, it may not be best for C.J.

Male Condoms

Male condoms are an effective method of contraception when used properly. The failure rate with condoms is 2% to 13% (see Table 47-1).[2] Many different brands of condoms are available in the United States. The brands differ in size, shape, color, material, and the presence or absence of lubricants or spermicide. The chief noncontraceptive benefit of latex condoms is the prevention of STIs (including gonorrhea, chlamydia, and HIV), and they can be used for vaginal, anal, or oral sex.[5] Condoms are readily available without a prescription and do not cause systemic side effects such as the hormonal methods. However, some report that condoms reduce sensitivity and spontaneity. The most commonly used and least expensive male condom is made of latex.[2] Male condoms made of polyurethane and lambskin are recommended for males or females allergic to latex. Polyurethane condoms are more expensive and sometimes break more easily than do latex condoms, but they also conduct heat better than do latex condoms.[103] Lambskin condoms also conduct heat well, but do not offer the same protection against STIs as latex and polyurethane. Lambskin condoms are not recommended for those who are concerned about STIs.[103]

Because the pre-ejaculatory secretions may contain sperm, the male condom should be applied before vaginal contact.[2] When using a male condom, the male or his partner should hold the tip of the condom and unroll it down to the base of the erect penis.[5,103] Most practitioners recommend lubricated condoms with reservoir ends to

prevent breakage and collect the ejaculate. Oil-based lubricants can degrade male latex condoms and should be avoided. Oil-based lubricants, however, may be used with polyurethane or lambskin condoms. Condoms should be used only once by their expiration date and stored in a cool, dry place, away from prolonged periods of heat or light.

Latex condoms would be best for C.J. and her partner to prevent the transmission of STIs.

Female Condoms

The female condom is less effective, with a 21% failure rate (Table 47-1)[2] (see http://www.fc2.us.com/).[104] The FC2™ (FC2, Miami, FL) is made of a nitrile sheath or pouch and polyurethane ring at the closed end of the pouch. It consists of a smaller, circular, inner ring (which secures the device around the cervix like a diaphragm) and a larger ring around the opening of the condom.

The inner ring should be compressed and inserted vaginally as far as it will go, and the larger ring remains outside of the vagina, protecting the external genitalia. Female condoms should also be inserted before sexual contact; they may be inserted up to 8 hours before intercourse. The FC2™ contains a silicone-based lubricant inside of the condom but additional lubricant may be used. Oil-based or water-based lubricants can be used with both female condoms. Just like male condoms, they should be used by their expiration date, not reused, and stored in a cool, dry place, away from heat or light.

Disadvantages of female condoms include cost, squeaking noise during use, and insertion difficulty.[2] Condoms may also break, although this is less likely with the female condom. Male and female condoms should not be used together because this may increase the risk of breakage.

An advantage for C.J. to use the female condom is that she has control of her own protection and does not need to rely on her

partner to make sure they are both protected. The female condom is a good alternative for C.J.

Vaginal Spermicides

Case 47-4, Question 2: C.J. would like to use a spermicide along with condoms. What options does she have and how effective are spermicides when used alone? What dosage form should C.J. use? How should she be instructed to use a vaginal spermicide? What side effects can be anticipated?

Vaginal spermicides currently are available as gels (jellies), suppositories, foams, and films.[2,103] Most of these products use a nonionic surfactant, nonoxynol-9, as the spermicide. First-year failure rates with these dosage forms range from 18% to 29% (Table 47-1). Most vaginal spermicides are available over the counter (OTC), a new prescription vaginal gel is available, Phexxi®. It does not contain nonoxynol-9 and instead is lactic acid 1.8%, citric acid 1%, and potassium bitartrate 0.4%.[105]

The different characteristics of the products can help guide C.J. when selecting a dosage form. Regardless of the dosage form, a new dose of spermicide should be applied before each act of intercourse.

Spermicides may cause genital irritation and, in some patients, lead to ulceration. Likely for this reason, spermicides have been shown to increase the transmission of STIs, including HIV, gonorrhea, and chlamydia. Cystitis and pyelonephritis have been reported with Phexxi®, and use in females with a history of recurrent urinary tract infection (UTI) or urinary tract abnormalities should be avoided.[105] Spermicides may not be the best choice for C.J. and her partner to prevent the risk of STI transmission.

EMERGENCY CONTRACEPTION

Case 47-4, Question 3: C.J. presents to a pharmacy 4 months later and says she missed her MPA injection last month. She had intercourse 4 nights ago using a condom and is worried she might become pregnant. She wants to know whether she should use the "morning-after pill." What do you tell C.J. about EC options? Is C.J. a candidate for EC?

EC, also referred to as the morning-after pill, is postcoital contraception useful for females who did not use a contraceptive (eg, forgot, were assaulted) or whose method failed (eg, broken condom, missed pill). EC is available in a few methods, which include oral pills or an IUD.

Emergency Contraceptive Pills

Emergency contraceptive pills (ECPs) are available in a variety of formulations known as *progestin-only*, *Yuzpe*, and *selective progesterone receptor modulators (SPRMs)*.

Currently, the one-dose progestin-only (levonorgestrel 1.5 mg) ECPs are available OTC to all ages.[106] The one tablet should be taken within 72 hours of unprotected intercourse, according to the package labeling. Studies, however, have shown that progestin-only ECPs are still effective if taken up to 120 hours (5 days) after unprotected sex.[107,108] Progestin-only ECPs reduce the risk of pregnancy by a few potential mechanisms: preventing ovulation, preventing fertilization, or preventing implantation.[2] They reduce the average risk of pregnancy by 89% after a single act of intercourse when taken within 72 hours. ECPs are most effective when taken as soon as possible after intercourse; therefore, treatment should not be delayed. Progestin-only ECPs may not be as effective in females with a BMI of ≥26 and should be recommended to use an alternative ECP, but treatment should not be denied due to BMI.[106] The most common side effects with ECPs are nausea and vomiting.[2] C.J. should be instructed that if she vomits within 1 hour of taking ECPs, the dose should be repeated. C.J.'s menses may come early or late, but she should take a pregnancy test if her menses does not come

within 3 weeks of taking ECPs. This may further be complicated if C.J. gets her next scheduled dose of injectable MPA.

As an alternative to progestin-only ECPs, regular COCs may be used as long as they contain levonorgestrel or norgestrel as the progestin. This is known as the Yuzpe method, which consists of high-dose progestin and high-dose estrogen. There are no marketed formulations of this method. Depending on the brand of COCs used, a differing number of pills are taken within 120 hours of unprotected intercourse as two separate doses 12 hours apart (see Table 47-1 footnote).[2] Compared with progestin-only ECPs, the Yuzpe method is associated with higher incidence of nausea and vomiting, and patients may wish to take an antiemetic before each dose.[107] Because progestin-only ECPs are widely available, easy to use, and more effective and have limited side effects, COCs are being used less often for EC.

Ulipristal acetate (ella®) is classified as an oral SPRM.[109] The 30-mg oral tablet should be taken within 120 hours of unprotected intercourse.[109] It is available by prescription only. Its mechanism of action is somewhat different from that of progestin-only ECPs. It has progesterone receptor antagonist and agonist effects; however, its main mechanism is through receptor antagonism at the uterus, cervix, hypothalamus, and ovaries, thus preventing ovulation even after the LH surge, which progestin-only ECPs may not do.[109] The only other SPRM on the market is mifepristone (RU-486), known for medical abortion use. Concerns were raised about the mechanism of ulipristal disrupting an existing pregnancy and leading to abortion. Current pregnancy exposure data do not suggest an increase in miscarriage. Ulipristal has not been shown to be as effective in females with a BMI of >30 and may be ineffective in females with a BMI of ≥35, but treatment should not be denied because of BMI.[106,109] It is recommended that those females use an alternative emergency contraceptive method.[106,109] Headache, dysmenorrhea, nausea, and abdominal pain were the most reported side effects in clinical trials.[109] If vomiting occurs within 3 hours of taking the dose, a repeat dose is recommended.[109]

In C.J.'s case, progestin-only ECPs are the better choice because she is taking medications that interact with COCs. She is within the window of 120 hours postcoitus, making OTC progestin-only ECPs an option. Ulipristal is another option and labeled for use 120 hours postcoitus, but would require a prescription and may delay C.J. from receiving timely EC.

Intrauterine Devices for Emergency Contraception

The copper-T IUD is also an effective method of EC when inserted within 5 days of unprotected sex.[2,107] There is no evidence that the progestin IUD is effective. An IUD must be inserted by a health care provider and as such may not be used regularly for EC. The biggest advantage of using an IUD for EC is that it provides continued contraception for the patient. In addition, it is effective in females regardless of their BMI. An IUD may be an option for C.J. if she would like to switch from MPA to an IUD. Updated CDC recommendations state there is no restriction for IUD use in HIV-positive females.[110] Having to see a provider for an IUD, however, is less convenient and makes ECPs the better choice for accessibility and timing.

MEDICAL ABORTION

Case 47-4, Question 4: C.J. presents to the clinic 4 weeks later stating that she missed her period and is concerned she may be pregnant. Her human chorionic gonadotropin test result is positive, confirming pregnancy. C.J. considers terminating the pregnancy, stating she is not ready to have a child and is concerned about the antiretroviral medication effects on the baby. What options are there for medical abortion?

It is estimated that about one-half of pregnancies are unintended, so it is important for these females to have safe options.[1] C.J. should

be counseled extensively about her options, including keeping the baby, adoption, and medical or surgical abortion. Compared with surgical abortion, medical abortion does not require a surgical procedure, so it is less likely to cause infection and is less costly.[2] Thus, some females feel more in control when choosing this option. However, some patients may not prefer medical abortion because it usually requires more medical visits and follow-up, has a slightly lower success rate (94%–97%; failures will need a surgical procedure), and involves more bleeding and cramping that usually lasts for 2 weeks.

There are many variations in how medical abortions are carried out, but the general treatment remains the same.[2] C.J. would first obtain baseline laboratory tests, including blood type and hemoglobin. She would be given either methotrexate, mifepristone, or both the same day to stop development of the pregnancy. In the United States mifepristone, a progesterone receptor blocker, is more commonly used. Misoprostol is given to induce uterine contractions and expel the pregnancy and can be administered alone or in combination with other medications.

An example regimen for a gestational age of ≤70 days (WHO also states <12 weeks), C.J. would be given mifepristone 200 mg orally on day 1, then a total of misoprostol 800 µg vaginally (6–48 hours after the mifepristone dose), buccally or sublingually (24–48 hours after the mifepristone dose).[2,111] For misoprostol-only regimens, a dose of 800 µg sublingually every 3 hours for two to three doses or every 3 to 12 hours vaginally or buccally for two to three doses.[2] Vaginal administration is considered most effective.[111] The WHO also lists a dose of misoprostol 400 µg instead of 800 µg for the misoprostol-only regimen.[111]

If using methotrexate, 50 mg/m^2 is given IM on day 1 followed by misoprostol 800 µg vaginally 3 to 7 days later.[2] Side effects may include nausea, vomiting, diarrhea, cramping, and vaginal bleeding (heavier than a menses). A repeat dose of misoprostol may be given if bleeding does not occur in 24 hours or abortion has not occurred by follow-up visit in 7 days. With either method, patients should follow up with their health care provider on about day 15 to make

sure the abortion is complete. If complete miscarriage has not occurred, another method may be used, such as aspiration, to remove all pregnancy tissues.

Infertility

Erin C. Raney

CORE PRINCIPLES		CHAPTER CASES
1	Infertility is the inability to conceive after 12 months of unprotected intercourse. A major predictor of infertility is the age of the female. Additional risk factors for both males and females include lifestyle factors, such as tobacco use and obesity, as well as primary and secondary causes of hypogonadism.	**Case 48-1 (Questions 1–3, 6) Case 48-2 (Questions 1, 2)**
2	The evaluation of infertility in females incorporates data from physical examination and laboratory assessments of pituitary and ovarian function. In males, the semen analysis and laboratory assessments of hormone levels provide key information related to gonadal function.	**Case 48-1 (Questions 3–6) Case 48-2 (Questions 1, 2), Figure 48-1, Table 48-2**
		Case 48-1 (Questions

3	Unexplained infertility is diagnosed after a thorough evaluation of both male and female reveals no identifiable cause. Treatment is empiric and often combines ovarian stimulation (OS) with intrauterine insemination (IUI) or in vitro fertilization (IVF).	**7–10)**
4	Clomiphene citrate (CC) is a selective estrogen receptor modulator that is considered a first-line agent for OS in patients with unexplained fertility. Aromatase inhibitors are under investigation as alternative oral agents.	**Case 48-1 (Questions 8–10)**
5	IVF is the most commonly used assisted reproductive technology (ART) or procedure that involves manipulation of oocytes and sperm. Medications are used to stimulate multiple follicles for oocyte retrieval and to optimize implantation after embryo transfer.	**Case 48-2 (Questions 3–9), Table 48-4**
6	OS with gonadotropins is accomplished with follicle-stimulating hormone (FSH) either alone or in combination with luteinizing hormone (LH). A gonadotropin-releasing hormone (GnRH) agonist or antagonist is administered to prevent interruption of the cycle by endogenous hormones. Human chorionic gonadotropin (hCG) is injected in a single dose to finalize follicular development for oocyte retrieval.	**Case 48-2 (Questions 4–7), Tables 48-3, 48-5–48-7, Figure 48-3**

7	A rare but serious complication of OS is ovarian hyperstimulation syndrome (OHSS). The risk is minimized by monitoring the development of follicles carefully with sequential transvaginal ultrasounds and serum estradiol levels.	**Case 48-2 (Questions 5, 7)**
8	Multiple gestation pregnancies are associated with maternal and neonatal risks, including preterm birth and extended neonatal intensive care. These risks are considered when determining embryo transfer and cryopreservation plans.	**Case 48-2 (Question 9)**
9	The diagnosis and treatment of infertility affects the couple emotionally, financially, and socially. Psychosocial support is an important aspect of care from the early phases of evaluation and diagnosis through all stages of treatment.	**Case 48-2 (Question 10), Table 48-8**

INTRODUCTION

Infertility is defined as the inability to conceive after 1 year of regular, unprotected intercourse.[1] The definition is based upon the observation that roughly 85% of couples with normal fertility will achieve pregnancy within 1 year.[2] Data from the National Survey of Family Growth (NSFG) in 2015 to 2017 revealed that 8.8% of females age 15 to 49 years were infertile and 12.7% had used infertility services.[3] Many factors affect infertility rates, but advancing maternal age appears to be a prominent influence.[4] The physiologic factors of reproductive aging are amplified by a trend toward delayed

childbearing in the United States. The mean maternal age at first birth is now ~28 years old, owing to more females delaying pregnancy until their 30s or 40s.[5]

The complex physical, psychological, and social implications have led to a national focus on infertility as a public health priority.[6] Treatment plans vary widely depending on the contributions of both female and male factors. An individualized approach is necessary to balance the risks and benefits of the various therapeutic options and maximize clinical outcomes.

PATHOPHYSIOLOGY AND DIAGNOSIS

CASE 48-1

Question 1: T.R. is a 32-year-old female who presents to her gynecologist with concerns that she and her husband, age 37, have not conceived despite having unprotected intercourse on average two to three times per week for the past 14 months. Her prior contraceptive method was a combined oral contraceptive, which she used for 12 years and discontinued 2 years ago. At that time, the couple used male condoms until 14 months ago, when they stopped using contraception altogether.

What is the recommended initial approach to this couple's concern?

Evaluation of infertility generally begins after a couple has attempted to conceive for at least 12 months without success. Evaluation after just 6 months of unsuccessful conception is recommended in females older than 35 years or in those with a history of conditions associated with infertility, such as amenorrhea, endometriosis, or pelvic inflammatory disease. Females older than 40 years may receive more immediate evaluation and treatment.[7]

This couple has failed to conceive after 14 months of regular, unprotected intercourse, which supports an evaluation of both partners at this time. The diagnostic process first involves a thorough assessment of medical conditions, lifestyle parameters, and medication exposures. This is followed by complete physical

examinations and laboratory assessments with other diagnostic procedures as warranted.

General Risk Factors

Case 48-1, Question 2: Additional information is obtained about the couple's social history. T.R. works as a bank teller, and her husband is a financial planner. Neither T.R. nor her husband smoke tobacco or use illicit substances. Both drink one to two cups of caffeinated coffee each day and drink alcohol socially, an average of one to three drinks each on weekends. What lifestyle factors may contribute to infertility in this couple?

Lifestyle factors such as tobacco or illicit drug use and caffeine intake are known contributors to infertility. In addition to the negative effects on fetal development during pregnancy, tobacco use can worsen ovulatory function. It also induces chromosomal changes that alter sperm function.[8] Caffeine intake should be limited to <200 mg/day. Although a link between alcohol use and infertility is not definitive, complete abstinence from alcohol is recommended once pregnancy is confirmed. The use of illicit substances such as marijuana impairs fertility and decreases the success of fertility treatments. Occupational and environmental exposures to pesticides, heavy metals, and toxins such as organic solvents used in dry cleaning and printing are additional contributors.[9]

The couple's lack of tobacco or illicit drug use eliminates these as potential contributors, and their occupations do not fit known high-risk exposure profiles. T.R. should be counseled on moderating caffeine and alcohol intake. Assessment of other causes of infertility is warranted.

Female Factor Infertility

OVULATORY DYSFUNCTION

Case 48-1, Question 3: T.R.'s medical history is significant for exercise-induced asthma diagnosed at age 10. Her medications include an albuterol inhaler used as needed for shortness of breath. She is 65 inches (165.10 cm) tall and weighs 140 pounds (63.50 kg). Her reproductive history reveals menarche at age 13, no prior pregnancies, and regular menstrual cycles ~25 to 26 days in length since discontinuing the oral contraceptive. She reports the menstrual bleeding phase to be 4 to 5 days in length and does not have excessive bleeding. A physical examination is performed along with a pelvic examination with no notable abnormalities. What information does this provide about possible female factors associated with infertility?

An important focus when evaluating the causes of infertility is ovulatory function, which is associated with up to 40% of female factor infertility.[2] A thorough reproductive history should document age of menarche, menstrual cycle patterns, premenstrual symptoms, and previous pregnancies. A history of regular menstrual cycles of 21 to 35 days with premenstrual symptoms or dysmenorrhea is considered consistent with ovulatory cycles.[2]

Ovarian function is regulated through complex feedback mechanisms within the hypothalamic–pituitary–ovarian axis (see Chapter 50, Disorders Related to the Menstrual Cycle, Fig. 50-1). This involves the release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary gland, and estrogen and progesterone from the ovaries. **Table 48-1** provides an overview of abbreviations commonly associated with diagnosis and management of infertility for use throughout the chapter.

Table 48-1
Common Abbreviations Associated With Infertility Diagnosis and Treatment

ART	Assisted reproductive technology
CC	Clomiphene citrate
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
hCG	Human chorionic gonadotropin

HSG	Hysterosalpingogram
hMG	Human menopausal gonadotropin
IUI	Intrauterine insemination
ICSI	Intracytoplasmic sperm injection
IVF	In vitro fertilization
LH	Luteinizing hormone
OHSS	Ovarian hyperstimulation syndrome
OI	Ovulation induction
OS	Ovarian stimulation

Conditions such as thyroid dysfunction, hyperprolactinemia, and polycystic ovary syndrome (PCOS) can disrupt these feedback mechanisms and induce anovulation. Signs may be evident upon physical examination, including an enlarged thyroid (thyroid dysfunction), abnormal discharge from the breast (hyperprolactinemia), or signs of hyperandrogenism (PCOS). Obesity is another feature associated with PCOS. Conversely, extremely low body weight and excessive exercise may negatively impact ovulatory function at the hypothalamic level. Weight gain improves menstrual regulation in females with anovulation associated with low body fat. Primary ovarian failure can result from exposure to chemotherapy agents or radiation treatments as well as ovarian surgery. As previously discussed, the aging process itself is characterized by diminished ovarian follicular reserve.[2,7]

T.R.'s reproductive history is consistent with regular menstrual cycles that are likely ovulatory. It would be helpful to identify whether she reports any symptoms of premenstrual syndrome or dysmenorrhea, which are associated with ovulatory cycles. Her physical examination is unremarkable, and her medical history does not reveal any conditions associated with anovulation. Her weight is not likely a factor because her body mass index of ~23 kg/m^2 is in the normal range. She has no known history of exposure to chemotherapy or ovarian surgery that could directly impact ovarian function. The only parameter consistent with female factor infertility

is T.R.'s age. At 32 years old, she may be experiencing an initial age-related decline in ovarian function consistent with infertility.

Case 48-1, Question 4: T.R. reports using a home ovulation test kit for the last two menstrual cycles that both yielded positive results. She is referred for a series of laboratory tests with the following findings:

Thyroid-stimulating hormone, 3.2 mIU/L
Prolactin, 8.4 ng/mL
Cycle day 3 FSH, 4 mIU/mL
Cycle day 3 estradiol, 38 pg/mL

What additional information about her ovulatory function can be determined from these results?

Several methods are available to further define ovulatory function. Although basal body temperature monitoring can indicate ovulation, the accuracy of this method is complicated by daily temperature fluctuations, inconsistent measurement technique, and illness. It has largely been replaced by the use of home ovulation test kits that detect urinary LH. The patient initiates daily urine tests during the follicular phase, with the initial testing day determined by the length and regularity of her menstrual cycle (**Fig. 48-1**). A positive test documents the LH surge, signaling that ovulation will occur in an average of 24 hours.[2] Home ovulation test kits that detect changes in cervical mucus or saliva samples are not typically used for diagnostic purposes. They are useful, however, for patients who are timing intercourse during their most fertile period around ovulation.[10] A serum progesterone concentration measured in the mid-luteal phase >3 ng/mL is considered consistent with an ovulatory cycle.[2]

Uterine phases	Menstrual	Proliferative	Secretory	Menstrual
Ovarian ohases	Follicular		Luteal	Follicular

Figure 48-1 The menstrual cycle. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

In patients who are anovulatory, additional laboratory assessments of thyroid function and prolactin levels document potential secondary causes.[2] Elevated testosterone levels may correspond with physical signs of hyperandrogenism and PCOS. The treatment of PCOS is discussed elsewhere (see Chapter 50, Disorders Related to the Menstrual Cycle).

Assessment of ovarian reserve may be performed in females older than 35 years to help guide fertility treatment choices. There are multiple methods that can be used. One involves the measurement of basal levels of serum FSH with or without estradiol between days 2 and 5 of the menstrual cycle, with day 1 being the first day of menses. Because the number of ovarian follicles declines with age, pituitary release of FSH increases. Therefore, an FSH level >10 IU/L suggests diminished ovarian function. A serum estradiol level above the typical level of 60 to 80 pg/mL is also associated with a poor prognosis for success with infertility treatments. A measurement of serum antimullerian hormone <1 ng/mL may also indicate diminished ovarian reserve.[7]

Direct visualization of the ovaries through a transvaginal ultrasound may be used in conjunction with hormone testing. The antral follicles, or those 2 to 10 mm in diameter, are responsive to FSH in the early follicular phase and decline in number with age. An antral follicle count <5 to 7 is considered low and may predict poor ovarian response to various infertility treatments.[7]

The laboratory assessment of T.R. provides additional data regarding her ovarian function. Ovulatory cycles are supported by the positive urinary LH surge with the home test kit as well as the normal (nonelevated) day 3 FSH and estradiol levels. Her normal

thyroid-stimulating hormone and prolactin levels indicate a low probability of secondary causes of anovulation. Because T.R. is younger than 35 and there are no other indicators of ovulatory dysfunction, additional testing of ovarian reserve may not be necessary. The initial findings of T.R.'s infertility assessment show that ovulatory dysfunction is not likely to be a contributor.

STRUCTURAL FACTORS

CASE 48-1, QUESTION 5: Because T.R. has normal ovulatory function, further causes of female factor infertility will be investigated. What testing is recommended to rule out structural causes of infertility?

Structural abnormalities in the uterine cavity or uterine (fallopian) tubes are associated with female factor infertility. These may develop in utero or result from scar tissue or lesions secondary to conditions such as endometriosis. In some cases of endometriosis, surgical interventions improve fertility outcomes, but this is highly dependent on the severity and location of the lesions.[11] Further discussion of the diagnosis and treatment of endometriosis is provided elsewhere (see Chapter 50, Disorders Related to the Menstrual Cycle). Pelvic inflammatory disease from sexually transmitted infections such as chlamydia or gonorrhea is a risk factor for tubal infertility. Impaired cervical mucus production and quality are additional structural factors that can impact sperm motility and the fertilization process.[2]

The use of invasive procedures to explore structural causes of female infertility is dictated by the reproductive history and findings of the physical examination and laboratory tests. Abnormalities of the ovaries, uterus, and uterine tubes are evaluated through various procedures. Transvaginal ultrasonography utilizes vaginal insertion of an ultrasound probe to visualize ovarian structure and developing follicles. A hysterosalpingogram (HSG) is performed to confirm normal uterine tube structure. During this process, dye is injected into the uterus through a catheter and visualized on x-ray to determine any blockages or malformations. Hysteroscopy and

laparoscopy are more invasive procedures that allow for direct visualization of the uterus or pelvic anatomy. These are typically reserved for further examination of abnormalities detected by initial testing.[2,7]

In the evaluation of this couple, it is important to verify T.R.'s sexual history and any possible exposures to sexually transmitted infections. An HSG can determine whether she has patent fallopian tubes and provide basic information about the shape of her uterine cavity. If there are abnormal findings, further hysteroscopic or laparoscopic procedures can be performed. A laparoscopy would fully evaluate any peritoneal adhesions from undetected endometriosis, but her medical history does not warrant this invasive procedure at this time.

Male Factor Infertility

Case 48-1, Question 6: The results of the HSG are normal, so the infertility assessment turns now to the evaluation of T.R.'s husband. He is healthy with no chronic medical conditions or medication use. He denies symptoms of low libido or signs of erectile or ejaculatory dysfunction during intercourse. A complete physical examination, including the genitalia, reveals normal findings. His semen analysis yields the following results:

Semen volume, 5 mL
Sperm number, 400×10^6
Sperm concentration, 112×10^6/mL
Sperm total motility, 65%
Sperm progressive motility, 61%
Sperm vitality, 80%
Sperm morphology, 30%
A second semen analysis confirms these results.

What conclusions about the cause of infertility can be made from these findings?

Infertility is associated with male factors in ~40% to 50% of couples.[7] Male factor infertility is often an outcome of impaired sperm production or function, which can originate from a variety of causes. Impaired sperm production associated with hypogonadism may

result from testicular trauma, cryptorchidism, radiation, or antiandrogen medications.[12,13] Varicoceles, or dilated scrotal veins, affect testicular function in up to 40% of males with infertility. The resulting abnormal venous perfusion and elevated testicular temperature impair spermatogenesis.[14] Genetic conditions may disrupt androgen synthesis or cause defects in the LH or FSH receptor. Azoospermia, or no presence of sperm in the ejaculate, is also apparent in certain genetic disorders, such as Klinefelter syndrome. Pituitary tumors can reduce FSH and LH secretion and impair sperm production. Sperm transport defects result from erectile dysfunction, retrograde ejaculation, or obstruction of the vas deferens or epididymis. Medications such as antidepressants or antihypertensives can worsen libido and ejaculatory function.[12,13]

A complete physical examination of the male is performed to identify signs of androgen deficiency, such as small testicular size or an abnormal pattern of male hair growth. However, the primary evaluation tool for male infertility is the semen analysis. Home test kits for male infertility that utilize a semen sample are not recommended for diagnostic purposes because a positive result merely confirms that the sperm count is above a predetermined level. There is no quantification of the number of sperm or evaluation of sperm quality, so it does not rule out sperm abnormalities. A detailed semen analysis of two samples on different occasions is recommended.[12] The World Health Organization publishes reference values for semen characteristics (**Table 48-2**).[15] Results lower than these cutoff values are not definitive for male factor infertility but do suggest the need to confirm the findings with a second semen analysis.[12]

Table 48-2

Semen Analysis: Lower Reference Limits for Selected Parameters

Parameter	Lower Reference Limit
Semen volume (mL)	1.5
Total sperm number (10^6/ejaculate)	39

Parameter	Lower Reference Limit
Sperm concentration (10^6/mL)	15
Total motility (progressive + nonprogressive, %)	40
Progressive motility (%)	32
Vitality (live spermatozoa, %)	58
Sperm morphology (normal forms, %)	4

Source: World Health Organization, Department of Reproductive Health and Research. *WHO Laboratory Manual for the Examination and Processing of Human Semen*. 5th ed. World Health Organization Press; 2010:224.

Abnormal findings on the semen analysis may be suggestive of the underlying cause of infertility. Low semen volume suggests structural causes of ejaculatory dysfunction. Additional hormone testing, including FSH, testosterone, and prolactin levels, may be necessary to distinguish factors associated with a low sperm count or motility. Low FSH and testosterone are consistent with hypogonadotropic hypogonadism.[12,13]

T.R.'s husband's medical history does not support an identifiable cause of altered sperm production or function. He does not report any signs of sexual dysfunction or take medications that may negatively affect libido or erectile or ejaculatory function. All components of the semen analysis are above the lower limit defined by the World Health Organization. His normal physical examination and medical history do not provide an identifiable male cause of infertility. In this case, the extensive testing of both T.R. and her husband has revealed no obvious contributor to infertility.

TREATMENT APPROACHES

Case 48-1, Question 7: The couple completes their evaluation and is diagnosed with unexplained infertility. What is the initial approach to treatment?

The diagnosis of unexplained infertility, or no identifiable cause after evaluation, accounts for up to 30% of cases.[16] The treatment approach is empiric but typically incorporates medications to stimulate ovulation, often in conjunction with intrauterine insemination (IUI) or other infertility procedures, which are discussed later in this chapter.

Regardless of the treatment approach, all couples pursuing pregnancy are encouraged to avoid tobacco, alcohol, and illicit substances and to limit caffeine intake. The female partner should take a daily supplement containing 400 µg of folic acid to reduce the risk of neural tube defects once pregnancy occurs. Any chronic medications must be evaluated for potential safety issues during pregnancy and discontinued or switched to a safer alternative. Patients are encouraged to achieve and maintain a normal weight.[9] Recommendations pertinent to T.R. include discontinuation of alcohol use, limited caffeine intake, and initiation of a daily multivitamin with 400 µg of folic acid. T.R. should also confirm plans for monitoring her asthma symptoms during pregnancy. Albuterol use during pregnancy will be continued, but the frequency of use will be monitored carefully.[17]

Ovulation Induction and Ovarian Stimulation

Ovulation induction (OI) is utilized in patients who are not ovulating to promote an ovulatory cycle. This method may be accompanied by timed natural intercourse or the use of insemination procedures to achieve pregnancy. Ovarian stimulation (OS) incorporates many of the same medications but is appropriate for patients who are already having ovulatory cycles but are still experiencing infertility. In addition, OS is appropriate for infertility procedures in which the development of multiple ovarian follicles is desirable (Case 48-2).[16] The general approach to medication use with both strategies is described subsequently.

Anovulatory females with adequate ovarian reserve and no other treatable cause are the candidates for OI. This process is designed

to mimic the hormonal patterns of the normal menstrual cycle. FSH guides the initial recruitment and development of ovarian follicles early in the menstrual cycle. This is followed by development of a dominant follicle and increased estradiol levels. The elevated estrogen triggers the LH surge and the release of the ovum mid-cycle for fertilization (see Fig. 48-1). The goal of OI is the development of a single dominant follicle.[18]

The choice of medications for OI is dictated by hypothalamic–pituitary–ovarian function. With adequate hypothalamic function, an oral regimen of CC, which exhibits estrogen agonist and antagonist activity, is often utilized first line. Clomiphene citrate (CC) inhibits estrogen binding in the hypothalamus to stimulate the release of GnRH and pituitary gonadotropins and induce ovarian follicular development. Oral aromatase inhibitors are not approved by the U.S. Food and Drug Administration (FDA) for OI but increase the release of GnRH and pituitary gonadotropins.[19]

If hypothalamic or pituitary dysfunction is detected or if oral regimens are not successful, injectable gonadotropins are administered. The most common gonadotropin regimens use FSH administered either alone or in combination with LH, depending on whether the patient has hypogonadotropic or eugonadotropic hypogonadism (**Table 48-3**).[18,20] Injections are initiated at low daily doses until a dominant follicle has matured. Ovulation is then triggered with an injection of human chorionic gonadotropin (hCG) to simulate the LH surge that naturally occurs mid-cycle. This is timed with natural intercourse or other infertility procedures to achieve pregnancy.[18]

Table 48-3

Gonadotropins for Ovulation Induction/Superovulation

Ingredient	Product Name	Strength/Dosage Form	Route of Admlnistration
hMG (menottopins)	Menopur*	Powdet for reconstilution: 75 IU FSH actlvity and 75 IU LH actMty/vial	SC
Recombinant FSH (fol-litropin alfa)	Gonal-f® multi-dose	Powder for reconstilution: 450 or 1050 IU FSH actlvity/vial	SC
	Gonal-f® RFF 75 IU	Powder for reconstitutlon: 75 IU FSH activlty/vial	SC
	Gonal-f® RFF Redi-(ect	Solution: 300, 450, or 900 IU FSH/pen	SC
Recombinant FSH (fol-lltropin beta)			
	Follistim® AQ cartrldge for Follistim Pen	Solution: 300, 600, or 900 IU FSH/cartridge	SC
Urinary hCG	Chorionic gonadotropin (generic)	Powder for reconstitution: 10.000 IU LH activity/vial	IM
	Pregnyl®	Powder for reconstilution: 10.000 IU LH actlvity/vial	IM
	Novarel"	Powder for reconstitution: 5000 or 10,000 IU LH activity/Vial	IM
Recombinant chorionic gonadotropin alfa	Ovidrel*	FVefilled syringe: 250-pg r-hCG/0.5 mL	SC

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; IM, intramuscular; LH, luteinizing hormone; r-hCG, recombinant human chorionic gonadotropin; SC, subcutaneous.

The oral and injectable medications used for OI are also incorporated into regimens for OS. They are administered in doses and schedules intended to develop multiple ovarian follicles, rather than one dominant follicle. This results in a greater number of oocytes available for fertilization. Because T.R. has ovulatory cycles, but has unexplained infertility, OS is the treatment approach considered most appropriate.

CASE 48-1, QUESTION 8: What medication regimen is recommended for T.R.'s unexplained infertility?

There are multiple methods for ovulation stimulation that utilize oral or injectable medications. CC is a common initial choice because of the convenience and low cost of an oral regimen and the widespread experience with its use.

CLOMIPHENE CITRATE

The competitive binding of CC to estrogen receptors in the hypothalamus stimulates the release of GnRH. This promotes

gonadotropin release from the anterior pituitary, leading to follicular development, increased estradiol production, and ovulation. As previously described, the mechanism of action of CC requires an intact hypothalamic–pituitary–ovarian axis.[16] The typical initial dosing regimen for CC is 50 mg once daily for 5 days starting between days 2 and 5 of the menstrual cycle. Ovulation usually occurs 5 to 10 days after the fifth dose is taken. If ovulation is documented but pregnancy does not occur, the same dose of CC is used in future cycles. If ovulation does not occur, then the dose is increased to 100 mg/day.[19,20]

OS for unexplained infertility with CC is recommended in combination with IUI, because this improves pregnancy and live birth rates over CC either alone or no intervention.[16] IUI introduces a processed semen sample directly to the uterus via a catheter placed through the cervix. The procedure is timed with ovulation to maximize sperm exposure for fertilization. This is accomplished by using a urinary ovulation home test kit to identify the natural LH surge or injecting hCG to trigger ovulation and planning the IUI 24 to 36 hours later. Owing to the nature of the procedure, patients with bilateral obstruction of the fallopian tubes are not the candidates for IUI.[16]

T.R.'s evaluation shows no evidence of hypothalamic or pituitary dysfunction, so she is an appropriate candidate for CC. Once her next cycle begins, she should initiate a 5-day regimen of CC 50 mg once daily starting on the fifth day of menstrual bleeding, with plans for an IUI following documentation of ovulation.

Case 48-1, Question 9: T.R. begins a regimen of CC and experiences hot flashes and nausea but chooses to complete the 5-day course. What is the likely cause of her symptoms?

Vasomotor symptoms are a common cause during a short treatment course of CC, occurring in ~10% of users. Additional side effects include headache, breast tenderness, irritability, mood swings, and nausea. Although visual disturbances are reported in

<2% of patients, symptoms such as blurred vision or light sensitivity should be reported and evaluated to prevent serious complications.[19,20] All medications for OS can result in multiple gestation pregnancies. CC for unexplained infertility is associated with multiple gestation in up to 12.5% of pregnancies.[16]

In this case, T.R. is experiencing side effects commonly associated with CC. They are not treatment limiting, and she is not reporting a change in vision that would require further evaluation. She can safely proceed with treatment by monitoring for an LH surge using a home ovulation test kit and undergoing IUI.

Case 48-1, Question 10: The pregnancy test after the first cycle of CC and IUI is negative. What other options are available for this couple?

Multiple treatment cycles with the combination of CC and IUI are commonly pursued. The aromatase inhibitor letrozole is also a suitable alternative to combine with IUI.

AROMATASE INHIBITORS

The aromatase inhibitor letrozole is supported as an oral alternative to CC, although it is not FDA labeled for this purpose. Aromatase is an enzyme that converts androstenedione to estrone and testosterone to estradiol. Aromatase inhibitors reduce systemic estrogen levels by blocking this conversion in the ovary, resulting in increased gonadotropin secretion and follicular development. The higher concentration of androgens that remains in the ovary increases follicular sensitivity to FSH and further facilitates development.[16]

The recommended administration schedule is letrozole 2.5 or 5 mg once daily for 5 days beginning on cycle days 3 to 5. Pregnancy rates with letrozole appear to be similar to that of CC.[16] Adverse effects experienced with aromatase inhibitors resemble those of CC and include vasomotor symptoms, nausea, and fatigue.[20]

T.R.'s vasomotor symptoms are well-documented with CC. Although the aromatase inhibitors are another oral option, similar

adverse effects may occur. If three to four cycles of OS plus IUI with oral agents are not successful, in vitro fertilization (IVF) is the appropriate next step.[16]

Assisted Reproductive Technology

OVERVIEW AND INDICATIONS

There are a variety of procedures to address infertility factors specific to each couple. Insemination processes are categorized separately from those using assisted reproductive technology (ART), or the manipulation of oocytes and embryos (**Table 48-4**).[21] The Centers for Disease Control and Prevention monitors ART in the United States through the National ART Surveillance System. The use of ART is trending upward, with the number of cycles increasing from just over 122,000 in 2003 to >260,000 in 2016.[22]

Table 48-4

Description of Select Infertility Procedures

Classification	Procedure	Description
Insemination	Intrauterine, intracervical	Delivery of a prepared semen sample to the intended site (cervix, uterus) during ovulation
Assisted reproductive technology	Assisted hatching	Mechanical or chemical separation of the blastocyst from the zona pellucida (membrane surrounding the oocyte) during embryonic development in vitro
	Cryopreservation	Freezing and storage of biologic material (gametes, zygotes, embryos, blastocysts) for future ART cycles
	Gamete intrafallopian transfer	Laparoscopic transfer of the unfertilized oocytes and sperm to the fallopian tube for fertilization
	In vitro fertilization—embryo transfer	Transfer of one or more embryos resulting from in vitro fertilization into the uterus through the cervix

Classification	Procedure	Description
	Intracytoplasmic sperm injection	In vitro injection of the sperm into the oocyte
	Preimplantation genetic testing	Examination of oocytes or embryos for specific genetic abnormalities
	Zygote intrafallopian transfer	Laparoscopic transfer of the fertilized oocyte (zygote) into the fallopian tube

ART, assisted reproductive technology.

Source: Zegers-Hochschild F, Adamson GD, Dyer S, et al. The international glossary on infertility and fertility care, 2017. *Hum Reprod*. 2017;32(9):1786–1801.

The primary ART is IVF, which involves retrieval of oocytes after OS, fertilization in vitro, and transfer of the embryo(s) directly to the uterus through the cervix, bypassing the uterine tubes (**Fig. 48-2**; Table 48-4).[21] Intracytoplasmic sperm injection (ICSI), or the injection of sperm directly into the oocyte during the fertilization process, accompanies IVF if severe sperm dysfunction is evident. A variety of ancillary procedures can be used based upon each couple's history and clinical presentation, including genetic screening and cryopreservation of embryos. ART also allows couples to use donor sperm and/or oocytes to overcome severe sperm or ovarian dysfunction that cannot be addressed through other methods. The option of using donor oocytes uniquely targets infertility due to diminished ovarian reserve.

Figure 48-2 In vitro fertilization process.

CASE 48-2

QUESTION 1: F.J., a 39-year-old female, and her 42-year-old husband are a recently married couple undergoing a comprehensive infertility evaluation after 6 months without conceiving. F.J.'s medical history is positive for seasonal allergic rhinitis, dysmenorrhea, and a history of chlamydia at age 21. Her current screen for sexually transmitted infections is negative. F.J.'s reproductive history reveals menarche at age 11, no prior pregnancies, and regular menstrual cycles ~30 days in length. Her body mass index is 21 kg/m^2. There are no abnormal findings on her physical examination. Her FSH and estradiol levels on cycle day 3 are 7 mIU/mL and 46 pg/mL, respectively. An antral follicle count reveals nine follicles. Her HSG shows complete occlusion of the left uterine tube and partial occlusion of the right uterine tube.

What findings support female factor infertility?

This couple is undergoing evaluation of infertility after only 6 months without conceiving because of F.J.'s advanced age (older

than 35) and history of chlamydia, which places her at increased risk of complications from pelvic inflammatory disease. The occlusion of her uterine tubes is most likely from the chlamydial infection at age 21. Laparoscopy would be necessary to rule out any additional causes such as endometriosis. Further hysteroscopic procedures are warranted to define the location and type of obstruction and to determine whether surgical repair is feasible.[23] Her regular menstrual cycle length and history of dysmenorrhea are supportive of an ovulatory menstrual cycle, and her FSH and estradiol levels as well as antral follicle count show adequate ovarian reserve. She is within the normal weight range and has normal findings upon physical examination. However, further laboratory testing may be warranted to confirm normal thyroid and pituitary function and rule out findings associated with PCOS.

Case 48-2, Question 2: F.J.'s husband has normal findings upon physical examination. His semen analysis yields the following results:

Semen volume, 3 mL
Sperm number, 41×10^6
Sperm concentration, 18×10^6/mL
Sperm total motility, 35%
Sperm progressive motility, 30%
Sperm vitality, 60%
Sperm morphology, 2%

A repeat analysis produces similar results. Additional laboratory findings include:

Testosterone, 650 ng/dL
FSH, 4 mIU/mL
Prolactin, 14.2 ng/mL

What is the significance of these findings for male factor infertility and the choice of ART for this couple?

The semen analysis is significant for sperm motility and morphology values below the lower reference limit defined by the World Health Organization. The semen volume, sperm number, and vitality measurements are just above the lower reference limit (see

Table 48-2).[15] Interventions to improve sperm parameters typically target the underlying cause if possible, such as treatment of hyperprolactinemia or supplementation with testosterone. In some cases, sperm production can be stimulated through the use of gonadotropins or CC. The use of CC is FDA labeled for use in females only, and there is no consensus on the optimal dosage regimen.[24] Given this patient's normal serum testosterone and FSH, CC or gonadotropins are not the recommended therapies. His prolactin is normal as well, ruling out this potential secondary cause. In this case, there is no identifiable cause of the abnormal parameters, so it is deemed idiopathic, without a known etiology.

Antioxidants such as vitamin C, vitamin E, folic acid, zinc, selenium, and L-carnitine are reported to counteract negative effects from oxidative stress on sperm. Some small studies have demonstrated improvement in sperm motility, concentration, and morphology.[25] F.J.'s husband may choose to take a daily antioxidant supplement as they move forward with other treatment modalities.

Insemination procedures are one approach to address abnormal findings on semen analysis. Bypassing the cervix and placing the sperm closer to the fallopian tubes near the time of ovulation can overcome lower sperm counts and motility issues. In regard to this couple, however, F.J. does not have patent uterine tubes and would not be a candidate for IUI. An ART procedure will be necessary to address both female and male infertility factors.

IVF is more appropriate than gamete intrafallopian transfer and zygote intrafallopian transfer due to F.J.'s tubal findings. Although surgical repair of the obstructed uterine tubes may be possible in some cases, many couples choose to bypass this option and pursue ART, especially when there are additional male factors.[23] F.J. will need a surgical evaluation to confirm whether this is recommended before proceeding to ART. F.J. is ovulatory with adequate ovarian reserve, so the use of donor oocytes is not required. Her husband's abnormal sperm parameters can be addressed through ICSI, with the option of using donor sperm in the future, if necessary.

IN VITRO FERTILIZATION

The basic steps in an IVF protocol include OS, oocyte retrieval, fertilization, embryo culture, and embryo transfer. Medications are primarily used during three main stages of IVF: OS, oocyte retrieval, and luteal phase support (**Table 48-5**). Treatment protocols vary widely in the medications used, dosing regimens, and timing of administration.[26] A sample IVF protocol representing F.J.'s experience is provided in **Figure 48-3**.

Table 48-5

Role of Medications in an In Vitro Fertilization Cycle

IVF Stage	Medications[a]	Role
Stage 1: ovarian stimulation	Oral contraceptives	Control the onset of menses and the start of controlled ovarian stimulation
	GnRH agonists or GnRH antagonists	Prevent a premature LH surge or disruption of controlled ovarian stimulation
	Gonadotropins (FSH or FSH plus LH)	Stimulate development of multiple ovarian follicles for oocyte retrieval
Stage 2: oocyte retrieval	hCG	Induce final follicular maturation to prepare for oocyte retrieval
Stage 3: luteal phase support	Progesterone	Maintain the endometrium for embryo transfer and implantation

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

[a]This list reflects the medications most commonly used during each stage. Alternate regimens vary widely by specialist.

Figure 48-3 Sample in vitro fertilization protocol (Case 48-2). GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin.

Case 48-2, Question 3: After the completed evaluation, the couple chooses to undergo IVF with ICSI. What medication regimen is recommended to initiate the IVF protocol?

Stage 1: ovarian stimulation

The purpose of OS for IVF is the development of multiple follicles for oocyte retrieval. Although oocyte retrieval and fertilization can be performed during a normal ovulatory cycle without stimulation, it is more common and many times necessary to use this process.

Oral Contraceptives

OS for IVF is designed to manipulate follicular development for oocyte retrieval at the most optimal stage of maturation. Many protocols start with the administration of oral contraceptives control the timing of the onset of the next menses in order to plan for

initiating the OS regimen.[26,27] This is particularly pertinent in females who have irregular or long menstrual cycles but may be used in those with regular menstrual cycles.

Gonadotropin-Releasing Hormone Analogs

Once the OS process begins, it can be interrupted by an endogenous surge of LH that triggers ovulation prematurely and threatens the success of the cycle. Most protocols use medications to limit the influence of any endogenous hormone levels as the cycle progresses. GnRH agonists have been used for this purpose for several decades. Administration of a GnRH agonist initially increases pituitary gonadotropin release, often referred to as a "flare." Continued daily administration leads to receptor downregulation and reduced pituitary secretion of LH and FSH, allowing for direct administration of the gonadotropins by injection.[27]

IVF regimens in the United States have traditionally either subcutaneous leuprolide or intranasal nafarelin (**Table 48-6**).[20] The leuprolide formulation is often dosed in "units" using an insulin syringe to permit measurement of small volumes. Daily doses of 10 to 20 "units" correspond with 0.5 to 1 mg using the 1-mg/0.2-mL product. Intranasal nafarelin has been studied in doses of 200 to 400 µg twice daily.[26]

Table 48-6

Gonadotropin-Releasing Hormone Analogs for In Vitro Fertilization

Analog	Product Name	Strength/Dosage Form	Route of Administration
GnRH agonist	Nafarelin acetate (Synarel®)	2 mg/mL solution (200 µg/spray)	Intranasal
	Leuprolide acetate	1-mg/0.2-mL kit	SC
GnRH antagonist	Cetrorelix acetate[a] (Cetrotide®)	0.25-mg kit	SC
	Ganirelix acetate[a]	250-µg/0.5-mL syringe	SC

GnRH, gonadotropin-releasing hormone; SC, subcutaneous.

[a]FDA labeled for use with assisted reproductive technology procedures.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

Treatment protocols are identified by the timing of GnRH agonist administration. In a traditional “long” protocol, a GnRH agonist is initiated during the follicular or luteal phase of the preceding menstrual cycle. Once gonadotropins are initiated, the GnRH agonist is continued at half the daily dose until ovulation is stimulated. If an oral contraceptive is used for pretreatment, the GnRH agonist is often initiated within the last week of the contraceptive regimen. In a “short” protocol, a GnRH agonist is administered in conjunction with the gonadotropins for the stimulation cycle. When used in this manner, the flare, or initial increase in gonadotropin production, aids in the initial recruitment and development of follicles. Many other variations of the long and short protocols that adjust the length of GnRH agonist use, dose, and timing of discontinuation are utilized, with wide variability among clinics.[26,27]

Alternatively, the immediate suppression of gonadotropin secretion using GnRH antagonists such as cetrorelix and ganirelix allows for a shorter duration of administration and improved convenience and is associated with a lower risk for ovarian hyperstimulation syndrome (OHSS) (see Table 48-6).[27,28] The GnRH antagonists are administered after the gonadotropin-induced follicular development is established, as either a higher dose single injection or a lower dose daily injection that is continued until ovulation is triggered.[27] Ganirelix is administered as a daily 250-μg subcutaneous injection, and cetrorelix is either a daily subcutaneous injection of 0.25 mg or a single 3-mg dose.[20] The timing of initiation is either “fixed” on a particular day of stimulation or “flexible” based on follicular development.[27] Available data suggest that there is no difference in pregnancy and live birth rates between GnRH agonist and antagonist protocols.[27,28]

In this case example, a protocol using a GnRH agonist is chosen for F.J. For the preparation phase, an injectable (such as leuprolide) or intranasal (nafarelin) product can be used. The administration of GnRH analogs in the long protocol is associated with hot flashes, headaches, and sleep disturbances due to hypoestrogenic effects. Local reactions at the injection site and nasal and throat irritation are adverse effects expected with the subcutaneous and intranasal

routes of administration, respectively.[20] However, the symptoms and duration of her seasonal allergic rhinitis should be clarified because the absorption of the intranasal product can be affected by sneezing, congestion, and the use of other intranasal medications. After discussion, F.J. agrees to administer leuprolide injections. Once she experiences her next menses, she will begin 21 days of an oral contraceptive. On day 16 of this regimen, she will initiate leuprolide 1 mg once daily as a subcutaneous injection in conjunction with the oral contraceptives. A calendar will be provided to help her track the daily doses.

Gonadotropins

Case 48-2, Question 4: F.J. completes the oral contraceptive regimen and starts her menses. A baseline ultrasound rules out ovarian cysts and confirms ovarian suppression. She continues daily injections of leuprolide at a dose of 0.5 mg once daily (half the initial dose) upon initiation of gonadotropins for follicular development. What is the recommended gonadotropin regimen for F.J.?

The exogenous administration of FSH either alone or in combination with LH is intended to mimic the natural process of follicular recruitment and maturation. Gonadotropins are available from urinary and recombinant methods (see Table 48-3).[20] Human menopausal gonadotropin (hMG) was the first gonadotropin used in the United States as early as the 1950s. The product is extracted from urine of postmenopausal females and standardized to contain 75 IU each of FSH and LH activity. Both LH and hCG are present in the preparation and contribute to the LH activity. The development of the recombinant FSH products (follitropin alfa and follitropin beta) further expanded treatment options in the late 1990s. Although they have unique chemical structures, they result in clinically similar effects.[27]

Dosage regimens for the gonadotropins are intended to promote multiple follicles for oocyte retrieval and vary widely among clinics. A common starting dose in fixed-dose protocols is 150 to 225 IU daily,

with further dose adjustments made based on the status of the developing follicles. Treatment may continue for 7 to 12 days, although longer courses may be necessary depending on follicular response. If subsequent cycles are needed, the initial treatment doses are chosen based on the stimulation achieved in the first cycle. Lower or higher gonadotropin doses may be recommended for patients predicted to be high or low responders, respectively.[27,28] F.J. is undergoing her first cycle of IVF and has no signs of hypothalamic or pituitary dysfunction, so she can receive FSH either alone or in combination with LH. The two recombinant FSH formulations are available in pen injection devices that avoid the need for reconstitution and reduce the complexity of the injection (see Table 48-3).[20] Patient education should focus on product-specific instructions for storage, preparation for injection, and the correct subcutaneous injection technique. All products have patient-friendly video demonstrations or handouts available on the Internet to facilitate this process. (For helpful training videos and patient handouts that describe the dose preparation and injection technique, see https://www.ferringfertility.com/wp-content/themes/fercor/pdf/IVF-Explained_011817.pdf, and https://www.ferringfertility.com/our-fertility-offerings/.) The patient should be instructed to anticipate possible injection-site reactions as well as psychological symptoms of irritability, mood swings, and depression, which may increase during this phase.[26,27]

After consideration of these issues, a recombinant FSH product is chosen for F.J. because of the convenience of the pen device. She will begin a dose of 225 IU of recombinant follitropin alfa injected subcutaneously once daily.

Case 48-2, Question 5: F.J. begins daily subcutaneous injections of follitropin alfa in addition to her leuprolide injections. What medication monitoring should be provided at this time?

The goal of gonadotropin therapy is to guide the development of multiple follicles for oocyte retrieval without increasing the risk for

OHSS, a rare but serious complication of OS. In its most severe form, this syndrome is characterized by increased systemic vascular permeability that can result in ovarian rupture, thromboembolism, renal failure, and acute respiratory distress syndrome. The risk for this condition correlates most directly with the development of multiple ovarian follicles. Additional risk factors appear to include younger age, low body weight, and history of PCOS or ovulation disorder. Routine monitoring of ovarian follicular development allows the clinician to maximize efficacy and reduce the risk for overstimulation.[29]

Typical monitoring includes vaginal ultrasounds with or without serum estradiol measurements performed every 1 to 3 days during the OS phase. The monitoring frequency increases as the follicular development advances, and the gonadotropin doses may be reduced or increased depending on the number and size of the follicles. If hyperresponse is evident, the cycle may be canceled before oocyte retrieval.[28,29]

Once F.J. initiates therapy, she is scheduled for vaginal ultrasound measurements every other day. This increases to daily monitoring on day 7 of the combination of leuprolide and follitropin alfa because the number and size of the follicles continue to increase.

Stage 2: oocyte retrieval

Chorionic Gonadotropin

Case 48-2, Question 6: F.J. presents for her daily monitoring on day 10, and it is determined that she is ready for oocyte retrieval. What medication regimen is recommended at this time?

Chorionic gonadotropin is administered in preparation for oocyte retrieval to simulate the effect of the physiologic LH surge on final oocyte maturation. The oocyte retrieval must be carefully timed to coincide with the completion of the oocyte maturation process, just before ovulation. Many clinics schedule oocyte retrieval between 34 and 36 hours after chorionic gonadotropin is injected.

Chorionic gonadotropin is available from urinary or recombinant sources. The urinary hCG product is administered as a single intramuscular injection of 5000 to 10,000 IU.[20] The dose of the recombinant product is 250 µg injected subcutaneously.[20] A single dose of a GnRH agonist is an alternate method of triggering LH release in IVF protocols that incorporate a GnRH antagonist.[27]

F.J. is instructed to inject a single 250-µg dose of recombinant chorionic gonadotropin subcutaneously. She will discontinue leuprolide and follitropin alfa at this time.

Ovarian Hyperstimulation Syndrome

Case 48-2, Question 7: F.J. undergoes a transvaginal oocyte-retrieval procedure 36 hours after the administration of recombinant chorionic gonadotropin, and there are nine oocytes available for fertilization. What additional counseling is recommended for F.J. after the oocyte retrieval?

As previously described, OHSS is a rare complication associated with OS. If symptoms develop, it is typically within 1 to 2 weeks after oocyte retrieval. It is generally categorized as mild, moderate, or severe and can occur early (within 10 days after oocyte retrieval) or late (after 10 days, often associated with a pregnancy). The clinical signs of OHSS are thought to result from increased capillary permeability owing to high levels of vascular endothelial growth factor. A mild presentation of OHSS consists primarily of gastrointestinal symptoms (abdominal pain, nausea, diarrhea, bloating) or weight gain, especially abdominal distension. A patient experiencing these symptoms will be instructed to avoid physical activity, maintain oral fluid intake, and monitor daily weights and urine output. More intensive outpatient monitoring of liver and renal function, electrolytes, and hematologic parameters may be necessary. If the condition progresses, the patient may require hospitalization for the treatment of severe outcomes, such as thromboembolism, renal failure, pulmonary distress, or ovarian rupture.[29,30]

There were no initial indications of hyperstimulation during F.J.'s OS regimen, so she will be instructed to monitor for signs of OHSS during the 2 weeks after oocyte retrieval. She should notify her physician if she experiences gastrointestinal symptoms or weight gain, even if the symptoms are mild. This will facilitate early monitoring to maximize safety during the remainder of the IVF process.

Stage 3: luteal phase support

Progesterone

Case 48-2, Question 8: After the oocyte retrieval, F.J. is in need of a regimen for luteal phase support. Which agent should be selected?

Supplemental progesterone is administered immediately after oocyte retrieval to provide additional "luteal phase support" during IVF. The luteal phase of the menstrual cycle (see Fig. 48-1) is dominated by progesterone released by the corpus luteum that prepares the endometrium for implantation of the fertilized ovum. The disruption of follicles during the oocyte-retrieval process delays the production of progesterone, necessitating supplementation. In addition, cycles that utilize a GnRH agonist may be complicated by residual inhibition of pituitary LH secretion and progesterone production into the luteal phase. The use of hCG, GnRH agonists, and estradiol for luteal phase support has been investigated; however, progesterone is the most common.[31]

Progesterone is available in oral, vaginal, or injectable formulations (**Table 48-7**).[20] Intramuscular injection of progesterone in oil in a daily dose of 50 mg was the first method used for supplementation and continues to be widely used. However, alternatives to progesterone in oil have been sought because of frequent reports of rash and discomfort at the injection site.[27,31]

Table 48-7

Commercially Available Progesterone Products Used in

Assisted Reproductive Technology

Product Name	Strength/Dosage Form	Route of Administration
Crinone®	8% vaginal gel[a]	Vaginal
Endometrin®	100-mg vaginal insert[a]	Vaginal
FIRST®-Progesterone VGS	100-, 200-mg vaginal suppository (compounding kit)	Vaginal
Progesterone®	50 mg/mL (oil)	Intramuscular
Prometrium®/micronized progesterone	100-, 200-mg capsule	Oral

[a]FDA labeled for luteal phase support.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

Vaginal progesterone preparations have gained popularity for luteal phase support owing to ease of administration and avoidance of injection-site reactions. The 8% progesterone vaginal gel and the 100-mg vaginal insert are the only commercially available FDA-labeled preparations for use in ART procedures. The gel is administered as one 90-mg applicator once or twice daily. The dose of the vaginal insert is 100 mg either twice a day (every 12 hours) or three times a day (every 8 hours).[20,28,31] Patient education should focus on the correct technique for intravaginal administration. Both products utilize a disposable applicator to facilitate correct placement. (Detailed patient instructions are provided by both manufacturers: https://www.ferringfertility.com/products/endometrin/; https://www.allergan.com/assets/pdf/crinone_pi.) The vaginal preparations may cause local irritation and vaginal discharge, although the vaginal gel is generally associated with less discharge than the inserts or suppositories. Clinical studies suggest no difference in pregnancy rates between vaginal and intramuscular formulations, so clinician and patient preferences often dictate the selection.[27,31]

Oral formulations are not recommended for the purpose of luteal phase support with ART because of lower absorption and reduced

pregnancy rates.[28,31] Compounded formulations are widely available, including oral micronized progesterone and progesterone vaginal suppositories, gels, and creams. In some cases, patients are instructed to insert oral progesterone formulations intravaginally.

Because the efficacy of the parenteral and vaginal formulations is similar, F.J. chooses the vaginal route. She is most comfortable with 8% progesterone vaginal gel applied once daily and is given instructions regarding the appropriate administration technique. Progesterone is initiated after oocyte retrieval until a pregnancy test is performed and may be continued until at least 8- to 10-week gestation, depending on the type of cycle protocol.[31]

Embryo Transfer

Case 48-2, Question 9: The IVF process using ICSI yields four cleavage-stage embryos. What considerations are necessary for embryo transfer?

After fertilization, the timing of the embryo transfer into the uterus depends on the stage of development. Cleavage-stage embryos are transferred 2 to 3 days postfertilization, whereas embryos in the blastocyst stage are transferred at day 5 or 6.[32] The number of embryos placed during this process must balance the risks of a multiple gestation pregnancy with the likelihood of successful implantation.

Multiple gestation pregnancies are associated with increased maternal and neonatal morbidity. The mother is at risk for complications such as premature labor, pregnancy-induced hypertension, and gestational diabetes. Preterm labor occurs in ~15% of single gestation pregnancies compared with 75% of triplet pregnancies. The neonates are more likely to experience fetal growth restriction and require intensive care for pulmonary, gastrointestinal, and neurologic complications.[33] Additional stressors include the financial and psychosocial implications of raising children with complex medical needs that may persist beyond infancy.[33]

F.J. is 39 years old experiencing her first cycle of IVF. The American Society for Reproductive Medicine (ASRM) has developed embryo transfer recommendations to limit high-order multiple pregnancies (three or more implanted embryos). Based on her age, if the embryos are judged to have good-quality morphology, no more than three cleavage-stage or two blastocysts should be transferred according to the ASRM guidelines.[32] A pregnancy test will be performed 9 to 12 days after the embryo transfer to determine the outcome of the cycle.

Long-term considerations

Alternate Protocols

Case 48-2, Question 10: After careful consideration, the couple decides to transfer two cleavage-stage embryos and reserve two for cryopreservation. Unfortunately, the embryo transfer procedure is unsuccessful, and the couple plans to pursue a second procedure. What considerations are necessary for future cycles?

Determining an action plan for subsequent procedures requires a thorough evaluation of the response to therapy during the first cycle. If OS is repeated for oocyte retrieval, hormone levels, follicular development, fertilization rates, and the numbers of viable embryos are all considered to determine whether dosage adjustments or alternate medication protocols are necessary. The European Society of Human Reproduction and Embryology suggests specific OS protocols for patients exhibiting low, normal, or high response in previous procedures.[28]

In this case, F.J. experienced adequate follicular development for oocyte retrieval without signs of OHSS. The fertilization procedure was successful, and two embryos were cryopreserved for future procedures. The couple can choose to avoid another stimulation process for oocyte removal and move to frozen embryo transfer. Medications remain important for the frozen embryo transfer process, which can occur in a natural cycle or a cycle induced

through the use of estrogen and progesterone, with or without GnRH agonists.[34]

Psychosocial Issues

The financial impact of ART is substantial. The ASRM cites the average cost of an IVF cycle in the United States to be between $10,000 and $15,000.[35] Costs vary widely between clinics, and many offer financial counseling and payment packages to facilitate treatment. In addition, the psychological stress of the diagnosis and treatment of infertility must be considered at all stages. For couples who undergo successive ART procedures, repeated failures are commonly accompanied by feelings of grief and frustration, and psychological distress is often the reason for discontinuing treatments. Levels of emotional distress, including symptoms of depression and anxiety, can increase with each unsuccessful cycle. This response appears to remit immediately with a successful pregnancy, but in those who continue to be unsuccessful, symptoms can still be significant even months posttreatment.[36]

This couple should be offered individual counseling and social support that extends beyond the initial pretreatment consultation to promote positive outcomes.[36] There are several patient-focused resources for informational fact sheets and videos, highlighting the financial, medical, and psychosocial issues of infertility (**Table 48-8**).

Obstetric Drug Therapy

Trisha LaPointe

CORE PRINCIPLES		CHAPTER CASES
1	The timing and quality of prenatal care can influence an infant's health and survival. Early comprehensive care can promote healthier pregnancies through early detection of risk factors, disease-state management, and encouragement of healthy behaviors.	**Case 49-1 (Questions 1–3)**
2	Important physiologic changes occur in almost all maternal organs during pregnancy to support the growth and development of the fetus.	**Case 49-1 (Question 4)**
3	Drug use during pregnancy presents a significant challenge to clinicians because of the potential adverse effect on the embryo, fetus, and newborn. A thorough assessment, including	**Case 49-1 (Question 5)**

	knowledge of the teratogenic potential of the drug, the critical period of exposure, and magnitude of risk, must be compared with the background risk.	
4	Gastrointestinal (GI) disturbances such as nausea and vomiting and gastric reflux that occur during pregnancy are common. Treatments include intravenous (IV) hydration, pyridoxine (vitamin B_6), antihistamines, and antiemetics for nausea and vomiting. Calcium carbonate, H_2-receptor antagonists, and proton-pump inhibitors may be used for reflux.	**Case 49-1 (Questions 6–10)**
5	Urinary tract infections can frequently occur during pregnancy and can easily be treated with nitrofurantoin, cephalexin, or penicillin if cultures are sensitive.	**Case 49-1 (Question 11)**
6	Diabetes mellitus is the most common maternal medical complication during pregnancy. Tight glycemic control can minimize neonatal and fetal morbidity and mortality associated with diabetic embryopathy.	**Case 49-2 (Questions 1–4) Case 49-3 (Questions 1, 2) Case 49-4 (Questions 1–4)**
7	Patients with pregnancy-associated hypertension can be grouped into the following categories: chronic hypertension, preeclampsia–eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.	**Case 49-5 (Questions 1–13)**

8	The induction of labor involves the artificial stimulation of uterine contractions that lead to labor and delivery.	**Case 49-6 (Questions 1–5)**
9	Premature birth is the leading cause of neonatal mortality (infant death age <1 month). Tocolytic therapy to stop contractions, corticosteroids for fetal lung maturity, and antibiotics for preterm premature rupture of membranes can help prolong the pregnancy.	**Case 49-7 (Questions 1–7)**
10	Infectious complications, including bacterial vaginosis and urinary tract infections, can lead to preterm labor. Chorioamnionitis, an infection of the chorion and amnion usually diagnosed during labor with elevations in temperature, should be treated with IV antibiotics until delivery. Patients infected with the human immunodeficiency virus (HIV) should receive IV zidovudine and continue their antiretroviral regimens during labor.	**Case 49-7 (Questions 8–11) Case 49-8 (Questions 1, 2)**
11	Obstetric postpartum hemorrhage is one of the top three causes of maternal mortality in the United States. Pharmacologic therapy for uterine atony includes oxytocin, methylergonovine, carboprost, misoprostol, and dinoprostone.	**Case 49-8 (Questions 3, 4)**
12	Alloimmunization occurs when a patient who is Rh D negative becomes	**Case 49-9 (Questions 1–5)**

	immunized after exposure to fetal erythrocytes that carry the D antigen. Rh_o(D) immune globulin should be given to all patients who are Rh D negative at 28 weeks' gestation.	
LACTATION AND DRUGS IN BREAST MILK		
1	Breast milk is recognized as the optimal source of nutrition for infants, with documented benefits not only to infants but also to mothers, families, and societies, and breast-feeding should be encouraged if possible.	**Case 49-10 (Questions 1, 2) Case 49-11 (Question 1)**
2	Most drugs are excreted in breast milk. The pharmacologic and adverse effects on the infant will be determined by the extent of oral bioavailability, distribution, metabolism, and rate of elimination. A milk-to-plasma ratio can be used to estimate the drug concentration in milk. The relative infant dose (RID) can be calculated to estimate the infant's exposure based on the volume of milk ingested.	**Case 49-8 (Question 2) Case 49-12 (Question 1) Case 49-13 (Question 1)**

INTRODUCTION

Parity and *gravida* are terms used to describe a pregnant person. Parity is the number of deliveries after 20 weeks' gestation. Parity is independent of the number of fetuses delivered (live or stillborn, single fetus, or twins) or the method of delivery. *Gravida* refers to the number of pregnancies a person has had regardless of the outcome.

For example, a person who is currently pregnant and has previously delivered one set of twins and had two spontaneous abortions is described as a gravida 4, para 1 (G4, P1).

Trimesters of Pregnancy

The average pregnancy is ~40 weeks when calculated from the first day of the last menstrual period (LMP). Pregnancy is typically divided into three trimesters, ~13 to 14 weeks each.[1] The first trimester includes the critical period of organogenesis, the time in which most of the vital organs are developing, which occurs between weeks 5 and 10. The time between the end of the 20th week of gestation and the end of the 28th day after birth is considered the perinatal period.

Delivery

Depending on the gestational age at the time of delivery, the result can be an abortion, preterm, term, or postterm birth. An abortion is a delivery before 20 weeks' gestation. A term infant is a fetus delivered between 37 and 42 weeks' gestation. A preterm birth is one occurring between 20 and 37 weeks' gestation, and a postterm (postmaturity) birth occurs after the beginning of 42 weeks' gestation. Parturition refers to labor, and the puerperium is the 6 to 8 weeks after delivery.

Preconceptional Care

CASE 49-1

Question 1: S.C. is a 29-year-old, G1, P1 female who is interested in becoming pregnant. Her past medical history is significant for hypothyroidism. She currently is taking levothyroxine 88 µg orally (PO) daily.

How would you provide appropriate counseling to S.C. with regard to preconceptional care?

It is estimated that 3.6 million live births were registered in the United States in 2020, with an estimated 77.7% of patients beginning prenatal care in the first trimester. This can be contributed to several statewide initiatives to increase education and access to prenatal care.[2] Although much improved, prenatal care is still not easily accessible to all patients. Early comprehensive care can promote healthier pregnancies through early detection of risk factors, disease-state management, and encouragement of healthy behaviors, and will help ensure normal fetal organogenesis. Appropriate preconception counseling and treatment of patients with preexisting high-risk medical conditions, such as diabetes, hypertension, and epilepsy, can greatly improve pregnancy outcomes. In 2019, the mortality rate in the United States (from birth through the first year of life) for infants of patients beginning prenatal care in the first trimester was 5.58/1000 live births.[3]

S.C. should see her primary care provider for regular physical examinations and evaluation of her thyroid function before becoming pregnant. Her first prenatal visit should generally occur by 8 weeks' gestational age when she becomes pregnant.[4]

Vitamins and Mineral Supplementation

Case 49-1, Question 2: S.C. asks you to recommend vitamin and mineral supplementation. When should she begin taking these vitamins and minerals?

A balanced diet that provides S.C. with multiple B vitamins, oil-soluble vitamins (A, E, D, and K), folic acid, and minerals (iron, calcium, phosphorus, magnesium, iodine, zinc) should be encouraged. S.C. should be started on a prenatal multivitamin if she has not yet started taking one. Prenatal vitamins should be taken months before conception to ensure that proper nutritional requirements are met during critical periods of organogenesis and fetal growth.

IRON REQUIREMENTS

Iron requirements increase during pregnancy because of maternal blood volume expansion, fetal needs, placenta and cord needs, and blood loss at the time of delivery.[5] Maternal iron deficiency can cause anemia during infancy, spontaneous abortion, premature delivery, and delivery of a low-birth-weight infant, and is associated with low neonatal iron stores.[5,6]

A female needs about 18 to 21 mg of iron/day during pregnancy; the body compensates by increasing iron absorption from the gastrointestinal (GI) tract by about 15% to 50%.[5] The average diet of patients in the United States does not meet these requirements because only about 6 mg of iron is absorbed from 1000 kcal of food. In addition, some patients may already have inadequate body stores of iron before pregnancy. For these reasons, the Centers for Disease Control and Prevention recommends screening for iron deficiency in pregnancy in addition to universal iron supplementation except when genetic conditions such as hemochromatosis are present.[7] Prenatal vitamins usually contain 30 to 60 mg of elemental iron. Patients with iron deficiency anemia should be given 60 to 120 mg of elemental iron daily. Iron deficiency anemia during pregnancy generally is associated with a hemoglobin and hematocrit <11 mg/dL and <33%, respectively, during the first and third trimesters or <10.5 mg/dL and <32%, respectively, during the second trimester. The classic morphologic changes observed in the erythrocytes in iron deficiency outside of pregnancy, hypochromia, and microcytosis are not prominent in pregnant patients. Serum ferritin, however, is low, which has the highest sensitivity and specificity for diagnosing iron deficiency.[6] S.C.'s hemoglobin and hematocrit should be assessed now and again at 26 to 28 weeks' gestation. If her hemoglobin and hematocrit are normal, the amount of iron in her prenatal vitamin should be sufficient.

FOLATE REQUIREMENTS

Folic acid is essential in the synthesis of DNA and RNA. Pregnant patients who take 0.4 to 0.8 mg of folic acid daily during the first trimester of pregnancy are significantly less likely to have a child with

neural tube defects (NTDs), such as spina bifida and anencephaly.[8,9] NTD can lead to stillbirth, neonatal death, or serious disabilities. Approximately 4000 pregnancies in the United States are affected by NTD each year.[9]

NTDs develop within the first month of pregnancy at a time when many patients are unaware of their pregnancy.[9,10] In 1992, the U.S. Public Health Service recommended that all patients with childbearing potential should consume 0.4 mg/day of folic acid to reduce the risk of an NTD-affected pregnancy.[11]

It may be difficult to meet the recommended daily allowance (RDA) for folic acid because foods contain only a small amount of this vitamin; overcooking and high-fiber diets also can reduce the amount of available folic acid from food. Most prenatal vitamins contain 0.8 to 1 mg of folic acid.

Folic acid supplementation is especially important in patients with a history of infants born with NTD. Patients who have had an NTD-affected pregnancy should receive genetic counseling because they have a 2% to 3% risk of having another such outcome. Patients with previous NTD-affected pregnancies who plan another pregnancy should take 4 mg/day of folic acid at least 1 month before conception and through the first 3 months of pregnancy.[11]

Patients who require 4 mg/day of folic acid should be prescribed folic acid tablets as an addition to combination prenatal multivitamins (which contain folic acid), rather than just increasing the number of multivitamin tablets. When several fixed-combination multivitamin tablets are taken daily, the patient could be exposed to a potentially teratogenic dose of vitamin A. High doses of folic acid do not prevent NTD better than 0.4 mg/day in patients without a previous history of NTD-affected pregnancies and may complicate the diagnosis of a vitamin B_{12} deficiency.[9]

S.C. should be counseled about the risks of NTD, and given she has no history of NTD, she should receive adequate folic acid during the remainder of her pregnancy from a daily prenatal vitamin.

CALCIUM REQUIREMENTS

Calcium is needed during pregnancy for adequate mineralization of the fetal skeleton and teeth, especially during the third trimester when teeth are formed and skeletal growth is greatest. The RDA for calcium during pregnancy is 1000 mg/day for females ages 19 years and older, and 1300 mg/day for teenagers younger than age 19 years.[12] Large maternal stores can provide calcium if dietary intake is inadequate; however, depleting maternal stores may put S.C. at risk for osteoporosis later in life. Foods rich in calcium (eg, milk, cheese, yogurt, legumes, nuts, dried fruits) or calcium supplements can be used to meet the calcium RDA.

Commercially Available Home Pregnancy Tests

Case 49-1, Question 3: S.C. starts prenatal vitamins that contain iron and folic acid immediately. Two months have passed, and now S.C. believes that she may be pregnant because per period is a couple of weeks late. She requests your assistance in selecting an over-the-counter commercially available home pregnancy test. How do these home pregnancy tests work and how should S.C. be counseled?

Commercially available home pregnancy tests are enzyme immunoassays with monoclonal or polyclonal antibodies that bind to human chorionic gonadotropin (hCG) in the urine.[13] hCG is detected in the maternal circulation and urine ~8 to 10 days after conception.[14] Concentrations in the urine closely parallel those in the maternal blood. The hCG serum concentrations increase rapidly, doubling every 2 days. Peak concentrations are achieved at 60 to 70 days of pregnancy. Thereafter, hCG concentrations decline and reach a low by ~120 days, at which point concentrations are maintained for the remainder of the pregnancy.[14]

hCG is composed of an α- and a β-subunit. The α-subunit is identical to the α-subunit of other pituitary hormones (eg, follicle-stimulating hormone, luteinizing hormone, thyroid-stimulating hormone); however, the β-subunit is specific to hCG. Pregnancy tests specific for this β-subunit are useful diagnostic tests for

confirming pregnancy.[1] They can provide accurate results within 1 to 2 weeks of ovulation.[1,13] Several kits are available. The tests can be performed privately and quickly and are easily interpreted. The results are obtained rapidly—within 1 and 5 minutes—and are highly accurate when performed at the start of the first missed menstrual period. Although home pregnancy tests are reportedly 98% to 100% accurate when used correctly, consumer studies have documented accuracy rates as low as 50% to 75% if product directions are not precisely followed.[13] Many home pregnancy tests include a second test, which should be repeated at a specified time after the first negative test result.

S.C. should purchase a product containing two tests and follow the instructions carefully. If the first test result is negative, S.C. should repeat the test in 1 week if she has not started menstruating. False-negative results occur when testing is done before the first day of a missed period or if the urine is not at room temperature.[13] False-negative results can also occur with an ectopic (outside the uterus) pregnancy or in patients with ovarian cysts and in those receiving menotropins or chorionic gonadotropin.[13] False-positive pregnancy test results are rare but can occur with serum testing if the person has circulating heterophilic antibodies directed against the animal-derived antigen used in pregnancy tests. These antibodies will not interfere with urine assays, however, because they are not present in urine.[15]

S.C.'s home pregnancy test result is positive. Because she is pregnant, she should be counseled on the possible fetal effects of any medications or herbal products she may be taking and advised to see her primary care provider as soon as possible.

Pregnancy-Induced Pharmacokinetic Changes

Case 49-1, Question 4: S.C. is now 6 weeks pregnant. She is concerned about any possible changes that might occur with her medications (levothyroxine 88 µg PO daily, prenatal vitamins). What pregnancy-induced pharmacokinetic changes that will affect her medication use might occur?

Important physiologic changes occur in almost all maternal organs during pregnancy to support the growth and development of the fetus. These physiologic changes affect the cardiovascular, respiratory, and GI systems; plasma volume, renal function, and hepatic enzymes can alter the absorption, distribution, metabolism, and elimination of drugs.[16] Alterations in the pharmacokinetics of drugs are influenced mainly by two factors: (a) maternal physiologic changes and (b) the effects of the placental–fetal compartment.[17]

ABSORPTION

Pregnancy-induced changes affecting drug absorption are (a) a decrease in intestinal motility owing to smooth muscle relaxation by progesterone, resulting in a 30% to 50% increase in gastric and intestinal emptying times; (b) a 40% decrease in gastric acidity, which increases gastric pH; and (c) altered bioavailability or absorption attributable to increased incidence of nausea and vomiting. Bioavailability may be increased for acid-labile drugs and decreased for drugs that require an acid medium for stability. Prolonged gastric and intestinal emptying times may decrease the maximum concentration (C_{max}) of a drug and the time to reach C_{max}, whereas the increased intestinal transit time may increase the area under the curve (AUC) and bioavailability of a drug. In contrast, pregnancy-induced vomiting may decrease the amount of drug ingested; it is therefore better to schedule medications during the evening when the incidence of nausea and vomiting is lower, or to use the rectal route for drug administration. In summary, the effect of pregnancy on drug absorption is variable and depends greatly on the physicochemical properties of the drug.[17] Increased blood flow to the maternal skin, which helps dissipate fetal heat production, may also increase the absorption of a topically (transdermal) administered medication.[16]

DISTRIBUTION

Changes in protein binding and increased plasma volume can theoretically increase the apparent volume of distribution (V_d) of

drugs during pregnancy. Plasma volume increases by 6 to 8 weeks' gestation and continues to expand to 40% to 50% above pregnancy volumes by 32 to 34 weeks' gestation.[16,17] Plasma volume expands even more with multiple gestations. The total body water (TBW) increases by 8 L; 40% of this increase can be attributable to the patient and 60% to the fetal–placental unit. This increase in TBW necessitates larger loading doses of water-soluble drugs (eg, aminoglycosides) because of the increase in V_d. A decrease in the C_{max} would be expected.

Plasma albumin concentrations decrease during pregnancy, mostly because of dilution by the increased plasma volume.[16,17] Albumin concentrations may also be decreased as a result of decreased synthesis or increased catabolism.[16] In addition, increased concentrations of steroid and placental hormones may decrease protein-binding sites for drugs.[18] These changes in protein binding generally result in decreased protein binding, increased free fraction (f_u) of drugs, and increased clearance of drugs when clearance is dependent on f_u (eg, valproic acid, carbamazepine).[18] When both f_u and intrinsic clearance are increased as is the case with increased cytochrome P450 (CYP) enzyme activity, both the total and free concentrations are decreased (eg, phenytoin, phenobarbital).[19] Total protein and α_1-acid glycoprotein concentrations remain fairly unchanged.

METABOLISM

Protein binding, activity of hepatic enzymes, and liver blood flow determine the hepatic clearance of drugs. Increases in estrogen and progesterone during pregnancy affect the hepatic metabolism by stimulating or decreasing different hepatic enzymes of the CYP system.[20] CYP3A4 and CYP2D6 activities are increased during pregnancy, which results in increased metabolism of certain drugs such as phenytoin.[17,20] On the other hand, CYP1A2, xanthine oxidase, and *N*-acetyltransferase activities are decreased, resulting in reduced hepatic elimination of drugs such as theophylline and

caffeine.[19,21] The clearance of caffeine can be decreased by 70%.[21] Hepatic blood flow as a percentage of the cardiac output is decreased; however, the absolute rate (in liters/minute) remains unchanged.[16] The activity of nonhepatic enzymes (eg, plasma cholinesterase) is also decreased.[19] The extent of the effect on drug therapy of these hepatic physiologic changes during pregnancy is difficult to quantify.

ELIMINATION

The glomerular filtration rate (GFR) begins to rise in the first half of the first trimester and increases by 50% by the beginning of the second trimester.[19] Renal blood flow also increases by 25% to 50% early during gestation. As a result, renal drug excretion (eg, β-lactams, enoxaparin, digoxin) can increase.[17] This increase in GFR necessitates dosage adjustments up to 20% to 65% for renally excreted drugs throughout pregnancy to maintain therapeutic concentrations.[20] The increased cardiac output and regional blood flow (eg, renal blood flow) primarily are caused by increased stroke volume and increased heart rate, which can increase drug distribution and drug excretion.

During pregnancy, the serum creatinine (SCr) concentration is lower because of the increased GFR, resulting in normal SCr values of 0.3 to 0.7 mg/dL in the first and second trimesters.[20] A normal value for SCr in nonpregnant adults is 0.6 to 1.2 mg/dL.[22] Similar changes occur with serum urea nitrogen and uric acid (UA) concentrations. These differences have important implications when assessing renal function during pregnancy. An SCr indicative of normal renal function in a nonpregnant female may be indicative of renal insufficiency in a person who is pregnant in their third trimester.

PLACENTAL–FETAL COMPARTMENT EFFECT

Maternal and fetal drug concentrations are dependent on the amount of drug that crosses the placenta, the extent of metabolism by the placenta, and fetal distribution and elimination of drug (**Fig. 49-1**).[17,20] Diffusion across the placenta is the main mechanism of drug

transfer; nonionized lipophilic substances are more readily transferred, whereas less lipid-soluble (eg, ionized) substances less readily cross the placenta.[17] Highly protein-bound or large-molecular-weight drugs (eg, heparin and insulin) do not cross the placenta. Both the immature fetal liver and placenta can metabolize drugs. Fetal drug accumulation can be problematic secondary to limited metabolic enzymatic activity along with the concern that approximately half of the blood flow from the umbilical vein bypasses the fetal liver and goes to the cardiac and cerebral circulations.[17] Another mechanism that can also lead to prolonged effects of drugs in the fetal compartment is ion trapping. This phenomenon occurs because the fetal plasma pH is more acidic than is the maternal plasma, causing weak bases (eg, usually nonionized and lipophilic substances) to diffuse across the placental barrier and become ionized in the more acidic fetal blood. The net effect is movement of drugs from the maternal to the fetal compartment. This equilibrium between the maternal and fetal compartments becomes important when therapeutic fetal drug concentrations are desired (eg, digoxin therapy for intrauterine fetal arrhythmias). Drugs are eliminated by the fetus primarily through diffusion back to the maternal compartment. As the fetal kidney matures, metabolites of drugs are excreted into the amniotic fluid.[17]

Figure 49-1 U.S. Food and Drug Administration (FDA) labeling. (From U.S. Food and Drug Administration. Pregnancy and lactation labeling (drugs) final rule. http://www.fda.gov/drugs/developmentapprovalprocess/developmentresources/labeling/ucm093307.htm.)

S.C.'s thyroid function should be checked regularly to assess the need for an increase in her levothyroxine dosage. During S.C.'s pregnancy, an increase in the V_d of thyroid hormones in the vascular, hepatic, and fetal–placental units, an increase in thyroxine-binding globulin resulting from a rise in estrogen, and an increase in placental transport and maternal metabolism of thyroxine will occur.[22] Most patients with hypothyroidism who are taking oral thyroid hormones before pregnancy, similar to S.C., will require an increase in their dosage by about 30% to 50% throughout their pregnancy and then will need decreased dose adjustments postpartum.[22]

TERATOGENICITY

Prevalence of Congenital Malformations

Case 49-1, Question 5: S.C. is currently 8 weeks pregnant and has become increasingly concerned about her medication use during pregnancy and the risk of birth defects. How should S.C. be counseled regarding the teratogenicity potential of levothyroxine use during pregnancy?

The largest concern with medication use during pregnancy is the risk of congenital malformations, defined as "structural abnormalities of prenatal origin that are present at birth and that seriously interfere with viability or physical well-being."[23] Congenital anomalies or birth defects are estimated to occur in 120,000 babies born per year.[10] Some drug-induced defects relate to changes in functions or conditions that are not structural abnormalities (eg, mental retardation, central nervous system [CNS] depression, deafness, tumors, or biochemical changes).[24] The broader term *congenital anomalies* includes the four major manifestations of abnormal fetal development—growth alterations, functional deficits, structural malformations, and fetal death.[25]

The background incidence of birth defects in the general population must be taken into consideration when interpreting the risk of drug-induced birth defects. The prevalence of major congenital malformations discovered at or shortly after birth in the general population is ~3%.[25] This number has been derived from large epidemiologic studies completed during the past several decades and depends on how terms are defined (eg, major vs minor congenital malformations), the thoroughness with which the infant is examined, and how long the exposed person is followed up after birth.[25] The collection of malformation data is a complicated task subject to numerous errors and biases. Some studies examined only "significant anomalies," others "major malformations," whereas still others reported only "live births" or "single births" or "birth weights >500 g." Stillbirths and spontaneous abortions, both often associated with congenital malformations, were excluded from epidemiologic data. Neurodevelopmental delays and growth retardation also are potential long-term effects that will not be diagnosed in the immediate postpartum period. The prevalence of congenital

anomalies is likely >3% if minor anomalies and long-term adverse effects are considered.

Despite the significant impact of drug-induced birth defects, it is difficult and unethical to conduct randomized controlled trials to assess the risk of fetal exposure to drugs in humans. Much of the data available are derived from epidemiologic studies, anecdotal experiences in humans, and animal studies. Because birth defects are species specific and influenced by many factors including genetic predisposition, the data must be carefully interpreted and the results not overgeneralized.

Causes of Malformations

CLASSIFICATION

Causes of congenital malformations are generally classified into one of five categories: (a) monogenic origin, (b) chromosomal abnormalities, (c) multifactorial inheritance, (d) environmental factors, and (e) unknown.[25] Single gene- and chromosomal-related defects account for ~25% of all congenital malformations in live-born infants (monogenetic, 7.5%–20%; chromosomal, 5%–6%).[24–26] *Multifactorial inheritance* refers to defects that are polygenic in origin; it has an environmental component. One surveillance program estimated that this interaction between genetic and environmental factors causes 23% of defects.[26] Congenital dislocation of the hip is an example of a defect in this category: The depths of the acetabular socket and joint laxity are genetically determined, and a frank breech malposition is one of the environmental factors.[27] In most cases, however, the environmental factors in multifactorial inheritance are unknown.

Environmental factors account for ~10% of malformations.[28] These include maternal conditions, mechanical effects, chemicals and drugs, and certain infectious agents. Maternal diseases associated with malformations include diabetes, phenylketonuria, virilizing tumors, and maternal hyperthermia. About 9% (range, 6.6%–13.0%) of infants of patients with diabetes develop major congenital defects,

primarily consisting of cardiovascular, neural tube, and skeletal malformations.[29] Mechanical effects, such as intrauterine compression and abnormal cord constriction, may result in fetal deformations.[28,29]

Probably, the best known of the teratogenic viruses is rubella, which can cause a fetal rubella syndrome consisting of cataracts, heart disease, and deafness.[30] In utero exposure to rubella in the first trimester can cause defects in up to 85% of fetuses. Cytomegalovirus infection occurs in 0.5% to 1.5% of newborns in the United States, resulting in deafness and mental retardation in 5% to 10% of these infants.[24] Characteristics of cytomegalic inclusion disease, the syndrome produced by cytomegalovirus, include intrauterine growth restriction (IUGR), microcephaly, and, at times, chorioretinitis, seizures, blindness, and optic atrophy. Herpes simplex 1 and 2 and varicella are also associated with malformations.[28]

The protozoan generally accepted as a teratogen is *Toxoplasma gondii*, which may be present in cat litter.[24] Most infants infected with *T. gondii* show no symptoms and develop normally. When toxicity does occur, the anomalies may consist of hepatosplenomegaly, icterus, maculopapular rash, chorioretinitis, cerebral calcifications, and hydrocephalus or microcephalous.[31] Because of the possible presence of *T. gondii* in cat litter, individuals should avoid cleaning or touching cat litter while pregnant. *Treponema pallidum* (syphilis) can cross the placenta and cause congenital syphilis as well as other defects, such as hydrocephaly, chorioretinitis, and optic atrophy.[30] In utero exposure to syphilis after the fourth month of pregnancy is associated with higher risk.

The final category, defects of unknown cause, comprises the greatest percentage of congenital malformations, accounting for about 60% to 65% of the total.[26]

Medication Use in Pregnancy and Teratogenicity

The term *teratogen* is used to denote an agent that has the potential under certain exposure conditions to produce abnormal development in the fetus.[25] Many patients have the general perception that use of any medication during a pregnancy can harm the developing fetus.[22] This thought may lead to consideration of terminating wanted pregnancies or withholding necessary drug therapy during the course of the pregnancy. The extent to which a drug will affect the development of the fetus depends on the physical and chemical properties of the drug as well as the dose, duration, route, and timing of exposure and the genetic composition and biologic susceptibility of the patient and fetus.[32,33] Numerous drugs have been associated with congenital anomalies, but only in a few cases has a consensus been reached that a specific agent is teratogenic. **Table 49-1**[34–36] lists those agents generally considered or suspected to be proven human teratogens. However, not all these teratogens will cause developmental toxicity with every exposure.

Table 49-1

Drugs With Suspected or Proven Teratogenic Effects in Humans

Alcohol	Growth restriction, mental retardation, midfacial hypoplasia, renal and cardiac defects
Androgens (testosterone)	Masculinization of female fetus
Angiotensin converting enzyme inhibitors and angiotensin receptor blockers	Pulmonary hypoplasia, hypocalvaria, oligohydramnios, fetal kidney anuria, and neonatal renal failure
Antithyroid drugs	Fetal and neonatal goiter with iodine use; small risk of aplasia cutis with methimazole
β-Blockers	IUGR and decrease in placental weight in β-blockers with intrinsic sympathomimetic activity if used in second and third trimesters
Carbamazepine	NTDs, minor craniofacial defects, fingernail hypoplasia
Cigarette smoking	IUGR, functional and behavioral deficits
Cocaine	Bowel atresias; heart, limbs, face, and genitourinary tract malformations; microcephaly;

	cerebral infarctions; growth restriction
Corticosteroids (systemic)	Oral cleft lip and palates if used during organogenesis
Cyclophosphamide	Craniofacial, eye, and limb defects; IUGR; neurobehavioral deficits
Diethylstilbestrol	Vaginal carcinoma and other genitourinary defects
Lamotrigine	Oral cleft lip and cleft palate[33]
Lithium	Ebstein anomaly
Methotrexate	CNS and limb malformations
Misoprostol	Möbius sequence (high doses) and spontaneous abortions
Nonsteroidal anti-inflammatory drugs	Constriction of the ductus arteriosus, oral clefts, cardiac defects, and possible spontaneous abortion
Paroxetine	Cardiovascular defects[34]
Phenytoin	Fetal hydantoin syndrome, growth retardation, CNS deficits
Streptomycin and kanamycin	Hearing loss, eighth cranial nerve damage; no ototoxicity reported with gentamicin, tobramycin, amikacin
Systemic retinoids (isotretinoin and etretinate)	CNS, craniofacial, cardiovascular defects
Tetracycline	Permanent discoloration of deciduous teeth
Thalidomide	Limb and skeletal shortening defects, internal organ defects
Topiramate	Cleft lip and cleft palate[35]
Trimethoprim	NTDs and cardiac defects
Vaccines (live)	Live attenuated vaccines can potentially cause fetal infection
Valproic acid	NTDs, developmental delay, and deficits
Vitamin A	Microtia, anotia, thymic aplasia, cardiovascular defects (high dose)
Warfarin	Fetal warfarin syndrome with nasal hypoplasia, stippled epiphyses, and skeletal and CNS defects

Teratogenic effects include the four major manifestations of abnormal fetal development, which include growth alterations, functional deficits, structural malformations, and fetal death.

Only drugs that are teratogenic when used at clinically recommended doses are listed. List is not an all-inclusive one.

CNS, central nervous system; IUGR, intrauterine growth restriction; NTDs, neural tube defects.

Sources: Briggs G, Freeman RK, Yaffe SJ. *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk*. 11th ed. Lippincott Williams & Wilkins; 2017; Koren G, Pastuszak A, Ito S. Drugs in pregnancy. *N Engl J Med.* 1998;338:1128–1137.

Because every pregnancy has the risk of an abnormal outcome regardless of drug exposure, the objective of evaluating data on drug exposure during pregnancy is to ascertain whether a particular drug increases the risk of developmental toxicity in the fetus beyond the background rate. The following basic principles of teratogenicity should be applied when assessing the potential for teratogenicity of drugs.

CRITICAL STAGE OF EXPOSURE

After fertilization, the development of the embryo and fetus is divided into three main stages: pre-embryonic period, embryonic period, and fetal period.[28] In the first 2 weeks after fertilization or the pre-embryonic period (0–14 days), little is known about the effects of drugs on human development. Exposure to a teratogenic agent during this period usually produces an “all or none” effect on the ovum[31]: The ovum either dies from exposure to a lethal dose of a teratogenic drug or regenerates completely after exposure to a sublethal dose. Some animal studies have suggested, however, that exposure to some drugs during the preimplantation stage can halt growth and development before implantation.[36] Although the damage can be repaired, intrauterine growth may be retarded in the offspring.

During the embryonic period (14–56 days after fertilization), when organogenesis occurs, the embryo is most susceptible to the effects of teratogens or other chemicals.[25,31] Exposure during this sensitive period may produce major morphologic changes (**Fig. 49-2**). These

stages of development differ significantly from that of other species, and knowledge of these stages is essential for the interpretation of the relationship between congenital malformations and drugs. For example, if a specific drug exposure occurs after the time of organ development, then a structural defect in that organ is less likely to be caused by that specific drug.

Figure 49-2 Critical stages of human development. (Adapted from Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Saunders; 2003. © 2003 Elsevier. With permission.)

The fetal period (57 days to term) includes most of the stages of histogenesis and functional maturation, although the latter continues for some time after birth.[28] Minor structural changes are still possible during histogenesis, but anomalies are more likely to involve growth and functional aspects such as mental development and reproduction.

DOSE–RESPONSE CURVE

All teratogens follow a toxicologic dose–response curve.[25] These teratogens have a threshold dose below which adverse effects will not occur. The threshold dose is the dosage in which the incidence of structural malformations, rate of fetal death, growth restriction, and functional deficits do not exceed the background rate in the general population.[25] Conversely, developmental toxicity may occur when the fetus is exposed to doses above the maximum or threshold dose. There may be an increase in the severity and incidence of malformations when the fetus is exposed to increasingly higher dosages. For example, the risk of major congenital malformations, including NTD and minor anomalies, is increased statistically in patients taking valproic acid dosages >1000 mg/day during the first trimester.[37]

EXTRAPOLATION FROM ANIMAL STUDIES

In the absence of human trials, data derived from animal studies are used to assess the level of risk of developmental toxicity in humans. Most newly marketed drugs often have to rely on preclinical data to develop an estimation of teratogenic risk based on animal studies until human data become available.[38] The dose used in experimental animal data is expressed as multiples of the human dose using plasma or serum AUC or dose per unit based on body surface area.[39] The drug appears to have a low risk of teratogenicity if the toxic dose in animals (based on AUC or milligram per square meter comparison) is >10 times the anticipated human dose.[40] Risk assessment using animal data is more complicated than just considering the dosage alone. Other major factors, including the effects of metabolism and active metabolites, species differentiation, route of administration, and type of defects, must be considered.[25]

GENETIC VARIABILITY

The most potent teratogenic agent will not produce malformations with every exposure.[25] The teratogenic potential of some drugs is influenced by the genotype of both the patient and fetus. Although

the effects of known teratogens can be predictable in the general population, the possibility of individual assessment is difficult. The same dose of a teratogenic agent exposed at the same gestational window will produce variable outcomes in different people. Genetic variability can confer differences in cell sensitivities, placental transport, drug metabolism, enzyme composition, and receptor binding, which may affect how much active drug will reach fetal tissues.[41] One study showed an increased susceptibility to the teratogenic effect of phenytoin, most likely caused by elevated levels of oxidative metabolites (epoxides). These epoxides are normally eliminated from the systemic circulation by enzymes called *microsomal epoxide hydrolase*. Patients who are homozygous for the recessive allele produce low levels of epoxide hydrolase, which may expose the fetus to higher levels of epoxides. These fetuses may be at a higher risk for fetal hydantoin syndrome.[42]

PLACENTAL TRANSFER OF DRUGS

At one time, the placenta was thought to present a barrier to the passage of drugs and noxious chemicals to the fetus. It is now known, however, that most medications cross the placenta to the fetus and, in general, what the patient consumes also is consumed by the fetus. Although the placenta acts as a biologic membrane, it initially is composed of four layers effectively separating two distinct individuals.[41] These layers are (a) the endothelial lining of the fetal vessels, (b) the connective tissue in the core of the villus, (c) the cytotrophoblast layer, and (d) the covering syncytium. During gestation, the placenta's surface area increases while its thickness decreases from ~25 mm during the first trimester to 2 to 6 mm at term. Both processes tend to favor the transfer of chemicals to the fetus.

Drugs, nutrients, and other substances cross the placenta by five mechanisms: (a) simple diffusion (eg, most drugs), (b) facilitated diffusion (eg, glucose), (c) active transport (eg, some vitamins, amino acids), (d) pinocytosis (eg, immune antibodies), and (e)

breaks between cells (eg, erythrocytes).[39,41,42] The latter two mechanisms are of no practical importance in the transfer of drugs.

Several factors influence the rate of drug transfer across the placenta, including molecular weight (MW), lipid solubility, ionization, protein binding, uterine and umbilical blood flow, and maternal diseases.[39] Drugs with MWs of <600 cross easily, whereas those of >1000 (eg, heparin) cross with difficulty or not at all. Because most drugs have MWs of <600, it is safe to assume that most drugs reaching the patient's circulatory system also will reach the fetus. As with other biologic membranes, lipid-soluble substances are transferred rapidly, with the rate of entry primarily governed by the lipid solubility of the nonionized molecule. Conversely, those molecules that are ionized at physiologic pH (eg, the cholinergic quaternary amines) cross slowly, whereas weak acids and bases with dissociation constant (pK_a) values between 4.3 and 8.5 are transferred rapidly to the fetus. The penetration of highly protein-bound drugs also is inhibited; only the free, unbound drugs cross the placenta.[38,39,41]

Uterine blood flow, a major factor in determining the rate of drug transfer, increases throughout gestation. Several variables can affect uterine blood flow and the rate of drug transfer, including maternal blood pressure (BP), cord compression, and drug therapy. Maternal hypotension reduces uterine blood flow and the rate at which substances are delivered to the membrane. Cord compression reduces the blood flow on the fetal side of the membrane. The use of drugs with α-adrenergic property (eg, epinephrine) may constrict uterine vessels and thereby reduce blood flow.[27] Maternal diseases, such as pregnancy-induced hypertension, erythroblastosis, and diabetes, change the permeability of the placenta and may reduce or increase transfer.[36]

Food and Drug Administration Risk Factors

In 1979, the U.S. Food and Drug Administration (FDA) introduced a system of rating pregnancy risks associated with pharmacologic

agents. This system categorizes all drugs approved after 1983 into one of five pregnancy risk categories, A, B, C, D, and X. It establishes the level of risks to the fetus based on available animal and human data and recommends the degree of caution that should be undertaken with each drug.[38,40–42] This system had many limitations. Effective in June 2015, the FDA introduced a pregnancy labeling and category system to include narrative text to provide more clinical management advice that includes consideration of both animal and human data (see Fig. 49-1).[43] The structured narratives include the following sections for each drug: (a) pregnancy (including considerations during labor and delivery), (b) lactation (includes nursing patient considerations), and (c) females and males of reproductive potential.[43] For specific information on the FDA pregnancy labeling,[43] visit http://www.fda.gov/drugs/developmentapprovalprocess/developmentresources/labeling/ucm093307.htm.

The former FDA pregnancy classification structure states that levothyroxine is a pregnancy category A drug but does not give any further specific information. The updated FDA-structured narrative states, "Levothyroxine (T_4) is compatible with all stages of pregnancy. Untreated or undertreated maternal hypothyroidism is associated with low birth weight secondary to medically indicated preterm delivery, preeclampsia or placental abruption, and with lower neuropsychological development of their offspring."[38] S.C. should be counseled that levothyroxine can safely be used during all trimesters of pregnancy including the period of organogenesis, which she is currently in at 8 weeks' gestation. She should not discontinue her levothyroxine. Thyroxine insufficiency has been shown to impair fetal and neonatal development. Levothyroxine therapy has not been observed to increase the risk of congenital malformations beyond the reported background risk of 3%.[38]

MANAGEMENT OF CONDITIONS IN PREGNANCY

Nausea and Vomiting

Case 49-1, Question 6: S.C. is now 10 weeks pregnant and reports nausea throughout the day, with emesis occurring two to three times daily. She is able to tolerate at least two meals a day and oral liquids. She reports very little weight gain since she became pregnant. Her current weight is 158.73 pounds (72 kg). S.C. states that certain smells such as fish, eggs, and beans cause her to gag. How long is her nausea and vomiting likely to last?

According to the American College of Obstetricians and Gynecology (ACOG), nausea and vomiting during pregnancy (NVP) is a common condition occurring in ~70% to 85% of pregnancies, during weeks 5 to 12 of gestation.[44] For most patients, NVP is a self-limiting condition that usually resolves after the first trimester with no long-term detrimental effect on the fetus.[47] About 91% of cases will resolve by 20 weeks of gestation.[45] The effects of NVP can have an impact on a person's daily activities, work productivity, and quality of life. Studies estimate that $130 million/year is spent on the hospitalization for severe NVP.[46] The cause of NVP is unknown, but is most likely multifactorial including hormonal, psychological, and neurologic factors. Changes in hormonal levels of estrogen, progesterone, and hCG have been implicated as a possible cause of NVP. Mild-to-moderate NVP has been associated with lower rates of miscarriage, preterm delivery, and stillbirth.[47]

NONPHARMACOLOGIC MANAGEMENT OF NAUSEA AND VOMITING

Case 49-1, Question 7: What nonpharmacologic approaches should S.C. try for her nausea and vomiting?

Most mild forms of NVP can be managed with psychological support and lifestyle and dietary changes. Advising S.C. to eat smaller frequent meals consisting of a low-fat, bland, and dry diet (eg, bananas, crackers, rice, toast), to avoid spicy and highly aromatic foods, and to take prenatal vitamins with iron at night may alleviate some of the symptoms. Meals high in protein are more likely to alleviate NVP than do carbohydrate-laden or fatty meals. Rest and avoidance of the sensory stimuli occurring from foods, and lotions that may contribute to the effects of NVP can also be helpful.[47] Advise S.C. to avoid the foods (ie, fish, beans, eggs, spaghetti sauce) that specifically trigger her gag reflex, which may induce emesis.

PHARMACOLOGIC MANAGEMENT OF NAUSEA AND VOMITING

CASE 49-1, QUESTION 8: S.C. has tried crackers and avoiding the foods that trigger her gag reflex but does not respond to nonpharmacologic treatment of her nausea and vomiting. What pharmacologic agent would be appropriate for her?

Antiemetics are indicated for the treatment of moderate-to-severe nausea and vomiting that fails to respond to nonpharmacologic interventions or when the nausea or vomiting threatens the patient's metabolic or nutritional status (eg, hyperemesis gravidarum). Traditionally, medications for NVP have been avoided during the first trimester because of fear of the possible teratogenic effects. Most antiemetic therapies (eg, antihistamines, multivitamins, phenothiazines) can be taken during pregnancy safely. **Table 49-2**[3,8,46,48–50] shows the most common antiemetics used during pregnancy. The goal of antiemetic therapy is to choose an effective medication to improve a person's quality of life by maintaining her nutrition and hydration needs, while ensuring fetal safety.

Table 49-2
Common Antiemetics Used for Nausea and Vomiting During

Pregnancy

Drug	Dose	Comments
Vitamin B_6 (pyridoxine)	10–25 mg PO tid	First-line therapy[45] Documented safety in pregnancy
Vitamin B_6 (pyridoxine)—doxylamine combination	Pyridoxine 10–25 mg PO tid–qid Doxylamine 12.5 mg PO tid–qid Doxylamine 10 mg/ Pyridoxine 10 mg PO qhs, max four tablets/day	First-line therapy Available OTC Well-documented safety in pregnancy through large meta-analysis[53] RX only
Antihistamines		
Diphenhydramine Meclizine Hydroxyzine Dimenhydrinate	25–50 mg PO every 8 hours 25 mg PO every 6 hours 25–50 mg PO every 4–6 hours 50–100 mg PO every 4–6 hours	First-line therapy Antihistamines have not been shown to be teratogenic.[49,54]
Phenothiazines		
Promethazine Prochlorperazine	12.5–25 mg PO, PR every 6 hours 5–10 mg PO every 6–8 hours	Second line of therapy Available as suppositories Also suppositories and buccal tablets Usually, add phenothiazine or metoclopramide to therapy if antihistamines fail.[45,50] Can cause EPS
Dopamine Antagonists		
Metoclopramide	10 mg PO every 6 hours	Usually, add phenothiazine or metoclopramide to therapy if antihistamines fail.[45,50] Avoid treatment >12 weeks' duration, risk of tardive dyskinesia Can cause EPS

Drug	Dose	Comments
Droperidol	1.25–2.5 mg IV/IM or continuous infusion 1 mg/hour for treatment of hyperemesis gravidarum[49]	Boxed warning regarding torsades de pointes, may need ECG during administration Continuous infusion of droperidol requires concomitant diphenhydramine 50 mg IV every 6 hours.
5-HT_3 Receptor Antagonists		
Ondansetron	4–8 mg IV/PO every 6–8 hours	Available as ODT tablets Does not cause sedation Studies suggest low risk in pregnancy.[38,55]
Glucocorticoids		
Methylprednisolone	16 mg PO every 8 hours × 3 days, then taper over 2 weeks	For refractory cases, last line of therapy Avoid use before 10th week of gestation, associated with oral cleft and palate.[38,45]
Ginger extract	125–250 mg PO every 6 hours	Available OTC as food supplement

ECG, electrocardiogram; EPS, extrapyramidal symptoms; IM, intramuscular; IV, intravenous; ODT, oral disintegrating tablet; OTC, over-the-counter; PO, by mouth; PR, per rectum; qid, four times a day; qhs, daily at bedtime; tid, three times a day.

The prescription delayed-release formulation, recently approved by the FDA, of 10 mg doxylamine with 10 mg of pyridoxine (vitamin B_6) called Diclegis® can be considered first-line therapy for the treatment of NVP. Several randomized controlled trials have

demonstrated its effectiveness in reducing NVP. Because of its safety and efficacy profile, doxylamine and pyridoxine are still considered first-line therapy and are available in combination as prescription or separately as over-the-counter products.[48,51–53]

Other antihistamine H_1 receptor blockers (eg, diphenhydramine, hydroxyzine, meclizine, dimenhydrinate) have been studied for NVP. The safety of antihistamines was supported in a meta-analysis including >200,000 first-trimester exposures, which did not find an increase in teratogenic risk.[54] Sedation is the main side effect that limits the use of this class of antiemetics.

Phenothiazines or metoclopramide is usually prescribed if antihistamines fail.[49,50] Phenothiazines (eg, promethazine, prochlorperazine) are generally considered safe for both the patient and fetus if used occasionally in low doses. A recent randomized trial compared IV metoclopramide versus IV promethazine in the treatment of hyperemesis gravidarum and found that both agents have similar efficacy. However, metoclopramide caused less drowsiness and dizziness.[49] Metoclopramide, a dopaminergic antagonist with prokinetic abilities, can control vomiting and gastric reflux associated with pregnancy. Oral metoclopramide can be added to an antihistamine (eg, hydroxyzine) or a regimen of doxylamine and pyridoxine.[49,50] A large cohort study of 3458 females exposed to metoclopramide in the first trimester failed to show an increase in congenital malformations. Metoclopramide issued a black box warning concerning the risk of rare incidences of tardive dyskinesia.[49,50] Risk of tardive dyskinesia increases with a longer duration of treatment and total cumulative doses; thus, length of therapy beyond 12 weeks should be avoided.[49,50]

The use of ondansetron, a 5-hydroxytryptamine type 3 antagonist, during pregnancy has increased owing to more experiences with its use. It is increasingly used for NVP and hyperemesis owing to ease of administration with oral disintegrating tablets and tolerability with minimal sedating side effects or poor fetal outcomes.[46,55] Methylprednisolone is an option for refractory cases; however, its

use during the first trimester is associated with a small but significant risk of fetal oral clefts.

Alternative therapies (eg, vitamin B_6, ginger root, acupuncture, acupressure) have improved NVP in a small number of patients.[38,45] S.C. may be started on doxylamine 10 mg and pyridoxine 10 mg two tablets PO at bedtime. S.C. may increase to two additional tablets in the afternoon if needed to a maximum of four tablets per day because of its safety and efficacy profile. Drug selection for S.C. mostly depends on the tolerability of adverse effects. If S.C. continues to have significant nausea and emesis on these antiemetics and fails to tolerate any oral liquids or solids, she should be advised to return to the clinic for evaluation and possibly be admitted for IV hydration and IV antiemetic therapy.

Case 49-1, Question 9: S.C. returns to the clinic a few weeks later at 12 weeks' gestation stating that she has lost about 8.82 pounds (4 kg) in the past 3 weeks, has been unable to tolerate any liquids or medication for 2 weeks, and feels dehydrated and dizzy. S.C. is referred for admission to the hospital. What recommendations should be given to S.C. to help control her nausea and vomiting?

Severe NVP can persist in <1% of pregnancies, leading to a condition called *hyperemesis gravidarum,* which can lead to detrimental effects on the patient and fetus. Weight loss of >5% of prepregnancy weight, ketonuria, and electrolyte abnormalities are associated with this condition. Treatment of hyperemesis gravidarum often requires hospitalization for parenteral fluid administration, electrolyte replacement, vitamin supplementation, and antiemetic therapy.[47] Metabolic acidosis, ketosis, hypovolemia, electrolyte disturbances, and weight loss may ensue if patients are not treated.[47] Reductions in lower esophageal pressure, gastric peristalsis, and gastric emptying may worsen nausea and vomiting.

In addition to ondansetron, used for NVP as mentioned earlier, droperidol, an intravenous (IV) dopamine antagonist, has been used extensively for many years in the treatment of hyperemesis and the prevention and treatment of postoperative nausea and vomiting.[38]

Although the FDA has mandated electrocardiographic monitoring for concern about the risk of prolonged QTc interval, large meta-analysis studies have failed to show an increased risk of arrhythmias when using droperidol at the low doses used for nausea and vomiting.[45] Limited experience with droperidol use in hyperemesis gravidarum has been documented in a small controlled trial.[51] Human and animal data suggest that droperidol carries a low risk of teratogenicity to the fetus.[38,49,50]

S.C. should be hydrated with IV fluids with electrolyte replacement therapy and multivitamins including pyridoxine. If hydration with multivitamins does not quell her nausea, IV ondansetron 4 to 8 mg every 4 to 6 hours should be given. IV droperidol therapy should be considered if ondansetron does not work. She should also be evaluated for other causes of nausea and vomiting if her symptoms persist (eg, gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer disease, pyelonephritis, and fatty liver of pregnancy).[47] Enteral nutrition may be needed in the treatment of hyperemesis gravidarum if S.C. cannot tolerate oral liquid and solid intake despite continuous IV antiemetics and hydration. Total parenteral nutrition should be reserved after multiple antiemetic regimens and enteral therapies have failed because of the substantial risks of catheter sepsis (25%) and thromboembolic clots.[45,46,49]

REFLUX ESOPHAGITIS

Case 49-1 Question 10: S.C. is now 30 weeks pregnant and no longer reports nausea or vomiting. However, now she has heartburn that worsens when she lies down. What causes reflux esophagitis in pregnancy, and how should S.C. manage this problem?

Reflux esophagitis or heartburn is a normal occurrence in pregnancy affecting approximately two-thirds of patients. The enlarging uterus increases intra-abdominal pressure, and estrogen and progesterone relax the esophageal sphincter. These two factors cause the reflux of stomach acid into the lower esophagus, producing symptoms of substernal burning worsened by eating, lying

down, or bending over. Lifestyle and dietary modifications, such as eating smaller meals, avoiding late meals close to bedtime, and elevation of the head of the bed, should be tried first. Avoidance of salicylates, caffeine, alcohol, and nicotine are encouraged to reduce the symptoms of reflux and fetal exposure to these harmful substances.

If these modifications are not successful, S.C. should try a calcium carbonate antacid. Animal studies have not shown antacids to have teratogenic effects.[38] Sodium bicarbonate can cause metabolic alkalosis and fluid overload and should be avoided. Despite evidence of fetal toxicity with aluminum, available data suggest that usual doses of aluminum-containing medications are not harmful to the fetus of a pregnant person with normal renal function. Sucralfate, which contains aluminum, appears to be safe in pregnancy. The American College of Gastroenterology has classified sucralfate as a medication with benefits that outweigh the risks when used in pregnant patients.[38]

H_2-receptor antagonists can be used safely during pregnancy because most studies in animals and humans have not found fetal harm with cimetidine, ranitidine, famotidine, or nizatidine.[38] If H_2-receptor antagonists fail to control symptoms, proton-pump inhibitors (PPIs) should be used as the next treatment option. Recent studies have shown that PPI use during the first trimester and throughout pregnancy is not associated with a significant increase in the risk of congenital anomalies. These studies suggest that PPIs can be safely used at any gestational age.[56,57]

URINARY TRACT INFECTIONS

Pathogenesis

Case 49-1, Question 11: S.C. is now 31 weeks pregnant, and a routine urine dip finding was positive for leukocyte esterase and nitrates. Her urine was sent

for urinalysis at her most recent prenatal visit and the result was positive for 10^5 colony-forming units (CFUs) of *Escherichia coli*. She does not report frequency and urgency when urinating and denies any fevers. Her temperature is currently 98.9 °F (37.17 °C). She denies any allergies to medications. What are the risks of having a urinary tract infection (UTI) during pregnancy, and how should S.C. be treated?

UTIs are one of the most common complications of pregnancy owing to hormonal and mechanical changes that increase the likelihood of bacteriuria. During pregnancy, increases in progesterone cause relaxation of ureteral smooth muscle, promoting urinary stasis. The enlarging gravid uterus can also mechanically compress the ureters, which may lead to urinary retention. Approximately 90% of pregnant patients may exhibit ureteral dilation or hydronephrosis, which can decrease bladder tone and ureteral tone. These physiologic changes, along with increases in the GFR, urine alkalization, and glucosuria, help promote bacterial growth.

Asymptomatic Bacteriuria and Acute Cystitis

UTIs during pregnancy can present as either asymptomatic bacteriuria (ASB) or acute cystitis. ASB is defined as the presence of significant bacteria, $>10^5$ CFU of bacteria, obtained by two consecutive clean-catch samples in the absence of any urinary symptoms.[58] In contrast, acute cystitis involves an infection of the bladder and manifests with signs and symptoms of frequency, urgency, dysuria, and hematuria without fever or evidence of systemic illness along with significant presence of bacteria of at least 10^5 CFU. Counts of $<10^5$ CFU with two or more organisms likely represent contamination and not true bacteriuria.

ASB is estimated to occur in 2.5% to 15% of pregnant patients, with about 80,000 to 400,000 cases occurring each year in the United States.[58,59] If ASBs are left untreated, they can lead to complications such as pyelonephritis, low-birth-weight infants, and premature delivery.[60] During pregnancy, treatment of ASB reduces the risk of developing pyelonephritis dramatically down from 20% to

35% to only 1% to 4%.[60] The U.S. Preventive Services Task Force recommends screening for ASB with a urine culture for all pregnant patients between 12 and 16 weeks of gestation or at the first prenatal visit if it occurs later.[61] The ACOG further recommends repeating a urine culture during the third trimester.[62]

Risk factors for ASB during pregnancy include diabetes, sickle cell disease, immunosuppression, human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome, urinary tract anatomic anomalies, and spinal cord injuries.[63] The primary sources of organisms that cause bacteriuria originate from existing vaginal and perineal flora and migrate up the urethra to cause ASB and cystitis; they include *E. coli* (most common pathogen isolated), *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterobacter* species, *Enterococcus, Staphylococcus saprophyticus*, and group B β-hemolytic *Streptococcus.*[63] Commonly used antibiotics include penicillins, cephalosporins, and nitrofurantoin. Antibiotic selection should be guided by antimicrobial susceptibility testing. For coverage of the most common organism, *E. coli,* oral nitrofurantoin, or cephalexin is often used. *E. coli* resistance to amoxicillin and trimethoprim–sulfamethoxazole has been increasing.[63,64] The antibiotic chosen should produce adequate concentration in the urine, have a low resistance rate, and be safe to use during pregnancy. A 7-day regimen of antibiotics should be used whenever possible.[63,64] A recent World Health Organization (WHO) multicenter, randomized, noninferiority trial found that a 7-day regimen with nitrofurantoin was more effective than a 1-day regimen was in treating pregnant patients with ASB, with bacteriologic cure rates of 86.2% and 75.7%, respectively.[64] Optimal antibiotics and duration of therapy have not been clearly identified and must be individualized for each patient based on cultures and sensitivity results.[60,63] For S.C., who likely has ASB, a 7-day course of nitrofurantoin is reasonable. At this gestation age of 31 weeks, nitrofurantoin can still be used safely. There is a small risk of hemolytic anemia in newborns when nitrofurantoin is used close to delivery.[38]

DIABETES MELLITUS

Diabetes mellitus is the most common maternal medical complication during pregnancy. Diabetes during pregnancy can be detected before or during pregnancy and can be separated into two groups: (a) *pregestational diabetes,* which includes patients who have been diagnosed before pregnancy with either diabetes type 1 or diabetes type 2, or (b) *gestational diabetes mellitus* (GDM), defined as carbohydrate intolerance first detected during pregnancy.[65]

More prevalent than pregestational diabetes, GDM accounts for >90% of diabetes cases during pregnancy and affects ~6% to 7% of live births each year.[66] It is estimated that 50% of patients with GDM will go on to develop type 2 diabetes 22 to 28 years postpregnancy.[67,68]

Pregestational diabetes accounts for the remaining 10% of cases. In the United States, >8 million patients have pregestational diabetes, affecting about 1% of live births each year.[71] Most patients with pregestational diabetes have type 2 diabetes characterized by peripheral insulin resistance and relative insulin deficiency.[69] The incidence of type 2 pregestational diabetes has been rapidly rising in the past decade, most likely because of the increasing prevalence of obesity. In contrast to type 2 diabetes, type 1 diabetes is characterized by complete insulin deficiency resulting from autoimmune destruction of pancreatic β cells.[69] Less than 0.5% of all pregnancies in the United States are complicated by type 1 diabetes.[70]

Fluctuating glucose levels during the first trimester may be the first signs of pregnancy for patients with pregestational diabetes owing to increased insulin resistance and reduced sensitivity to insulin action. Placental hormones (eg, human placental lactogen, progesterone, prolactin [PRL], placental growth hormone, and cortisol) are thought to be responsible for the increase in insulin resistance during pregnancy. The ACOG classifies diabetes in pregnancy according to the White classification, modified to include gestational diabetes

according to glycemic control. The White classification relies on age at onset, duration of diabetes, and presence of vascular complications for patient classification (**Table 49-3**).

Table 49-3

Modified White Classification of Diabetes During Pregnancy

Class of Diabetes	Age of Onset	Duration	Vascular Complications	Treatment of Choice During Pregnancy
Class A1	First diagnosed during pregnancy	During pregnancy	None	Diet, exercise
Class A2	First diagnosed during pregnancy	During pregnancy	None	Diet, exercise plus oral hypoglycemics or insulin
Class B	Older than 20 years	<10 years	None	Insulin therapy
Class C	Between 10 and 19 years	>10 years, <19 years	None	Insulin therapy
Class D	Younger than 10 years	>20 years	Background retinopathy Hypertension Microalbuminuria	Insulin therapy
Class F	At any age	Any duration	Nephropathy Macroalbuminuria (>500 mg/day)	Insulin therapy
Class H	At any age	Any duration	Arteriosclerotic heart disease	Insulin therapy
Class R	At any age	Any duration	Proliferative retinopathy Vitreous hemorrhage	Insulin therapy
Class T	At any age	Any duration	Renal transplantation	Insulin therapy

Preexisting Diabetes Mellitus

FETAL AND INFANT RISKS

CASE 49-2

QUESTION 1: K.H., a 27-year-old, 132.28-pound (60-kg) female known to have type 1 diabetes since age 12, has married recently and wishes to have children. She has been conscientious in her diabetes care and self-monitors her blood glucose concentrations two to three times a day (fasting and before meals). During the past month, her fasting blood glucose concentrations have ranged from 90 to 140 mg/dL. Today, her fasting blood glucose and glycated hemoglobin (HbA_{1c}) laboratory results are 134 mg/dL and 7.8%, respectively. Her BP is 145/94 mm Hg, renal function is normal, SCr is 0.8 mg/dL, and she does not have proteinuria. K.H. reports tingling and pain in her toes. Her current medications include lisinopril 5 mg PO daily, insulin glargine (Lantus®) 16 units

subcutaneously (SC) every day at bedtime with an insulin lispro (Humalog®) sliding scale of 2 to 10 units before each meal. She reports eating only two meals a day and no snacks in between.

How will diabetes affect the health of the offspring?

Perinatal mortality for infants of patients with diabetes has declined dramatically with strict maternal metabolic control, improved fetal surveillance, and neonatal intensive care.[71] Fetal and neonatal mortality rates are ~2% to 4%, and the risk of spontaneous abortion in patients with well-controlled type 1 diabetes is equal to that of patients without diabetes.[72] The incidence of stillbirth is greatest after 36 weeks' gestation in patients with poor glycemic control, fetal macrosomia (see subsequent discussion), maternal vascular disease, ketoacidosis, or preeclampsia.[65]

The leading cause of perinatal mortality is major congenital anomalies that occur in 9% to 14% of infants born to patients with diabetes. The major malformations observed include NTDs and other anomalies involving the cardiac, renal, and GI systems, and, rarely, caudal regression syndrome.[66] Many congenital anomalies occur during organogenesis, before the seventh week of gestation, when patients are often unaware that they are pregnant.[73] A direct correlation exists between higher HbA_{1c} levels and increased frequency of anomalies.[73] Patients with elevated HbA_{1c} values during the time of conception have a significantly higher incidence of infants with anomalies compared with patients with HbA_{1c} closer to the normal range of 4.0% to 5.6%.[74] The risk of fetal anomalies increases dramatically to ~20% to 25% when HbA_{1c} levels are near 10%.[73] HbA_{1c} levels >12% are associated with the same risk of anomalies as infants exposed to known teratogens such as thalidomide, isotretinoin, or alcohol during organogenesis.

Macrosomia, defined as birth weight >8.82 pounds (4 kg), is thought to be caused in part by fetal hyperglycemia and hyperinsulinemia.[65] Fetal hyperglycemia occurs when glucose crosses the placenta and subsequently stimulates fetal pancreatic β cells to release excessive insulin. Hyperinsulinemia promotes

excessive fetal growth in adipose tissue, causing disproportional fat concentration around the shoulders and chest and doubling the risks of trauma (eg, shoulder dystocia) during vaginal delivery.

Infants of patients with diabetes also are at increased risk for prolonged hypoglycemia after delivery, respiratory distress syndrome (RDS), hypocalcemia, polycythemia, and hyperbilirubinemia during the neonatal period.[66]

K.H. should be informed that stringent preconception glycemic control is essential for preventing early pregnancy loss and congenital malformations in the infant.[71] Tight glucose control, especially in the months before pregnancy and early in the first trimester, will maximize her chance of having a healthy baby. She should be educated before pregnancy about healthy practices she can institute now to improve a successful pregnancy outcome.

MATERNAL RISKS

Case 49-2, Question 2: K.H. wants to know what health risks she might incur from becoming pregnant and what measures could minimize these risks?

A prepregnancy assessment, including a history and physical examination, is necessary to determine the risks of or contraindications to pregnancy for K.H. She should be evaluated for ischemic heart disease, neuropathies, or retinopathy, and her renal status must be assessed.[71] Pregnancy can exacerbate the vascular complications of diabetes. For instance, diabetic retinopathy can worsen if strict glycemic control is implemented quickly in pregnant patients with proliferative retinopathy; progression to end-stage renal disease can occur in patients with mild-to-moderate renal insufficiency (eg, SCr >1.5 mg/dL or proteinuria >3 g/24 hours).[66,69] The presence of gastroparesis should be noted because it will make controlling her glucose more difficult.[71]

Controlling K.H.'s diabetes before she becomes pregnant may benefit her hypertension and neuropathies and will minimize

maternal and fetal problems. Good metabolic control of her diabetes can minimize progression of her diabetes.[73]

PRECONCEPTION MANAGEMENT

CASE 49-2, QUESTION 3: What prepregnancy interventions relative to her general health and diabetes should K.H. undertake before she attempts to become pregnant?

Pregestational care for K.H. should ideally begin 6 months before conception.[71] Recommendations for patients with diabetes who want to conceive include suggesting birth control methods until stringent glycemic control can be achieved, consulting a dietitian to develop a patient-specific nutritional diet to attain healthy weight targets, and implementing a self-monitoring blood glucose regimen.[71] Good glycemic control (HbA_{1c} levels close to normal) should be achieved months before conception to minimize risks of major congenital anomalies. K.H.'s current regimen may not achieve euglycemia (see Chapter 53, Diabetes Mellitus). Her insulin therapy should be titrated to reduce her average blood glucose range from 90 to 120 mg/dL, targeting an HbA_{1c} of <6.5% without frequent episodes of hypoglycemia.[71,74] In addition, K.H. should be started on prenatal vitamins containing at least 400 µg of folic acid.

Her BP of 145/94 mm Hg is high and should be decreased to a diastolic BP of about 80 mm Hg to minimize risks for preeclampsia (see Case 49-5, Question 6) or exacerbation of her disorder. Many patients with pregestational diabetes, such as K.H., are likely on an angiotensin converting enzyme inhibitor (ACEI) or angiotensin receptor blocker for hypertension treatment or for renal protective effects. Before pregnancy and during preconception planning, K.H. should be switched to another antihypertensive (eg, methyldopa, labetalol, or calcium channel blockers) because recent studies have observed possible increased rates of congenital cardiac malformation associated with the use of ACEIs in the first trimester.[75] Further confirmatory studies are needed to define the risk of using

ACEIs during the first trimester. However, use of ACEIs is absolutely contraindicated during the second and third trimesters of pregnancy.[38,75]

CASE 49-2, QUESTION 4: After lowering her BP to 125/80 mm Hg with labetalol 200 mg PO twice daily and her HbA_{1c} to 7.3%, K.H. discontinues her oral contraceptive and returns to the clinic 5 months later and is noted to be about 4 weeks' pregnant. How should her diabetes be managed at this time?

TYPE 1 DIABETES TREATMENT IN PREGNANCY

Goals of therapy

The overall goal of treatment of K.H.'s diabetes is to reduce the maternal and fetal morbidity and mortality associated with diabetes. Treatment of diabetes (see Chapter 53, Diabetes Mellitus) should include dietary management, appropriate maternal weight gain, insulin therapy to normalize glycemic control, and exercise.

Dietary management

The goals of dietary management for diabetes during pregnancy are directed at ensuring fetal growth and development, appropriate maternal weight gain, and normalizing maternal glucose concentrations. Patients often benefit from individualized diets developed by a dietitian. Neonatal macrosomia has been associated with high postprandial glucose levels; therefore, a reduction in postprandial hyperglycemia is an important goal.

Blood glucose and glycated hemoglobin monitoring

K.H. should begin to self-monitor her blood sugars more intensively at fasting, before meals, 1 hour postprandially, at bedtime, when she feels symptomatic hypoglycemia, and at 3:00 AM to rule out dawn phenomenon versus Somogyi effect.[76] The goal of therapy is to maintain fasting glucose levels <90 mg/dL, premeal values of <100 mg/dL, and 1-hour postprandial levels of 100 to 120 mg/dL.[66,69] Tight glycemic control without incidence of hypoglycemic episodes,

targeting HbA_{1c} levels in the normal range, is the goal. Adjusting therapy based on postprandial glucose levels (as opposed to preprandial levels) can lower HbA_{1c} levels and decrease the risk of macrosomia, neonatal hypoglycemia, and cesarean delivery. HbA_{1c} levels can be drawn at each trimester to reveal the glycemic control during the previous 3 months.[68,69]

Insulin therapy

Insulin analogs (eg, lispro, aspart, glargine) are genetically engineered by recombinant DNA technology and usually differ by a few amino acids from human insulin. Concerns about insulin analog use during pregnancy include placental drug transfer and antibody formation.[77] The use of lispro (Humalog®) and aspart (Novolog®) insulin during pregnancy is supported by several studies that found minimal passage across the placenta, an absence of antibody formation, and no adverse maternal or fetal effects. Although the rapid onset of insulin lispro and aspart can increase adherence and patient satisfaction, it also may increase the incidence of hypoglycemia. Insulin glargine (Lantus®), a long-acting insulin analog, allows for once-daily dosing and produces a peakless basal level of insulin. Only case reports have examined the safety and efficacy of insulin glargine during pregnancy.[38] Glargine is usually reserved for patients with very brittle and sensitive insulin-dependent type 1 diabetes. Neutral protamine Hagedorn (NPH) insulin is usually used twice daily during pregnancy in lieu of insulin glargine as a basal insulin because it helps control fasting blood sugars better than does a peakless basal insulin. Newer insulin analogs such as insulin detemir (Levemir®) and insulin glulisine (Apidra®) have not yet been adequately studied during pregnancy and should not be used until further studies clarify their teratogenicity risk.[39]

Glycemic control is most difficult to establish during the first trimester of pregnancy because of the effect on blood sugars of maternal fluctuating hormones.[66,69] K.H.'s insulin regimen should be optimized by changing from insulin glargine to NPH insulin (with a 1:1 ratio) to help better control her fasting blood sugars and

instituting a standard insulin lispro dosage before meals based on her carbohydrate intake. Sliding scale insulin therapy is rarely used during pregnancy.[66,69] Insulin dosages commonly need to be monitored more strictly (every 2–4 days until glycemic control is achieved) during the first trimester and adjusted usually upward every 2 to 3 weeks during pregnancy.

TYPE 2 DIABETES TREATMENT IN PREGNANCY

Insulin therapy

CASE 49-3

QUESTION 1: V.W. is a 36-year-old G3, P0 with class B diabetes at 15 weeks' gestation with a history of two spontaneous miscarriages occurring last year. She was diagnosed with diabetes 5 years ago during a routine physical examination. She is morbidly obese with a body mass index (BMI) of 49 kg/m^2, height of 65 inches (165.10 cm), and weight of 295 pounds (133.81 kg). She recently found out that she was pregnant and has not had any prenatal care. Her current medications include metformin 1000 mg PO twice daily and glipizide 5 mg PO daily. She states she has been noncompliant with checking her blood sugars, maintaining a diabetic diet, and taking her medication. Her last HbA_{1c}, which was 8.3%, was 2 months ago.

Which medication and treatments should V.W. be started on?

Insulin is the hypoglycemic agent of choice during pregnancy because it does not cross the placenta and has an established safety record for both patient and fetus. The goal with insulin therapy is to imitate the glucose levels of a healthy pregnant person. Rapid glycemic control is of utmost importance during this critical period of organogenesis when vital organs are developing.[73]

Insulin requirements may vary, depending on the trimester. The first trimester is characterized by unstable diabetes, followed by a stable period.[65] During the first trimester, glucose and gluconeogenic substances in the blood are taken up by the fetus, which can lead to a decrease in maternal insulin requirements and increased episodes of hypoglycemia. On average, insulin dosages range from 0.7 to 0.8 units/kg/day in the first trimester.[66,69] If nausea and vomiting occur

during this time, glycemic control may be unstable and should be monitored closely. At about 24 weeks' gestation, insulin requirements begin to increase from 0.8 to 1 unit/kg/day, and insulin doses may need to be adjusted every 5 to 10 days.[66,69] These needs continue to increase during the third trimester from 0.9 to 1.2 units/kg/day, which may be twice as much as the prepregnancy dose, in part because of the placental hormones (ie, lactogen, PRL, estrogen, and progesterone), which antagonize the action of insulin. Weight-based dosing may not accurately assess the insulin requirements in all pregnant patients, especially in the obese population. Insulin regimens must be individualized for each patient, taking into consideration their educational level, compliance, and schedule constraints. Dosage adjustments must take into account the level of activity, meal plan, and other factors (eg, steroid use, stress, infections) that may affect glucose control. Some patients may be admitted into the hospital in the first trimester to (a) rapidly gain glucose control, (b) accurately assess their insulin requirements, and (c) institute an individualized insulin regimen under careful monitoring of blood sugars.[65]

An insulin regimen with three to four daily injections is most successful at maintaining adequate glucose control. Biosynthetic human insulin (eg, regular and NPH insulin) is the usual treatment of choice in pregestational diabetes mellitus because of its chemical, biologic, and immunologic equivalency to pancreatic human insulin.[38] These insulins have the most established safety profile during pregnancy, but they require more stringent timing of meals during the day.[38]

V.W. should be switched from her oral hypoglycemic agents to insulin therapy with biosynthetic human regular insulin and NPH insulin. Metformin and glipizide should be discontinued. The total daily insulin dosage can be calculated by taking into account V.W.'s gestational age and actual body weight. Her total daily dose equals 0.8 units/kg × 295.42 pounds (134 kg), or 107 units daily. Using three injections per day, her dosage would be 47 units of NPH insulin plus 24 units of regular insulin SC 30 minutes before breakfast, 18 units of regular insulin SC 30 minutes before dinner, and 18 units SC of

NPH insulin at bedtime. V.W.'s treatment plan needs to include dietary management; appropriate counseling on maternal weight gain during pregnancy given her morbid obesity; instructions on how to draw up, mix, and inject her insulin therapy to normalize glycemic control; and moderate exercise and walking 20 to 30 minutes after each meal. She should be taught to inject SC only in the abdomen area where insulin is best absorbed during pregnancy. V.W. should also be given a glucometer and taught how to self-monitor her blood sugars four times daily, at fasting and 1 hour postprandially (after the last bite of food from each meal) to target fasting blood glucose levels <90 mg/dL and 1-hour postprandial levels <120 mg/dL.

Oral hypoglycemic use in type 2 diabetes during pregnancy

Although oral hypoglycemic agents are used commonly to treat type 2 diabetes in nonpregnant patients, they are rarely used as monotherapy during pregnancy. A switch to insulin therapy is recommended before conception, if possible, or at the time the pregnancy is confirmed because many patients have inadequate control with oral hypoglycemic agents.[66–69] If insulin is not started before conception, patients should be strongly counseled to stay on oral hypoglycemics to adequately control blood glucose until insulin therapy can be implemented. Often, patients will discontinue oral hypoglycemics from fear of taking any medication in pregnancy, resulting in hyperglycemia during the critical period of organogenesis.

The ACOG recommends that the use of oral hypoglycemics for the treatment of type 2 diabetes during pregnancy be individualized until more safety and efficacy data become available.[66–71] There is limited experience with oral hypoglycemic use in type 2 diabetes during pregnancy. Metformin, a biguanide, has been used during pregnancy for hyperinsulinemic insulin resistance or in the treatment of infertility in patients with polycystic ovarian syndrome (see Chapter 50, Disorders Related to the Menstrual Cycle). Patients taking metformin should be switched to insulin therapy unless specific circumstances (eg, high insulin requirements during the second or third trimester)

warrant its use.[77]. Studies have shown that the sulfonylureas are inferior to both insulin and metformin and increase risk of neonatal hypoglycemia.[74]

Case 49-3, Question 2: Should an oral hypoglycemic be added to V.W.'s insulin regimen?

V.W. should remain on insulin therapy with three injections daily. Her insulin regimen should be adjusted every 2 to 3 days until glycemic control is achieved and targeted blood glucose levels are reached without significant hypoglycemia episodes. Metformin should only be added if V.W.'s total daily insulin requirement exceeds 250 to 300 units. If metformin is added, insulin dosages should be decreased to at least half the amount in anticipation of increased insulin sensitivity.

Gestational Diabetes Mellitus

DIAGNOSTIC CRITERIA

CASE 49-4

Question 1: J.B. is a 22-year-old Asian female in the 24th week of her first pregnancy. She is 62 inches (157.48 cm), 165.35 pounds (75 kg; prepregnancy weight), and her BMI is 30 kg/m^2. At her regular prenatal visit, her obstetrician recommends an oral glucose screening test for GDM. Her HbA_{1c} was 5.8%. Although her mother has diabetes, J.B. has had no glucosuria during pregnancy.

Is J.B. at risk for GDM?

GDM is defined as carbohydrate intolerance that develops or is recognized during pregnancy regardless of severity, necessity for treatment, time of onset, or persistence after pregnancy.[78] GDM occurs in about 7% (range, 1%–14%), and the prevalence varies with the population and methods of detection.[78] Complications noted in the offspring of affected patients include macrosomia,

hypocalcemia, hypoglycemia, polycythemia, and jaundice. Patients with GDM are more likely to experience pregnancy-induced hypertensive disorders or require a cesarean delivery. They also are at risk for type 2 diabetes later, and their children have an increased risk for obesity and diabetes later in life.

Risk factors for GDM include age older than 25 years, obesity (BMI ≥25 kg/m^2), family history of diabetes, previous delivery of an infant weighing >8.82 pounds (4 kg), a history of stillbirth, a history of glucose intolerance, or current glycosuria.[78] African Americans, Hispanic, Asian, Native American, and Pacific Islander females also are at increased risk for GDM.[66,78]

J.B. is at risk for GDM because she is Asian and obese, and she has a family history of diabetes. Her HbA_{1c} at 26 weeks' gestation was normal and ruled her out for overt diabetes. J.B. should undergo the standard screening for gestational diabetes with a 50-g, 1-hour glucose challenge. It is not essential for J.B. to fast before this test. The diagnosis of GDM is important to the patient and the fetus because of the increased risks of fetal hyperinsulinemia and macrosomia.

GESTATIONAL DIABETES MELLITUS TREATMENT

Case 49-4, Question 2: J.B. is screened with a 50-g, 1-hour glucose challenge resulting at 161 mg/dL. Because her screening test was elevated, a diagnostic 3-hour oral glucose tolerance test (OGTT) was given to her the next day, which required her to be fasting. The results of the 3-hour OGTT showed a fasting plasma glucose of 96 mg/dL, a 1-hour glucose of 183 mg/dL, 2-hour glucose of 140 mg/dL, and 3-hour glucose of 126 mg/dL. These results confirm that J.B. has GDM. How should she be managed?

J.B. requires extensive education about a gestational diabetes diet, use of a glucometer, the signs and symptoms of hyperglycemia and hypoglycemia, and treatment of low blood glucose. She should start to monitor her blood glucose four times daily, at fasting and 1 hour after the end of each meal. She should return to the clinic in 1

week for an assessment of her blood sugars to evaluate the need for medication therapy (insulin vs glyburide treatment).

It is suggested that 60% to 85% of patients with GDM can control their glucose with dietary modifications and regular exercise; however, management with medications (insulin vs oral hypoglycemics) should be initiated if dietary management fails to maintain fasting plasma blood glucose concentrations at ≤95 mg/dL or to achieve a 1-hour postprandial plasma concentration of <140 mg/dL.[74] **Figure 49-3** outlines recommendations for screening and diagnosis of gestational diabetes.

Figure 49-3 Recommendations for screening and diagnosis of gestational diabetes. FBG, fasting blood glucose; GDM, gestational

diabetes mellitus; OGTT, oral glucose tolerance test. (Sources: Cunningham FG, Leveno KJ, Bloom SL, et al. Diabetes Mellitus. In: Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 24th ed. McGraw-Hill, 2014:1125-1146; White P. Classification of obstetric diabetes. *Am J Obstet Gynecol.* 1978;130(2):228–230.)

Case 49-4, Question 3: J.B. returns to the clinic at 30 weeks' gestation with glucometer and logbook for a blood glucose assessment. She has been compliant with her diabetic diet and blood sugar monitoring for the past 4 weeks. She has been able to control her blood sugars with diet and moderate walking after meals. However, she has noticed that her fasting blood glucose has risen in the past week to an average of 98 mg/dL and her dinner postprandial values are averaging 139 mg/dL. How should J.B. be managed at this time?

Treatment of GDM with insulin therapy is implemented similar to the treatment for pregestational diabetes. An optimal insulin regimen for GDM has not been determined. Similar dosing with a weight-based, split-mixed multidose regimen is used. The insulin regimen must be tailored specifically to the needs of the person to successfully achieve target blood glucose levels.

More recently, the Metformin in Gestational Diabetes trial examined whether metformin treatment could provide outcomes equivalent to that of insulin treatment. Patients with GDM at 20 to 33 weeks' gestation were randomly assigned to open-label treatment with metformin (titrated up to 2500 mg with the option to add supplemental insulin if glycemic control was not achieved) or to insulin treatment alone.[79] The two groups achieved similar primary outcomes (composite score of neonatal morbidities), but 46% of the group allocated to metformin required supplemental insulin therapy. Those requiring supplemental insulin were more obese and had higher elevations of glycemic values at presentation. The results indicate that metformin can be used during pregnancy for GDM, but will less likely be successful as monotherapy in patients with higher glucose levels.[79] Metformin is usually reserved for patients with high insulin requirements (>300 units daily) in the second and third

trimesters.[38] More randomized trials are needed to further determine and to better understand the role of oral hypoglycemic agents in pregnancy.

Other oral hypoglycemics, such as the sulfonylureas, have inferior data and increase risk of adverse effects.[74]

J.B. is a good candidate for insulin therapy because she is at >30 weeks' gestation and has a fasting blood sugar level <110 mg/dL. Doses should be increased or decreased to achieve glycemic control.

RISK OF DEVELOPING DIABETES MELLITUS

CASE 49-4, QUESTION 4: Why is J.B. at risk for developing diabetes mellitus after delivery?

Glucose tolerance normalizes after delivery for most patients. Patients with GDM, however, have a 15% to 50% chance of developing nongestational diabetes within 5 to 16 years.[72] The highest risk is in patients who are obese or were diagnosed before 24 weeks' gestation or who had marked hyperglycemia during or soon after pregnancy. The risk of developing GDM in a future pregnancy is estimated to be 50%.[66,78]

J.B. should try to minimize the potential for development of insulin resistance by exercising and maintaining a normal weight. She should also have her glucose checked with a 2-hour OGTT at her postpartum appointment 6 weeks after delivery and then at least every 1 to 3 years with screening of either fasting blood sugar or HbA_{1c}. In addition, J.B. should be instructed about the importance of using an effective birth control method to prevent unplanned pregnancies. She also needs to schedule regular appointments with her primary care clinician.

HYPERTENSION AND PREECLAMPSIA

Chronic Hypertension

CLINICAL PRESENTATION

CASE 49-5

QUESTION 1: T.D., a 37-year-old G1, P0, Black female with obesity was diagnosed with stage 1 hypertension several months before her pregnancy (BP, 135–145 mm Hg systolic and 90–95 mm Hg diastolic). She had no cardiovascular risk factors (ie, smoking, diabetes mellitus, dyslipidemias) and was prescribed a trial of lifestyle modification (ie, weight loss and exercise). When she initiated prenatal care at 16 weeks' gestation, her BP ranged from 130 to 135 mm Hg systolic pressure and 82 to 85 mm Hg diastolic pressure. Her BP today at 28 weeks is 142/90 mm Hg. Her serum chemistry values are creatinine (SCr) at 0.6 mg/dL and UA at 4 mg/dL. A random urinalysis did not demonstrate proteinuria. Ultrasound confirms an adequately growing fetus at 28 weeks' gestation.

What type of hypertension does T.D. have? What is the likelihood T.D. has preeclampsia?

Hypertensive disease occurs in 5% to 8% of all pregnancies and is a major cause of maternal and perinatal morbidity and mortality.[80] From 15% to 24% of maternal deaths in developed countries are attributed to hypertensive disorders in pregnancy.[81,82] *Hypertension in pregnancy* is defined as a systolic BP of at least 140 mm Hg or a diastolic BP of at least 90 mm Hg on two separate occasions at least 6 hours apart.

Patients with pregnancy-associated hypertension can be grouped into the following categories: chronic hypertension, preeclampsia–eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.[80] After delivery, *gestational hypertension* is ultimately delineated as either (a) transient hypertension of pregnancy if preeclampsia is absent during delivery and BP normalizes by 12 weeks postpartum or (b) chronic hypertension if BP remains elevated.[80]

Chronic hypertension is defined as hypertension diagnosed before conception or before the 20th week of gestation, or hypertension persisting beyond 12 weeks postpartum.[80] Hypertension noted after

the 20th week of gestation might be difficult to classify, particularly if a patient has had inadequate prenatal care without appropriate BP monitoring.

Patients with chronic hypertension, similar to T.D., commonly have a normal BP during the first half of pregnancy because of the physiologic decline of BP during the second trimester.[83] BP usually returns to the prepregnancy level by the third trimester. T.D.'s diastolic pressure decreased from the prepregnancy levels of 90 to 95 mm Hg to 86 to 90 mm Hg during the second trimester. It is normal for T.D.'s BP to increase during the third trimester. These changes in BP make it difficult to differentiate chronic hypertension from preeclampsia during the second half of pregnancy in patients with late prenatal care or inadequate BP monitoring. It is also difficult to diagnose preeclampsia superimposed on existing hypertension using BP measurements alone. A sharp increase in T.D.'s pressure of >30 mm Hg systolic or >15 mm Hg diastolic could be consistent with preeclampsia. Without coexisting proteinuria (≥0.3 g/24 hours or ≥1+ in a random urine sample) or evidence of renal dysfunction, a diagnosis of preeclampsia would be a reach.[83] T.D. has no proteinuria, and a normal SCr and serum UA. T.D. has chronic hypertension, but it is unlikely that T.D. has preeclampsia at this time.

RISK FACTORS FOR PREECLAMPSIA

Case 49-5, Question 2: What risk factors does T.D. have for developing preeclampsia?

Preeclampsia is a pregnancy-specific condition usually occurring after 20 weeks' gestation and consisting of hypertension with proteinuria.[83] Preeclampsia can affect multiple organ systems (eg, kidney, liver, hematologic, CNS). The signs and symptoms are often unpredictable and can be mistaken for other disorders. Because edema is so common in normal pregnancy and is not specific, it is no longer used as a criterion for the diagnosis of preeclampsia.

Preeclampsia is a consequence of progressive placental and maternal endothelial cell dysfunction, increased platelet aggregation, and loss of arterial vasoregulation. A variant of preeclampsia is hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome. HELLP can also be life-threatening and may not always present with proteinuria and increases in BP.[84]

When patients with preeclampsia exhibit seizures, the term *eclampsia* is used. Patients with preeclampsia may unpredictably progress rapidly from mild-to-severe preeclampsia and to eclampsia within days or even hours. Eclampsia is a potentially preventable complication of preeclampsia. About 20% of patients who experience eclampsia have a diastolic BP <90 mm Hg or no proteinuria.[85]

The term *gestational hypertension* is used when BP is increased during pregnancy or is increased in the first 24 hours postpartum in a patient without signs or symptoms of preeclampsia and without preexisting hypertension.[80] Patients with gestational hypertension are at high risk for recurrence during subsequent pregnancies.

Preeclampsia occurs most commonly during the first pregnancy (two-thirds of cases). Obesity and increasing maternal age are risk factors.[86] Chronic diseases that increase the risk of preeclampsia include diabetes mellitus or insulin resistance and renal disease. Pregnancy-associated risk factors include multifetal gestations, UTI, certain fetal chromosomal anomalies, and hydatidiform moles. A family history of a sister or mother with preeclampsia significantly increases the risk of developing preeclampsia. Patients with previous preeclampsia are at high risk for recurrence in subsequent pregnancies, particularly if it developed before 30 weeks' gestation.[86,87] In addition to her age and obesity, chronic hypertension is the most significant aspect of T.D.'s medical history, which confers a 25% risk of developing superimposed preeclampsia.[87]

Monitoring

Case 49-5, Question 3: What subjective and objective data should be monitored in T.D. for the development of preeclampsia?

T.D. should have her BP monitored frequently. If protein is detected in a random urinalysis, then a 24-hour urine collection for protein and creatinine can be repeated to determine accurately the degree of proteinuria and severity of disease.[80] Periodic ultrasounds should be obtained to assess fetal growth because IUGR is common in pregnant patients with chronic hypertension. T.D. should be taught to recognize and immediately report all signs and symptoms of preeclampsia, such as nondependent edema (ie, swelling of face or hands), headaches, and visual disturbances. The latter two are signs of severe preeclampsia and may indicate impending eclampsia. Upper abdominal pain also can be a sign of severe preeclampsia, indicating hepatic subcapsular hemorrhage.[86] Because T.D. has chronic hypertension, worsening of hypertension alone may not be a reliable sign of superimposed preeclampsia. Proteinuria is the best indicator of superimposed preeclampsia in a pregnant patient with chronic hypertension and no renal disease.[85]

Antihypertensive drug therapy

Case 49-5, Question 4: Should T.D.'s chronic hypertension be treated with antihypertensive drugs to prevent preeclampsia?

The goal of antihypertensive therapy for patients with chronic hypertension during pregnancy is to minimize the risks to the patient of an elevated BP without compromising placental perfusion.[84] The value of treating pregnant patients with chronic antihypertension drugs remains an area of ongoing debate. A sustained diastolic BP of >100 mm Hg may cause maternal vascular damage, especially if the diastolic pressure is >105 to 110 mm Hg.[86] Morbidity is unlikely with a diastolic BP of <100 mm Hg. Therefore, many clinicians recommend treatment with antihypertensive drugs to lower diastolic pressures of >100 to 110 mm Hg.[80] Treatment of a diastolic BP of

<100 mm Hg should be reserved for patients with chronic hypertension and target-organ damage (eg, left ventricular hypertrophy) or underlying renal disease because antihypertensive drugs can decrease placental blood flow, which might increase fetal growth restriction.[88,89] Treatment of mild-to-moderate hypertension is associated with a decrease in the risk of developing severe hypertension by ~50%, but the overall risk of developing preeclampsia is unchanged.[90] Furthermore, there is no evidence of a reduction in the risk of stillbirth, fetal growth restriction, or preterm birth if patients with chronic hypertension with systolic BP of 140 to 169 mm Hg or diastolic BP of 90 to 109 mm Hg are given antihypertensive therapy.[90] Moreover, patients treated with antihypertensive therapy were more likely to experience adverse drug effects compared with those who received placebo or were untreated. Antihypertensive therapy, however, is required to reduce the risk of cardiovascular morbidity such as heart or renal failure and acute risk of stroke in pregnant patients with severe hypertension (diastolic >110 mm Hg).

T.D. has normal renal function and her BP is <100 mm Hg; she does not need antihypertensive drug treatment at this time. If T.D. had been on drug therapy before conception, some experts would have her continue it during the pregnancy.[80,85,88] In such cases, however, the doses of the antihypertensive agents often need to be lowered or discontinued altogether to prevent hypotension because the maternal BP naturally decreases during the second trimester. Perinatal outcomes in patients with untreated chronic hypertension who do not progress to preeclampsia are similar to those of the general obstetric population.[85] Although chronic hypertension is a major risk factor for preeclampsia, treating T.D.'s uncomplicated mild chronic hypertension is unlikely to prevent the development of preeclampsia.

Methyldopa

Case 49-5, Question 5: When T.D. returns to the clinic 2 weeks later at 30 weeks' gestation, her BP ranged from 160 to 165 mm Hg systolic pressure and 85 to 92 mm Hg diastolic pressure. Which medication should T.D. be started on?

Methyldopa, a centrally acting α-agonist that decreases sympathetic outflow to decrease BP, is the most commonly used antihypertensive agent for chronic treatment of hypertension in pregnancy in the United States. The usual starting dose of 750 to 1000 mg/day, to be administered in three to four daily divided doses, can be increased to 2 or 3 g/day if needed. Higher doses may be needed to control BP in pregnancy.[91]

Methyldopa, classified as category B for fetal risk, has the longest and best safety record of all antihypertensive agents during pregnancy. Despite its common use, few adverse effects have been reported in neonates exposed to methyldopa in utero. In addition, no congenital anomalies are associated with methyldopa.[38]

Dizziness and sedation, accompanied by a loss of energy, are among the most common adverse effects reported by pregnant patients.[91] Generally, these adverse effects occur early in therapy and tend to subside, but may recur with an increased dosage. Problems with postural hypotension usually do not occur in pregnant patients.[91] Patients should be monitored for methyldopa-induced liver damage.[87] Other drugs used to treat hypertension in pregnancy include labetalol and calcium channel blockers. A review of drug therapies for the treatment of chronic hypertension in pregnancy is listed in **Table 49-4**.[92–97]

Table 49-4

Drugs for Treatment of Chronic Hypertension in Pregnancy and Lactation

Drug	Dose	Comments

Drug	Dose	Comments
Methyldopa	750–1000 mg/day start twice a day, increase up to 2–3 g/day, divided in three to four doses if needed[99]	Longest safety record in pregnancy. Considered a first-line drug.[88] Dizziness, sedation, and lack of energy are common symptoms, which tend to resolve. Can cause liver toxicity. Low breast milk concentrations, so considered safe in breast-feeding
Labetalol	200–400 mg/day start, increase to up to 2400 mg/day, divided into two or sometimes three doses	Combined α- and β-receptor antagonist properties. Considered a first-line drug.[88] Increasingly preferred to methyldopa owing to fewer side effects. Neonatal effects could include bradycardia and hypotension. Low concentration in breast milk and generally considered safe in breast-feeding[92]
Other β-blockers	Various	Atenolol, in particular, associated with decreased placental weight and IUGR.[94,95] IUGR thought to be related to β-blocker–induced increased vascular resistance in patient and fetus. Atenolol, acebutolol, metoprolol, nadolol, and sotalol can have high milk-to-plasma ratios and accumulate in breast milk, creating potential risk for neonatal blockade.[96,97] Propanolol found in only small amounts in breast milk and generally considered safe, but infants should be monitored for hypotension, bradycardia, and blood glucose changes.
Nifedipine, long-acting	30 mg/day start, increase to up to 120 mg/day, once daily	Limited pregnancy data on nifedipine or other calcium channel blockers such as verapamil, diltiazem, and amlodipine. Concentrations of nifedipine in breast milk are low and considered compatible with breast-feeding[107,108]

Drug	Dose	Comments
Diuretics	Various	Not first-line agents, although probably safe.[88] Concern regarding potential interference with normal blood volume expansion in pregnancy. Avoid if preeclampsia or IUGR already present. Concentration low in breast milk, but may decrease milk production
ACEI or ARB	Contraindicated	Contraindicated in pregnancy in all trimesters. Fetal renal failure when used after first trimester, resulting in oligohydramnios, limb contractures, pulmonary hypoplasia, skull hypoplasia, and irreversible neonatal renal failure.[38] Increased risk of major birth defects with first-trimester ACEI exposure.[75] Minimal amounts of captopril and enalapril in breast milk and both considered compatible with breast-feeding.[229] Minimal amounts of benazepril in breast milk

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin II receptor blocker; IUGR, intrauterine growth restriction.

T.D. should be started on methyldopa 500 mg PO three times daily. If T.D. cannot tolerate the side effects, she can be switched to labetalol 200 mg PO twice daily. The only antihypertensive drugs absolutely contraindicated during pregnancy are ACEI and angiotensin II receptor blockers because of the association with fetal and newborn morbidity and mortality.[88]

Mild Preeclampsia

Case 49-5, Question 6: T.D. returns to her obstetrician 1 week later at 31 weeks' gestation with mild hand and leg edema. She has 1+ proteinuria by dipstick, and her BP is 155/102 mm Hg. An ultrasound finding demonstrates fetal growth restriction. Laboratory results are as follows:

SCr, 0.9 mg/dL
Serum UA, 6.0 mg/dL
Aspartate aminotransferase (AST), 25 units/L
Alanine aminotransferase (ALT), 16 units/L
Platelets, 230,000/μL

She is currently on labetalol 200 mg PO twice daily and has been compliant with her medications.

What signs and laboratory evidence are consistent with preeclampsia in T.D.? Does she have mild or severe preeclampsia?

ETIOLOGY AND PATHOGENESIS

The causes of preeclampsia currently remain unknown. Although the pathogenesis begins early in pregnancy, the disease is not clinically evident until the latter half of the pregnancy and persists until the fetus is delivered.[98] Incomplete physiologic placental vascular bed changes and endothelial cell dysfunction are integral to the pathogenesis of preeclampsia.

Placental ischemia

Early in a normal pregnancy, the trophoblastic migration and invasion of the uterine spiral arteries result in physiologic changes within the placental vascular bed that facilitate maximal intervillous blood flow. The physiologic changes within these spiral arteries are responsible for creating a fixed low-resistance arteriolar circuit, which increases blood supply to the growing fetus. In preeclampsia, these physiologic changes do not occur completely, resulting in decreased perfusion and, consequently, placental ischemia.[98,99]

Endothelial damage

An intact vascular endothelium assists in preserving the integrity of vasculature, mediating immune and inflammatory responses, preventing intravascular coagulation, and modulating the contractility of the underlying smooth muscle cells.[99]

In normal pregnancy, prostacyclin is increased 8 to 10 times, creating an increased ratio of prostacyclin to thromboxane A_2.[98] The biologic dominance of prostacyclin along with nitric oxide plays an important role in maintaining vasodilation throughout pregnancy. Prostacyclin may be responsible for vascular refractoriness to angiotensin II in normal pregnancy. In preeclampsia, the ratio of prostacyclin to thromboxane A_2 is reversed. Thromboxane A_2 is

biologically dominant during preeclampsia, leading to increased vascular sensitivity to angiotensin II and norepinephrine.[98] The increased release of thromboxane A_2 is believed to be caused by endothelial cell dysfunction. The end result is vasospasm, which further increases endothelial cell dysfunction and increases BP.[98] Reduced activity of nitric oxide synthase and decreased nitric oxide–dependent or nitric oxide–independent endothelium-derived relaxing factors are believed to increase the vasoconstrictive potential of pressures such as angiotensin II.[80]

Endothelial cell dysfunction in pregnancy is thought to be caused by oxidative stress. Intermittent hypoxic and reperfusion injury that occurs as a consequence of decreased placental perfusion may increase oxidative stress.[98,99] Endothelial damage eventually leads to disruption of the vascular lining, which causes leaking capillary membranes, allowing fluid to leak into the interstitium.[99] In severe preeclampsia, this results in hypovolemia, hemoconcentration, and, consequently, an increase in hematocrit. The loss of plasma volume, vasospasm, and microthrombi decrease perfusion of the kidney, CNS, liver, and other organs. The loss of intravascular proteins in the urine secondary to renal damage, and through damaged epithelia, decreases plasma oncotic pressure and leads to a rapid onset of nondependent edema. The imbalance of endogenous procoagulants and anticoagulants produces platelet consumption and results in thrombocytopenia and coagulation defects.[99]

T.D.'s diastolic BP is now higher than it was before her pregnancy and has increased by 12 mm Hg in the past 3 weeks. Although an increase in BP by itself is not diagnostic of preeclampsia, the new finding of proteinuria confirms the diagnosis. Other evidence for preeclampsia includes the elevated serum UA concentration, which is a sensitive marker for preeclampsia, and elevated SCr.[86] T.D. denies headaches, visual disturbances, and abdominal pain, which are symptoms of severe preeclampsia. The transaminases and platelet count are normal; therefore, she does not have HELLP syndrome at this time. T.D.'s clinical presentation is consistent with mild preeclampsia; however, a 24-hour urine collection should be

obtained to measure protein excretion, quantify the urine output, and further rule out severe preeclampsia.

TREATMENT OF PREECLAMPSIA

General principles

Case 49-5, Question 7: T.D. is admitted to the hospital. The 24-hour urine protein is 500 mg/24 hours. Although fetal growth is restricted, all other fetal testing is reassuring. After 24 hours, her BP decreased to 140/95 mm Hg. Her platelet counts remained stable and >200/mL, and transaminases were normal. No other signs and symptoms of preeclampsia were noted. How should T.D.'s mild preeclampsia be managed?

The delivery of the fetus is the only cure for preeclampsia and would be the best treatment option for T.D. if she were at >37 weeks' gestation. T.D. has mild disease, however, and is not close to term. Her delivery should be postponed because premature delivery increases neonatal morbidity and mortality. T.D.'s fetus is somewhat growth restricted, which is common in patients with chronic hypertension, with or without superimposed preeclampsia. If T.D.'s fetus is severely growth restricted or if subsequent fetal biophysical testing is abnormal, premature delivery would be indicated.[80] Because neither of these is evident in the present circumstances, T.D. should continue her pregnancy under very close medical supervision. It has been suggested that continued hospitalization is appropriate for patients with preterm onset of mild preeclampsia, such as T.D.[80] This would allow for rapid intervention in case of rapid progression of disease or associated complications. Probably, a role exists for outpatient monitoring of select patients with very frequent maternal and fetal monitoring, and rehospitalization for worsening disease.[80]

T.D. is also a candidate for administration of glucocorticoids for fetal lung maturation (see Case 49-7, Question 7). Bed rest in the lateral decubitus position is usually suggested and may help reduce BP and promote diuresis by decreasing vasoconstriction and improving renal and uteroplacental perfusion.

T.D. should have her BP measured regularly each day. Liver transaminases, platelets, and creatinine should be measured periodically and whenever her clinical status changes. She also should be assessed for symptoms of severe preeclampsia (eg, headaches, visual disturbances, epigastric or right upper quadrant pain). Fetal surveillance is indicated.[80] One approach is to perform a modified biophysical profile, a test performed to ensure fetal well-being using ultrasonography measuring fetal breathing, tone, movement, and amniotic fluid volume with an assessment in fetal heart rate, twice a week and whenever maternal clinical status changes, and an ultrasound for fetal growth every 3 to 4 weeks.

Severe Preeclampsia

CLINICAL PRESENTATION

Case 49-5, Question 8: T.D.'s BP for about 2 weeks ranged from 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic with bed rest. Her proteinuria remained stable at 1+ to 2+ by dipstick. During the past 2 days, T.D.'s BP started to increase again, and today her BP is 160/112 mm Hg and her urine dipstick is 3+. She reports headaches, dizziness, and visual disturbances and has significant edema in her face, hands, legs, and ankles. T.D. is transferred to the Labor and Delivery Unit for delivery. Pertinent laboratory results are as follows:

SCr, 1.3 mg/dL
UA, 6.7 mg/dL
AST, 30 units/L
ALT, 16 units/L
Total bilirubin, 1 mg/dL
Platelets, 95,000/mL
Hematocrit, 38%
Hemoglobin, 13 g/dL
Random urine protein, 4+

Estimated fetal weight by ultrasound is 1700 g, which is between the 10th and 25th percentile for a gestational age of 34 weeks. What signs, symptoms, and laboratory evidence of severe preeclampsia support this diagnosis in T.D., and what complications may occur?

T.D. has developed severe preeclampsia.[84] Her systolic and diastolic BP are >160 and 112 mm Hg, respectively. She has >3+ protein in a random urine sample, and her SCr is elevated. She reports headaches and visual disturbances. T.D. is also thrombocytopenic because her platelet count is 95,000/mL. Although her liver transaminases are currently normal, she may be developing HELLP syndrome, a variant of severe preeclampsia associated with a high incidence of maternal and perinatal morbidity and mortality. Therefore, her laboratory values should continue to be monitored even as delivery is being planned.

COMPLICATIONS

T.D. is at risk for cerebral hemorrhage, cerebral edema, encephalopathy, coagulopathies, pulmonary edema, liver failure, renal failure, and eclamptic seizures.[85,86] Severe preeclampsia is dangerous not only to T.D. but also to her fetus because uteroplacental perfusion is compromised. T.D. requires drug treatments to both lower her BP and prevent eclampsia, as well as for the delivery.

ACUTE TREATMENT OF SEVERE HYPERTENSION

Case 49-5, Question 9: How should T.D.'s severe hypertension be treated?

The goal of antihypertensive therapy in T.D. is to prevent cerebral complications (eg, encephalopathy, hemorrhage).[85] Although it is important to reduce the maternal BP, it must be accomplished gradually while the fetus is in utero because a sudden large drop in maternal BP could result in the reduction of uteroplacental perfusion.[86] Because of the potential for fetal bradycardia during or after acute treatment of maternal hypertension, continuous fetal heart rate monitoring should be considered.

Hydralazine

Hydralazine, a direct arterial smooth muscle dilator, has in the past been the drug of choice for the acute treatment of severe hypertension in pregnancy.[85,91] This drug induces a baroreceptor-mediated tachycardia and increases cardiac output, which increases uterine blood flow because the BP is lowered.[86]

The onset of antihypertensive effect for hydralazine ranges from 10 to 20 minutes, and duration of action ranges from 3 to 6 hours after an IV dose.[86,100] Therefore, doses of hydralazine should not be repeated more frequently than every 20 to 30 minutes to prevent drug accumulation.[91] Nausea, vomiting, tachycardia, flushing, headache, and tremors could occur. Some of these hydralazine-induced adverse effects mimic symptoms associated with severe preeclampsia and imminent eclampsia, making it difficult for a clinician to differentiate between drug-associated and disease-related problems.[91] Fetal hydralazine serum concentrations are reportedly the same as or higher than maternal serum concentrations, but drug-associated fetal abnormalities have not been reported.[38]

Labetalol

Labetalol is also a commonly used drug to treat severe hypertension during pregnancy. It should be administered IV in increasing doses of 20, 40, and 80 mg every 10 minutes to a cumulative dose of 300 mg or until the diastolic pressure is <100 mm Hg.[101] The onset of action is within 5 minutes, and its effect peaks in 10 to 20 minutes with a duration of action ranging from 45 minutes to 6 hours.

IV labetalol is as effective as IV hydralazine in lowering BP in patients with hypertension during pregnancy, but has fewer reported adverse effects.[91–102] In a meta-analysis of β-blocker trials for the treatment of hypertension in pregnancy, labetalol was associated with less maternal hypotension, fewer cesarean deliveries, and no increase in perinatal mortality.[102] Labetalol also does not appear to decrease uteroplacental blood flow even with a decrease in maternal BP.[91] Labetalol reduces cerebral perfusion pressure, which occurs in up to 43% of patients with severe preeclampsia, without negatively

affecting cerebral blood flow.[103] Decreased cerebral perfusion pressure may prevent progression to eclampsia. However, it should be avoided in patients with asthma and decompensated heart failure.[104,105] Labetalol has also been associated with higher rates of neonatal bradycardia and hypotension than has hydralazine, but not higher rates of neonatal intensive care admission.[106,107]

Nifedipine

Nifedipine has been used in doses of 10 mg for acute treatment of severe hypertension during pregnancy because it can be given PO.[91] Nifedipine is effective in decreasing BP without reducing uteroplacental blood flow or decreasing fetal heart rate. Short-acting nifedipine capsules are no longer recommended for the treatment of acute hypertensive urgency, however, because of the risk of stroke or myocardial infarction, and it was never FDA approved for this indication. Immediate-release nifedipine continues to be used to treat hypertension in pregnancy, however, because this unique patient population may not be at high risk for ischemic events secondary to atherosclerotic disease.[88] Calcium gluconate or calcium chloride should be available for IV administration in the event of sudden hypotension. Caution should be used when giving nifedipine to patients concomitantly treated with magnesium sulfate because these drugs have synergistic effects, causing hypotension and neuromuscular blockade.[106]

Several studies comparing immediate-release oral nifedipine with IV labetalol in hypertensive emergencies of pregnancy have found them to be equally effective in lowering BP.[107,108] Nifedipine lowers BP to <160 mm Hg systolic and <100 mm Hg diastolic earlier than labetalol does,[107] but it increases cardiac index[108] (see Chapter 16, Hypertensive Crises). The use of sustained-release nifedipine capsules as an alternative is associated with a delay in BP control to 45 to 90 minutes, which is probably not acceptable.[100]

Hydralazine 5 mg IV for 1 to 2 minutes should be administered to T.D. and repeated in doses of 5 to 10 mg every 20 to 30 minutes to a cumulative dose of 20 mg.[85] T.D. should have repeated

measurements of her BP at 15-minute intervals. Because intervillous blood flow depends on maternal perfusion pressure, the goal is to decrease the diastolic pressure to not <90 mm Hg.[85,100] Lowering the maternal BP excessively may decrease uteroplacental perfusion and compromise the fetus. A hypotensive overshoot can be observed with hydralazine, particularly in the setting of volume depletion, which is typical of preeclampsia.[100] If one or two doses of hydralazine are not effective in lowering T.D.'s diastolic to <100 mm Hg, labetalol 20 mg IV every 10 to 15 minutes can be given.

Eclampsia

MAGNESIUM SULFATE PROPHYLAXIS

CASE 49-5, QUESTION 10: T.D. will undergo an induction of labor for her severe preeclampsia. Which medication should be given to T.D. to prevent seizures?

The precise mechanism of anticonvulsant action of magnesium for the prevention and treatment of eclamptic seizures is unknown. The anticonvulsant activity may be partly mediated through blockade of an excitatory amino acid receptor, *N*-methyl-D-aspartate.[106] Seizures are thought to be caused by decreased cerebral blood flow because of vasospasm. Magnesium sulfate is a potent cerebral vasodilator and increases the synthesis of prostacyclin, an endothelial vasodilator. It also causes a dose-dependent decrease in systemic vascular resistance, which may explain its transient hypotensive effect. Magnesium may also protect against oxidative injury to endothelial cells.[106]

Although termination of the pregnancy is the definitive treatment for severe preeclampsia, the intrapartum and immediate postpartum periods are also the periods of greatest risk for eclampsia.[84] Although the incidence of eclampsia is extremely low, maternal morbidity and mortality are high.[109] In the United States, it has been the usual practice to treat all patients with preeclampsia with

magnesium sulfate during labor and for 12 to 24 hours postpartum.[80,85] In the United Kingdom, however, it is common to reserve magnesium sulfate therapy for severe preeclampsia.[110] The evidence for magnesium sulfate preventing the progression of disease in patients with mild preeclampsia had been largely anecdotal in the past. In a large international study of >10,000 females, published in 2002, magnesium sulfate clearly decreased the risk of eclampsia in females with preeclampsia by 58% compared with placebo.[110] An observational study of nearly 2500 females with mild preeclampsia (BP of 140/90 mm Hg and 1+ protein) found an incidence of eclampsia of about 1% without the use of seizure prophylaxis.[111]

In a prospective, randomized study, magnesium sulfate was superior to phenytoin for the prevention of eclampsia in hypertensive pregnant patients.[109] In addition, magnesium sulfate was more effective than was nimodipine for seizure prophylaxis in patients with severe preeclampsia.[112,113]

A regimen of magnesium sulfate 4 to 6 g IV as a loading dose followed by a continuous infusion of 2 g/hour is the most commonly used regimen in the United States.[114] Lower dosages (eg, 1 g/hour) have been associated with treatment failures.[115] IV loading doses of 6 g followed by continuous infusions of 2 g/hour maintain therapeutically effective magnesium serum concentrations between 4 and 8 mg/dL.[114] Because magnesium is excreted by the kidneys and will accumulate in cases of renal dysfunction, the continuous infusion rate must be lowered with oliguria or an elevated SCr.

Because of the potential for infusion errors and significant patient morbidity and even mortality with accidental overdoses of magnesium sulfate, the Institute of Medicine has identified magnesium sulfate as a high-risk medication.[115] All infusions of magnesium sulfate must be given through a controlled pump designed to protect against free flow. If such an infusion pump is not available, the intramuscular (IM) route of administration should be used. Dispensing premixed IV bags from the central pharmacy with a standardized concentration of magnesium sulfate and limiting the total grams of magnesium sulfate in each dispensed IV bag also can

help guard against inadvertent overdose. Dispensing the loading dose in a separate small bag (eg, 4 g in 100 mL) from the maintenance bag (eg, 20 g in 200 mL) also may be helpful.[116]

Magnesium sulfate should be given to T.D. to prevent eclamptic seizures during labor.[80] T.D. should be loaded with magnesium sulfate 4 g IV given for 30 minutes and then started on a continuous infusion of 2 g/hour.

MONITORING MAGNESIUM SULFATE THERAPY

Case 49-5, Question 11: T.D. has been given magnesium sulfate 4 g IV for 30 minutes and was then started on a continuous infusion of 2 g/hour. What subjective and objective data should be monitored during treatment of T.D. with magnesium?

Deep tendon reflexes (patellar reflex), respiratory rate, and urine output should be monitored periodically during treatment with magnesium sulfate.[109] The loss of patellar reflexes, the first sign of magnesium toxicity, generally occurs at serum concentrations of 8 to 12 mg/dL. The respiratory rate should be monitored hourly and should be >12 breaths/minute. Respiratory arrest can occur with serum concentrations >13 mg/dL. Urine output should be carefully monitored and should be at least 100 mL every 4 hours (or 25 mL/hour).[109] Magnesium serum concentrations are not routinely measured unless renal dysfunction is evident with oliguria or elevated SCr because magnesium is almost entirely excreted by the kidney.[106,109] Hypocalcemia and hypocalcemic tetany also can occur secondary to elevated magnesium and can be reversed by calcium gluconate 1 g (10 mL of a 10% solution) slow IV push for 3 minutes. Neuromuscular depression can occur in infants whose mothers received magnesium sulfate.[38] Parenteral magnesium sulfate is safe and rarely causes maternal or neonatal toxicity when administered properly but requires stringent, built-in system safeguards to avoid unintended dosing errors.[116]

Case 49-5, Question 12: How long should magnesium sulfate be continued in T.D.?

Depending on the severity of preeclampsia, magnesium sulfate therapy usually is continued for 24 hours after delivery, which should be the same for T.D.[117] Patients with severe preeclampsia or preeclampsia superimposed on chronic hypertension are at greater risk for disease exacerbation when magnesium sulfate is discontinued too soon.

TREATMENT OF ECLAMPSIA

Case 49-5, Question 13: T.D. delivers vaginally and her magnesium infusion was discontinued by mistake 3 hours postpartum. T.D. experiences an eclamptic seizure 4 hours later when her nurses discover that the magnesium is disconnected. What is appropriate drug therapy for eclampsia?

Lorazepam, diazepam, phenytoin, and magnesium sulfate have all been used to treat eclampsia. The use of magnesium sulfate to treat these seizures results in less maternal morbidity and mortality and less neonatal morbidity.[109,118] Generally, higher serum concentrations of magnesium sulfate are needed to treat than to prevent eclamptic seizures. However, the same therapeutic range guides both prophylaxis and treatment.[119] Seizures unresponsive to magnesium sulfate treatment should prompt an evaluation for other cerebrovascular events (eg, cerebral hemorrhage or infarction).[114] Lorazepam 2 to 4 mg slow IV push stat should be given for seizure cessation. T.D. should be reloaded with magnesium sulfate and continued on a magnesium infusion for 24 to 48 hours.

DRUG THERAPY MANAGEMENT IN LABOR AND DELIVERY

Induction of Labor

MECHANISMS OF TERM LABOR

In pregnancy, many hormones and peptides, including progesterone, prostacyclin, relaxin, nitric oxide, and parathyroid hormone–related peptide, inhibit uterine smooth muscle contractility. Labor at term occurs because the myometrium is released from its quiescent state.[120] For example, as progesterone concentrations decrease near term gestation, estrogen may stimulate uterine contractility.

Uterine activity is divided into four phases: quiescence (phase 0), activation (phase 1), stimulation (phase 2), and involution (phase 3). Each of these phases is stimulated or inhibited by several factors.[120] During activation, uterotropins such as estrogen, and, possibly others, stimulate a complex series of uterine changes (eg, increased myometrial prostaglandin and oxytocin receptors and myometrial gap junctions), which are important for the coordination of contractions. These changes help prime the myometrium and cervix for stimulation by the uterotonins oxytocin and prostaglandins E_2 and F_2a. The cervix softens, shortens, and dilates, a process referred to as *cervical ripening.* Uterine stimulation is responsible for the change in myometrial activity from irregular to regular contractions. During phase 3, involution of the uterus occurs after delivery and is mediated mostly by oxytocin.[120]

The exact stimulus of the biochemical scheme leading to labor in humans is unknown. The fetus may help facilitate this process by affecting placental steroid production through mechanical distension of the uterus and by activating the fetal hypothalamic–pituitary–adrenal axis. Ultimately, these lead to increased production of oxytocin and prostaglandins by the fetoplacental unit.

Labor is divided into three stages. Weak, irregular, rhythmic contractions (Braxton–Hicks contractions or “false labor”) may happen for weeks before the onset of true labor. The first stage begins with the start of regular uterine contractions and ends with complete cervical dilation. Stage 1 is divided further into the latent phase, active phase, and deceleration phase. During the latent

phase, the cervix effaces (thins) but dilates minimally. The contractions become progressively stronger and longer, better coordinated, and more frequent. The duration of the latent phase is the most varied and unpredictable of all aspects of labor and can continue intermittently for days. During the active phase, contractions are strong and regular, occurring every 2 to 3 minutes. The cervix dilates from 3 to 4 cm to full dilation, usually 10 cm. The second stage starts with complete cervical dilation and ends with the delivery of the fetus. The third stage of labor is the time between the delivery of the fetus and the delivery of the placenta.

INDICATIONS, CONTRAINDICATIONS, AND REQUIREMENTS

CASE 49-6

QUESTION 1: J.T., a 28-year-old primigravida, is admitted to the labor and delivery suite for labor induction. She is at 42 weeks' gestation by dates and ultrasound and has a normal obstetric examination. Cervical examination reveals an unfavorable cervix for labor induction; Bishop score is 4.

What are the indications and contraindications for labor induction in J.T.?

The induction of labor involves the artificial stimulation of uterine contractions that lead to labor and delivery. Induction of labor is indicated when the benefits to either the patient or fetus outweigh those of continuing the pregnancy. Examples may include preeclampsia, chorioamnionitis (infection of the fetal membranes, see Case 49-7, Question 11), fetal demise, significant fetal growth restriction, maternal medical problems, and postterm pregnancy.[121] Postterm pregnancy (≥42 weeks' gestation), as in J.T.'s case, is one of the most common indications for induction of labor.[121] Contraindications to labor induction are similar to those for spontaneous labor and vaginal delivery and include, but are not limited to, active genital herpes infection, placenta previa (placenta implanted over the internal cervical opening), prior classic uterine incision, transverse fetal lie (lying longitudinally across the uterus), and prolapsed umbilical cord. Maternal complications that are

associated with induction include increased rates of chorioamnionitis and uterine atony (loss of tone in uterine musculature; see Case 49-8, Question 4) resulting in hemorrhage, as well as a twofold to threefold increased risk of cesarean delivery, particularly in patients who are primigravida.[122]

A complete assessment of both patient and fetus should be performed before inducing labor.[121,123] Gestational age must be assessed accurately before the induction of labor to avoid the inadvertent delivery of a preterm fetus.[121,122] When delivery is necessary before 34 weeks' gestation with intact membranes or before 32 weeks' gestation with ruptured membranes, antenatal corticosteroids should be administered (see Case 49-7, Question 7).[123,124]

The degree of cervical ripeness and readiness for induction of labor should be assessed.[121,125] Success of labor induction is directly related to the favorability of the cervix.[126,127] The Bishop method of evaluating cervical ripeness assigns a score based on the station of the fetal head relative to the maternal ischial spines and the extent of cervical dilation, effacement (thinning of the cervix), consistency, and position.[122,125] Bishop scores of >8 are associated with rates of vaginal delivery similar to those after spontaneous labor.[121] Conversely, Bishop scores of ≤4, as documented in J.T., are associated with a high likelihood of failed induction and cesarean delivery. As a result, significant research has been directed toward methods of improving the Bishop score and cervix ripeness before stimulation of uterine contractions. However, patients with low Bishop scores who undergo cervical ripening before induction of labor still have higher rates of cesarean delivery compared with spontaneous labor.[126] Nevertheless, cervical ripening appears to have some benefits in decreasing time to delivery, shortening labor, and successfully improving Bishop score.[121]

Cervical ripening can be accomplished pharmacologically or mechanically. Pharmacologic methods include the administration of prostaglandins (E_2 and E_1) or low-dose oxytocin. Mechanical methods include membrane sweeping (or membrane stripping), and

intracervical balloons.[121,123,125] Osmotic or hygroscopic dilators (eg, Dilapan®, Lamicel®) work by absorbing cervical mucus and gradually swelling, thereby dilating the cervical canal.[122,125] In the setting of a favorable Bishop score, labor induction is accomplished most commonly by amniotomy (artificial rupture of the fetal membranes) and oxytocin administration.[121,122]

CASE 49-6, QUESTION 2: What pharmacologic agents can be used for cervical ripening in J.T.?

Although labor induction is medically indicated in J.T. to decrease the risk of an adverse fetal outcome with continuing a postterm pregnancy, such as macrosomia, asphyxia, meconium aspiration, and intrauterine infection, her cervix is unfavorable for induction, and she is a candidate for cervix ripening.

CERVICAL RIPENING

Misoprostol (Cytotec®)

Prostaglandins induce cervical ripening and enhance myometrial sensitivity to oxytocin by promoting the breakdown of collagen and increasing the submucosal hyaluronic acid and water content.[121,122,125] Misoprostol is a prostaglandin E_1 analog approved for use in the prevention of nonsteroidal anti-inflammatory drug–induced peptic ulcer disease. It also has been used for cervical ripening and the induction of labor in patients despite the lack of approval by the FDA for these latter indications.[128,129] In two large meta-analyses, misoprostol was more effective for cervical ripening and labor induction than for either placebo or treatment with dinoprostone (prostaglandin E_2).[128,129] In comparison, intravaginal misoprostol produced labor more often during cervical ripening and resulted in a reduced rate of cesarean deliveries, shorter delivery times, and a greater incidence of vaginal delivery within 24 hours but had a higher incidence of uterine contraction abnormalities than either dinoprostone vaginal insert or dinoprostone endocervical gel.[128–132] Uterine tachysystole, excessively frequent uterine

contractions, without fetal heart rate abnormalities was more common with misoprostol use. Maternal and neonatal outcomes were similar in both groups. The need for oxytocin is decreased significantly in patients treated with misoprostol compared with patients treated with dinoprostone.[131]

Oral misoprostol has also been studied for cervical ripening, but comparisons of vaginal and oral misoprostol are complicated by wide variations in dose and dose interval.[132] A meta-analysis of available studies concluded that the only consistent finding was a reduction in low 5-minute Apgar scores with oral misoprostol but no difference in neonatal intensive care unit admissions. When comparing all studies with a wide range of doses, oral misoprostol resulted in similar rates of vaginal delivery not achieved in 24 hours, uterine tachysystole with fetal heart rate changes, and cesarean delivery compared with vaginal misoprostol.[122]

Misoprostol 25 µg (one-fourth of an unscored 100-µg tablet) is inserted into the posterior vaginal fornix and repeated as needed every 3 to 6 hours.[130,131] Higher doses of 50 µg are associated with increased uterine contractile abnormalities.[128,132] Continuous fetal heart rate and uterine monitoring is recommended throughout the administration of misoprostol.[133] If oxytocin is indicated after cervical ripening, administration should be delayed at least 4 hours from the last dose of misoprostol.[121]

Misoprostol should not be used in patients with previous uterine scars because of the risk of uterine rupture.[121,130,132] Although misoprostol is a known teratogen in the first trimester of pregnancy, particularly if used in an unsuccessful attempt at medical abortion, there are no such reports with exposure beyond the first trimester.[38,130] Misoprostol's low cost and ease of administration are advantages compared with dinoprostone, and there is extensive clinical experience with this agent; however, its lack of FDA approval for cervical ripening and induction of labor is a disadvantage. Clinical trials of a controlled-release misoprostol vaginal insert are currently ongoing.[133]

Prostaglandin E2 (dinoprostone)

There are two FDA-approved forms of dinoprostone available for cervical ripening. Up to half of the patients treated with dinoprostone experience labor and deliver within 24 hours, some without oxytocin.[134,135] Dinoprostone cervical gel (Prepidil Gel®) contains dinoprostone 0.5 mg per 3-g syringe (2.5 mL gel) and is administered endocervically. The dinoprostone cervical gel must be refrigerated, and dinoprostone vaginal inserts must remain frozen until administration. Dinoprostone slow-release insert (Cervidil®) contains dinoprostone 10 mg and is inserted vaginally.[136] Postterm patients with unfavorable cervices who receive dinoprostone have shorter durations of labor, and require lower doses of oxytocin, compared with placebo or no therapy.[125,134,135,137] A large meta-analysis that included >10,000 patients found that the use of vaginal prostaglandin E_2 compared with no treatment or placebo was associated with increased rates of vaginal delivery within 24 hours, increased rates of cervix ripening, reduced need for oxytocin augmentation, and no difference in cesarean section. However, the risk of uterine tachysystole with fetal heart rate changes was increased.[138]

Both dinoprostone products are effective for cervical ripening, leading to successful induction of labor.[125,134,135,137] The two dinoprostone formulations differ in dosing and application.[139,140] The dinoprostone 10-mg vaginal insert slowly releases dinoprostone 0.3 mg/hour for a 12-hour period.[136] The insert is contained within a knitted pouch attached to a long tape. Advantages of the vaginal insert include that it is easier for the clinician to place and less uncomfortable for the patient. In addition, the insert can be removed with the onset of active labor or the development of uterine tachysystole with concurrent fetal heart rate tracing abnormalities. It should be removed within 12 hours of placement or after active labor develops, the membranes rupture, or there is evidence of tachysystole with fetal heart rate changes.[140] If dinoprostone cervical gel is used, the dose can be repeated in 6 to 12 hours if there is an inadequate change in the cervix and only minimal uterine activity, but

no more than three total doses are recommended.[140] The manufacturer of Prepidil® recommends a delay in initiation of oxytocin of 6 to 12 hours once the gel has been placed compared with a shorter delay of only 30 to 60 minutes after the vaginal insert has been removed. An initial period of uterine and fetal monitoring of up to 2 hours should occur after placement of the intracervical gel, with continued monitoring thereafter if regular uterine contractions develop and persist.[121]

The most serious side effect associated with dinoprostone administration is uterine hyperstimulation with or without an abnormal fetal heart rate tracing. The incidence of uterine hyperstimulation associated with the use of dinoprostone intravaginal insert is about 5%; the rate of occurrence for dinoprostone endocervical gel is about 1%.[121] Uterine hyperstimulation occurs more frequently if the Bishop score is >4 before administration of dinoprostone and can occur up to 9.5 hours after placement of the intravaginal insert.[121,140] Use of the vaginal insert requires continuous monitoring of fetal heart rate and uterine activity for as long as the insert is in place and for at least 15 minutes after its removal because of possible uterine hyperstimulation anytime during its administration.[137] Most episodes of uterine hyperstimulation with the use of the vaginal insert occur during active labor and resolve within a few minutes of the removal of the insert.[135] Uterine contraction abnormalities may be avoided if the insert is promptly removed at the onset of labor.[128] Both dinoprostone formulations are associated with fever, nausea, vomiting, and diarrhea, and neither is associated with adverse neonatal outcomes.[121,136,139]

For J.T., misoprostol 25 µg should be administered intravaginally every 3 to 6 hours for cervical ripening. Misoprostol is the most cost-effective option for cervical ripening.

OXYTOCIN

Mechanism of action

Case 49-6, Question 3: Twelve hours after administration of two 25-µg doses of misoprostol, J.T.'s cervix has responded and her Bishop score is now 9, but she has not developed a consistent pattern of uterine contractions. What drug therapy should be initiated at this point?

Synthetic oxytocin should be administered to J.T. to stimulate uterine contractions for accomplishing delivery. Oxytocin increases the frequency, force, and duration of uterine contractions.[141] The uterine response to oxytocin increases throughout pregnancy beginning at ~20 weeks' gestation and increases considerably at 30 weeks' gestation.[142] Oxytocin is indicated for both the induction and augmentation of labor. A prolonged latent phase or dystocia (difficult labor) caused by uterine hypocontractility in the active phase of labor is the indication for augmentation with oxytocin.[142]

Dosing and administration

Case 49-6, Question 4: How should oxytocin be administered to J.T.?

Oxytocin should be administered by continuous IV infusion using a controlled infusion device. The goal of oxytocin administration is to induce uterine contractions that dilate the cervix and aid in the descent of the fetus while avoiding uterine hyperstimulation and fetal distress.[141] There are two opposing views about oxytocin administration for the induction or augmentation of labor. One view is that oxytocin infusions should mimic physiologic doses in the range of 2 to 6 mU/minute, with the goal being vaginal delivery with as little uterine hyperstimulation and fetal distress as possible.[121] The other view is that oxytocin should be used in pharmacologic doses to cause strong uterine contractions, with the goals being shortened labor, timely correction of dysfunctional labor, decreased cesarean deliveries, and reduced maternal morbidity.[121]

Oxytocin plasma concentrations increase linearly with increasing doses, and steady state is reached within 20 to 40 minutes. However, oxytocin serum concentrations correlate poorly with uterine

activity.[143] Factors that may affect response to oxytocin include parity, gestational age, and cervical dilation.[143]

Despite many randomized controlled trials and much experience with oxytocin, the optimal starting doses, dosage increments, dosing intervals, and maximal doses are different in the various protocols.[141,142,144] Starting doses range from 0.5 to 6 mU/minute, and dose increment intervals range from 15 to 60 minutes.[121] Waiting for 30 to 40 minutes between each dosage rate increase allows time to assess the response at steady state. Most low-dose protocols usually start oxytocin 1 to 2 mU/minute and increase the rate of infusion by 1 to 2 mU/minute every 30 to 40 minutes.[141,145] High-dose protocols start oxytocin at 3 to 6 mU/minute with incremental increases of 3 to 6 mU/minute every 20 to 40 minutes. The maximal dose of oxytocin has not been established.[121] The ACOG recommends that obstetrics departments of hospitals develop guidelines for the consistent preparation and administration of oxytocin.[121]

Oxytocin protocols using higher doses or shorter dose adjustment intervals (15–20 minutes) for augmentation of labor generally result in fewer cesarean deliveries for labor dystocia, which is an abnormally slow progress of labor.[145–147] The incidence of uterine hyperstimulation during labor induction is higher with high-dose protocols (initial dose of 6 mU/minute with incremental increases of 6 mU/minute), however, when compared with shorter dosing adjustment intervals of 20 minutes or with longer dose adjustment intervals of 40 minutes.[147] Patients undergoing labor induction with high-dose oxytocin have a higher incidence of uterine stimulation and cesarean deliveries for fetal distress, but a reduced incidence of failed inductions and neonatal sepsis compared with patients treated with low-dose oxytocin.[147] In general, lower maximal doses are needed for augmentation of labor than for induction of labor.[144,148]

J.T. should be started on an infusion of oxytocin 10 units diluted in 1000 mL of an isotonic solution (concentration 10 mU/mL) at 1 mU/minute. She should have continuous uterine and fetal heart rate monitoring throughout the infusion to detect abnormal uterine contraction patterns or fetal heart rate patterns. The goal is to

establish a pattern of three to five uterine contractions of 60 to 90 seconds' duration per 10-minute period.[146] The oxytocin infusion should be increased by 1 to 2 mU/minute every 30 to 40 minutes as needed for inadequate progression of labor (cervical dilation rate of <1 cm/hour).[121,149] Fluid intake and urine output should be assessed hourly.

Adverse effects

Case 49-6, Question 5: What are the adverse effects and complications of oxytocin for which J.T. should be monitored?

Uterine hyperstimulation, usually associated with excessive maternal dosing or increased myometrial sensitivity to oxytocin, may result in uterine rupture, vaginal and cervical lacerations, precipitous delivery, abruptio placentae, emergency cesarean delivery for fetal distress, and postpartum hemorrhage secondary to uterine atony. In general, neonatal outcomes associated with oxytocin use do not differ from those achieved by spontaneous labor.[146] Although oxytocin has only weak antidiuretic properties, water intoxication resulting in seizures, coma, and death has been reported.[121] Oxytocin is structurally and functionally related to vasopressin, also known as antidiuretic hormone. Administration of high concentrations of >40 mU/minute and for long periods is associated with hyponatremia, which can lead to lethargy, drowsiness, generalized seizures, and potentially irreversible neurologic injury. IV bolus administration may cause paradoxical relaxation of vascular smooth muscle, leading to hypotension and tachycardia. J.T. should be monitored for uterine hyperstimulation with fetal heart rate deceleration because it is the most common adverse effect of oxytocin.[121,142]

Preterm Labor

Preterm delivery occurred in 12.8% of births in the United States in 2006, representing a 20% increase since 1990.[3] Approximately 55% of singleton preterm births follow spontaneous preterm labor, and ~8% follow preterm premature rupture of the chorioamniotic membranes.[150] Premature birth is the leading cause of neonatal mortality (infant death <1 month of age), resulting in ~70% of deaths.[150,151] Prematurity is the second leading cause of infant mortality at younger than 1 year of age, and resulted in 17% of such deaths in 2006.[8] However, the more inclusive classification of mortality as being "preterm related" was linked to 36.1% of all infant deaths in 2006.[8]

ETIOLOGY

Spontaneous preterm labor is a heterogeneous syndrome, and several known pathways can lead to preterm birth. These pathways include excessive uterine distension, decidual hemorrhage, activation of the maternal and fetal hypothalamic–pituitary system, and intrauterine infection leading to inflammation. These pathways ultimately lead to a final common response with production of uterine and cervical proteases and uterotonins, which result in progressive cervical ripening and dilation; weakening of the chorioamniotic membranes, which leads to rupture; and uterine contractions. Ultimately, delivery of the infant occurs. Infection, if present, triggers an inflammatory response that results in the release of cytokines, prostaglandins, and proteases, which stimulate uterine activity, induce cervix softening and dilation, and weaken the chorioamniotic membranes.[152] Variations in maternal and fetal genes coding for cytokines have been implicated in the apparent genetic predisposition to preterm birth found in some families and racial groups.[153] Thrombin is another uterotonic agent, which can cause uterine contractions, and has been implicated in causing preterm labor associated with vaginal bleeding caused by placental abruption.[154] Studies have shown a relationship between increasing maternal corticotropin-releasing hormone (CRH) and delivery timing.[155] Maternal and fetal stress can activate the hypothalamic–

pituitary system and result in the rapid increase in maternal CRH before premature birth. Infection can also activate the fetal hypothalamic–pituitary system, increasing CRH, cortisol, and, ultimately, prostaglandins.[152,154] Despite some progress in recent years, much remains unknown about the etiology of preterm birth, and little is known about how preterm birth can be prevented.

CLINICAL PRESENTATION AND EVALUATION

CASE 49-7

QUESTION 1: B.B., a 17-year-old White female, G2, P1, and at 29 weeks' gestation, is admitted to the obstetric unit with backache, cramps, and uterine contractions. She has no symptoms of preterm premature rupture of the membranes (PPROM). She had a previous preterm birth at 32 weeks' gestation. Cervicovaginal secretion findings are positive for fetal fibronectin. A pelvic examination reveals that her cervix is 2 cm dilated and 80% effaced, which is increased from 1 cm at her prenatal visit last week. Cervical culture results for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* from her previous visit are negative. Vaginal wet-mount preparations are also negative for bacterial vaginosis (BV) and *Trichomonas vaginalis.* Vital signs, urinalysis, and complete blood count with differential are normal. Uterine contractions and fetal heart rate are being monitored. Ultrasound reveals a fetus of 30 weeks' gestation size with an estimated weight of 1200 g.

What signs, symptoms, and laboratory evidence support a diagnosis of preterm labor?

B.B. has backache and uterine contractions, which are symptoms of preterm labor. Most patients with preterm contractions are not in labor, however, which results in frequent overdiagnosis. In addition, contractions during preterm labor are frequently not painful, are not detected by the person, and thus are not a sensitive marker for preterm labor. Fibronectin, a protein that serves as an adhesive between the fetal membranes and decidua, normally disappears from the cervical secretions after the first half of pregnancy, reappearing only at term as labor approaches.[156] A negative fibronectin test result can exclude imminent preterm delivery in a patient at risk for preterm delivery, between 24 and 34 weeks'

gestation with intact amniotic membranes, and with cervical dilatation of <3 cm.[157] Because of fibronectin's high negative predictive value of >95% for delivery in the next 1 to 2 weeks, it can be used to avoid overdiagnosis of preterm labor. Although fibronectin testing will yield false-positive results in the presence of blood, vaginal bleeding itself is independently associated with preterm birth. B.B. has the criteria necessary to establish a firm diagnosis of preterm labor. Not only is her fibronectin test result positive but she has persistent contractions with a documented change in cervix dilatation.

RISK FACTORS

Case 49-7, Question 2: What risk factors does B.B. have for spontaneous preterm labor?

B.B. has several risk factors for preterm delivery. The strongest predictor of preterm birth is prior preterm birth. She has a twofold or higher increased risk of preterm delivery because of one previous preterm delivery.[156] If this pregnancy also ends prematurely, her risk for a third preterm birth in her next pregnancy will be sixfold higher than that in the normal population.[156] Recurrence risk rises as the gestational age of the prior preterm birth decreases, especially for deliveries at <32 weeks. Her young age may also be a risk factor. A maternal age younger than 18 or older than 35 years is associated with spontaneous preterm birth, although it is difficult to separate age from the confounding factors associated with age.[156] Her race likely does not contribute to her risk. Black race is an independent risk factor for both preterm labor and lower neonatal birth weight. Other risk factors include low maternal weight before pregnancy, smoking, second- or third-trimester bleeding, multiple gestation, and uterine anomalies, which B.B. does not have.[120,156] Studies of cervix length by transvaginal ultrasound imaging have demonstrated that shorter lengths are associated with greater risk for preterm delivery; however, the positive predictive value varies widely.[156,157] Maternal

infections, such as untreated UTIs and pneumonia, are associated with preterm delivery. In addition, genital organisms such as *Gardnerella vaginalis*, *C. trachomatis*, *N. gonorrhoeae*, *Ureaplasma urealyticum*, and *T. vaginalis*, are also associated with preterm births.[141] Although it is important to identify patients at risk for spontaneous preterm delivery, only half of all preterm deliveries occur in patients with known risk factors.[156]

TOCOLYSIS

Goals of therapy

Treatment of spontaneous preterm labor primarily has been directed at slowing or stopping contractions (tocolysis), which are the obvious, although likely late, sign of impending preterm birth. It has been presumed that if successful, this should prevent or delay preterm birth. Few placebo-controlled trials have been conducted of agents used to diminish contractions (tocolytics), and most data suggest delay of delivery by at most 1 to 2 days.[158] This might be because of the heterogeneous causes of spontaneous preterm birth and because tocolytic agents may not arrest the underlying process that led to contractions. Most studies have been unable to demonstrate a clear benefit of tocolysis on neonatal morbidity and mortality. Instead, they have evaluated surrogate end points, such as pregnancy prolongation or number of preterm births before various cutoff points.[159] The value of prolonging pregnancy will vary by gestational age, and might be substantial if time is gained to administer glucocorticoids to improve fetal lung maturation and decrease the risk of intraventricular hemorrhage (see Case 49-7, Question 7). All patients at risk for preterm birth within 7 days and between 24 and 34 weeks' gestation should be considered for glucocorticoid therapy.[124,159,160] Delay of delivery can also allow transport to a facility best equipped to care for both patient and premature newborn.

CASE 49-7, QUESTION 3: What are the goals of tocolysis for B.B.?

Numerous factors affect the decision to treat preterm labor with a tocolytic agent. Fetal factors precluding tocolysis include nonreassuring fetal monitoring, significant IUGR, and lethal congenital anomalies. Maternal factors include evidence of chorioamnionitis, other significant maternal infections or illness, preeclampsia, and advanced labor.[156] Tocolysis is less likely to be effective in patients with cervical dilation of >3 cm and is usually unsuccessful if the patient is in advanced labor (cervical dilation >5 cm).[156] Because the etiology of preterm labor is multifactorial, B.B. should be evaluated thoroughly and periodically for potential causes of preterm labor and treated appropriately when diagnosed. For example, UTIs are associated with preterm labor, and they should be diagnosed and treated if present.[156] In addition, some would also perform amniocentesis to exclude subclinical chorioamnionitis as a cause of preterm labor before initiating or continuing tocolysis, and to evaluate lung maturity at later gestational ages.[160] B.B. has no evidence of overt infection or other complications, and has no contraindications to tocolysis. Prolonging gestation, even for a few days, would be beneficial because B.B. is only at 29 weeks' gestation.

Case 49-7, Question 4: How should B.B.'s preterm labor be managed? Which tocolytic agent should be used?

TOCOLYTIC AGENTS

Magnesium sulfate

Magnesium sulfate is the most frequently used parenteral tocolytic agent in the United States and is also prescribed for the prevention and treatment of eclampsia. Magnesium sulfate relaxes uterine smooth muscle at maternal serum levels of 5 to 8 mg/dL.[156] The mechanism by which it exerts this effect is not understood completely, but involves inhibition of myosin light-chain kinase activity by competition with intracellular calcium, reducing myometrial contractility.[159]

Despite its widespread use, the evidence for magnesium's efficacy in prolonging gestation is inadequate. In two published, randomized, placebo-controlled trials, no benefit in mean prolongation of pregnancy or mean neonatal birth weight was demonstrated. In meta-analyses of both placebo-controlled trials of magnesium for tocolysis compared with other active drugs, no prolongation of pregnancy was seen with magnesium.[158,161] Several small randomized controlled studies have directly compared magnesium with parenteral β-adrenergic agonists, mostly ritodrine.[158] Three of the four showed no differences in birth outcomes. One of the four suggested prolonged pregnancy with magnesium added to ritodrine compared with ritodrine alone. Studies on the efficacy of β-adrenergic agonists (mostly ritodrine) versus placebo have been mixed, but on balance suggest delay of delivery for 48 hours, but not for 7 days. Therefore, because most trials comparing magnesium with β-adrenergic agonists did not show differences, it has been presumed that magnesium is equally effective. Magnesium is better tolerated than are the β-adrenergic agonists, with fewer maternal side effects.[158] Magnesium is contraindicated in patients with myasthenia gravis and must be used with caution in renal failure.

β-Adrenergic agonists

β-Adrenergic agonists are not the first-line choice for preterm labor because of high costs and the significant potential for maternal adverse effects described subsequently.[156,158] Both ritodrine, the only medication approved by the FDA for the treatment of preterm labor, and terbutaline bind to β_2-adrenergic receptors in uterine smooth muscle and ultimately inhibit smooth muscle cell contractility. Results of randomized controlled trials of ritodrine have been mixed; however, a meta-analysis that included 1320 patients treated with β-agonists demonstrated fewer births at 48 hours but no change in number of births at 7 days. No benefit on neonatal morbidity or mortality was seen; however, the studies are limited by sample size.[162,163] The continued use of β-agonists can result in the

development of tachyphylaxis to its effects on the myometrium and may in part explain treatment failures with these drugs.[156,163]

Terbutaline is available for IV, SC, and PO administration. One dose of terbutaline 0.25 mg SC is often administered to patients with mild contractions and cervical dilation <2 cm. IV β-sympathomimetics are used in cases with more severe and frequent contractions and cervical dilation >2 cm. However, because of potential adverse maternal side effects such as increased heart rate, transient hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema, and myocardial ischemia, the FDA issued a black box warning in 2011 against the use of injectable terbutaline beyond 48 to 72 hours. The FDA also recommended against any use of oral terbutaline for preterm labor owing to both lack of efficacy and the potential for significant maternal side effects.

β-Adrenergic Adverse Effects

β-Adrenergic agonists are not selective for myometrial β_2-adrenergic receptors at pharmacologic doses, and this accounts for their high incidence of adverse effects.[164] Maternal adverse effects such as pulmonary edema, palpitations, tachycardia, myocardial ischemia, hyperglycemia, hypokalemia, and hepatotoxicity result in discontinuation of therapy in up to 10% of patients.[156] Pulmonary edema can occur and, if not recognized promptly, can lead to acute respiratory distress syndrome (ARDS) and death.[156] β-Sympathomimetics should not be used in patients with underlying cardiac disease or arrhythmias, hypertension, diabetes mellitus, severe anemia, or thyrotoxicosis.[156] In addition, these drugs should be avoided if there are signs of chorioamnionitis such as maternal leukocytosis, fetal tachycardia, or maternal fever.[155]

The most commonly reported fetal or neonatal adverse effects associated with β-agonist therapy include tachycardia, hypotension, hypoglycemia, and hypocalcemia, especially if the drug is being administered within hours of delivery.[156,164] Maternal hyperglycemia causing fetal hyperglycemia and hyperinsulinemia can lead to neonatal hypoglycemia if not properly monitored postnatally. Fetal

tachycardia rarely leads to fetal myocardial ischemia or hypertrophy.[164] In summary, although β-sympathomimetic drugs have been used commonly in the past, they are now used much less frequently because of side effect profiles and safety concerns.[156]

Indomethacin

Prostaglandins F_{2a} and especially E_2 are important regulators of myometrial contractility and cervical ripening.[120] Prostaglandin synthesis requires cyclooxygenase (COX), also known as prostaglandin synthetase, to convert arachidonic acid to prostaglandin G_2. COX inhibitors such as indomethacin decrease prostaglandin production, which decreases contractions and inhibits cervical change. As with other tocolytics, these drugs have not been adequately studied in multiple randomized controlled trials. A review of available randomized trials of indomethacin compared with placebo found significant reductions in patients delivering at <37 weeks' gestation, an increase in gestational age at delivery, and a trend toward fewer deliveries at 48 hours and 7 days.[165] In three of eight trials comparing COX inhibitors with other tocolytics, a reduction in both delivery before 37 weeks' gestation and maternal drug reactions was noted. Also, seen in these studies was a trend toward a reduction in delivery within 48 hours.[165] Indomethacin is well tolerated, and GI upset can be mitigated by antacids when it occurs. However, the available studies are inadequately powered to evaluate neonatal safety and outcomes.[165,166]

Although well tolerated by the patient, concerns exist about the fetal and neonatal effects of prostaglandin synthetase inhibition. Indomethacin crosses the placenta rapidly, and fetal levels rapidly approach maternal levels.[164,166] Because indomethacin can decrease fetal urine output leading to oligohydramnios, the amniotic fluid index should be followed and indomethacin discontinued if it falls <5 cm (normal range, 5–25 cm). Oligohydramnios generally resolves within 48 to 72 hours of the discontinuation of indomethacin. The fetal ductus arteriosus, which is critical to allow blood from the right ventricle to bypass the fluid-filled lungs, constricts in 25% to 50% of

fetuses exposed to indomethacin in utero, but generally is reversible.[156] Permanent closure of the ductus arteriosus, however, can lead to fetal right heart failure and even intrauterine demise. The risk of neonatal adverse effects is increased with drug exposure of >48 hours, as well as use after 32 weeks' gestation when premature closure of the ductus occurs more frequently.[156] An increased risk of maternal postpartum hemorrhage has also been reported with indomethacin use but did not reach significance in a meta-analysis.[165] Indomethacin should not be used in the presence of oligohydramnios or suspected fetal renal or cardiac anomaly (see Chapter 105, Neonatal Therapy).

More serious fetal and neonatal effects have been reported in some retrospective and observational studies, including neonatal necrotizing enterocolitis, intraventricular hemorrhage, and renal failure.[166–168] It is difficult, however, to discern whether these complications are causally related to indomethacin or to the use of the drug in cases of refractory preterm labor caused by subclinical intra-amniotic infection.[166,169] An analysis of the risks and benefits of indomethacin suggested its continued use as second-line treatment for preterm labor between 24 and 32 weeks' gestation in patients with contraindications to other tocolytics.[166] Typical dosing regimens include a loading dose of 50 to 100 mg either rectally or PO followed by a maintenance dose of 25 mg PO every 4 to 6 hours for 24 to 48 hours.[167]

Calcium channel blockers

The calcium channel blockers nifedipine and nicardipine inhibit preterm contractions by decreasing calcium influx into uterine smooth muscle and inhibiting myometrial contractions. No placebo-controlled trials have been performed with nifedipine, the most commonly used calcium channel blocker. A meta-analysis of 12 randomized trials including a total of 1029 patients found that calcium channel blockers were superior to other tocolytics (mostly β-mimetics) in reducing preterm births within 7 days and before 34 weeks' gestation.[169] A more recent study of 192 patients comparing

nifedipine with magnesium sulfate for preterm labor found no differences in delivery in 48 hours, gestational age at delivery, or deliveries before 32 or 37 weeks' gestation.[170] Maternal side effects were significantly fewer in patients receiving calcium channel blockers compared with other tocolytics.[169–171]

Maternal side effects can include tachycardia, headache, flushing, dizziness, nausea, and hypotension in the patient with hypovolemia.[164] Nifedipine does not adversely affect uteroplacental blood flow or fetal circulation. Concurrent use with magnesium should be avoided because the combination may potentiate neuromuscular blockade.[106,160,164] The starting dose is usually 10 mg PO with repeated doses of 10 mg every 15 to 20 minutes for persistent contractions, up to a maximum of 40 mg in the first hour.[172-175] Depending on the tocolytic effect, nifedipine is then maintained at 10 to 20 mg PO every 4 to 6 hours.[172] Overall, nifedipine appears to be an attractive alternative for short-term tocolysis because the drug is usually well tolerated.[176]

B.B. should be started on a magnesium sulfate 6-g IV loading dose for 30 minutes followed by 2 g/hour continuous IV infusion through a controlled infusion pump. The hourly rate of magnesium administration for B.B. may be increased until she has one or fewer contractions per 10 minutes or a maximum of 4 g/hour is attained. B.B.'s deep tendon reflexes, respiratory rate, and urine output should be monitored regularly. Close monitoring of fluid balance is important because fluid overload has been associated with pulmonary edema and the drug is renally excreted.[172]

Magnesium serum concentrations are commonly evaluated every 6 to 12 hours in an effort to minimize adverse effects.[177] The patellar reflex disappears with magnesium serum concentrations between 9 and 10 mg/dL, and as long as deep tendon reflexes are present, many practitioners will not measure concentrations. To prevent inadvertent overdoses, a controlled infusion device should always be used to deliver magnesium as a continuous infusion. Hypocalcemia and tetany can occur with hypermagnesemia. Neuromuscular blockade and respiratory arrest develop with magnesium serum concentrations of 15 to 17 mg/dL, and cardiac arrest develops with

greater concentrations. The toxic effects of magnesium can be rapidly reversed with 1 g of parenteral calcium gluconate, which should be readily available when patients are receiving magnesium infusion.[164]

The most common side effects of magnesium loading doses are transient hypotension, flushing, a sense of warmth, headache, dizziness, lethargy, nystagmus, and dry mouth.[156,172] Other adverse effects reported with magnesium are hypothermia, paralytic ileus, and pulmonary edema, which may occur in 1% to 2% of patients treated with magnesium sulfate.[172] Pulmonary edema occurs less frequently with magnesium sulfate than with parenteral β-sympathomimetics but is more commonly encountered with prolonged infusions, multifetal pregnancy, and the use of multiple tocolytics.[164] Treatment consists of discontinuing magnesium sulfate and administration of the diuretic furosemide.

Fetal magnesium serum concentrations are similar to maternal concentrations.[172] The most common neonatal adverse effects are hypotonia and sleepiness. Hypotonia may continue for 3 or 4 days in the neonate because of decreased renal elimination of magnesium.[178–181] Rarely, assisted mechanical ventilation for neuromuscular depression may be needed.[172]

DURATION OF TOCOLYSIS

Acute therapy

Case 49-7, Question 5: B.B. has been maintained on magnesium sulfate continuous IV infusion for ~48 hours. The dose was increased to 3 g/hour shortly after the start of the infusion. B.B. has had no contractions for the past 24 hours. How long does she need to be treated? Should she be weaned off magnesium sulfate?

B.B.'s contractions have completely stopped for 24 hours. Some protocols maintain magnesium sulfate for 12 to 24 hours after successful tocolysis, or for the time it takes to complete the course of corticosteroids. The weaning of magnesium sulfate is unnecessary,

and simple discontinuation of the magnesium infusion is an easier and less costly option.[176,182]

Chronic maintenance therapy

Case 49-7, Question 6: B.B. heard that preterm labor can return once stopped and asks whether she should stay on medication. Should B.B. be started on chronic maintenance tocolytic therapy?

Maintenance tocolysis has been used in an attempt to prevent recurrence of preterm labor and prolong gestation in patients in whom preterm labor was terminated successfully with parenteral tocolytics. β-Adrenergics and oral calcium channel blockers have been evaluated for maintenance therapy.[183] Results of meta-analysis of trials comparing placebo or no treatment with oral β-adrenergics for maintenance therapy after acute preterm labor showed no benefit in delay of delivery, births at <34 or 37 weeks' gestation, or neonatal complications.[184] Moreover, increases in maternal adverse effects occurred, primarily tachycardia, hypotension, and palpitations. Lastly, inadequate data exist to support the use of calcium channel blockers as maintenance therapy.[160] B.B. should not be started on chronic maintenance tocolysis because there is not compelling evidence that continued suppression of contractions after acute tocolysis reduces the rate of preterm birth or neonatal morbidities.[155,159]

ANTENATAL GLUCOCORTICOID ADMINISTRATION

Case 49-7, Question 7: Given B.B. is in preterm labor at 29 weeks' gestation, what medication can be given to help facilitate fetal lung maturation?

B.B. should be given betamethasone 12 mg IM now and a second dose 24 hours later to facilitate fetal lung maturation by increasing production of fetal lung surfactant, thereby reducing the incidence and severity of RDS.[124] Antenatal corticosteroid administration (betamethasone and dexamethasone) also decreases the incidence

of intraventricular hemorrhage, necrotizing enterocolitis, and neonatal death.[124] The greatest reduction in RDS occurs when delivery can be delayed 24 hours up to 7 days after starting treatment. Repeated weekly corticosteroid courses should not be given because of the association with decreased birth weight and head circumference, hypothalamic–pituitary–adrenal axis suppression, deleterious effects on cerebral myelination and lung growth, and neonatal death (particularly in neonates born to patients who received three or more courses).[125,185] However, a randomized clinical trial has now demonstrated a significant reduction in neonatal respiratory morbidity and composite neonatal morbidity when patients with preterm labor and intact membranes who had received an initial course of steroids at <30 weeks' gestation were treated again with a single rescue course of steroids (betamethasone 12 mg IM × two doses, 24 hours apart) if >2 weeks had passed and the gestational age was <33 weeks.[186] This rescue course was administered if there was judged to be a recurrent risk of preterm birth. Although long-term outcome data are not yet available, the ACOG now recommends consideration of a single rescue course of steroids under these specific circumstances.[125]

The National Institutes of Health (NIH) Consensus Panel and the ACOG recommend a course of antenatal betamethasone or dexamethasone (dexamethasone 4 mg IM × every 12 hours, for four doses) for all patients in preterm labor between 24 and 34 weeks' gestation.[124,125] Betamethasone, however, might be the preferred agent because fewer IM injections are needed and because in meta-analysis it was associated with a greater reduction in RDS compared with dexamethasone.[185] That conclusion, however, is not based on direct comparison of betamethasone with dexamethasone and should be interpreted with caution. One study, although limited by its retrospective nature, also suggested an advantage of betamethasone over dexamethasone in the reduction of periventricular leukomalacia, a finding associated with later risks for cerebral palsy.[187] In cases of PPROM, the NIH Consensus Panel recommends that corticosteroids may be given up to 32 weeks' gestation in the absence of chorioamnionitis.[124,125] Recent meta-

analysis supports the efficacy of corticosteroids in the reduction of neonatal death, RDS, duration of ventilator use, and intraventricular hemorrhage in infants born after ruptured membranes.[185] Patients at >32 weeks' gestation can be considered for amniotic fluid testing for the presence of phosphatidylglycerol or a lecithin-to-sphingomyelin ratio of >2 because these are indicators of fetal lung maturation.[185] Corticosteroids are not recommended for use in pregnant patients who are at >34 weeks' gestation unless there is an indication of fetal lung immaturity (see Chapter 105, Neonatal Therapy).

Infectious Complications During Pregnancy and Labor

Case 49-7, Question 8: Preterm labor is often associated with an infectious etiology or source. Does B.B. need to be started on any antibiotic therapy because she is in preterm labor?

PRETERM PREMATURE RUPTURE OF MEMBRANES

Increasing evidence associates preterm labor with intra-amniotic infections.[152,186] Of preterm births, 20% to 40% may be caused by an infectious or inflammatory process.[156] Intrauterine infection is associated with ~80% of early preterm deliveries.[154] Most of the bacteria found in amniotic fluid and the placenta are believed to have ascended from the vagina.[156] It has been suggested that the microbes responsible for preterm birth are already present in the endometrium before conception or early in the pregnancy, causing a chronic, subclinical infection weeks to months before eventually causing PPROM or labor.[154,156]

When PPROM has occurred, spontaneous labor and delivery occur, on average, within 7 days, although longer intervals from PPROM to delivery occur with earlier gestational ages.[187] The use of a short course of antibiotics has been shown to prolong the period between PPROM and delivery (the latency period) and decrease neonatal morbidity.[187] In the largest and best-designed trial of

antibiotic treatment of PPROM, patients between 24 and 32 weeks' gestation treated with ampicillin and erythromycin had both prolonged pregnancies and lower rates of chorioamnionitis.[188] Their newborns experienced decreased mortality, as well as decreased morbidity including RDS and necrotizing enterocolitis. These effects were not owing to tocolytics or corticosteroids because these were exclusionary factors. These results were confirmed by the results of a large meta-analysis including >6000 patients, although information on the best choice of antibiotics was less clear.[189,190] Therefore, patients with PPROM benefit from antibiotic therapy with a broad-spectrum regimen, and IV ampicillin plus erythromycin for 48 hours followed by 5 days of oral amoxicillin plus erythromycin for a total of 7 days' treatment is a reasonable choice.[191]

B.B. should not be started on any PPROM antibiotic regimen because her membranes are not ruptured. Antibiotics have not been proved to prevent premature births in the setting of acute preterm labor.[158] There is currently no role for antibiotic use to prolong pregnancy or reduce neonatal morbidity in preterm labor with intact membranes, and it may be associated with long-term harm.[158,192] There may be a role for treatment of BV antenatally to reduce the risk of preterm birth in patients with a past history of spontaneous preterm birth.

BACTERIAL VAGINOSIS

Some, but not all, studies have demonstrated that screening and treating asymptomatic patients who are at high risk for preterm delivery for BV may reduce the risk of preterm birth.[158,160] A polymicrobial overgrowth of mostly anaerobic bacteria, BV, is one of the most common genital infections in pregnancy, and it is associated with an increased risk of preterm delivery.[193] Treatment of patients with BV who had a prior preterm delivery with oral metronidazole in combination with erythromycin decreased the risk of recurrent preterm delivery in one randomized clinical trial, but there was no difference for patients without a history of recurrent preterm birth.[194,195] In addition, a meta-analysis including 622

patients with prior preterm birth found no reduction in the risk of preterm birth before 37 weeks' gestation after treatment of BV with antibiotics, but did find a reduction in PPROM. In addition, in patients with BV who were treated with oral antibiotics before 20 weeks' gestation, there was a reduction in preterm birth at <37 weeks.[195] B.B. does not have BV; therefore, treatment with metronidazole is unnecessary.

GROUP B STREPTOCOCCUS INTRAPARTUM PROPHYLAXIS

Antibiotics should be given to patients if delivery is anticipated resulting either from preterm labor with intact membranes or after PPROM to prevent group B streptococcal (GBS) infection in the newborn. Other broad-spectrum antibiotic therapy to prevent preterm delivery should not be given routinely to patients in preterm labor with intact membranes.

Approximately 10% to 30% of pregnant patients are colonized with GBS or *Streptococcus agalactiae* in the vagina or rectum, and 1% to 2% of neonates born to colonized patients experience early-onset invasive GBS disease in the absence of IV intrapartum antibiotic prophylaxis.[196] One-fourth of all cases of neonatal GBS infections occur in preterm newborns. B.B.'s fetus, therefore, is at risk for invasive GBS infection from vertical transmission (patient to infant) of bacteria during labor or delivery. The mortality rate for GBS is reported to be between 5% and 20%. Fortunately, the incidence of GBS has declined to a rate of 0.34 to 0.37 cases per 1000 live births in recent years owing to prevention efforts.[196] During pregnancy, GBS infection can cause maternal UTI, amnionitis, endometritis, and wound infection. Antibiotics given to the patient during preterm labor and delivery help prevent neonatal GBS disease, which may lead to sepsis, pneumonia, and meningitis. In the past decade, the routine administration of intrapartum antibiotic prophylaxis to certain subsets of pregnant patients has led to a 70% reduction in the overall incidence of GBS disease.[196] The decision to treat patients with intrapartum antibiotics has been based on either a positive vaginal and rectal GBS culture result routinely obtained at 35 to 37 weeks'

gestation or one or more of the following risk factors without culture screening: (a) previous infant with invasive GBS disease; (b) GBS bacteriuria during any trimester of the current pregnancy; and (c) unknown GBS status at onset of labor and any of the following—delivery at <37 weeks' gestation, amniotic membrane rupture at ≥18 hours, or intrapartum temperature of ≥100.4 °F (38 °C).[196]

Vaginal and rectal GBS cultures should be obtained from B.B., and she should be given a loading dose of penicillin G injection 5 million units, followed by 2.5 to 3.0 million units IV every 4 hours until delivery, while awaiting success of tocolysis and culture results. The Centers for Disease Control and Prevention guidelines recommend that the benchmark for optimal prophylaxis should be antibiotics given at least ≥4 hours before delivery. Penicillin G is preferred over ampicillin because it has a narrower spectrum of antimicrobial activity. If B.B. had a severe allergy to penicillin, sensitivities to clindamycin and erythromycin should be requested at the time of culture in the event GBS is found because of increasing resistance to these drugs. If the isolate is susceptible to both clindamycin and erythromycin, then clindamycin 900 mg IV every 8 hours should be used until delivery. Erythromycin is no longer recommended as an option for treatment because it is often associated with inducible resistance to clindamycin. If the isolate is not susceptible to both clindamycin and erythromycin or if sensitivities are not available, patients who are allergic to penicillin and at high risk for anaphylaxis should receive vancomycin 1 g IV every 12 hours until delivery. Patients who are allergic to penicillin but at low risk for anaphylaxis should receive cefazolin 2 g IV initially, then 1 g IV every 8 hours until delivery.[192,193] Because B.B. is only at 29 weeks' gestation and in preterm labor, she has not yet had her GBS culture obtained, which normally occurs at 35 to 37 weeks. Until the results of her rapid testing for GBS culture returns, she should receive penicillin G 3 million units IV every 4 hours until delivery to prevent perinatal GBS infection.

Case 49-7, Question 9: B.B.'s culture results are negative for GBS growth. She is still at high risk for imminent delivery. Should penicillin G administration

be discontinued?

Penicillin should be discontinued at this time. Vaginal and rectal cultures need not be repeated if B.B. delivers within the next 4 weeks. If tocolysis is successful and delivery is delayed for >4 weeks, obtaining cultures and starting penicillin G preemptively should be repeated at that time. Intrapartum prophylaxis is effective only if antibiotics can be given immediately before and during delivery.

Case 49-7, Question 10: B.B.'s contractions are gone, and her cervical examination remains unchanged for 48 hours. She is able to be discharged home undelivered but is counseled to stay on bed rest for the duration of the pregnancy. B.B. has a significant history of a prior preterm delivery at 32 weeks' gestation. What medication should be recommended to B.B. now and in her next pregnancy, to decrease her risk and prevent another preterm delivery from occurring?

Recent studies have shown that progesterone supplementation can help reduce preterm births, but should only be used in patients who have had a prior documented history of a spontaneous preterm birth before 37 weeks' gestation.[197] The optimal progesterone product is not known (vaginal suppositories, oral capsules, or IM injectables). Progesterone should be offered to patients such as B.B. who have had a prior history of spontaneous preterm delivery.[198] A recent randomized, double-blinded, placebo-controlled trial found a significant reduction in the rate of preterm deliveries in these high-risk patients with a prior documented history of preterm delivery with the use of 17-α hydroxyprogesterone (17-OHP).[199] The rate of preterm delivery in the treatment group was 6.3% versus 54.9% in the placebo group.[199] 17-OHP is given as an IM injection prepared as 250 mg/mL once weekly. Therapy should be initiated at 16 to 20 weeks' gestation and continued until 37 weeks' gestation.[199] 17-OHP is widely available from compounding pharmacies, and, most recently, a commercially marketed FDA-approved drug called Makena® has been released into the market.[200] Although B.B. is

already 29 weeks pregnant, she should be started on 17-OHP therapy at 250 mg/mL injected IM once weekly until 37 weeks. She should be counseled that progesterone should be started earlier at 16 weeks in her next pregnancies. The compounded 17-OHP is more affordable, cost-effective, and equally as effective as the marketed Makena® product.[200]

Case 49-7, Question 11: B.B. returns to labor and delivery at 36 5/7 weeks' gestation with spontaneous rupture of the membranes and is found to be 4 cm dilated and 80% effaced. Her vital signs currently are a BP of 106/79 mm Hg, heart rate of 80 beats/minute, and respiratory rate of 12 breaths/minute with 99% oxygenation on room air. Intrapartum fetal monitoring shows a reassuring reactive fetal heart rate with variability. After being in labor for about 16 hours, her temperature spikes up to 101.1 °F (38.39 °C). What are the risks of an elevated fever during labor, and how should B.B. be treated?

Chorioamnionitis

Chorioamnionitis is an infection of the amniotic fluid, membranes, and placenta occurring before, during, or immediately after birth.[194] Intra-amniotic infections occur in ~1% to 5% of term pregnancies and may complicate up to 15% of cases of preterm labor.[204] Maternal fevers are usually the most common clinical presentation in many patients. Diagnosis is based on the presence of fever, defined as ≥100.4 °F (38 °C) measured twice at least 4 hours apart, or a temperature of 101 °F (38.33 °C) measured once. Patients may also present with maternal tachycardia (>100 beats/minute), fetal tachycardia (160 beats/minute), uterine tenderness, foul odor from amniotic fluid, and maternal leukocytosis.[194,195] The exclusion of other sources of infection such as UTI, viral illness, abscesses, and drug-induced fever (ie, epidural, misoprostol) must be made. Common organisms ascending from vaginal flora causing polymicrobial intra-amniotic infections include genital mycoplasmas such as *U. urealyticum* and *Mycoplasma hominis,* anaerobes including *G. vaginalis,* enteric gram-negative bacilli, and GBS.[195,196]

The two most prominent risk factors of intra-amniotic infections are the number of digital examinations and duration of labor.[194]

Maternal complications from intra-amniotic infections include bacteremia, suboptimal uterine contractility, and risk of postpartum hemorrhage.[195] Increases in rates of neonatal sepsis, pneumonia, meningitis, and mortality have been shown in infants whose mothers had chorioamnionitis.[198] Furthermore, inflammation, intrapartum fever, and infection increase the risk of long-term neurodevelopmental delay and cerebral palsy in these neonates.[201] The risk of cerebral palsy is at least twofold to fourfold higher in infants who were exposed to intra-amniotic infection in utero.[201]

Early administration of broad-spectrum antibiotics immediately after the diagnosis of chorioamnionitis has been shown to have both maternal and neonatal benefit versus postpartum antibiotic administration. A common regimen implemented is ampicillin 2 g IV every 6 hours in addition to gentamicin dosed to a target peak of 8 μg/mL and trough of 1 μg/mL.[195] Standard dosing of gentamicin every 8 hours is preferred over once-daily dosing to prevent elevated fetal serum peak levels, although no adverse effects of high-dose therapy were noted.[202] Clindamycin 900 mg IV every 8 hours may be added to the regimen to cover anaerobic organisms. If fevers persist for >24 hours on triple antibiotics with ampicillin, gentamicin, and clindamycin, metronidazole can be substituted for clindamycin to help broaden anaerobic coverage.[195] Other options for antibiotic coverage include extended-spectrum penicillins (ie, piperacillin–tazobactam, ampicillin–sulbactam) or second-generation cephalosporins (ie, cefoxitin and cefotetan).[195] Intrapartum antibiotics administered about 1 hour after infusion produce adequate bactericidal concentrations in the fetus and placental membranes.

With a fever of 101.1 °F (38.39 °C), B.B. meets criteria for a clinical diagnosis of chorioamnionitis. However, she does not exhibit any other symptoms of systemic infection such as tachycardia, uterine tenderness, or fetal tachycardia, which is quite common. Gentamicin and ampicillin should be started promptly after diagnosis to decrease the risk of neonatal sepsis and to avoid possible neurodevelopment sequelae. In addition, clindamycin can be added

to cover anaerobic organisms. B.B.'s risk factors for chorioamnionitis include multiple digital examinations, preterm labor, spontaneous labor, and long duration of labor. Antibiotics should be continued until B.B. is afebrile for at least 24 to 48 hours or until delivery. Ultimately, immediate antibiotic administration and delivery of the offending source is paramount to ensure fetal health and safety.

Human Immunodeficiency Virus in Labor and Breast-feeding

CASE 49-8

QUESTION 1: S.L. is a 23-year-old G1, P0 at 38 weeks' gestation and is positive for HIV. She is presenting to labor and delivery with spontaneous rupture of membranes and is having regular contractions every 5 minutes. Her last HIV RNA levels were undetectable, and her CD4 count was 400 cells/mL. Her current combination antiretroviral therapy (cART) consists of zidovudine (AZT), lamivudine, and atazanavir/ritonavir, which was started 2 years ago.

What are the risks of HIV perinatal transmission in S.L., and what medications must be started while she is in labor?

Current recommendations state that all HIV-infected pregnant patients should receive intrapartum AZT if the HIV RNA level is >1000 copies/mL, and their infants should receive neonatal AZT immediately after delivery for 6 weeks with a consideration for a 4-week treatment plan if the patient has been maintained on a cART regimen throughout the pregnancy.[203] Many factors must be taken into consideration, including cost, ease of administration for compliance, individual antiretroviral therapy (ART) resistance patterns, and risks of side effects with the possibility of teratogenicity.[204] Generally, if a patient on cART becomes pregnant, she should continue on therapy throughout the pregnancy, including the first trimester.[203] Patients who did not require cART before becoming pregnant should start cART prophylaxis after the first trimester but not later than 28 weeks of gestation.[203] cART is more effective in preventing perinatal HIV transmission if it is started

earlier, before 28 weeks' gestation versus 36 weeks' gestation.[203] All patients infected with HIV should be counseled and offered cART during pregnancy to prevent perinatal transmission regardless of HIV RNA levels.[203] Avoid the use of stavudine and didanosine entry and fusion inhibitors in patients of childbearing age and during the first trimester, if possible, owing to issues of toxicity and teratogenicity.[203] Efavirenz in the updated guidelines can be continued to be used if the patient was on an efavirenz-based regimen. A fetal ultrasound is recommended. Further studies are needed to help identify the effectiveness and safety of other cART regimens. Cesarean section delivery is highly recommended.[203]

S.L. should continue on her ART (AZT, lamivudine, and atazanavir/ritonavir) during labor without missing any doses. Prophylactic neonatal AZT should be administered to the infant at a dose of 4 mg/kg (actual weight) PO every 12 hours, within 6 to 12 hours of birth, for a total duration of 6 weeks.[203]

Case 49-8, Question 2: Should S.L. breast-feed her infant if her HIV RNA levels are undetectable and her CD4 counts are 400 cells/μL?

Although S.L. is currently on effective cART to suppress her HIV RNA levels and maintain her CD4 levels, she should not breast-feed. Breast-feeding is not recommended for HIV-infected patients in the United States because of safer and affordable alternatives such as formula. Prophylactic cART in the infant and patient does not entirely eliminate the risk of perinatal transmission through breast milk.[203]

POSTPARTUM HEMORRHAGE

Prevention

Case 49-8, Question 3: S.L. successfully has a normal spontaneous vaginal delivery with an estimated blood loss of 400 mL. Which medications should be

given to S.L. routinely after delivery?

Oxytocin is administered routinely after the delivery of the placenta to promote uterine contraction and vasoconstriction. Meta-analysis of randomized clinical trials demonstrates that the use of oxytocin preventively in the third stage of labor reduces the risk of hemorrhage and need for medical therapy for uterine atony.[205] Uterine atony, the condition in which the uterus fails to contract after delivery of the placenta, is the most common cause of postpartum hemorrhage.[206] Risks factors for uterine atony include induction and augmentation of labor, prolonged labor, an overdistended uterus such as with twins or polyhydramnios, and previous postpartum hemorrhage.[206] Oxytocin 10 to 20 units IM or diluted in 0.5 to 1 L of parenteral fluid and given as an IV infusion of 200 mU/minute until the uterus is firmly contracted reduces the risk of postpartum hemorrhage secondary to uterine atony.[207] Oxytocin should never be administered undiluted as a bolus dose because it can cause severe hypotension and cardiac dysrhythmias.[207]

MISOPROSTOL

Misoprostol 400 to 600 µg can be administered PO in the third stage of labor to prevent postpartum hemorrhage.[208,209] In a comparison of 600 µg of oral misoprostol with parenteral oxytocin for prevention of postpartum hemorrhage, oxytocin was marginally but statistically more effective and had fewer side effects.[210] Misoprostol also can be administered rectally. Rectal administration is associated with a lower incidence of fever and shivering, which is common with misoprostol administered PO during the third stage of labor.[210] The rectal route of administration also is associated with lower maximal serum concentrations and lower time to maximal concentrations than when the drug is administered PO. Although not as effective as oxytocin in preventing postpartum hemorrhage, misoprostol, which is inexpensive, stable at room temperature, and not administered parenterally, may be preferred in settings of meager resources for the management of the third stage of labor.

S.L. should receive an infusion of oxytocin 20 units in 1 L of lactated Ringer solution at 125 mL/hour.

Treatment

Case 49-8, Question 4: Within a few hours of delivering, S.L. has visible vaginal bleeding. She has a distended uterus, and the hemorrhage is attributed to uterine atony. Uterine massage, which is standard treatment, does not control the bleeding. What other pharmacologic options are available to treat her postpartum hemorrhage in addition to the infusion of more oxytocin at this time?

ERGOT ALKALOIDS

If the postpartum hemorrhaging does not respond to oxytocin administration, ergonovine maleate (Ergotrate®) and its semisynthetic derivative, methylergonovine maleate (Methergine®), can be used because of their potent uterotonic effects. IM administration is associated with less frequent adverse effects (nausea, vomiting, hypertension, headache, chest pain, dizziness, tinnitus, diaphoresis) than is the IV route.[207] Ergot alkaloids should be avoided in patients with hypertension and eclampsia because of the potential for arrhythmias, seizures, cerebrovascular accidents, and, rarely, myocardial infarction. The dose of both drugs is 0.2 mg administered IM every 2 hours as needed. This may be followed by 0.2 to 0.4 mg administered PO two to four times daily for 2 to 7 days to promote involution of the uterus (**Table 49-5**).[207]

Table 49-5
Uterotonic Medications Used for Postpartum Obstetric Hemorrhage

Drug	Dose	Comments
Oxytocin (Pitocin®)	40 IU in 1 L NS or lactated Ringer solution 10 IU IM if no IV site available	Do not give as undiluted IV bolus, can cause hypotension.

Drug	Dose	Comments
Methylergonovine maleate (Methergine®)	0.2 mg IM every 2–4 hours	Contraindicated in hypertensive patients
Carboprost tromethamine (Hemabate®)	0.25 mg IM every 15–90 minutes, not to exceed eight doses	Caution in use with patients with asthma, can cause bronchoconstriction
Misoprostol (Cytotec®)	1000 µg PR given once	Can also be given orally or sublingually, but PR is preferred route

IM, intramuscular; IV, intravenous; NS, normal saline; PR, per rectum.

15-METHYL PROSTAGLANDIN F2A (CARBOPROST TROMETHAMINE)

Bleeding caused by uterine atony that is unresponsive to oxytocin can be treated with 15-methyl prostaglandin $F_{2\alpha}$-tromethamine, also known as carboprost tromethamine (Hemabate®).[206] Carboprost tromethamine, as with naturally occurring prostaglandins, stimulates uterine contraction and decreases postpartum hemorrhage; it is more potent and has a longer duration of effect than its parent compound, prostaglandin $F_{2\alpha}$.

Carboprost tromethamine is approved for IM use, but it has been also administered through direct myometrial injection.[207,211] Intramyometrial administration has been associated with severe hypotension and pulmonary edema.[212] An initial dose of 0.25 mg IM is given followed by 0.25 mg every 15 to 90 minutes.[207,211] The total cumulative dose should not exceed 2 mg (eight doses maximum).[211] Carboprost tromethamine is effective in treating 60% to 85% of patients with uterine atony who have failed standard treatment.[207] Improvement in bleeding typically occurs after one to two injections.

The most common adverse effects of carboprost tromethamine are GI, including nausea, vomiting, and diarrhea. Flushing and fever

also occur frequently. Many of the adverse effects are related to the contractile effect of this drug on smooth muscle.[211] Hypertension, although rare, typically occurs in patients with preexisting hypertension or preeclampsia. The potent vasoconstricting and bronchoconstricting properties of carboprost can cause uterine rupture, as well as pulmonary and cardiac problems. Carboprost must be used with caution in patients with asthma and is relatively contraindicated in the presence of pulmonary, cardiac, renal, or hepatic disease.[206,211]

MISOPROSTOL

Several case series and small randomized trials have reported that misoprostol might be useful in the treatment of postpartum hemorrhage caused by uterine atony. The available data are very limited, however, and large randomized trials are needed to clarify the efficacy of misoprostol compared with standard therapies, as well as the optimal dose and route of administration.[213] A recent double-blind, randomized, placebo-controlled clinical trial was performed to clarify the role of misoprostol in the treatment of postpartum hemorrhage.[214] Treatment was either 800 µg of sublingual misoprostol or 40 IU of oxytocin in 1 L of IV fluid given for 15 minutes. Resolution of active bleeding occurred within 20 minutes in 89% to 90% of patients in each study arm, demonstrating no advantage to misoprostol over standard IV therapy with oxytocin. Furthermore, patients who received misoprostol had significantly more shivering and fever >104 °F (40 °C). In areas with meager resources, misoprostol may offer advantages (low cost, prolonged stability, and oral formulation), but the role of misoprostol as an adjunctive therapy when oxytocin is already available remains uncertain.[207]

S.L. does not have any contraindications (ie, asthma or hypertension) to any of the postpartum hemorrhage medications. She should be given oxytocin 40 IU in 1 L of lactated Ringer solution given for 15 minutes. Methylergonovine maleate 0.2 mg IM and misoprostol 1000 µg rectally can be given in succession after

oxytocin if bleeding does not subside. Lastly, carboprost tromethamine 0.25 mg IM is an option if those medications fail to control bleeding.

PREVENTION OF RH D ALLOIMMUNIZATION

Maternal–Fetal Rh Incompatibility

CASE 49-9

QUESTION 1: G.G., a 34-year-old primigravida, had her ABO blood group and Rh status determined during her initial prenatal visit. She is found to be type O, Rh negative. Her husband is type O, Rh positive.

What are the risks associated with Rh incompatibility that could affect G.G.'s fetus?

Blood group incompatibility between a pregnant patient and her fetus can result in alloimmunization of the patient and hemolytic anemia in the fetus. When a person is exposed during pregnancy, labor, or delivery to an antigen found on the fetus's red blood cells (RBCs; ie, AB, Rh complex) that is not found on her own RBCs, she forms antibodies against the fetus's antigen. This is referred to as *alloimmunization.* These antibodies, particularly immunoglobulin (Ig) G antibodies, cross the placenta and can interact with the fetal RBC antigens. The pregnancy in which the alloimmunization has occurred usually results in an unaffected child. The risk is carried on in subsequent pregnancies when maternal antibodies from a tiny amount of blood (<0.1 mL) can cross from the patient to the child, which can result in the destruction of RBCs and lead to hemolytic disease of the newborn (HDN). Most serious cases of HDN are caused by Rh alloimmunization involving the D antigen. The other four alleles of the Rh gene complex code for the antigens C, c, E, and e. They are also serious, but less common, causes of alloimmunization.[215]

A patient who is Rh D negative becomes immunized after exposure to fetal erythrocytes that carry the D antigen. The likelihood of having an offspring who is Rh D positive is determined by whether a father who is Rh D positive is homozygous or heterozygous for the D antigen. If the father is homozygous for the D antigen, all of his offspring will be D positive (Rh positive). If he is heterozygous for the D antigen, then there is a 50% chance that his offspring will be Rh positive.

Pregnant patients can produce detectable IgG antibodies to Rh antigens within 6 weeks to 6 months.[216] These antibodies can cross the placenta during subsequent pregnancies and destroy fetal Rh D–positive RBCs. Of patients who are Rh D negative and who do not receive Rh_o(D) immune globulin during pregnancy, 17% will become alloimmunized during a term pregnancy, with most cases occurring at the time of delivery.[217]

The severity of Rh-associated HDN or erythroblastosis fetalis depends on the concentration of maternal antibodies. The placental transfer of large amounts of antibody can cause substantial RBC destruction. This initially results in anemia and hyperbilirubinemia with compensatory extramedullary erythropoiesis (eg, liver, spleen). In severe hemolytic diseases, the fetus might develop hepatosplenomegaly, portal hypertension, edema, ascites, and hepatic and cardiac failure. The clinical presentation of profound anemia, anasarca, hepatosplenomegaly, cardiac failure, and circulatory collapse is termed *hydrops fetalis.*[216]

The severity of Rh-associated HDN generally worsens with each pregnancy in the patient who is alloimmunized if her fetus is Rh positive. Thus, it is important to discuss the consequences of alloimmunization with any person who is known to be alloimmunized and wishes to have more children in the future.[217]

Rh_o(D) Immunoglobulin

Case 49-9, Question 2: What interventions should be undertaken to prevent G.G. from becoming alloimmunized?

ANTEPARTUM PROPHYLAXIS

G.G. should have antibody screens at the beginning of each pregnancy and postpartum. Although the American Association of Blood Banks recommends that an antepartum screen should also be obtained at 28 weeks' gestation, the cost-effectiveness of such screening has not been studied, and it is estimated that sensitization before 28 weeks occurs at a rate of <0.18%. Therefore, the ACOG has suggested that the decision to obtain a third-trimester antibody screen should be dictated by individual circumstances.[217] As pregnancy progresses, both the incidence and the degree of fetomaternal hemorrhage increase. Administrating Rh_o(D) immune globulin to G.G. before or shortly after exposure to fetal Rh D–positive RBCs will prevent her from becoming alloimmunized. Giving Rh_o(D) immune globulin at 28 weeks' gestation has been shown to decrease the antepartum sensitization rate from ~2% to 0.1%.[217] One mechanism by which Rh_o(D) immune globulin might prevent sensitization is by suppression of the primary immune response to the D antigen.[216] The anti-D immune globulin binds the D antigen, and this complex is filtered by the spleen and lymph nodes, whereby it inhibits D antigen–specific B cells from proliferating.

POSTPARTUM PROPHYLAXIS

A second dose of Rh_o(D) immune globulin should be repeated within 72 hours of delivery. A larger dose is needed if a large transplacental bleed occurs at the time of delivery (0.4% of cases). Therefore, all patients who are Rho(D) negative and who deliver a newborn who is Rho(D) positive should be tested to detect fetal RBCs in maternal blood (eg, Kleihauer–Betke test) to calculate the correct dose of Rh_o(D) immune globulin. If a person at risk for sensitization has not been given Rh_o(D) immune globulin within 72 hours, she should still be treated as soon as possible because it has been demonstrated that protection can be seen in some individuals up to 13 days after exposure to Rh-positive RBCs.[217]

ADVERSE EFFECTS OF RH_o(D) IMMUNE GLOBULIN

The plasma from which immune globulin is obtained is tested for viral infections, and the manufacturing process used to produce Rh_o(D) immune globulin inactivates viruses such as HIV, hepatitis B virus, and hepatitis C virus.[218] Adverse reactions associated with the use of anti-D immune globulin are rare. Pain and swelling at the injection site and rash are the most common adverse reactions. Hypersensitivity reactions such as anaphylaxis, although rare, can occur owing to a small amount of IgA in the product. Rh_o(D) immune globulin (RhoGAM) is a latex- and thimerosal-free (contains no mercury) drug.[218]

Prophylaxis for First- and Second-Trimester Events and Procedures

CASE 49-9, QUESTION 3: G.G. will undergo amniocentesis at 16 weeks' gestation. Will she need a dose of Rh_o(D) at that time?

Rh_o(D) immune globulin should be given after all clinical events (eg, spontaneous abortion) or procedures (eg, abortion, amniocentesis, fetal blood sampling, or chorionic villus sampling) in which fetomaternal hemorrhage is a risk in an Rh-incompatible pregnancy.[218] Although little evidence supports the need for prophylaxis in the early first trimester, adverse effects are rare and potential benefits are thought by most experts to outweigh the risks.[217,218] Although a 50-µg dose (MICRhoGAM) is available for first-trimester use (eg, chorionic villus sampling or abortion), many hospitals do not stock this dose and so a 300-µg standard dose is often given.

LENGTH OF PROTECTION

Case 49-9, Question 4: G.G. had an amniocentesis at 16 weeks for which she received $Rh_o(D)$ immune globulin 300 µg IM. Will she need another dose at 28 weeks' gestation? How long will this dose protect G.G. against alloimmunization?

G.G. will still need a dose of 300 µg repeated at 28 weeks' gestation and within 72 hours postpartum if her infant is $Rh_o(D)$ positive. The half-life of $Rh_o(D)$ immune globulin is ~23 to 26 days.[218] Without a large fetomaternal hemorrhage, a standard dose of 300 µg will protect against alloimmunization for up to 12 weeks. If >12 weeks have lapsed between receipt of anti-D immune globulin and delivery, many practitioners recommend administering another antepartum dose.[217,218]

Failure of Immunoprophylaxis

Case 49-9, Question 5: What are the most common reasons for $Rh_o(D)$ alloimmunization during pregnancy?

The most common reasons for Rh D alloimmunization are (a) failure to give a dose of anti-D immune globulin at 28 weeks' gestation, (b) failure to give $Rh_o(D)$ immune globulin in a timely manner postpartum to patients who have delivered an $Rh_o(D)$-positive or untyped fetus, and (c) failure to recognize clinical procedures and situations that increase maternal risk for alloimmunization (ie, amniocentesis, abortions).[216,217]

Thus, G.G. should be told that with proper prophylaxis with anti-D immune globulin, there is little chance for her to become alloimmunized. She need not worry about her present pregnancy or future pregnancies.

LACTATION

Lactation is controlled primarily by PRL, but the entire process is under the intricate control of several hormones. Breast tissue maturation during pregnancy is influenced by many factors, including estrogen, progesterone, PRL, insulin, growth hormone, cortisol, thyroxine, and human placental lactogen.[219] PRL concentrations gradually increase during pregnancy, but high estrogen and progesterone concentrations inhibit milk secretion by blocking PRL's effect on the breast epithelium.[219,220] It is the dramatic decrease in progesterone that triggers lactogenesis or milk secretion for the first 3 days after delivery. Infant suckling at the breast is necessary to maintain an adequate milk supply beyond postpartum day 3 or 4. Nipple stimulation transmits sensory impulses to the hypothalamus to initiate PRL release from the anterior pituitary and oxytocin from the posterior pituitary. PRL stimulates the production and secretion of breast milk, and oxytocin stimulates the contraction of the myoepithelial cells in the breast alveoli and ducts so that milk can be ejected from the breast (milk letdown). Oxytocin also can be secreted through other sensory pathways, which is why patients can release milk on hearing, smelling, or even thinking about their infants. PRL, however, is released only in response to nipple stimulation.

PRL synthesis and release depend on the inhibition of hypothalamic PRL inhibitory factor (PIF) secretion. PRL secretion is regulated primarily by dopamine-releasing neurons. Activating the dopamine receptors on the PRL-secreting cells of the anterior pituitary inhibits the release of PRL. PIF is believed to be closely associated with dopamine.[219,220]

Although PRL controls the volume of milk produced, once lactation is established, milk production is regulated by infant demand. Lactation eventually ceases if milk is not removed from the breast. Absence of suckling stops milk letdown and restores the normal production of PIF. Decreased blood flow to the breast reduces oxytocin delivery to the myoepithelium. Consequently, milk secretion stops within a few days.[219,220]

Stimulation

NONPHARMACOLOGIC MEASURES

CASE 49-10

Question 1: C.C., a 22-year-old female, vaginally delivered her first child, a healthy term infant. C.C. plans to breast-feed and was educated about breast-feeding during obstetric visits and prenatal classes. After giving birth, C.C. tried to breast-feed in the delivery room with great difficulty. Afterward, she became extremely apprehensive and continued to have trouble breast-feeding.

What can be done to encourage C.C. and help her with lactation?

The most effective stimulus for lactation is suckling. Many patients nurse in the delivery room after uncomplicated vaginal deliveries because nursing increases maternal–infant bonding and helps establish good milk production. If a patient does not nurse immediately after delivery, she should be encouraged to do so as soon as she is physically able. C.C. did try to nurse after delivery, but experienced problems that may have been related to her emotional or physical state, or to the physical state of her infant. The nursing staff should encourage and support C.C. emotionally to help her relax, be comfortable, and relieve her anxiety about breast-feeding. Health care personnel also should emphasize appropriate feeding techniques and proper positioning for breast-feeding. Allowing C.C.'s infant to sleep in her room, rather than in the nursery, may help C.C. develop a breast-feeding routine.

Most new patients who have difficulty breast-feeding initially respond to the emotional and educational support of a good obstetric nursing staff. Few require pharmaceutical intervention.

ENHANCEMENT OF MILK PRODUCTION

Case 49-10, Question 2: C.C. was successful in establishing breast-feeding. Despite good technique and adequate nutrition, however, she had trouble maintaining adequate milk production after about 2 to 3 weeks and was forced

to supplement her infant with formula. How can C.C.'s milk production be enhanced?

Although not an FDA-approved indication, metoclopramide can be used to stimulate lactation in patients with decreased or inadequate milk production.[38,221–223] Metoclopramide, a dopamine antagonist, increases PRL secretion. This is particularly useful in patients whose infants do not breast-feed effectively (eg, preterm infants).[224] Metoclopramide 10 mg PO three times daily for 1 to 2 weeks has been shown to help restore milk production.[38,221–223] Improvement in lactation occurs within 2 to 5 days of starting therapy and persists after discontinuing metoclopramide.

The estimated total daily dose of metoclopramide ingested by the nursing infant of a patient on 30 mg/day is 1 to 45 µg/kg/day.[38] This is below the maximal recommended infant daily dose of 0.5 mg/kg/day. Maternal doses of 30 mg/day do not alter PRL, thyroid-stimulating hormone, or free thyroxin serum concentrations in breast-fed infants.[224] The only adverse effect reported in nursing infants has been intestinal gas.[38,225] The short-term use of metoclopramide for reestablishing lactation appears to be safe, even in preterm infants.[38,221]

Recent randomized control trials have examined the effects of metoclopramide on breast milk volume and duration in patients with recent preterm deliveries and found that breast-feeding outcomes were poor despite medication treatment and lactation support.[225,226] In this special population, patients likely need lactation support through various resources addressing nutritional, medical, and psychosocial interventions.

Suppression

CASE 49-11

Question 1: After delivery of a nonviable fetus at 24 weeks' gestation, J.G., a 26-year-old G2, P2, informs her obstetrician that she wishes to suppress her lactation.

What methods are available to suppress lactation?

Suppression of lactation is indicated for patients who do not want to breast-feed, patients who have delivered a stillborn infant, and those who have had an abortion. Both drugs and nonpharmacologic methods have been used. In 1988, the FDA, however, recommended against drug-induced suppression of lactation.[227] The only drug therapy that the FDA recommends in patients who are not breast-feeding is analgesic for the relief of breast pain. Bromocriptine was approved for the postpartum suppression of lactation; however, the FDA rescinded its approval for that indication because of cardiovascular complications (eg, stroke, myocardial infarction) associated with its use.[220]

If breast stimulation is avoided (with or without the use of a breast binder), breast milk production will continue, leading to engorgement and distension of breast alveoli. This leads to the termination of lactation after several days. Approximately 40% of patients using this method experience breast discomfort and pain; 30% experience milk leakage from their nipples.[227,228] Ice packs may be applied to the breasts for comfort, and a mild analgesic may be used if necessary.

DRUG EXCRETION IN HUMAN MILK

Breast milk is recognized as the optimal source of nutrition for infants, with documented benefits not only to infants but also to mothers, families, and societies.[229] Evidence indicates that breast-feeding decreases the incidence or severity of many infectious processes (eg, otitis media, respiratory infections, UTIs) in infants. In children and adults who were breast-fed, the risk of developing certain medical illnesses also may decrease (eg, obesity, inflammatory bowel disease, celiac disease, childhood leukemia).[230] Breast-feeding may also positively influence cognitive and intellectual development in children and young adults.[231] Numerous benefits to the mother also have been identified, such as decreased

postpartum blood loss, more rapid uterine involution, earlier return to prepregnancy weight, and decreased risks of breast cancer, ovarian cancer, and osteoporosis.[229]

The perception that nursing should be discontinued while the patient is medicated persists, although only a finite number of drugs are absolutely contraindicated during lactation.[95] Unlike the use of drugs during pregnancy, drug excretion in breast milk can be approximated to a certain extent. Actual measurements of drug concentrations in milk and clinical observations in breast-fed infants have been published for selected drugs.

Pharmacokinetics

Different pharmacokinetic models of drug excretion in milk have been described.[232] A two-compartment open model presents the maternal fluids as one compartment and breast milk as the other. After ingestion, the drug gets absorbed into the maternal compartment, with a proportion of drug passing into breast milk and the remaining portion distributed in, and eliminated from, the maternal system. Drugs reaching breast milk will ultimately leave this compartment either by diffusing back into maternal fluids or through milk production and nursing.[233] A more popular model describes drug excretion in milk using a three-compartment model that incorporates the pharmacokinetics of the patient, mammary tissues, and infant.[234] The overall risk to the infant depends on the amount of drug bioavailable to the patient, the amount reaching breast milk, and the actual amount of drug ingested and bioavailable to the nursing infant.

Transfer of Drugs From Plasma to Milk

Transfer of drugs from maternal plasma to milk is generally through passive diffusion.[232] Low-molecular-weight, water-soluble substances diffuse through small, water-filled pores, whereas lipid-soluble compounds pass through lipid membranes.[233] Many factors

affect the excretion of drugs in breast milk, and they should be carefully assessed before making a recommendation. The extent of drug passage into breast milk is often expressed quantitatively as the milk-to-plasma (M/P) ratio. This ratio should not be used as the sole determinant of whether a drug is safe for use during breast-feeding (see the section on Estimating Infant Exposure).

Several parameters affect drug excretion into breast milk (**Table 49-6**). The pK_a of a drug partially determines how much drug can reach the milk, because only the nonionized portion of free drug is transferred. Human milk, with an average pH of 7.1, is slightly more acidic than is plasma. In general, drugs that are weak acids (eg, penicillin) tend to have a higher concentration in plasma than in milk (M/P <1). Conversely, the concentration of weak bases (eg, erythromycin) in milk is more likely to be higher or to reach an equilibrium with that measured in plasma (M/P ≥1).[38,219,232] Once in the milk, the proportion of the ionized weak base rises in the relatively acidic solution, and thus drug trapping occurs. Drug reabsorption has been found for some agents, and the prevention of passage back into the plasma by trapping may be clinically important. Lipid solubility also is determined to a large extent by the degree of ionization because drugs with relatively high lipid solubility exist in the nonionized form. Diffusion through lipid membranes is probably the most important pathway for drug transfer. Although pH, pK_a, and lipid solubility are important elements, other factors may significantly modify predictions based solely on these chemical characteristics. Two of these other factors are protein binding and MW.[38,232] Drugs with high MWs such as insulin (MW >6000) are less likely to transfer into breast milk, whereas those <300 transfer more readily.[38] Highly protein-bound drugs such as glyburide (99% protein bound) are less likely to be transferred into breast milk, although infants should still be monitored for signs of hypoglycemia.

Table 49-6

Factors Affecting the Fate of Drugs in Milk and the Nursing Infant

Maternal Parameters
▪ Drug dosage and duration of therapy ▪ Route and frequency of administration ▪ Metabolism ▪ Renal clearance ▪ Blood flow to the breasts ▪ Milk pH ▪ Milk composition
Drug Parameters
▪ Oral bioavailability (to patient and infant) ▪ Molecular weight ▪ pK_a ▪ Lipid solubility ▪ Protein binding
Infant Parameters
▪ Age of the infant ▪ Feeding pattern ▪ Amount of breast milk consumed ▪ Drug absorption, distribution, metabolism, elimination

pK_a, dissociation constant.

Drug transfer also is influenced by the yield of milk, which is related to blood flow and PRL secretion.[232] Lactation is associated with a high blood flow to the breasts, but little is known about this flow during or between feedings. The milk yield (volume) differs slightly depending on the duration of lactation and the time of day. A diurnal pattern has been observed, with highest yields at 6:00 AM and lowest yields at 6:00 PM or 10:00 PM. The mean composition of mature human milk is ~87% aqueous solution, 3.5% lipids, 8%

carbohydrate (83% of which is lactose), 0.9% protein, and 0.2% nitrogen.[232] The proportions of these components may vary widely from person to person and even within the same person. For example, hind milk (breast milk that is expressed last and contains more fat) contains fourfold to fivefold the fat content of foremilk (breast milk that is expressed first and is high in water content, water-soluble vitamins, carbohydrates, and protein), whereas colostrum (first milk, secreted late in pregnancy and in the first few days after delivery) contains little fat. Fat content also has exhibited a diurnal variation.

After a drug reaches the milk, it equilibrates between the aqueous and lipid phases. The nature of this equilibration can modify how much drug actually reaches the infant. Infant feeding patterns differ significantly from one baby to another. The time spent suckling at each breast, and the volume of milk taken in, also determine the amount of drug ingested, especially if the drug has partitioned into one phase more so than into the other. Once the infant ingests the drug via breast milk, the pharmacologic and adverse effects on the infant will be determined by the extent of oral bioavailability, distribution, metabolism, and rate of elimination. These pharmacokinetic parameters differ, depending on the infant's age and whether he or she was born prematurely or at term.

CASE 49-12

Question 1: H.P. is a 25-year-old G3, P3 who recently was diagnosed with a distal deep vein thrombosis (DVT) in her lower left extremity confirmed by a Doppler ultrasound at 5 weeks' gestation. She has a significant history of having multiple DVTs in her prior pregnancies, and her thrombophilia workup result was negative. During her pregnancy, she was on therapeutic low-molecular-weight heparin (LMWH) 80 mg (weight, 167.55 pounds [76 kg]) SC every 12 hours. Her dosage was increased to 100 mg SC every 12 hours after subsequent anti-factor Xa levels were subtherapeutic. Her LMWH was discontinued 24 hours before she received an epidural for labor pain. After delivery, H.P. is restarted on LMWH and then changed to warfarin on day 5. H.P. also is breast-feeding.

Do either of these drugs present a risk to the nursing infant?

Heparin does not cross into breast milk (see the section on Drug Excretion in Human Milk) because of its high MW (~12,000) and is therefore safe in breast-feeding. Warfarin is a weakly acidic drug (pK_a 5.05) that is highly ionized at physiologic pH (>99%) in maternal serum.[232] It also is highly protein bound (97%).[38] These pharmacokinetic parameters make warfarin very unlikely to transfer into breast milk. Case reports in lactating patients confirm that warfarin is not detected in breast milk or infant plasma.[38] The American Academy of Pediatrics (AAP) considers warfarin compatible with breast-feeding,[92] and it is widely considered to be safe in breast-feeding.[92,235] There are no studies to guide duration of anticoagulation in patients who have had a DVT associated with pregnancy. However, most recommend anticoagulation for at least 6 weeks postpartum, with total duration of anticoagulation of a minimum of 6 months after the thromboembolic event.[235] H.P. can safely breast-feed her infant while she is on LMWH and warfarin.

Estimating Infant Exposure

The actual amount an infant will ingest is difficult to determine owing to varying maternal, drug, and infant parameters. Available data generally are from single or small numbers of case reports or pharmacokinetic studies involving a few patient–infant pairs. An M/P ratio is sometimes used alone as the basis for a recommendation, but this should be avoided because its accuracy can be affected by many factors such as the time of sampling after maternal ingestion (peak vs steady state), dose, length of therapy, route of administration, and milk composition.[232] A RID is sometimes reported in resources or literature, which is expressed as a percentage of the maternal dose.[232] Generally, a RID of <10% is interpreted as an acceptable level. This must be interpreted with caution, however, taking into account other variables such as the age and health of the infant and the safety profile of the drug. It is also important to note that these are estimated values, often based on data collected from one or only a few individuals. However, applying these equations

using measurements specific to a person and her infant is not clinically practical. Compared with the M/P ratio, experts believe that the RID is a better estimate of infant exposure.

Sampling during maternal peak drug concentration attempts to approximate the highest amount of drug that can reach the infant. This assumption is inherently flawed because peak drug concentration in the patient does not necessarily equate with peak drug concentration in milk at that same point in time.[232,236] The amount of drug an infant actually receives also depends on the volume of milk ingested. Even if a drug has a high M/P ratio, the actual amount received by the infant could be low if only a small volume of milk was consumed. Therefore, an M/P ratio describes the likelihood of drug excretion into breast milk, but it does not indicate the level of infant exposure. In general, drugs with lower M/P ratios (<1) are preferred over those with higher M/P ratios (>1) during breast-feeding, but other parameters such as maternal condition and therapeutic efficacy should be considered.

Infant exposure to a drug via ingestion of breast milk can be estimated for some drugs. The M/P ratio is used to estimate the drug concentration in milk (Eq. 49-1) and the dose the infant may ingest (Eq. 49-2).[232,236,237] The variables required to calculate Eq. 49-1 can be located in the published literature, but only for some drugs. The actual volume of milk ingested by the infant is difficult to estimate, but the average consumption is ~150 mL/kg/day. The estimated infant dose can then be used to calculate a RID, which is expressed as a percentage of the maternal dose.[236]

$$\text{Drug concentration in milk} = \text{Maternal plasma drug concentration} \times \text{M/P}$$

(Eq. 49-1)

$$\text{Infant dose (mg/kg/day)} = \text{Drug concentration in milk} \times \text{milk volume (mL/kg/day)}$$

(Eq. 49-2)

$$\text{RID \%} = \text{Infant dose (mg/kg/day)/maternal dose (mg/kg/day)} \times 100 \quad \text{(Eq. 49-3)}$$

The maternal dose is 50 mg/200.62 pounds (91 kg) = 0.55 mg/kg/day. The infant dose is calculated to be 80 ng/mL (1 µg/1000 ng) (1 mg/1000 µg) (150 mL/kg/day), which equals 0.012 mg/kg/day. The RID equals the actual infant dose (0.012 mg/kg/day) divided by the actual maternal dose (0.55 mg/kg/day) × 100, which equals 2.18%. Therefore, the exposure likely does not represent a risk. K.J. can continue to take hydrochlorothiazide while breast-feeding. The AAP classifies hydrochlorothiazide as compatible with breast-feeding.[38,92]

CASE 49-13

QUESTION 1: K.J., a breast-feeding, 200.62-pound (91-kg) person, is taking hydrochlorothiazide 50 mg PO daily. The drug has a long elimination half-life of about 12 hours. Peak milk levels of the drug occur 5 to 10 hours after a dose. In a recent study, the drug was excreted into milk with a mean concentration of 80 ng/mL.

Based only on dose, does this drug represent a significant risk to K.J.'s nursing infant?

Reducing Risk of Exposure

If pharmacologic treatment is medically necessary for a nursing patient, every attempt should be made to minimize infant exposure to the drug. Methods of reducing risks have been proposed.[229,232,234] **Table 49-7** summarizes critical factors that should be considered. Except for drugs that are contraindicated during lactation, the decision to continue or discontinue nursing while receiving medication is ultimately the patient's. Therefore, patient education is an integral component in this decision-making process. The patients should be informed of the potential risks, or lack thereof, associated with a drug. They also should be made aware that certain risks may be minimized by altering feeding pattern and drug administration

time and by carefully monitoring the infant for early signs of adverse effects.

Table 49-7

Reducing Risk of Infant Exposure to Drugs in Breast Milk

A drug should be used only if medically necessary, and treatment cannot be delayed until the infant is ready to be weaned.
Drug Selection
Consider whether the drug can be safely given directly to the infant.
Select a drug that passes poorly into breast milk with the lowest predicted M/P ratio, and a RID <10%.
Avoid long-acting formulations (eg, sustained release).
Consider possible routes of administration that can reduce drug excretion into milk.
Determine length of therapy and if possible avoid long-term use.
Feeding Pattern
Avoid nursing during times of peak drug concentration.
If possible, plan breast-feeding before administration of the next dose.
Other Considerations
Always observe the infant for unusual signs (eg, sedation, irritability, rash, decreased appetite, failure to thrive).
Discontinue breast-feeding during the course of therapy if the risks to the fetus outweigh the benefits of nursing.
Provide adequate patient education to increase understanding of risk factors.

M/P, milk-to-plasma ratio; RID, relative infant dose.

Resources for Drugs and Lactation

Comprehensive sources reviewing drug use in lactation are available to assist clinicians in weighing the potential risks versus benefits of patients using medications while breast-feeding. **Table 49-8** lists

some medications that are contraindicated during lactation. The AAP Committee on Drugs periodically reviews the transfer of drugs and other chemicals into human milk and publishes their findings.[92] The Committee identifies drugs that should be avoided during breast-feeding, drugs that should be used with caution, drugs whose effects on infants are unknown but of concern, and those considered usually compatible with breast-feeding. This rigorous review is an ongoing process, and new guidelines are published every few years; therefore, the reader should locate the latest AAP recommendations available. In addition to the AAP guidelines, several other references also offer comprehensive information and recommendations on drug use in lactation.[38,92,234]

Table 49-8

Drugs Considered Contraindicated During Lactation

Drug or Drug Class	Effects on Nursing Infants
Amphetamines[a]	Accumulate in breast milk and may cause irritability and poor sleep patterns
Antineoplastics	Potential for immune suppression; cytotoxic effects of drugs on dividing cells in infants unknown[2]
Cocaine[a]	Excreted in milk; contraindicated because of CNS stimulation and intoxication
Ergotamine	Potential for suppressing lactation; vomiting, diarrhea, and convulsions have been reported.[92] Considered contraindicated by some clinicians. AAP recommends using with caution.
Heroin[a]	Possible addiction if sufficient amounts ingested
Immunosuppressants	Potential for immune suppression
Lithium	Milk and serum concentrations average 40% of maternal serum levels. Potential for toxicity exists. Considered contraindicated by some clinicians. AAP recommends using with caution.
LSD[a]	Probably excreted in milk
Marijuana[a]	Excreted in milk

Drug or Drug Class	Effects on Nursing Infants
Misoprostol	Excretion in milk has not been studied but contraindicated because of potential for severe diarrhea in infant.
Phencyclidine[a]	Potent hallucinogenic properties
Phenidone	Massive scrotal hematoma and wound oozing after herniotomy in one infant; contraindicated
Requiring Temporary Cessation of Breast-feeding	
Radiopharmaceuticals	Halt breast-feeding temporarily to allow clearance of radioactivity from milk. Suggested times for individual agents are as follows: copper-64 (^{64}Cu) 50 hours; gallium-67 (^{67}Ga) 2 weeks; indium-111 (^{111}In) 20 hours; iodine-123 (^{123}I) 36 hours; iodine-125 (^{125}I) 12 days; iodine-131 (^{131}I) 2–14 days; radioactive sodium 96 hours; technetium-99m (^{99m}Tc) 15 hours–3 days; ($^{99m}TcO_4$) (^{99m}Tc macroaggregates) 15 hours–3 days

This list is not an all-inclusive one. Selected drugs are listed by drug class and not by individual names.

AAP, American Academy of Pediatrics; CNS, central nervous system; LSD, lysergic acid diethylamide.

[a]All drugs of abuse are contraindicated during lactation.

Pharmasoft Medical Publishing; 2014.

Most drugs are excreted into breast milk to some extent; the reader is referred to specialty sources for an in-depth review of the drug in question. The best sources for information regarding drugs in lactation are (a) *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk* by Briggs et al[38] and (b) TOXNET, an online lactation database (LactMed) sponsored by the NIH, accessible at https://www.nlm.nih.gov/toxnet/index.html and click on LactMed. These two databases are peer reviewed and contain referenced sources. Categories assigned to these drugs may change because new data become available for specific drugs.

ACKNOWLEDGMENT

The author acknowledges Kimey D. Ung, Jennifer McNulty, and Gerald G. Briggs, BPharm, for their contributions to this chapter in earlier editions.

Disorders Related to the Menstrual Cycle

Laura M. Borgelt and Karen M. Gunning

CORE PRINCIPLES		CHAPTER CASES
1	A normal menstrual cycle involves the hypothalamus, anterior pituitary gland, ovaries, and endometrial lining of the uterus to create hormonal release. This process results in follicle development, ovulation, and either pregnancy or menstruation every 28 days (average) during reproductive life.	
2	Polycystic ovary syndrome (PCOS) is a heterogeneous disorder that presents with signs and symptoms of hyperandrogenism (eg, acne, hirsutism) or ovulatory dysfunction.	**Case 50-1 (Question 1)**
3	Long-term complications of PCOS may	**Case 50-1 (Question 2)**

	include impaired glucose tolerance, diabetes, metabolic syndrome, infertility, endometrial cancer, and obstructive sleep apnea.	
4	Treatment for PCOS involves nonpharmacologic and pharmacologic management. Pharmacologic management targets the pathophysiologic aspects of the syndrome and individual goals of treatment. Oral contraceptives are preferred when contraception is desired; letrozole is warranted when pregnancy is desired.	**Case 50-1 (Questions 3–7)**
5	Dysmenorrhea, or painful cramping that occurs with the onset and first days of menstruation, can be categorized as either primary (without underlying uterine pathology) or secondary as a result of uterine pathology, including endometriosis, uterine polyps, or fibroids; complications of intrauterine contraceptive device use; or pelvic inflammatory disease. A careful history can distinguish most cases of primary dysmenorrhea from secondary dysmenorrhea, which should always be investigated further to identify its underlying etiology.	**Case 50-2 (Questions 1, 2)**
6	Dysmenorrhea is the single largest cause of lost productivity and school absence among adolescent females. Health care providers can play a	**Case 50-2 (Questions 3–8)**

	significant role in patient education and the development of rational evidence-based nonpharmacologic and pharmacologic therapy plans that include nonsteroidal anti-inflammatory drugs (NSAIDs) and/or hormonal contraceptives to decrease symptoms and improve functionality.	
7	Endometriosis is defined as the presence of functional endometrial tissue occurring outside the uterine cavity. It is the most common cause of secondary dysmenorrhea in young females and can result in chronic pelvic pain, infertility, and dyspareunia. A significant delay in diagnosis of endometriosis is common, and recognition of the potential for a diagnosis of endometriosis, through a careful history and physical, is important to start appropriate care.	**Case 50-3 (Question 1)**
8	Pain control in endometriosis is directed at suppression of endometrial implants that respond to estrogen with bleeding, resulting in subsequent inflammation and pain. Pharmacologic therapy is directed at reducing inflammation (via use of NSAIDs) and reduction in estrogen through use of hormonal contraception) or by use of gonadotropin-releasing hormone (GnRH) agonists or antagonists. A treatment plan should take into account	**Case 50-3 (Questions 2–4)** **Case 50-4 (Question 1)** **Case 50-5 (Question 1)**

	cost, ease of use of therapy, adverse effects, and the patient's desire for future fertility.	
9	Endometriosis treatment plans that include GnRH agonists or antagonists may also require the use of "add-back" therapy. Add-back therapy is the addition of progestins with or without estrogens to decrease drug-related menopausal side effects, including hot flashes, vaginal dryness, and decreases in bone density.	**Case 50-4 (Question 1)**
10	More than 200 premenstrual symptoms have been described as occurring during the days before menstruation. It is not until the symptoms have a decidedly negative influence on the physical, psychological, or social function of a female that premenstrual syndrome (PMS) or premenstrual dysphoric disorder (PMDD) exists. Both PMS and PMDD have physical and/or behavioral symptoms that occur in the luteal phase with resolution within a few days of menstruation, lasting across at least two menstrual cycles, and disrupt normal activities. PMDD is a more severe form of PMS with prominent symptoms of anger, irritability, and internal tension.	**Case 50-5 (Questions 1, 3)**
11	Mind–body approaches and chasteberry have been studied as nonprescription	**Case 50-5 (Question 2)**

	options and have shown some benefit in PMS.	
12	Treatment for PMS and PMDD includes lifestyle modifications, psychological interventions, selective serotonin reuptake inhibitors (SSRIs), oral contraceptives, and GnRH agonists. Because serotonin is critical in the pathogenesis of these disorders, SSRIs have become the treatment of choice for PMDD and severe PMS.	**Case 50-5 (Question 4)**

INTRODUCTION

The average 28-day menstrual cycle is controlled by feedback biologic mechanisms involving the hypothalamus, anterior pituitary gland, ovaries, and endometrial lining of the uterus.[1] The hypothalamus synthesizes gonadotropin-releasing hormone (GnRH) and secretes the hormone in a pulse-like manner with varying frequencies throughout the menstrual cycle (typically every 60–90 minutes). GnRH stimulates the anterior pituitary to produce and release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH is important for stimulating growth of ovarian follicles and LH is critical for ovulation and sex steroid production. FSH and LH act on the ovaries to produce estrogen and progesterone. Estrogen in turn acts on the hypothalamus and anterior pituitary, in a negative feedback manner, to stop FSH and LH secretion (**Fig. 50-1**).

The menstrual cycle can be divided into three phases: the follicular phase, ovulation, and the luteal phase (**Fig. 50-2**).[1] The day bleeding begins is referred to as the first day (or day 1) of the menstrual cycle. Bleeding usually occurs from days 1 to 5 of the cycle, although may be longer in some patients. The follicular phase begins at the onset of menstruation and lasts ~10 to 14 days (see Fig. 50-2). At the beginning of this phase, several follicles begin to develop within the ovary. In the second half of the follicular phase, most of the developing follicles atrophy, whereas the dominant follicle develops further and produces estrogen in increasing amounts. Elevated estradiol levels during the ovulatory phase lead to a surge in LH and FSH. The LH surge is responsible for final-stage growth and maturation of the follicle, ovulation, and the formation of the corpus luteum. Ovulation usually occurs 14 days before the last day of the cycle and is followed by the luteal phase. The luteal phase is 13 to 15 days in duration and is the least variable part of the human reproductive cycle.[1] During this progesterone-dominant phase, the corpus luteum produces progesterone and estrogen. Progesterone prepares the endometrium for the implantation of a fertilized ovum. If implantation does not occur, corpus luteum regression causes a decrease in the levels of estrogen and progesterone. When these hormone levels decrease, the endometrium cannot be maintained and is sloughed off (menstrual phase). Using the average 28-day cycle as an example, day 28 is the last day of the cycle and is the day before bleeding begins again for the next menstrual cycle.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) affects ~6% to 21%, or ~1 in 10, patients of reproductive age, making it the leading cause of anovulatory infertility and the most common endocrine abnormality for this age group.[2,3] This syndrome, or constellation of symptoms, was first described in 1935 by Stein and Leventhal when they reported infertility and amenorrhea in seven patients with enlarged cystic ovaries.[4] Excessive male-pattern hair growth and obesity were added later to the description of this syndrome.[5] PCOS also has been referred to as Stein–Leventhal syndrome, polycystic ovary, polycystic ovarian disease, hyperandrogenic chronic anovulatory syndrome, metabolic reproductive syndrome, and functional ovarian hyperandrogenism. The name polycystic ovary syndrome has been most widely accepted because “syndrome” best describes the

heterogeneous nature of this disorder. However, there have been recommendations to change the name because it focuses on the polycystic ovarian morphology, which is not necessary for diagnosis.[6] It has been suggested that the name should include the complex metabolic, reproductive, hypothalamic, pituitary, ovarian, and adrenal interactions of the syndrome.

Diagnostic Criteria

The diagnosis of PCOS is complicated by patients presenting with varying signs and symptoms of PCOS and because precise and uniform criteria for diagnosis have not been firmly established. Three major diagnostic criteria for PCOS have been proposed by different organizations.

The initial diagnostic criteria were developed in 1990 during an expert conference sponsored by the U.S. National Institutes of Health and U.S. National Institute of Child Health and Human Development. The panel concluded that the major criteria for PCOS should include (in order of importance): (a) hyperandrogenism (clinical signs of hyperandrogenism such as hirsutism) or hyperandrogenemia (biochemical signs of hyperandrogenism such as elevated testosterone levels), (b) oligo-ovulation (infrequent or irregular ovulation with fewer than nine menses per year), and (c) exclusion of other known disorders such as hyperprolactinemia, thyroid abnormalities, and congenital adrenal hyperplasia.[7] The second set of criteria was proposed at an expert conference in Rotterdam sponsored by the European Society for Human Reproduction and Embryology and the American Society for Reproductive Medicine in 2003.[8] They concluded that the presence of two of these three features, after exclusion of related disorders, confirmed diagnosis of PCOS: (a) oligo-ovulation or anovulation, (b) clinical or biochemical signs of hyperandrogenism, or (c) polycystic ovaries. Recent guidelines suggest that one of four phenotypes should be used with a diagnosis of PCOS; however, clinical implications of using these phenotypes are unclear (**Table 50-1**). The

third set of criteria was developed by a task force of the Androgen Excess Society in 2006 with a complete report including phenotyping in 2009.[9,10] These criteria include hyperandrogenism (hirsutism or hyperandrogenemia), ovarian dysfunction (oligo-ovulation or polycystic ovaries), and exclusion of other androgen excess or related disorders. Recent practice guidelines support the Rotterdam criteria for diagnosing PCOS and specifically indicate that serum anti-müllerian hormone (AMH) levels should not yet be used as an alternative for the detection of polycystic ovary morphology or as a single test for the diagnosis of PCOS.[11]

Table 50-1

Phenotypes of Polycystic Ovarian Syndrome Based on Rotterdam Criteria

Phenotype	Androgen Excess	Ovulatory Dysfunction	PCOM on Ultrasound
A	X	X	X
B	X	X	
C	X		X
D		X	X

PCOM, polycystic ovary morphology.

Criteria for diagnosis of PCOS in adolescence can be difficult to assess because of typical changes during puberty and is different than those used for older patients of reproductive age.[11,12] Specific criteria to improve diagnostic accuracy and avoid overdiagnosis include irregular menstrual cycles; hyperandrogenism defined as hirsutism, severe acne and/or biochemical hyperandrogenism confirmed using validated high-quality assays; and exclusion of other disorders that mimic PCOS. Pelvic ultrasound is not recommended for diagnosis of PCOS within 8 years postmenarche because of the high incidence of multifollicular ovaries in this life stage and AMH levels are not recommended for PCOS diagnosis. In recent

guidance, irregular menstrual cycles in this population were more clearly defined according to years postmenarche.[12] Irregular menstrual cycles in adolescents are defined as <21 or >45 days if 1–3 years postmenarche, <21 or >35 days or <8 cycles per year if more than 3 years postmenarche, and >90 days for any one cycle if more than 1 year postmenarche. Irregular menstrual cycles within the first year postmenarche are considered part of the normal pubertal transition. Adolescents who have features of PCOS but do not meet diagnostic criteria may be considered “at risk” for PCOS and reassessment is advised at or before full reproductive maturity (ie, 3 years postmenarche for menstrual irregularity or 8 years postmenarche for pelvic ultrasound). Adolescents with PCOS should be screened for anxiety and depression and assessment of eating disorders warrants consideration.

Clinical Characteristics

Common clinical signs of hyperandrogenism in PCOS include hirsutism, acne, and alopecia. Hirsutism, the most common of these characteristics, occurs in 70% to 80% of patients with PCOS.[13] However, ethnic variations in the presentation and manifestations of PCOS can be seen and should be considered. Examples include a higher body mass index (BMI) in Caucasian females; more severe hirsutism in Middle Eastern, Hispanic, and Mediterranean females; increased central adiposity, insulin resistance, diabetes, metabolic risks, and acanthosis nigricans in Southeast Asians and Indigenous Australians; lower BMI and milder hirsutism in East Asians; and higher BMI and metabolic features in Africans.[11]

Hirsutism is defined as an excess of thickly pigmented body hair in a male-pattern distribution and is commonly found on the upper lip, lower abdomen, and around the nipples. Patients seeking treatment for hirsutism may be evaluated for PCOS. Acne affects over 40% of patients with PCOS compared with ~20% in the general population.[14] The prevalence of alopecia, or female-pattern hair loss, occurs in

20% to 30% of patients with PCOS, typically in the third decade of life.[15]

Ovulatory dysfunction in PCOS is typically described as oligo-ovulation or anovulation, presenting clinically as a female with irregular, infrequent, or absent menstrual bleeding. A majority of patients with PCOS and oligo-ovulation have menstrual dysfunction, usually oligomenorrhea or amenorrhea. The menstrual disturbances usually begin in the peripubertal years; however, menstrual cycles in patients with PCOS become more regular as they approach menopause.

Obesity (defined as a body mass index [BMI] ≥30 kg/m^2) is likely not a cause of PCOS, but it occurs in 50% to 80% of patients with PCOS and in nearly three times more patients with PCOS than those without PCOS.[16,17] Central or abdominal obesity is the typical pattern. Central obesity is a risk factor for the development of diabetes and heart disease and, when present in a female with PCOS, worsens the clinical features (eg, insulin resistance) of the syndrome. Therefore, lifestyle modification with appropriate diet and exercise is a cornerstone of therapy for many patients with PCOS.

Pathophysiology

The pathophysiology of PCOS is complex. The primary abnormalities underlying PCOS include functional ovarian hyperandrogenism because of inappropriate gonadotropin secretion that can be aggravated by insulin-resistant hyperinsulinism.[18] **Figure 50-3** displays the closely integrated relationship between these mechanisms in the development of PCOS.

Figure 50-3 Pathophysiology of PCOS. DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-stimulating hormone; IGF-1, insulin-like growth factor 1; IGFBP, insulin-like growth factor–binding protein; LH, luteinizing hormone; PCOM, polycystic ovarian morphology; SHBG, sex hormone–binding globulin; TG, triglycerides. (Source: Yau TT, Ng NY, Cheung LP, et al. Polycystic ovary syndrome: a common reproductive syndrome with long-term metabolic consequences. *Hong Kong Med J*. 2017;23(6):622–634.)

Data to support a genetic basis for PCOS have accumulated, and genome-wide association studies have identified 19 risk gene loci in

the neuroendocrine, metabolic, and reproductive pathways of PCOS.[19–22] Additional analyses suggest a causal link between PCOS and variants associated with other aspects of the syndrome such as BMI, fasting insulin, menopause timing, depression, and male-pattern baldness.[23] Daughters born to mothers with PCOS have a fivefold higher risk for inheriting PCOS.[24,25] However, known genetic risk alleles account for <10% of PCOS heritability; therefore, other etiologic factors also have to be considered.[11]

GONADOTROPIN SECRETION

In PCOS, there is an increased frequency of GnRH stimulation, leading to an increase in LH pulse frequency and amplitude, while FSH secretion remains normal or low. The development of a dominant follicle does not occur because LH secretion occurs too early in the menstrual cycle. Therefore, a female is left with several immature follicles and usually will not ovulate. It is not clear whether the abnormal pulse frequency of GnRH is a result of genetic association or neuroendocrine mechanisms.[26] A female with this abnormality does not enter the luteal phase of her menstrual cycle, leaving estrogen unopposed. Unopposed estrogen leads to endometrial hyperplasia and increases the risk for endometrial cancer. Increased LH stimulation also leads to increased steroidogenesis in the ovary, leading to excess androgen production. Amenorrheic patients have high AMH serum concentrations and higher antral follicle counts compared with both oligomenorrheic patients and regularly cycling patients with PCOS.[27] Additionally, concentrations of AMH tend to remain persistently elevated over time in patients with PCOS.

EXCESS ANDROGEN PRODUCTION

Androgen production occurs in the theca cell of the ovary to facilitate follicular growth and estradiol synthesis in the granulosa cell. In patients with PCOS, hypersecretion of LH and insulin increases the production of androgens, causing abnormal sex steroid synthesis, hyperandrogenism, and hyperandrogenemia. The dysregulation in

steroid synthesis and metabolism is believed to result primarily from a dysfunction of the cytochrome P-450 (CYP) genes involved in steroidogenesis and especially activities that are required to form androstenedione.[28] Androstenedione is then converted to testosterone or is aromatized by the aromatase enzyme to form estrone. Theca cells in patients with PCOS are more efficient than normal theca cells at the conversion to testosterone.[18] Also, a similar steroid pathway occurs in the adrenal cortex, and, when hyperandrogenism or hyperinsulinemic state exist, androgen production is further enhanced.[18]

Elevated androgen levels are seen in most patients with PCOS, mostly as increased free testosterone concentrations. Calculated free testosterone, free androgen index, or calculated bioavailable testosterone should be used to assess biochemical hyperandrogenism in the diagnosis of PCOS.[11] High-quality assays such as liquid chromatography–mass spectrometry and extraction/chromatography immunoassays should be used for the most accurate assessment of total or free testosterone.[11] Clinical assessment is the primary tool for assessment of excess androgen.

INSULIN

Patients with PCOS generally exhibit an increased risk of insulin resistance, yet the cellular and molecular mechanisms for insulin resistance are different than those seen with obesity and type 2 diabetes.[18] Insulin resistance is associated with reproductive and metabolic abnormalities in patients with PCOS and can occur in both obese and nonobese patients. There are several mechanisms by which this occurs. One proposed mechanism is a postbinding defect in insulin-receptor signaling.[18,29] The insulin resistance in PCOS has been shown to be a selective, tissue-specific process where insulin sensitivity is increased in the ovarian androgenic pathway (causing hyperandrogenism), but insulin resistance is seen in other tissues involved with carbohydrate metabolism, specifically in the fat and muscle. Hyperinsulinemia results because of the compensatory increase in insulin secretion secondary to insulin resistance.

Insulin has both direct and indirect roles in PCOS. In the ovary, insulin acts alone or synergistically with LH to increase androgen production in theca cells. In the liver, insulin inhibits the synthesis of sex hormone–binding globulin (SHBG), a key protein that binds to testosterone, and thus increases the free fraction of androgens available for biologic activity. Therefore, hyperinsulinemia is a major contributor to both hyperandrogenism and hyperandrogenemia in PCOS. Treatments targeted to improve insulin resistance in patients with PCOS have shown improvements in ovulatory function, hirsutism, androgen levels, and metabolic profiles.[29] Indirectly, insulin may enhance the amplitude of LH pulses, further exacerbating the gonadotropin secretion defect in PCOS.[29]

CASE 50-1

Question 1: B.F. is a 21-year-old female with mild hair growth above her upper lip, mild acne, and a history of irregular menstrual periods. Since age 12, she has had six to nine periods per year at intervals that vary from 30 to 70 days. When she does have a period, she considers them to be "normal" without pain or excessive bleeding. Her irregular periods were not bothersome until recently when she became sexually active and worries about becoming pregnant. She uses condoms for birth control. She reports no other medical conditions. B.F. is 67 inches (170.18 cm) tall and weighs 180 pounds (81.65 kg; BMI 28.2 kg/m^2). Her vital signs today are as follows: blood pressure (BP) 116/80 mm Hg, heart rate (HR) 68 beats/minute, temperature 98.6 °F (37 °C), and respiratory rate (RR) 18 breaths/minute. Her physical examination is normal, with the exception of noted excessive facial hair and mild acne. She takes a multivitamin daily and acetaminophen as needed for headaches. She has no known medication allergies.

What signs and symptoms does B.F. have that are consistent with PCOS?

B.F. exhibits several signs and symptoms that would indicate the presence of PCOS. According to the Rotterdam criteria, her history of abnormal menstrual periods (oligomenorrhea) and clinical signs of hyperandrogenism, including hirsutism and acne, would indicate PCOS with phenotype B. B.F. is overweight, which is common in patients with PCOS but is not considered a criterion for diagnosis. Before a diagnosis of PCOS is made, laboratory testing to exclude

other related causes of her symptoms would have to be performed. Studies may include prolactin, thyroid-stimulating hormone, testosterone, and 17-hydroxyprogesterone concentrations to rule out hyperprolactinemia, hypothyroidism, virilizing tumor, and congenital adrenal hyperplasia, respectively. PCOS is primarily diagnosed by clinical assessment; therefore, these tests assist only in confirming or excluding a diagnosis. Although an assessment of polycystic ovarian morphology (PCOM) is not necessary for diagnosis in this case, if it needed to be done, a transvaginal ultrasound should be performed and the threshold for PCOM is a follicle number per ovary of ≥20 and/or an ovarian volume ≥10 mL on either ovary, ensuring no corpora lutea, cysts, or dominant follicles are present.[11]

Long-Term Complications

Case 50-1, Question 2: B.F. has a mother with diabetes and hypertension and a father with type 2 diabetes mellitus (T2DM), hypertension, and dyslipidemia. Her significant laboratory values include the following:

Fasting glucose, 102 mg/dL
Low-density lipoprotein (LDL), 150 mg/dL
High-density lipoprotein (HDL), 52 mg/dL
Triglycerides, 130 mg/dL
Total cholesterol, 228 mg/dL

What risk does B.F. have for experiencing long-term complications from PCOS?

B.F. has an increased risk for experiencing impaired glucose tolerance, diabetes, and metabolic syndrome, especially considering her family history. Furthermore, the diagnosis of PCOS places her at possible increased risk for sleep apnea and endometrial cancer.

IMPAIRED GLUCOSE TOLERANCE AND DIABETES

Studies have shown that patients with PCOS have a higher prevalence of impaired glucose tolerance, gestational diabetes, diabetes, and insulin resistance compared with patients without the

syndrome.[11,30,31] The risk of diabetes is higher when patients with PCOS are overweight or obese.[31] Therefore, screening and diagnosis of these conditions is important for patients with PCOS. B.F. is overweight and her mildly elevated fasting glucose and overweight suggest that she may be at increased risk for impaired glucose tolerance.

Glycemic status should be assessed at baseline in all patients with PCOS and every 1 to 3 years thereafter based on the presence of other diabetes risk factors.[11] An oral glucose tolerance test (OGTT), fasting plasma glucose (FPG), or HbA_{1c} should be performed to assess glycemic status with OGTT recommended in high-risk patients with PCOS (including a BMI >25 kg/m^2 or in Asians >23 kg/m^2, history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of T2DM, hypertension or high-risk ethnicity).[11] Measurement of insulin or insulin resistance is not recommended at this time.

METABOLIC SYNDROME AND CARDIOVASCULAR RISK

Approximately one-third to one-half of patients with PCOS have metabolic syndrome.[32] Using a joint statement by the International Diabetes Federation; the American Heart Association; the National Heart, Lung and Blood Institute; the World Heart Federation; the International Association for the Study of Obesity; and the International Atherosclerosis Society, metabolic syndrome is present when a patient exhibits any three of these symptoms: increased waist circumference, with ethnic-specific waist circumference cut-points; triglycerides ≥150 mg/dL or treatment for elevated triglycerides; HDL cholesterol <40 mg/dL in males or <50 mg/dL in females, or treatment for low HDL; systolic blood pressure ≥130, diastolic blood pressure ≥85, or treatment for hypertension; or FPG ≥100 mg/dL or previously diagnosed type 2 diabetes.[33] For waist circumference in the U.S. population, >35 inches (88.9 cm) for females and >40 inches (101.6 cm) for males is the common cut-off. It is believed that insulin resistance and hyperandrogenism are contributing factors to metabolic syndrome in patients with PCOS.[34]

Common cardiometabolic features in patients with PCOS include low HDL, high triglycerides, increased BMI and waist circumference, high blood pressure, elevated fasting glucose, and presence of markers for early atherosclerosis (eg, increased C-reactive protein concentrations, increased carotid intima-media thickness).[35] These create increased risk for cardiovascular disease (CVD) and T2DM, especially among those with phenotype A and B.[35,36] Data have shown increased risk of incident MI (HR 1.38, 95% CI 1.11–1.72), angina (HR 1.60, 95% CI 1.32–1.94), and revascularization (HR 1.50, 95% CI 1.08–2.07), in young patients with PCOS compared to those without PCOS.[37]

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) is cessation of breathing that occurs during sleep. It can disrupt sleep and cause daytime fatigue. Patients may not be aware that they are having the symptoms of OSA, which include snoring and a gasping or snorting when breathing resumes. Studies indicate that the prevalence of OSA in PCOS is higher than expected and cannot be explained by obesity alone.[38] OSA appears to be a prevalent and important determinant of insulin resistance, glucose intolerance, and type 2 diabetes in PCOS.[39] This can be treated with continuous positive airway pressure (CPAP), which may help metabolic dysfunction.

ENDOMETRIAL HYPERPLASIA AND CANCER

Chronic anovulation in patients with PCOS results in an endometrium that is exposed to the prolonged effects of estrogen unopposed by progesterone. Therefore, PCOS is a risk factor for endometrial hyperplasia. Patients with PCOS have a two- to sixfold increased risk of endometrial cancer, but absolute risk remains low.[11] In one study, patients with PCOS were at significantly increased risk for endometrial cancer compared to controls (OR: 2.8, 95% CI: 1.3–5.9; $P = .008$) and that risk increased further when patients older than 54 years were excluded from analysis (OR: 4.1, 95% CI: 2.4–6.8; $P < .001$).[40] Optimal prevention for endometrial hyperplasia and

endometrial cancer is not known, but clinicians could endorse combined oral contraceptives (COCs) or progestin therapy in those with cycles longer than 90 days.[11]

Treatment Goals

Case 50-1, Question 3: B.F. worries about becoming pregnant when she does not have regular periods. She also has mild hair growth above her upper lip, which is somewhat bothersome. Given these concerns, what are the treatment goals for B.F.?

The primary goals for B.F. are to prevent pregnancy and address her hirsutism. Additionally, treatment goals in B.F. would include maintaining a normal endometrium, blocking the actions of androgens at target tissues, reducing insulin resistance and hyperinsulinemia, reducing weight, and preventing long-term complications. Other goals of treatment in patients with PCOS may include correcting anovulation or oligo-ovulation and improving fertility.

Therapy goals should encompass both long-term and short-term objectives because the response to nonpharmacologic and pharmacologic therapy is slow, often requiring 3 to 9 months. Addressing long-term goals can minimize the risk for future complications, and specifying short-term goals can improve motivation and adherence to therapy.

NONPHARMACOLOGIC TREATMENT

Case 50-1, Question 4: B.F. has indicated that she would like to lose weight. B.F. does not smoke, drinks one to two beers on weekends, and exercises by walking 20 minutes twice weekly. What nonpharmacologic method(s) would be most effective?

Dietary changes have been significantly related to decreased insulin resistance and body composition in patients with PCOS.[41]

The DASH diet was shown to be more effective in improving insulin sensitivity in PCOS, and calorie-restricted diets may be optimal for weight loss. Achievable goals such as 5% to 10% weight loss over 6 months in those with excess weight can have significant clinical improvements.[11] Lifestyle intervention (preferably including diet, exercise, and behavioral strategies) should be recommended in those with PCOS and excess weight, for reductions in weight, central obesity, and insulin resistance. A 5% to 10% weight loss in B.F. would be 9 to 18 pounds (4.08–8.16 kg) and may be achieved through a combination of calorie-restricted, healthy diet, and exercise. Weight reduction should be considered first-line therapy in all patients with PCOS who are overweight or obese, and this should be recommended for B.F.

EXERCISE

Exercise is a key component in the attainment and maintenance of weight loss. To prevent weight gain and maintain health, adults should exercise a minimum of 150 minutes per week of moderate-intensity physical activity or 75 minutes per week of vigorous intensities (or an equivalent combination of both), including muscle strengthening activities on 2 nonconsecutive days per week.[11] Adolescents should exercise at least 60 minutes per day with moderate-to-vigorous intensity physical activity with bone and muscle strengthening muscle at least three times weekly. For modest weight loss, preventing weight gain, and greater health benefits, a minimum of 250 minutes per week of moderate-intensity activities or 150 minutes per week of vigorous intensity (or an equivalent combination of both) with muscle strengthening on 2 nonconsecutive days per week is recommended. B.F. should increase her exercise to at least 150 minutes per week of moderate intensity for at least 3 days of the week. If she is going to continue walking as her exercise, she should walk at a brisk pace. Titrating her time to a goal of exercising 30 minutes daily will help her lose weight.

Pharmacologic Treatment

Case 50-1, Question 5: B.F. would like to improve her menstrual irregularity and be sure that she will not get pregnant. If possible, she would also like to minimize her hirsutism and acne. What options would be appropriate to recommend for B.F.?

Several different pharmacologic options could be recommended to B.F. (**Table 50-2**). Consideration of her personal characteristics, preferences, and values is important in recommending pharmacologic treatment. A COC will address her concerns about irregular menstruation, hyperandrogenism, and pregnancy prevention. An insulin sensitizer would improve her menstrual irregularity and possibly reduce her hirsutism and acne, but it does not address her desire to prevent pregnancy. An antiandrogen, such as spironolactone, would address only hyperandrogenism, and other agents would have to be used concurrently to address pregnancy prevention and the other hormonal and metabolic alterations in PCOS.

Table 50-2
Selected Treatment Options for Polycystic Ovarian Syndrome

Drug Class (Example)	Purpose of Therapy	Mechanism of Action	Effective Dose	Side Effects
Combined oral contraceptive (estrogen and progestln)	Menstrual cycliclty, hlrsutlsm, acne	Suppresses LH (and FSH) and thus ovarian androgen production; increases sex hormone–bindlng globulin, which decreases free testosterone	One tablet orally daily for 21 (or 24) days, then 7 day (or 4 day) pIll-free interval	Breast tenderness, break-through bleeding, mood swings, libido changes
Progestins (medroxypr ogesterone)	Menstrual cyclicity	Creates withdrawal bleeding by transformlng proilferative endometrium into secretory endometrium	5–10 mg orally daily for 10–14 daysevery 1–2 months	Breakthrough bleeding, spotting, mood swings
Biguanide (mecformin)	Impaired glucose tolerance, type 2 diabetes	Decreases hepatic glucose production, secondarlly reducing insulin levels, may have direct effects on steroldogenesis	1500 mg orally daily in divided doses (up to 2550 mg/day)	Gastrointestinal problems, diarrhea, abdominal pain
Antiandrogen (spironolactone)	Hirsutism, acne	Inhibits androgens from binding to androgen teceptor	50–100 mg orally twice daily	Hyperkalemla, polymenorrhea, headache, fatigue
Aromatase Inhibitor (letrozole)	Ovulation induction	Inhibits androgen-to-estrogen conversion to directly affect hypothalamic–pituitary–ovarian function and increase FSH secretion and ovarian follicle development	2.5 mg orally daily for 5 days; may increase to 7.5 mg	Nausea, headaches
Antiestrogen (clomiphene citrate)	Ovulation induction	Increases GnRH secretion, which induces rise in FSH and LH	50 mg orally daily for 5 days; may Increase to 150 mg	Vasomotor symptoms, gastrointestinal problems

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

COMBINED ORAL CONTRACEPTIVES

Estrogen–progestin combination therapy with a COC is the treatment of choice for patients seeking regularity in menstrual cycles and relief from hyperandrogenic symptoms (see Chapter 47, Contraception, for a list of possible therapies). The estrogen component suppresses LH, resulting in a reduction of androgen production, and increases hepatic production of SHBG, thereby reducing free testosterone. The progestins in various COCs possess variable androgenic effects, so the choice of the COC may be considered to minimize androgenic exposure.

COCs therapy in PCOS should be initiated with a formulation that contains a low dose or very low dose of estrogen (20–30 μg of ethinylestradiol or equivalent) and a progestin informed by general population guidelines.[11] For B.F., a COC containing ethinylestradiol and desogestrel would prevent pregnancy, improve menstrual cycle regularity, and reduce her signs of hyperandrogenism (hirsutism and

acne). If B.F. desired monthly cycles, she could take the typical 21/7 regimen (21 days active pill, 7 days inactive pill) or a 24/4 regimen (24 days active pill, 4 days inactive pill). Although not specifically evaluated in patients with PCOS, a monophasic regimen may also be prescribed using extended cycles of 84 or even 365 days. Extended regimens reduce the number of cycles per year while providing contraception. Regardless of the COC selected, one of the long-term benefits is that her risk for endometrial cancer would be reduced by 30% to 50%, even up to two decades after discontinuation.[42] She should continue therapy for as long as she desires contraception and minimization of the androgenic effects of PCOS. Higher doses of ethinylestradiol (30–35 µg) may be needed for better suppression of ovarian androgens and management of hyperandrogenic features. Although transdermal or vaginal ring preparations are potential options, they have not been well studied in PCOS.

Case 50-1, Question 6: Two months later, B.F. reports she is experiencing mood swings and weight gain on her ethinylestradiol/desogestrel oral contraceptive. She is debating if she wants to continue with the COC and would like to explore other treatment possibilities. What other therapy options may be beneficial for B.F. if she considers this COC to be intolerable?

AGENTS FOR INSULIN RESISTANCE

Improving insulin sensitivity with insulin-sensitizing agents is associated with a decrease in circulating androgen levels, improved ovulation rate, and improved glucose tolerance. Metformin and glucagon-like peptide-1 (GLP-1) agonists appear to be the most promising agents for patients with PCOS. Thiazolidinediones have been evaluated, but they are not recommended in patients with PCOS who do not have diabetes because of limited clinical data, potential weight gain, and a possible association with cardiovascular adverse events.

Metformin

Metformin inhibits hepatic glucose output, providing lower insulin concentrations and reducing androgen production in the ovary. Metformin in addition to lifestyle could be recommended in patients with PCOS, especially those with BMI ≥25 kg/m^2 for the treatment of weight, hormonal, and metabolic outcomes.[11] Metformin has minimal effectiveness for hirsutism or acne. Metformin can be used in combination with COCs if desired goals are not being achieved.

The most commonly used and most effective dose of metformin in PCOS is 500 mg orally three times daily (tid). It should be titrated slowly to this effective dose; doses up to 2000 or 2550 mg daily may be necessary for individual circumstances. The gastrointestinal (GI) side effects of diarrhea, nausea, vomiting, and abdominal bloating are usually transient and dose related and can be minimized by taking with food instead. Renal function should be evaluated at least annually in patients using metformin because it is contraindicated in those with estimated glomerular filtration rate (eGFR) <30 mL/minute/1.73 m^2 and is not recommended in patients with eGFR between 30 and 45 mL/minute/1.73 m^2.

Glucagon-like peptide-1 agonists

Although not specifically approved for PCOS, GLP-1 agonists such as exenatide and liraglutide have been evaluated in patients with PCOS. A meta-analysis showed that GLP-1 receptor agonists were significantly more effective than metformin in improving several key parameters in these patients.[43] Specifically, compared with metformin, GLP-1 receptor agonists were more effective in improving insulin sensitivity (standard mean difference [SMD] −0.40, 95% confidence interval [CI] −0.74 to −0.06, P = .02) and reducing BMI (SMD −1.02, 95% CI −1.85 to −0.19, P = .02) and abdominal girth (SMD −0.45, 95% CI −0.89 to −0.00, P = .05). GLP-1 receptor agonists were associated with a higher incidence of nausea and headache than metformin. GLP-1 agonists, with or without metformin, offer a unique opportunity to expand the treatment options available to patients with PCOS.

AGENTS FOR HIRSUTISM

Although frequently used, antiandrogens do not have FDA-approved uses for the treatment of female hirsutism or acne in the United States. Spironolactone is commonly prescribed to patients for hirsutism. Finasteride has been used for female hirsutism, but its lack of specificity for type I 5α-reductase in the pilosebaceous unit and toxicity may make this a suboptimal treatment choice. Flutamide is effective for hirsutism, but it is not used because of hepatotoxicity. These three agents have improved efficacy over placebo but are similar to each other.[44] Eflornithine hydrochloride has been approved for topical use in treating facial hirsutism but has not been well studied in patients with PCOS. Electrolysis and laser treatments may be acceptable physical approaches to hair removal for patients with PCOS.

Spironolactone

Spironolactone acts by competitively inhibiting dihydrotestosterone (DHT) from interacting with its androgen receptor. This causes a decrease in the activity of ovarian-produced testosterone. Treatment with 100 mg or rarely 200 mg of spironolactone for 6 to 9 months is very effective in reducing hair growth.[45] Spironolactone may be associated with possible teratogenicity (feminization of the male fetus), so it is prudent to advise patients to avoid pregnancy for at least 4 months after the discontinuation of spironolactone. It is recommended that spironolactone be used with a COC to avoid teratogenicity as well as the side effect of polymenorrhea (more frequent menses) when used as monotherapy. Spironolactone in combination with a COC would also improve hormonal and metabolic manifestations of PCOS as well. Serum potassium and renal function should be monitored because this aldosterone antagonist can cause hyperkalemia. Furthermore, spironolactone should not be used with a COC containing drospirenone because of potential risk for hyperkalemia.

Finasteride

Finasteride is a type II 5α-reductase inhibitor, which decreases the conversion of testosterone to DHT. Compared with spironolactone, finasteride is as effective in patients with hirsutism.[44] The dose of 5 to 7.5 mg orally daily typically takes 6 months for clinical improvement. It is critical to avoid pregnancy while taking this drug owing to the potential teratogenic effect of abnormal genitalia in the male fetus. Finasteride should not be touched or handled by patients who are or may be pregnant. This danger limits the usefulness of finasteride in patients with PCOS because most are of childbearing age or desire pregnancy.

B.F. should be encouraged to continue her COC for at least 3 months as most COC side effects resolve within 3 months of use. If B.F. decides that the side effects from the COC are intolerable, an appropriate recommendation for B.F. would be spironolactone 50 mg orally daily. She should continue this therapy for as long as she desires the benefits of this therapy, but it will not provide contraception. B.F. should ensure proper contraception is used while taking spironolactone to avoid teratogenicity.

Case 50-1, Question 7: B.F. successfully used oral contraceptives for 7 years. After getting married 2 years ago, B.F. and her husband have decided to have children. She lost 30 pounds (13.61 kg) with diet and exercise when she got married and has been able to maintain that weight loss. They have been trying to get pregnant for the last 18 months. The reason for infertility has been identified as oligo-ovulation associated with PCOS. What treatments for ovulation induction should be used in B.F. and why?

Anovulation or oligo-ovulation in patients with PCOS is usually first treated with diet, exercise, and weight reduction. Weight loss improves pregnancy rates and reduces miscarriage rates in patients with PCOS. B.F. has been successful at losing weight and now must consider agents for ovulation induction.

AGENTS FOR OVULATION INDUCTION

Letrozole

Although not approved by the FDA for this purpose, letrozole should be considered first-line treatment for ovulation induction in patients with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, pregnancy, and live birth rates.[11,46] It is a highly selective aromatase inhibitor, preventing androgen-to-estrogen conversion and improving ovulation rates.[47] It appears beneficial over clomiphene citrate for ovulation rates and live birth rates likely because it does not block estrogen receptors in both central and peripheral target tissues, and normal central feedback mechanisms remain intact.[48,49] Although similar risk for twin gestation, another potential benefit for the use of letrozole is a lower risk of high-order multiple births compared to clomiphene citrate.[46,48]

The initial dose of letrozole is 2.5 mg once daily for 5 days, starting on day 3, 4, or 5 following menses or progestin-induced bleed, and the dose may be increased to 5 mg/day for 5 days in subsequent cycles if ovulation does not occur. The maximum dose is 7.5 mg/day, and letrozole has been used for up to five cycles.[46] If letrozole alone does not provide an adequate response, patients who received the combination of letrozole and CC had a statistically higher ovulation rate compared with those who received letrozole alone.[47]

Clomiphene citrate

Clomiphene citrate induces ovulation via an antiestrogenic effect on the hypothalamus. GnRH secretion is increased, which increases LH and FSH production. The increase in FSH concentrations causes appropriate follicle development and estrogen secretion, which produces a positive feedback on the hypothalamic–pituitary system to create an LH surge for ovulation. This often results in adverse events related to vasomotor symptoms and mood swings.

The usual initial dose of clomiphene citrate is 50 mg orally daily for 5 days, started on day 5 after a spontaneous or progestin-induced menses. The clinician must determine if ovulation occurs with each cycle through laboratory testing, ultrasound monitoring, or both. If ovulation does not occur, the dose can be increased by 50 mg orally daily up to 150 mg orally daily; however, doses >100 mg orally daily

for 5 days are not recommended. A repeat cycle can be administered as early as 30 days after the previous cycle as long as pregnancy has not occurred. If conception does not occur, patients can use clomiphene for three to four cycles before considering another regimen. Long-term cyclic therapy is not recommended beyond a total of six cycles because of potential ovarian cancer risk. For patients who do not respond to letrozole, clomiphene, or the combination, the recommended second-line intervention is either exogenous gonadotropins or laparoscopic ovarian surgery.[46] In vitro fertilization would be considered third-line therapy.[11]

Patients with PCOS exhibit unique clinical features and have individual concerns that should be addressed when making treatment recommendations. Assessment should include gathering relevant medical information, such as menstrual history, signs and symptoms of hyperandrogenism, time course of symptoms, weight history, previous agents tried, and family history. If PCOS is suspected, laboratory assessments should be performed to rule out any other related disorders. Once a diagnosis has been made with the appropriate phenotype identified, a recommendation about treatment must consider the patient's priorities and motivation. For B.F., letrozole would likely be the pharmacologic agent of choice. Ovulation induction and live birth occur in ~48% and 27% of patients with PCOS, respectively, using letrozole.[48] The initial dose would be 2.5 mg orally once daily for 5 days, started on day 3 after a spontaneous or progestin-induced menses. If nonresponse occurs, the dose may be increased by 2.5 mg and up to a maximum of 7.5 mg daily for 5 days on following cycles. Although side effects (eg, fatigue, dizziness) can occur, the benefit of this therapy outweighs the risk for B.F. Appropriate follow-up for B.F. should include quality-of-life measures, laboratory monitoring when necessary, and medication adherence monitoring. Providers should be educators, facilitators, and empathetic listeners to help patients with PCOS become informed and actively engaged in their therapy plan.

DYSMENORRHEA

Dysmenorrhea, or painful cramping that occurs with the onset and first days of menstruation, can be categorized as either primary (without underlying uterine pathology) or secondary (owing to underlying uterine pathology). Secondary dysmenorrhea can result from uterine conditions, including endometriosis, uterine polyps, or fibroids; complications of intrauterine device (IUD) use; or pelvic inflammatory disease.

Up to 90% of adolescents report some pain with menstruation, and up to 15% experience pain that is sufficiently severe and disabling to interfere with activities of daily life.[50] Dysmenorrhea is the single largest cause of lost productivity and school absence among adolescent girls. It most commonly begins within 1 to 2 years after the onset of menses, and up to 91% of adult patients report some pain with menses, of which up to 28% experience severe pain and/or limitation of activity.[51]

Clinical Characteristics

CASE 50-2

QUESTION 1: A.B., a 15-year-old female, presents at the pharmacy with her father with severe cramping pain associated with her menstrual cycles. The pain predictably begins with the onset of menses and has been occurring for the past 4 years but is now limiting A.B.'s ability to play sports. A.B. states that she experienced her first menstrual period at age 11. The pain usually is "like a fist, clenching and relaxing," and it starts in the pelvic area, and radiates to her lower back. She reports no headache, but usually has diarrhea and some nausea, without vomiting. Her symptoms are most severe during the first 12 to 24 hours of her menses, then subside during the next few days. She usually takes two acetaminophen 325-mg tablets when her pain begins and then one tablet every 4 to 6 hours, as needed, with little relief. She has taken no other medications for her symptoms, has no known allergies to medications, and is not taking any other medications. She has no other medical problems. Her social history is significant for occasional social use of nicotine vapes. A recent physical examination was within normal limits.

Which of A.B.'s symptoms are consistent with primary dysmenorrhea?

No specific diagnostic criteria exist for primary dysmenorrhea. Typically, the diagnosis is one of exclusion and is based on response to known effective therapy. If patients do not respond to therapy, an investigation of pelvic pathology and secondary dysmenorrhea should occur.[52] A.B.'s symptoms that are typical of primary dysmenorrhea include cramping pain in the suprapubic area, which may radiate into the back and thighs, nausea, and diarrhea. Some patients also experience vomiting, fatigue, headache, lightheadedness, flushing, loss of appetite, irritability, nervousness, and insomnia.[52] Symptom severity seems to correlate with patients who have early menarche (onset of menses before age 12) and those with increased duration and quantity of menstrual flow.[50] Risk factors for dysmenorrhea include age younger than 20 years, depression or anxiety, perceived high life or work stress, nulliparity, menorrhagia, and smoking.[50,51]

Primary dysmenorrhea occurs only with ovulatory cycles, which typically begin after the first year following menarche. Dysmenorrhea occurring several years after menarche is most likely secondary dysmenorrhea. Because A.B.'s pain began within 1 year of menarche and her physical examination is normal, a treatment trial can be initiated without further investigation into the secondary causes of dysmenorrhea. The typical pattern of dysmenorrhea is to have pain beginning up to 12 hours before menses, increasing in severity for up to 24 hours, and continuing with reduced intensity for 24 to 72 hours.[52] A.B.'s description of pain, as a cramping–relaxing cycle, as well as the timing of the onset of pain in relation to her menses is typical for dysmenorrhea. Likely, her symptoms will decrease with age, after the onset of sexual activity, and after childbirth.[50]

Pathophysiology

Case 50-2, Question 2: What underlying pathophysiology explains A.B.'s symptoms and guides us to rational pharmacotherapy?

In the normal menstrual cycle, prostaglandins are released by the endometrium in the late luteal phase inducing contraction of the uterine smooth muscle and subsequent sloughing of the endometrium, leading to menstrual flow and the beginning of the follicular phase of the next cycle. Patients with primary dysmenorrhea appear to have increased prostaglandin secretion, inducing more intense uterine contractions, leading to decreased uterine blood flow and uterine hypoxia, which results in cramping and pain that are the hallmarks of dysmenorrhea.[52] The decreasing levels of progesterone in the late luteal phase trigger the release of arachidonic acid from cell membranes, ultimately resulting in the production of prostaglandins and leukotrienes.[50,52]

The importance of prostaglandin secretion in the pathology of primary dysmenorrhea is confirmed by studies of the exogenous administration of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and PGE_2, each of which produce pain and uterine contractions similar to those observed in patients with primary dysmenorrhea.[53] These prostaglandins, with potent platelet disaggregation and vasodilatory properties, also induce nausea, vomiting, and diarrhea. Thus, A.B.'s pain, nausea, and diarrhea may be caused by elevated prostaglandin levels. This also explains the rationale for the effectiveness of the two main treatments for primary dysmenorrhea: nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit prostaglandin synthesis, and hormonal contraceptives, which minimize the progesterone increase typically seen in the luteal phase.

Nearly 85% to 90% of patients initially thought to have primary dysmenorrhea respond to NSAIDs with or without oral contraceptive therapy. The remaining patients deserve further investigation into potential causes of secondary dysmenorrhea.

Treatment

NONPHARMACOLOGIC TREATMENT

CASE 50-2, QUESTION 3: What nonpharmacologic therapies may be effective for the treatment of A.B.'s symptoms of primary dysmenorrhea?

A.B. should be educated about the causes of primary dysmenorrhea, its associated symptoms, and the rationale behind nonpharmacologic and pharmacologic treatment options. Nonpharmacologic therapies that may have benefit in the relief of A.B.'s symptoms include aerobic exercise, yoga, heat therapy, and tobacco cessation.

Exercise, particularly aerobic exercise, has been correlated with decreased menstrual pain and pain intensity in observational and randomized studies, and is, in all patients, associated with positive general health benefits.[54] In addition, yoga has demonstrated benefit in the reduction of pain and pain intensity in patients with dysmenorrhea.[55] The benefit may be because of improved pelvic blood flow and decreased ischemia or increased release of β-endorphins. Application of local heat to the lower abdomen has been studied in three well-designed clinical trials.[56–58] Heat plus ibuprofen (400 mg orally tid) demonstrated a reduction in the time to pain relief compared with an unheated patch plus ibuprofen in two controlled studies.[56–58] With few adverse effects, heat, in the form of a heating pad or heated patch or wrap device, and exercise (aerobic or yoga) represent reasonable and safe suggestions for patients with dysmenorrhea.

Patients should be advised and assisted in efforts to discontinue tobacco use as there is an association with increased risk and severity of dysmenorrhea in patients who smoke.[50] There is no solid evidence to recommend any specific dietary supplements or vitamins to alleviate menstrual pain.[59]

A.B.'s treatment plan should be based on her specific symptoms, response to previous therapy, and any adverse effects of therapy. The regimen of acetaminophen that A.B. is currently using is not providing relief owing to its relative lack of effect on prostaglandin

activity. For A.B., discussion of the nonpharmacologic therapies, particularly continuous low-level heat applied at onset of symptoms, exercise/yoga, and smoking cessation, provide low-risk, potentially beneficial, and low-cost suggestions for pain relief, in addition to drug therapy. A.B. should be informed that continuous heat therapy via heat "wraps" or hot water bottle or heating pad should not be used while sleeping.

Case 50-2, Question 4: A.B. states that her pain is decreased about 50% with the use of a heating pad and heat wraps, but she finds them bulky and hard to use when she is not at home. She asks about the use of Midol™. What would be effective over-the-counter (OTC) pharmacologic options for A.B.?

Although nonpharmacologic therapy with heat, exercise, and smoking cessation may have benefit, often the use of pharmacologic therapies is required to further improve functionality.

OVER-THE-COUNTER PHARMACOLOGIC THERAPY

OTC pharmacologic therapy for primary dysmenorrhea is focused on reducing prostaglandin activity. Anti-inflammatory drugs act by directly inhibiting prostaglandin synthesis. NSAIDs provide relief from the symptoms of primary dysmenorrhea for most patients (see Case 50-2, Question 5, for further information). Naproxen (as the sodium salt) and ibuprofen are approved without a prescription for the treatment of primary dysmenorrhea. Acetaminophen is of limited efficacy in the treatment of dysmenorrhea when compared with NSAIDs or hormonal contraception.

Other therapies, including OTC products marketed for dysmenorrhea and other menstrual disorders (eg, Pamprin, Midol) are combination products that may include weak muscle relaxants (such as pyrilamine, pamabrom), diuretics (caffeine), and acetaminophen, all of which have limited efficacy for the specific treatment of dysmenorrhea. Because they do not address the underlying pathophysiology of primary dysmenorrhea, OTC combination products, narcotic analgesics, and acetaminophen do not have a role in the treatment of primary dysmenorrhea, and

combination products, in particular, may have excessive adverse effects with minimal benefit.

Adolescents with dysmenorrhea frequently use OTC medications to treat primary dysmenorrhea, usually without consultation from a health care professional.[60] This lack of professional advice results in the use of lower doses that may not be as effective to treat symptoms. Many patients choose ineffective combination medications and/or acetaminophen, indicating patients would benefit from pharmacist advice regarding OTC treatments of dysmenorrhea.[60] Ibuprofen 200 to 400 mg orally up to three times daily is a reasonable initial plan for A.B.'s dysmenorrhea.

Prescription pharmacologic agents: nonsteroidal anti-inflammatory drugs

Case 50-2, Question 5: A.B. has tried ibuprofen 400 mg tid starting at onset of her cramping symptoms but has not had optimal relief. A.B. presents to her family physician for an evaluation. What prescription medications could be recommended for A.B.'s dysmenorrhea?

The NSAIDs are effective for treatment of dysmenorrhea, but in some cases, OTC doses are not adequate and prescription-strength NSAIDs or hormonal contraceptives may be required for improved relief. Hormonal contraceptives reduce the amount of endometrial proliferation and, as a result, decrease the amount of prostaglandins secreted. By inhibiting ovulation, hormonal contraceptives eliminate the cyclic changes in progesterone that induce prostaglandin release. Choice of therapy depends on the need for contraception, concomitant medical conditions, and preference of the patient. Treatment efficacy can be monitored by evaluating pain relief, improved functionality, reduced absenteeism, and relief of other symptoms (eg, diarrhea, nausea) associated with dysmenorrhea. Prescription-strength NSAIDs should be tried for two to three cycles before switching to other agents.

Initial selection of NSAID therapy should be based on effectiveness, incidence of adverse effects, cost, patient history of previous benefit, and availability. In a Cochrane review, 80 trials of NSAIDs for treatment of primary dysmenorrhea were reviewed to assess for any differences in efficacy or safety among the different NSAIDs.[61] When compared with placebo, NSAIDs were significantly more effective (OR, 4.50; 95% CI, 3.85–5.27). When compared with acetaminophen, NSAIDs were, as expected, significantly better at reducing symptoms (OR, 1.90; 95% CI, 1.05–3.44). In limited head-to-head trials comparing NSAIDs, no significant differences in efficacy were seen, with the exception of aspirin being slightly less effective than other NSAIDs when directly compared. Adverse effects seen in these trials were generally mild GI (nausea, upset stomach) and neurologic (sleepiness, dizziness, headache) symptoms.

Some data suggest that an oral loading dose of naproxen sodium (550 mg) might improve pain control in dysmenorrhea.[50] Loading doses generally are twice the regular dose. If A.B. experienced adverse effects with the higher loading dose, an alternative strategy is to initiate dosing 24 hours before menses is expected to start, based on the calendar if the patient has predictable cycles, or based on the start of premenstrual-syndrome–type symptoms. This prophylactic dosing may be helpful, especially for patients who have severe dysmenorrhea with absenteeism and decreased work or school productivity.[61] Although no specific evidence supports the use of scheduled NSAID dosing regimens, avoiding as needed (PRN) dosing may provide consistent serum levels to maintain reduced prostaglandin levels. As the duration of therapy is typically limited to 2 or 3 days, risk of adverse effects is outweighed by the potential benefit of loading doses, prophylactic dosing, and scheduled versus PRN therapy.

The next step for A.B. could include initiating naproxen sodium 550 mg orally at the beginning of menses, followed by 275 mg every 8 hours thereafter for the 2 to 3 days she experiences cramping.

Adverse Effects

Case 50-2, Question 6: What adverse effects might A.B. experience from her NSAID?

All NSAIDs have a similar adverse effect profile. Nausea, vomiting, indigestion, anorexia, diarrhea, constipation, abdominal pain, melena, and bloating are common GI symptoms.

Careful attention should be given to previous trials of NSAIDs for dysmenorrhea and other conditions, because patients may respond favorably to one NSAID over another. If a 2- or 3-month trial at appropriate doses of one NSAID is unsuccessful for A.B., another agent from a different chemical class may be tried. Because dysmenorrhea is most prevalent in younger patients who tend to be healthy, the risk of adverse events may be lower than would be expected in an older population.

Contraindications

Case 50-2, Question 7: What medical history information is important to collect to avoid serious adverse effects with NSAIDs?

A.B. should be questioned about medication allergies and any prior history of ulceration or GI bleeding; a history of cardiovascular and renal disease, although uncommon in young patients, should be elicited before prescribing therapy. A thorough medication history, including OTC agents and dietary supplements, is important. Particular attention should be paid to any potential therapeutic duplications (eg, prescription and OTC NSAIDs), drug–drug (eg, warfarin), and drug–disease (hypertension) interactions.

Patients who are allergic to aspirin or have a history of allergic reaction to any NSAID should not use NSAIDs. A.B. has not had a previous allergic reaction to NSAID or aspirin; she is not taking any medications that may interact and does not have any history of

medical problems that would prevent her from a trial of NSAID therapy.

Hormonal contraception

Oral Contraceptives

Case 50-2, Question 8: After 6 months of treatment, A.B. has some relief from her pain, nausea, and diarrhea with the naproxen sodium, but is unhappy with the amount of time that she is spending at home because of menstrual cramps. She is asking about other treatment options for further pain relief. What other options are available for A.B.?

As mentioned previously, hormonal contraceptives may be an option for A.B. if prescription NSAIDs are not adequate for her symptoms. Oral contraceptives (OCs) suppress ovulation, decrease menstrual fluid volume, and decrease prostaglandin production and uterine cramping.[50,52] OCs alone, or in combination with an NSAID, are appropriate as first-line treatment in patients with or without a need for contraception.[50,52] OCs relieve dysmenorrhea symptoms in 50% to 80% of patients within 3 to 6 months after beginning hormone therapy.[62] A Cochrane review of OCs and primary dysmenorrhea found OCs containing <35 µg of ethinylestradiol to be effective at reducing pain but failed to demonstrate a significant difference between various 35-µg ethinylestradiol OC formulations.[62] Selection of an OC should be based on factors presented in Chapter 47, Contraception. A continuous versus cyclic regimen of administration may result in a reduction in days in pain.[63] This reduction may not be sustained over time, as a randomized controlled trial evaluated the use of continuous dosing of OCs compared to the traditional 21 active days, 7 placebo days regimen, with an initial benefit in favor of decreased pain in the continuous dosing group at 1 and 3 months that was lost after 6 months of use.[64]

Adverse effects and contraindications associated with OC use must be considered (see Chapter 47, Contraception). Although serious complications from OC use are uncommon in young, healthy

patients, breakthrough bleeding and spotting, nausea, and breast tenderness may occur, especially early in treatment. A.B. may choose to add an OC to her naproxen sodium, with potentially improved pain relief compared with either agent alone. Pain that does not respond to either course of therapy, investigation for causes of secondary dysmenorrhea would be appropriate.

Other Hormonal Contraceptive Agents

Other hormonal contraceptive agents that suppress ovulation have also been used in the treatment of primary dysmenorrhea, although none have undergone rigorous trials for this indication.[50] The levonorgestrel intrauterine system (IUS) is associated with amenorrhea and a reduction in dysmenorrhea over time, unlike the copper IUD, which may result in increased pain, cramping, and blood loss. Three years after insertion, fewer patients with a levonorgestrel IUS reported menstrual pain (60% baseline, 29% after 3 years), with 47% of patients with amenorrhea.[65] In patients with primary dysmenorrhea who desire long-term contraception or who have contraindications to estrogen, the levonorgestrel IUS would be a reasonable option.

Medroxyprogesterone depot injection is another hormonal contraceptive agent that has been used to treat primary dysmenorrhea. Negative effects of medroxyprogesterone injections on bone density and body weight should be balanced with potential benefit when considering this option (see Chapter 47, Contraception). Progestin contraception implants represent another option, without the effect on bone density or weight.[50,52] Given that A.B.'s past history does not include any absolute contraindications to COCs and her dysmenorrhea symptoms have not been well-controlled with prescription NSAIDs, she is a candidate for combined hormonal contraception. A trial of COCs would be an appropriate plan for better control of her dysmenorrhea. She should be counseled that hormonal contraceptives may require 3 or more months to provide maximal relief of symptoms. The goals of therapy, namely, reduction in pain and associated symptoms, as well as

improvement in functionality, should be explained to A.B. and reviewed at each contact.

ENDOMETRIOSIS

Endometriosis is a chronic inflammatory disorder characterized by the presence of functional endometrial tissue occurring outside the uterus. It is the most common cause of secondary dysmenorrhea in young patients and can result in chronic pelvic pain, infertility, and dyspareunia.[52,66] The ovaries are commonly the site of endometriosis, which can also be found in the pelvic peritoneum, cervix, vagina, vulva, rectosigmoid colon, and appendix.

Less common sites of implantation of endometrial tissue include the umbilicus, scar tissue resulting from surgery, kidneys, lungs, and even arms and legs.[66] Endometriosis is present in up to 47% of patients with infertility. Overall, it is difficult to determine the prevalence of endometriosis, because many patients do not experience symptoms or seek treatment, and formal diagnostic criteria currently require visual identification of endometrial tissue during surgery. In patients who have laparotomies for any reason, endometriosis is identified in 5% to 15%. This increases to 33% in patients with chronic pelvic pain.[67] In contrast to primary dysmenorrhea, endometriosis usually occurs in patients who have been menstruating for some time; with pain occurring anytime throughout the cycle. Endometriosis symptoms are rarely seen in patients near the menarche, after menopause, or in amenorrheic patients. The average age at diagnosis is 28 years, and even, before diagnosis, patients with endometriosis have higher health care costs and utilization, particularly emergency room utilization, than age-matched controls.[66,68]

Diagnostic Criteria

Diagnosis of endometriosis is difficult, with a delay in diagnosis in the range of 8 to 12 years from initial symptom presentation.[69] Endometriosis, interstitial cystitis, irritable bowel syndrome, and pelvic adhesions represent the four most common causes of chronic pelvic pain (defined as pain not associated with the menses, severe in nature, resulting in functional disability, and lasting at least 6 months).[67,69] The delay in diagnosis is the unfortunate consequence of the lack of diagnostic biomarkers and its similarities to other conditions. There are at least two international and five national guidelines for the diagnosis and treatment of endometriosis, and they are inconsistent in many of their recommendations for diagnosis.[70] The physical examination is often normal, although the most common physical finding is a fixed retroverted uterus, with scarring and tenderness. A definitive diagnosis is only possible with visualization of endometriosis on laparoscopy, although this is not considered as absolutely necessary today as it has been in the past.[69] Although no diagnostic criteria currently exist, endometriosis can be staged at the time of laparoscopy according to the Revised American Fertility Society Classification of Endometriosis.[70,71] The stages are classified as minimal (stage I), mild (stage II), moderate (stage III), and severe (stage IV), as determined by an accumulated point total, with points based on the location of the endometrial lesions, the size of the lesions, the presence and extent of the adhesions, and the degree of obliteration of the posterior cul-de-sac. The classification system is designed to document the location and extent of endometriosis and does not predict infertility, aid in treatment selection or outcomes, or predict recurrence of the disease. Making diagnosis and prognosis even more challenging is that reported severity of pelvic pain and level of functional disability are not correlated to the stage of endometriosis.[66,67]

Pathophysiology

Although the first description of endometriosis was made in the 1860s, the precise etiology of endometriosis remains a mystery.

Several theories exist regarding the origins of endometriosis, and the exact etiology is probably a complex interplay between physical and individual patient-specific immunologic factors.[66,67]

The most commonly cited theory is that of retrograde menstruation or the flow of menstrual fluid, endometrial cells, and other debris backward through the uterine (fallopian) tubes, resulting in implantation in the peritoneal cavity. Once endometrial cells reach the peritoneum, stimulated angiogenesis (potentially by estrogen, among other factors) appears to be a determinant of the development and growth of lesions.[66,72] Also at this point, the lesion stimulates an immune response, triggering the activation of macrophages, as well as cytokine and growth factor release. Peritoneal lesions may contribute to more distant disease by spread via hematogenous or lymphatic routes, or even by movement owing to iatrogenic causes, such as cesarean section and other forms of gynecologic surgery. Although the retrograde menstruation theory makes scientific sense, it has been discovered that retrograde menstruation occurs in nearly all patients who are menstruating (90%), and not all patients have endometriosis. This suggests that an additional factor, such as genetic susceptibility or altered immunity, or altered hormone receptor functioning such as progesterone resistance, must be present for the pathogenesis of endometriosis in certain patients.[72]

Another theory for the etiology of endometriosis is the coelomic metaplasia theory. This theory rests on the belief that the coelomic epithelium, the fetal originator tissue for the reproductive tract, retains its ability to differentiate into multiple cell types.[66,67] The trigger for differentiation is thought to be, in part, estrogen or environmental factors. This theory would explain the presence of endometriosis in prepubertal girls, in females born without a uterus, and in the rare cases of endometriosis seen in males. Genetics also plays a role in the development of endometriosis. For first-degree relatives of females with severe endometriosis, there is a six times higher rate of developing endometriosis when compared with females who do not have affected relatives. These patients also have more severe disease and disease that appears earlier in life.[69]

More than 15 different gene and gene-product abnormalities have been documented in patients with endometriosis, although currently no genetic tests or any biomarker tests are predictive or used clinically for the diagnosis of endometriosis.[67,70]

Once endometrial tissue becomes implanted, hormones are necessary for their continued growth. As with intrauterine endometrium, the implants of endometriosis possess estrogen, progesterone, and androgen receptors. The endometrial implants may, however, respond differently to hormonal stimulation than normal endometrium. In general, estrogens stimulate the implants, whereas androgens or lack of estrogen results in implant atrophy. Because of their complex hormonal effects, progestins have variable effects on the implants.[73] In addition, lesions also show high levels of estrogen biosynthesis, owing to abnormally increased aromatase activity, with a concomitant decrease in the inactivation of estrogen, resulting in high intralesional estrogen concentrations.[73] The responsiveness of endometrial implants to ovarian hormones plays a role in the pathology of endometriosis. Withdrawal of estrogen and progesterone causes the endometrial implants to bleed, leading to an inflammatory response in the adjacent tissues. Repetitive cycles of bleeding and inflammation lead to the development of scar tissue and adhesions between adjacent peritoneal tissues. On laparoscopy, these areas of involvement appear as multiple hemorrhagic foci composed of endometrial epithelium, stroma, and glands. Ovarian endometriosis usually involves the formation of endometriomas, blood-filled cysts (“chocolate cysts”) ranging in size from microscopic to 10 cm. Nodules may form on uterosacral ligaments. Fibrosis usually is present with the endometrial implants, and extensive adhesions may form between pelvic structures.

Clinical Characteristics

CASE 50-3

QUESTION 1: N.H. is a 35-year-old female who has been married for 6 years and is currently using COCs pills taken 21 days per month to prevent pregnancy. She and her spouse have been contemplating the timing of a pregnancy but have not yet attempted to become pregnant. She presents to her gynecologist to discuss preconceptual planning and reports that she has been having severe lower abdominal cramps, associated with her menses, occurring on day 1 and lasting until day 4 or 5. This has been occurring for the past 4 years after many years of pain-free cycles when she was using a levonorgestrel intrauterine device for contraception and has recently been increasing in severity. The pain is slightly relieved by ibuprofen 400 mg orally tid, and during the past 6 months, she has had to work from home at least 1 to 2 days per month owing to pain that has been increasing in frequency. On further questioning, she also reports mild-to-moderate pain that occurs randomly in her cycle, associated with low-back pain, constipation with painful defecation, and pain with intercourse. Her menstrual history reveals menarche at age 10 with regular cycles every 26 to 27 days and heavy menses for 6 to 7 days. She reports discussing her symptoms with her mother, who described similar symptoms during her childbearing years.

N.H. is 67 inches (170.18 cm) and weighs 145 pounds (65.77 kg). She does not smoke and does not drink alcohol. She plays recreation league basketball and softball but does not have a regular exercise regimen. She usually eats five servings of fruits or vegetables per day, but does not like to drink milk. She is concerned about her heart because her father had a cardiac stent placed at age 40, and she has been told she has high cholesterol.

Her physical examination is normal, with the exception of tenderness on palpation of the posterior fornix, and a fixed retroverted uterus. A pregnancy test, and tests for gonorrhea and chlamydia, HIV and hepatitis C, are negative, and a Pap smear is within normal limits.

What subjective and objective data in N.H.'s presentation are compatible with a diagnosis of endometriosis?

A patient presenting with endometriosis may have signs and symptoms that are difficult, initially, to distinguish from primary dysmenorrhea (**Table 50-3**).[66,67] N.H.'s symptoms of lower abdominal cramps accompanying her menses are often mistaken for primary dysmenorrhea when other history details are not evaluated in total. Another key detail is emergence of increased symptoms after stopping her IUD and starting a cyclic regimen of combined hormonal contraceptive pills. N.H.'s age and her nulliparity are consistent with the characteristics of patients with endometriosis. Although endometriosis has been diagnosed in patients of all ages, it

most commonly occurs in patients in their late 20s and early 30s who have delayed pregnancy or who have infrequent pregnancies. On average, patients with endometriosis have seen seven physicians for their symptoms prior to being diagnosed with endometriosis.[67]

Table 50-3
Primary Versus Secondary Dysmenorrhea

Characteristic	Primary Dysmenorrhea	Secondary Dysmenorrhea
Onset	Around menarche	Any age (while menstruating)
Timing in menstrual cycle	Worse on day 1, lasts 24–48 hours	Increases in severity, may last days
Change over time	Stable, predictable	Increasing pain with increasing age
Symptoms	Low-back pain, premenstrual syndrome, nausea, bloating	Low-back pain, dyspareunia, diarrhea or constipation, dysuria, infertility
Signs	Normal pelvic examination	Fixed retroverted uterus, tenderness, but may be completely normal

Adapted with permission from Reddish S. Dysmenorrhea. *Aust Fam Physician*. 2006;35(11):842–849.

N.H.'s menstrual pattern of short cycle length with prolonged flow is characteristic of patients with endometriosis. Risk factors for endometriosis are related to exposure to estrogen (ie, early menarche and late menopause) and shorter menstrual cycle length (<28 days) with longer duration of menstrual flow (≥6 days), as well as having a mother or sister with endometriosis, as may be true with N.H.'s mother.[74] Patients who have four or more pregnancies lasting more than 6 months have a 50% lower risk of being diagnosed with endometriosis, and there is a decrease in risk of endometriosis that is parallel to duration of time spent in breast-feeding.[74] Regular physical exercise appears to be protective.[67]

N.H.'s chief problems center on her progressive pelvic pain occurring throughout the cycle, with worsening during menses,

constipation, and pain with intercourse (dyspareunia). Patients who report deep pain during intercourse may have a fixed, retroverted uterus (as N.H. does) or endometriosis located in the posterior fornix of the vagina or along the uterosacral ligaments.[66,69] This pain may persist for several hours after intercourse. Other symptoms such as the constipation and painful defecation N.H. is experiencing are associated with endometriosis and may (but not always) depend on the organs affected by the location of the endometrial tissue (**Table 50-4**).[67] Depression also is a common symptom in patients with endometriosis, particularly those with chronic pelvic pain, and may express as sadness, somatic symptoms, and inability to work or carry on activities of normal living.[69]

Table 50-4

Location of Endometriosis and Associated Symptoms

Sites	Symptoms
Pelvic	
Cervix	Abnormal uterine bleeding
Ovaries	Dysmenorrhea
Peritoneum	Dyspareunia
Rectovaginal septum	Infertility
Uterosacral ligaments	Pelvic pain
Intestinal	
Abdominal scars	Intestinal obstruction
Sigmoid colon	Midabdominal pain
Small intestines	Nausea
	Painful defecation
	Rectal bleeding
Urinary Tract	
Bladder	Cyclic flank pain
Ureter	Hematuria
	Hydronephrosis

Sites	Symptoms
	Hydroureter

Source: American College of Obstetricians and Gynecologists. ACOG practice bulletin no. 114: management of endometriosis. *Obstet Gynecol.* 2010;116:223–236.

Although it is unclear yet whether infertility will be a problem in N.H., endometriosis occurs in up to 47% of patients with infertility.[66] The cause of endometriosis-associated infertility is not clear, but is probably caused by a combination of factors, which may include physical distortion of the pelvic architecture, inflammatory factors (including prostanoids, cytokines, and growth factors that may interfere with normal reproductive processes), impaired folliculogenesis (follicle development), or defects in fertilization or implantation.[66] Treatment for endometriosis, in inducing a "pseudomenopause," results in impaired fertility while the disease is actively being treated.

N.H.'s limited physical findings are not uncommon in patients with endometriosis; physical findings, other than visualization of endometrial tissue during exploratory surgery, may not be present, and outward physical findings may have no correlation with the stage of endometriosis determined with surgery. Many symptoms and physical findings of endometriosis can be associated with other gynecologic conditions or diseases (particularly irritable bowel syndrome), and, if the patient is not responsive to empiric therapy, laparoscopy is indicated to confirm the diagnosis. N.H.'s negative pregnancy, HIV, hepatitis c, chlamydia, and gonorrhea tests, as well as her normal Pap smear, are reassuring. Although many biomarkers have been and are being studied, none have demonstrated sufficient sensitivity and specificity to be clinically useful.[70]

Treatment

Case 50-3, Question 2: N.H.'s pain is uncontrolled after trials of three different NSAIDs (ibuprofen, naproxen, and meloxicam) and she would like relief to improve her functionality at work and home. Given the potential mechanisms behind the pathophysiology of endometriosis, what therapeutic approaches are appropriate for the treatment of endometriosis in N.H.?

Therapy for endometriosis should be individualized and consider N.H.'s desire for future fertility, severity of symptoms, extent of disease, and potential for infertility. This should be done with the knowledge that a high likelihood exists of recurrence and a lack of good prognostic indicators for future severity. The goals of treatment are to relieve symptoms and, if desired, to preserve or improve fertility. Options currently available to treat endometriosis include definitive and conservative surgery, hormonal therapy with estrogen–progestin combinations used continuously or progestins, including IUDs alone, danazol, aromatase inhibitors, GnRH agonists, GnRH antagonists, and expectant management. Pharmacologic treatment of endometriosis is based on manipulation of this hormonal response: danazol, GnRH agonists, GnRH antagonists, progestins, aromatase inhibitors, and estrogen–progestin combination all result in endometrial tissue atrophy. No treatment has been shown to provide 100% protection against recurrence when discontinued; even surgical removal of the uterus and ovaries is associated with recurrence rates of up to 10%.[66] Two international and five national guidelines for treatment are available, and they are generally limited by the poor quality and limited depth of evidence for most treatments; and there are significant differences in the recommendations in the various guidelines, with little homogeneity.[70,75]

PAIN MANAGEMENT: PHARMACOLOGIC THERAPY

Nonsteroidal anti-inflammatory drugs

NSAIDs, particularly those available as OTC products, are often the first medications that patients try for relief of pain from endometriosis, often before they are officially diagnosed. NSAIDs

may provide some relief of mild symptoms, particularly in patients with endometriosis who have pain associated with the menses (see Dysmenorrhea section) and are an appropriate first choice for patients with mild symptoms who do not desire contraception. They should not be the only therapy offered to patients with confirmed endometriosis, as evidence supporting their benefit for endometriosis pain is limited.[76] Clinicians should be aware of and consider the potential for endometriosis in patients with noncyclic pain, including pain that does not respond to an appropriate trial of an NSAID. N.H. has tried three different NSAIDs with limited relief; a higher dose or trial of another NSAID is not an appropriate strategy at this time. Additional treatment should be considered.

Combined hormonal contraceptives

For patients who do not receive pain relief from a trial of an NSAID, a reasonable next step for those patients desiring contraception is the use of combined hormonal contraceptives (pill, patch, ring). They may be used alone or in combination with NSAIDs. Combined contraceptives improve symptoms of endometriosis by inhibiting ovulation, decreasing hormone levels, reducing menstrual flow, potentially to the point of amenorrhea. These mechanisms contribute to atrophy of endometrial implants. When used, the most appropriate regimen is continuous dosing, so that there is not a “placebo week” that allows for growth of endometrial implants.[77] A Cochrane review found that the pain reduction seen with OCs (≤35 μg of ethinylestradiol) is similar to a GnRH analog (goserelin).[76] After surgery, continuous regimens appear to provide better pain symptom control than cyclic regimens.[78]

Progestins

Similar to OCs, injectable, oral, implantable, and IUD progestins reduce symptoms of endometriosis by inhibiting ovulation, reducing hormone levels, and inducing endometrial atrophy. They may be particularly useful if estrogen use is contraindicated. Regimens used include oral medroxyprogesterone, depot medroxyprogesterone (see

Case 50-3, Question 4), etonogestrel implants, or levonorgestrel IUDs. Several studies have evaluated the use of the levonorgestrel IUDs as a means of providing consistent progestin dosing. Levonorgestrel IUDs have the advantage of providing longer-term contraception than other available progestin-only contraceptives. A meta-analysis evaluated the efficacy of levonorgestrel IUD 52 mg as postoperative maintenance therapy for endometriosis, compared to danazol, GnRH agonists, and OCs, and found pain relief comparable to GnRH agonists, and decreased recurrence similar to OCs and danazol, with improved patient satisfaction compared to OCs.[79] A 3-year direct comparison of the levonorgestrel IUS versus depot medroxyprogesterone was conducted in patients with moderate-to-severe endometriosis for medical control of symptoms after conservative surgery.[80] Although symptoms were improved with both regimens, more IUS patients remained adherent to the regimen, and at 3 years, bone density was increased in the IUS group and decreased in the depot group.

Gonadotropin-releasing hormone agonists

GnRH agonists induce a pseudomenopausal state, resulting in the relief of endometriosis symptoms. Because the GnRH agonists have a longer half-life than endogenous GnRH, their binding to GnRH receptors in the pituitary results in downregulation of the hypothalamic–pituitary–ovarian axis, decreasing release of FSH and LH, leading to low estrogen levels and amenorrhea.[73] GnRH agonists are available in a variety of dosage forms, outlined in **Table 50-5**. When compared in clinical trials, GnRH agonists have efficacy that is similar to OCs, progestins, and danazol, but their increased cost and adverse effect profile (including menopausal-type symptoms and decreased bone density) make them second-line agents, after OCs and progestins.[81,82] In addition, because they initially cause an increase in release of FSH and LH, they can provoke an initial worsening of symptoms, followed by improvement of symptoms as the GnRH receptors become desensitized, resulting in complete suppression of estradiol.

Table 50-5

Gonadotropin-Releasing Hormone Agonists and Antagonist

GnRH Analog (Brand Name)	Strength	Dosage Form	Dosage Regimen
Nafarelin (Synarel®) (agonist)	2 mg/mL delivers 200 µg/spray	Intranasal	200–800 µg bid
Leuprolide (Lupron®) (agonist)	3.75 mg, 11.25 mg	IM depot	3.75 mg/month or 11.25 mg every 3 months
Goserelin (Zoladex®) (agonist)	3.6 mg, 10.8 mg	SC implant	3.6 mg implant every month or 10 8 mg implant every 3 months
Elagolix (Orilissa®) (antagonist)	150 mg, 200 mg	Oral tablet	150 mg once daily for up to 24 months 200 mg twice daily for up to 6 months

Bid, twice daily; GnRH, gonadotropin-releasing hormone; IM, intramuscular; SC, subcutaneous.

Gonadotropin-releasing hormone antagonists

GnRH antagonists (eg, elagolix) work similarly to GnRH agonists with a few key differences. The antagonists immediately block and result in complete suppression of the GnRH receptor, which is rapid and dose dependent. This means that they do not result in an initial exacerbation of symptoms as can be seen with the GnRH agonists. Because the blockade of GnRH receptors is dose dependent, there is a hope this may balance efficacy directed at endometriosis pain reduction, while trying to reduce the menopausal-like adverse effects of blocking GnRH receptors.[82] In placebo-controlled clinical trials, higher doses are more effective at reducing endometriosis pain and are associated with adverse effects similar to GnRH agonists, requiring add-back therapy to minimize menopausal-like adverse effects.[81]

Aromatase inhibitors

Aromatase, the enzyme responsible for the synthesis of estrogens, is required for the conversion of androstenedione and testosterone to estrone and estradiol.[83] Although aromatase inhibitor (AI), OCs, progestins, and GnRH agonists/antagonists all decrease serum levels of estrogen, only AIs decrease secretion and production of estrogen by endometrial tissue itself. Anastrozole and letrozole are type II AIs, binding reversibly to the enzyme to produce a beneficial effect on endometriosis symptoms.[83] Although AIs effectively

decrease estrogen conversion in the periphery, addition of an agent to reduce ovarian estrogen levels is also necessary in premenopausal patients; hence, most of the studies in this population have included double therapy with AIs and OCs or GnRH agonist.[83]

Further research is needed to determine the role of AIs in the treatment of endometriosis, because currently they do not have an FDA indication for the treatment of endometriosis. Their use should be reserved at this time for those patients with severe endometriosis who have failed other therapies.[83]

Danazol

Danazol, an androgenic drug derived from 17-ethinyl testosterone, also induces a pseudomenopausal state by increasing androgen levels and decreasing estrogen levels. It inhibits the enzymes involved in ovarian steroidogenesis and increases the metabolic clearance of estradiol. By creating a hypoestrogenic, hypoprogestogenic state, danazol causes anovulation, amenorrhea, and atrophy of endometrial implants. Although effective at decreasing pelvic pain, danazol is poorly tolerated because of its significant side effects, which include weight gain, voice changes, edema, acne, hot flashes, vaginal dryness, hirsutism, liver disease, and increased cholesterol; these occur in up to 85% of patients who are treated.[66] Because of safety concerns, use should be limited to 6 months at a time and should only be initiated in patients after all other therapy options have failed.

PAIN MANAGEMENT: NONPHARMACOLOGIC THERAPY

Definitive surgery

Definitive surgery, referring to total abdominal hysterectomy, bilateral salpingo-oophorectomy, and removal of all visible endometriosis, theoretically should eliminate the risk of recurrence of the disease. These procedures are not an option for the many patients with endometriosis who desire pregnancy in the future. They are invasive surgeries, reserved for those patients whose pain is unresponsive to

other therapies or to conservative surgery. Furthermore, removal of all endometriosis is difficult, and recurring pain is not uncommon. Sinaii et al surveyed patients with endometriosis regarding treatments and benefits, and found that, of the 1160 patients surveyed, 12% had had definitive surgery, with 40% reporting the surgery was successful, 33% reporting partial benefit, 5.6% reporting no benefit, and 6% of patients reported increased pain and symptoms after surgery.[84]

Conservative surgery

In contrast to definitive surgery, conservative surgery (involving ablation and removal of implants, and lysis of adhesions) preserves fertility and is commonly conducted during the initial diagnostic laparoscopy. In the Sinaii et al survey, 70% of patients had undergone laparoscopy with removal of lesions, with 30% considering the procedure a success, 50% reporting partial benefit, 15% with no difference in symptoms, and 10% reporting increased symptoms.[84] On average, patients reported having three surgical procedures.[84] Drug treatment is used after conservative surgery, as it is not possible to remove all lesions, many of which are difficult to visualize.

Clinical trials in endometriosis have not singled out one treatment as the treatment of choice for all patients, with most investigations demonstrating equivalence of the studied therapies. An NSAID and combined hormonal contraception (eg, N.H.'s contraceptive vaginal ring) are the drugs of choice for initial management, owing to their safety profile, and, in this case, the contraceptive agent's dual utility in preventing conception. As a next step, progestins, GnRH agonists/antagonists, and AIs are options. Because of adverse effects and poor tolerability, danazol should be reserved as an agent of last choice. If N.H. were uninterested in having children in the future, surgical sterilization would be an option. Conservative surgery, including removal of endometriomas and adhesions and ablation of visible lesions is not curative, but a combination of conservative surgery, followed by postoperative drug therapy

directed at endometriosis, has been shown to prolong the duration of pain relief and decrease recurrence after surgery.[85]

Case 50-3, Question 3: N.H. has not had a problem in the past tolerating a variety of contraceptive products but does have some problems with daily medication adherence and would like to avoid giving herself injections if possible. How does this information assist in the selection of therapy for her endometriosis?

N.H. is a smoker, with poor calcium intake and some cardiovascular risk factors (family history, high cholesterol), who would rather avoid self-injectable medication and has trouble with daily medication taking. Danazol, with its ability to increase cardiovascular risk factors and extensive side effects, is not a good option. Although some GnRH analogs are available as nasal sprays or injectable implants, the significant risk of decreased bone density and menopause-like adverse effects place them as a second-line option. Progestins, particularly the long-acting progestins, either in the form of the medroxyprogesterone acetate 3-month depot or subcutaneous injection or the levonorgestrel IUS make these appropriate first-line options for N.H., although the risk of diminished bone density with depot formulations remains an issue. An alternative option that would not provide contraceptive benefits would be the GnRH antagonists (elagolix) as they are available as oral tablets. More significant adverse effects with this medication class would point to the use of the progestins initially, reserving the GnRH antagonists until additional therapy is needed.

Case 50-3, Question 4: N.H. would like to start the levonorgestrel IUS, but her insurance company will not pay for it to be used in the treatment of endometriosis because of its lack of FDA indication. She decides to start depot medroxyprogesterone acetate (DMPA). What information can you provide her regarding use and the benefits and risks of treatment?

DMPA is available in two dosage forms: 150 mg to be given intramuscularly (IM) every 3 months and a 104-mg formulation given

subcutaneously (SC) every 3 months. Product choice may be based on insurance coverage or the potential for the patient to self-administer (the SC product is more patient-friendly). Because N.H. does not want to self-inject, either choice, administered by her provider's office, or a pharmacist if law allows, would be an appropriate option. Although the DMPA does provide the contraception N.H. desires, she should be informed that it may take longer than usual (up to 1 year) to become pregnant after discontinuation. More than 80% of patients treated with progestins will experience partial or complete pain relief.[73] Although devoid of the menopause-like adverse effects of other medications used to treat endometriosis, DMPA is associated with weight gain (which may be significant in some patients), bloating, and irregular periods or bleeding for several months, with most users eventually experiencing amenorrhea. To reduce bone density loss, which is significant but less than with GnRH agonists, N.H. should be advised to ensure her daily intake by diet or supplementation of calcium is at least 1000 mg/day, and at least 400 to 600 international units of vitamin D per day, receive smoking cessation counseling and pharmacotherapy as appropriate, and start a regular weight-bearing exercise regimen. She should be monitored for pain relief, weight gain, amenorrhea or bleeding changes, and adherence to the quarterly injections. If N.H. desires conception, significant planning is required, and she may require a different therapy for her endometriosis as she regains fertility.

GONADOTROPIN-RELEASING HORMONE AGONISTS/ANTAGONISTS AND ADD-BACK THERAPY

CASE 50-4

Question 1: M.F., a 24-year-old single female with a history of moderate-to-severe endometriosis, has been treated with some benefit with NSAIDs (three different NSAIDs at appropriate doses), COCs, and the levonorgestrel IUS. She has no desire for conception and is looking for pain relief. She has also had two conservative laparoscopic surgical procedures, each of which was successful, with pain relief lasting 6 months to 1 year. She recently had her "last ever" (by

her description) surgical procedure and is looking to extend the improvement she has seen previously after surgery. She does not mind injections but has had trouble with adherence in the past.

What options are available for the treatment of M.F.'s pain?

M.F. has tried numerous pharmacologic and surgical treatments (NSAIDs, combined oral contraception, and progestin-only contraception) for endometriosis with limited benefit. Given that she does not desire pregnancy at this time, GnRH analogs, GnRH antagonists, aromatase inhibitors, and danazol are other options. Leuprolide, nafarelin, and goserelin are GnRH analogs (agonists) typically used for the treatment of endometriosis (see Table 50-5). Although GnRH analogs have not been shown to produce better results than the therapies M.F. has already used, they may provide her with pain relief as they represent a different mechanism of action. Choice of GnRH agonist is driven by patient choice of administration method (nasal twice daily [bid] with nafarelin, monthly SC implant with goserelin, or IM injection either once monthly or once every 3 months with leuprolide). In M.F.'s case, the once every 3 months dosing with leuprolide would be most desirable for her, eliminating the need for daily administration. Efficacy is similar for all the GnRH agonists. Before use of these agents, pregnancy, undiagnosed vaginal bleeding, and breast-feeding should be ruled out. Because M.F. does not desire conception, and use of the GnRH agonists is contraindicated in pregnancy, she should be counseled regarding choices of nonhormonal contraceptive agents.

Usual therapy duration is 6 months, although a small pilot study suggested long-term treatment (up to 10 years) with estrogen add-back therapy is without major adverse effects, with continued efficacy.[86] Add-back therapy is based on the concept of an estrogen threshold hypothesis, formulated by Barbieri,[87] which states that there is a critical amount of estrogen that exacerbates endometriosis and below that level the presence of estrogen serves to decrease adverse effects but does not have an adverse effect on the disease itself.[87] Add-back therapy should be initiated at the beginning of

GnRH agonist therapy to try to reduce the occurrence of all hypoestrogenic adverse effects.[86]

Estrogen-containing OCs contain a dose of estrogen that is above the threshold, and they should not be used for add-back therapy. Doses of estrogen equivalent to 0.625 mg of conjugated equine estrogen have been studied in combination with either medroxyprogesterone 2.5 mg daily or norethindrone 5 mg daily. No studies have demonstrated superior efficacy or safety of one regimen over another. Patients using add-back therapy should consume in diet or supplements a total of 1000 mg of calcium daily and have vitamin D levels in the normal range.

Therapy beyond 3 to 6 months requires the use of add-back therapy to reduce the risk of hypoestrogenic complications. Monitoring for efficacy includes monitoring for amenorrhea, decreases in pain and dyspareunia, and quality of life. After discontinuation of GnRH agonists, menses and ovarian function return to normal in 6 to 12 weeks, although benefits may be maintained for another 6 to 12 months.[67]

GnRH antagonists represent a newer option with a similar yet distinct mechanism of action compared to GnRH agonists for the second-line treatment of endometriosis pain in patients who are not desiring conception. Elagolix is an oral GnRH antagonist approved for treatment of endometriosis-related pain. Although lower doses may reduce adverse effects because of a dose-dependent effect on estrogen suppression, higher doses that more completely suppress estrogen may be needed for symptom control and may also require add-back therapy as with GnRH agonists to reduce adverse effects including detrimental effects on bone.

Adverse effects

Adverse effects should be discussed in detail with M.F. because they differ significantly from the other therapies she has tried. Adverse effects are related to the induction of the pseudomenopausal state. Nearly all patients experience hot flashes; vaginal dryness and insomnia also are common. GnRH agonists/antagonists do not affect

SHBG or testosterone levels, so the androgenic side effects of danazol, including changes in lipid profiles, are not experienced with these agents.[66] Significant bone loss can occur with GnRH agonists and high doses of GnRH antagonists, necessitating adequate calcium and vitamin D intake, and estrogen add-back therapy to decrease loss.

A reduction in bone density is a significant concern with GnRH agonists, even at 3 months after the onset of therapy, and is particularly concerning because these agents are being used in young patients, many of whom have not reached their peak bone mass.

Monitoring for decreases in bone density should be accomplished via dual-energy x-ray absorptiometry scan every 24 months if GnRH therapy is continued. M.F. should also be counseled regarding adequate calcium and vitamin D intake, smoking cessation, and a regimen of weight-bearing exercise.

Based on insurance coverage and patient preference, M.F. should initiate a GnRH agonist or antagonist therapy, with add back if GnRH agonist therapy is used. A 6-month trial followed by an evaluation of symptom control is reasonable. If a GnRH antagonist is used and a higher dose is required, the patient should be evaluated for the need for add-back therapy.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual disorders affect up to 12% of patients.[88] The premenstrual syndrome (PMS) and the more severe variant premenstrual dysphoric disorder (PMDD) are characterized by the presence of behavioral and/or physical symptoms that interfere with a female's life and occur repetitively in the second half of the menstrual cycle and typically resolve within the first few days of menses. More than 200 premenstrual symptoms have been

described, including positive symptoms such as increased energy, libido, and ability to relax, as well as negative symptoms such as abdominal distension, fatigue, headaches, and crying spells. It is not until the symptoms have a decidedly negative influence on the physical, psychological, or social function of a female that PMS or PMDD occurs.

The symptoms of PMS and PMDD experienced by patients can vary widely. The most common affective or behavioral symptom of PMS is mood swings. Other frequent nonphysical behavioral symptoms include irritability, anxiety/tension, sad or depressed mood, increased appetite/food cravings, sensitivity to rejection, and diminished interest in activities.[89] The most common physical manifestations of PMS are abdominal bloating and an extreme sense of fatigue. Other common symptoms include breast tenderness, headaches, hot flashes, and dizziness.[89]

Diagnosis

No specific physical findings or laboratory tests can be used to make a diagnosis of PMS. Several different organizations have attempted to provide diagnostic criteria for PMS and PMDD; their criteria are inconsistent and disparate. The International Society for Premenstrual Disorders (ISPMD) published a consensus statement in 2011 that defined core premenstrual disorders as typical, pure or reference disorders associated with spontaneous ovulatory menstrual cycles, and variant premenstrual disorders that are separate from core premenstrual disorders and exist where more complex features are present (eg, symptoms result from underlying disorder or exogenous progesterone administration).[90] Core premenstrual features (somatic and psychological symptoms) must occur during all or part of the 2-week premenstrual phase and resolve during or shorting after menstruation. A symptom-free interval between the end of menstruation and the time of ovulation must occur. This cyclic pattern must also occur in most (typically two out of three) menstrual cycles. Lastly, the severity of symptoms must

(a) affect normal daily functioning; (b) interfere with work, school performance, or interpersonal relationships; or (c) cause significant distress. Core premenstrual disorders is an umbrella term for PMS and PMDD.

The American Psychiatric Association has developed criteria for PMDD.[91] The criteria for PMDD focus on the mood and mental health symptoms, leading to a higher level of dysfunction compared with PMS. These criteria require prospective documentation of physical and behavioral symptoms (using diaries) being present for most of the preceding year; five or more symptoms present during the week prior to menses, resolving within a few days after menses starts; and PMDD may be superimposed on other psychiatric disorders, provided it is not merely an exacerbation of those disorders. One or more of the following symptoms must be present: mood swings, sudden sadness, or increased sensitivity to rejection; anger, irritability; sense of hopelessness, depressed mood, or self-critical thoughts; and tension, anxiety, or feeling on edge. Additionally, one or more of the following symptoms must be present to reach a total of five symptoms overall: difficulty concentrating; change in appetite, food cravings, or overeating; diminished interest in usual activities; easy fatigability or decreased energy; feeling overwhelmed or out of control; breast tenderness, bloating, weight gain, or joint/muscles aches; and sleeping too much or not sleeping enough. Symptoms must have been present in most menstrual cycles that occurred the previous year, and the symptoms must be associated with significant distress or interference with usual activities (eg, work, school, social life).

Although criteria for PMS and PMDD are different, they share three essential characteristics: (a) symptoms must occur in the luteal phase and resolve within a few days of menstruation, (b) symptoms are documented for at least two menstrual cycles and are not better explained by other physical or psychological conditions, and (c) symptoms are sufficiently severe to disrupt normal activities. Auditable standards for diagnosis and treatment of premenstrual disorders have been created to prioritize recommendations in clinical care.[92]

The role of genetic factors in the predisposition to PMS and PMDD is an area of active exploration. Some studies suggest that patients with mothers reporting PMS are more likely to develop PMS than those with unaffected mothers (70% vs 37%, respectively).[93,94] One article found that traumatic events, such as physical threat, childhood sexual abuse, and severe accidents, increased the risk of developing PMDD.[95]

Pathophysiology

The wide range of symptoms exhibited in patients with PMS or PMDD can be explained by multiple possible mechanisms, probably a result of interactions between sex steroids and central neurotransmitters.[96] Alterations in neurotransmitters, primarily reductions in serotonin and decreases in central γ-aminobutyric acid (GABA) mediated inhibition, triggered by normal hormonal fluctuations of the menstrual cycle appear to be the most probable factors for the development of PMS or PMDD. These potential mechanisms provide a rational basis for the symptoms that appear in PMS and PMDD, but also support the therapeutic benefits of treatments that increase serotonin or GABA levels. Patients with PMS typically have normal concentrations of serum estrogen and progesterone, but they may have an abnormal response to normal hormonal changes. Many treatments have limited and variable efficacy, which reinforces the argument that PMS or PMDD is a result of multiple factors.

CASE 50-5

Question 1: M.P., a 30-year-old female, presents with significant mood changes that occur the week before her menstrual cycle. She experiences increased irritability and anxiety as well as breast tenderness and abdominal bloating. These symptoms usually subside the first or second day after her menses begin. For 2 to 3 weeks after her menstrual period, M.P. is her “normal, usual self” until the symptoms begin again just before her next menstruation. She has had these symptoms every month for the past several years. She states that she is very uncomfortable when these symptoms occur. Although

she is able to work most of the time, she typically avoids going out with her friends when she has these symptoms. Her menstrual cycles are regular, occurring every 28 to 30 days with a light flow lasting 3 to 4 days.

Pelvic, cardiovascular, and neurologic examinations are normal, and all laboratory assessments are within normal limits. Her serum pregnancy test was negative, and she is not sexually active. She has no significant past medical history, and she does not take any medications.

What symptoms does M.P. have that are consistent with a diagnosis of PMS?

M.P. has affective symptoms that include irritability and anxiety, and somatic symptoms include breast tenderness and abdominal bloating. These symptoms occur during the luteal phase of the menstrual cycle, resolve within 4 days of menses, and do not recur until after day 12 of her cycle. M.P.'s symptoms appear to be affecting her social activities. She states that these symptoms have been present for years and that they occur every month, although she has not prospectively recorded this information. M.P. does not meet the criteria for PMDD because her symptoms are not severe or markedly impairing her ability to participate in daily activities.

Treatment: Premenstrual Syndrome

Case 50-5, Question 2: M.P. asks about nonprescription therapy. Which agents, if any, are appropriate for M.P.?

The management of premenstrual disorders has been outlined by the ISPMD.[92,97] Treatment may be aimed at symptoms, especially if one particular symptom is dominant. Mind–body approaches may be helpful for mild symptoms. Vitamins and minerals that have been studied but have demonstrated minimal benefit include calcium, magnesium, and pyridoxine. The use of vitamin B_6, high doses of calcium supplements, or other vitamins are not recommended in any guidelines given the low-quality evidence and the potential for harm. Chaste tree or chasteberry may be helpful for PMS, but its role in PMDD is unclear. Acetaminophen and NSAIDs may be beneficial for the physical symptoms of PMS, but diuretics found in various OTC

products (eg, ammonium chloride, caffeine, pamabrom) have limited data and unproven efficacy. Given the high placebo response rate in PMS, only agents with clinically proven efficacy should be used.

MIND–BODY APPROACHES

Evidence regarding mind–body approaches for PMS is somewhat limited. Because these modalities are risk-free and are generally accepted as components of a healthy lifestyle, they are favored in the treatment of PMS. Mind–body approaches that have demonstrated benefit in PMS include relaxation response, cognitive-behavioral therapy, yoga, aerobic exercise, and light therapy. Exercise may be especially helpful for physical symptoms.[98]

CHASTE TREE OR CHASTEBERRY

Chasteberry (Vitex agnus-castus or VAC) is the fruit of the chaste tree, a small shrublike tree native to Central Asia and the Mediterranean region. Liquid or solid extracts from the dried ripe chasteberry are used to make chasteberry capsules and tablets. The mechanism of action of chasteberry relative to PMS is unclear, but several trials have reported its beneficial effects. A systematic review found chasteberry to be more effective than placebo and well-tolerated.[99] A randomized, double-blind, placebo-controlled trial of 170 patients taking chasteberry extract 20 mg daily for three menstrual cycles showed a treatment response rate of 52% compared with 24% for placebo ($P < .001$).[100] Individual symptoms of irritability, mood alteration, anger, headache, and breast fullness were reduced. Bloating was not significantly altered compared with placebo. The incidence of side effects was low, but long-term safety is unknown. A prospective, randomized, placebo-controlled study in 67 Chinese patients showed that one VAC tablet daily containing 40 mg of herbal drug produced an 85% efficacy rate compared with a 56% efficacy rate for placebo on symptom scores after three treatment cycles.[101] Studies comparing chasteberry with fluoxetine in PMDD have conflicting results and do not support its use in PMDD.[99] In general, data indicate that chasteberry 20 to 40 mg may be

effective for PMS, but should probably not be used as routine treatment for either PMS or PMDD.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND DIURETICS

NSAIDs have been used to relieve the physical symptoms (eg, headache, joint pain) of PMS, but do not improve the mood symptoms. Regimens have included taking naproxen or mefenamic acid during the luteal phase and stopping therapy after menses begin. Diuretics commonly found in OTC products, such as ammonium chloride, caffeine, and pamabrom, are not effective.

Although several OTC options are available to M.P. and trials including chasteberry have shown some positive findings, the evidence is not compelling because of methodologic limitations and lack of substantial efficacy. Mind–body approaches, such as yoga and relaxation, are part of a healthy lifestyle and could be recommended to M.P. because M.P. is having mood symptoms (ie, anxiety); NSAIDs would not be an effective recommendation.

CASE 50-5, QUESTION 3: M.P. has been eating well and exercising four to five times per week, including two sessions of yoga. She also has been taking naproxen sodium 220 mg orally bid without significant reduction of her symptoms. Her physician requests that she keep a daily dairy for two consecutive cycles to document her symptoms. What information should be included in this tool?

M.P. should keep a daily diary for two consecutive menstrual cycles to demonstrate a temporal relationship between her symptoms during the luteal phase and to document the severity of these symptoms (**Table 50-6**). In addition, she should indicate the presence of menstrual flow, weight, and daily basal body temperature readings to help determine when ovulation occurs. The diary establishes a baseline for each patient and documents the most troublesome symptoms. Once therapy is selected for these symptoms, the diary can aid in assessing patient response.

Table 50-6
Menstrual Cycle Daily Diary Chart

Month 1

Grading Severity of Symptoms:
1 = Mild; general awareness of discomfort but does not interfere with daily activities
2 = Moderate; interferes with activities but not disabling
3 = Severe; symptoms disabling, unable to meet daily social, family, or work obligations
* = Menstrual bleeding
Blank = no symptoms

Each Day
1. List the major symptoms (mood, physical, emotional, behavioral) that you experience during your menstrual cycle
2. Grade the severity of the symptom if present (1–3)
3. Record daily weight
4. Record basal body temperature, which helps determine ovulation date
5. Check the days of the cycle when menstrual flow occurs

Day of month	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31

Treatment: Premenstrual Dysphoric Disorder

Case 50-5, Question 4: M.P. returns to clinic with the diary presented in Table 50-6. The physician determines that M.P. has PMDD. What evidence supports this diagnosis and what should be recommended to M.P. for treatment?

M.P. meets the criteria for PMDD as evidenced by her symptoms during the one week before her menstrual cycle (luteal phase). Specifically, she has at least five symptoms required for the

diagnosis of PMDD: sadness or depression (core symptom), fatigue, irritability, inability to concentrate, breast tenderness, and bloating. She rated several of those symptoms as severe, which indicates the symptoms are disabling and she is unable to meet her daily obligations. There is no reason to suspect any other disorder based on her history. PMDD seems to be the most likely diagnosis for M.P.

Therapy options at this time include lifestyle modifications, psychosocial interventions such as cognitive-behavioral therapy, and pharmacologic therapy. Psychotropic drugs targeted to her most severe symptoms may include selective serotonin reuptake inhibitors (SSRIs), serotonergic tricyclic antidepressants, and anxiolytics. OCs have also been approved for PMDD and could be considered.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Serotonin is critical in the pathogenesis of PMDD, and for that reason, SSRIs have become the treatment of choice for PMDD and severe PMS (**Table 50-7**).[92] SSRIs have demonstrated efficacy in reducing irritability, depressed mood, dysphoria, psychosocial function, and the physical symptoms of PMDD, including bloating, breast tenderness, and appetite changes. Fluoxetine, sertraline, and paroxetine controlled release each have an approved indication for PMDD.

Table 50-7

Selective Serotonin Reuptake Inhibitors for the Management of Premenstrual Syndrome or Premenstrual Dysphoric Disorder

Drug (Brand Name)	Daily Dosing Regimen (mg)	Intermittent Dosing Regimen (mg)[a]
Citalopram (Celexa)	5–30	10–30
Escitalopram (Lexapro)	10–20	10–20
Fluoxetine (Prozac or Sarafem[b])	20–60	20 or 90 weekly
Paroxetine controlled release (Paxil CR)[b]	12.5–25	12.5–25

Drug (Brand Name)	Daily Dosing Regimen (mg)	Intermittent Dosing Regimen (mg)[a]
Sertraline (Zoloft)[b]	50–150	100

[a]Day 14 until the onset of menses.

[b]Medication has FDA-approved indication for premenstrual dysphoric disorder.

The onset of SSRI effect in patients with PMDD or severe PMS is much more rapid than when these agents are used for treatment of major depression or anxiety disorders. Patients may experience symptom relief or resolution within the first days of treatment versus 4 to 8 weeks for other psychological disorders. Several different dosing strategies have been employed, including continuous dosing (once daily), intermittent dosing (last 2 weeks of menstrual cycle or luteal phase), and semi-intermittent dosing (continuous administration throughout the cycle with increased doses during luteal phase).[102] Continuous dosing would be reasonable for patients with concurrent mood or anxiety disorders or those who may have difficulty remembering the timing of the intermittent dosing. Intermittent dosing should be considered for patients with regular menstrual cycles who are able to adhere to the regimen, an absence of symptoms during the follicular phase, concerns about long-term effects (eg, sexual dysfunction) or cost of daily therapy, and few side effects at treatment initiation. Studies evaluating these dosing strategies have reported equal efficacy for continuous or intermittent strategies; treatment should be individualized based on patient history, willingness to adhere to therapy, and drug response. A beneficial effect can be expected with the first SSRI use. If the response is suboptimal, the dose can be increased in the next cycle. The most common side effects of SSRIs include nausea, headache, insomnia, and decreased libido.

In a systematic review of 31 randomized controlled trials including fluoxetine, paroxetine, sertraline, escitalopram, and citalopram, SSRIs reduced overall self-rated symptoms significantly more effectively than placebo (end scores for moderate-dose SSRIs: SMD −0.65, 95% CI −0.46 to −0.84, nine studies, 1276 patients).[102]

Withdrawals because of adverse effects were significantly more likely in the SSRI group (moderate dose: OR 2.55, 95% CI 1.84–3.53, 15 studies, 2447 patients) with side effects being dose dependent and most commonly reported as nausea (NNH = 7), asthenia or decreased energy (NNH = 9), somnolence (NNH = 13), fatigue (NNH = 14), decreased libido (NNH = 14), and sweating (NNH = 14). Overall quality of the evidence was considered to be low-to-moderate with poor reporting of methods as the prominent weakness, but it was concluded that SSRIs are effective in reducing PMS symptoms whether taken in the luteal phase only or continuously.

COMBINATION ORAL CONTRACEPTIVES

A treatment approach with COCs allows for suppression of the hypothalamic–pituitary–ovarian axis to minimize cyclic changes in gonadal steroids and may be preferred over SSRIs if/when contraception is a high priority.[92] Two low-dose COC formulations containing 20 µg ethinylestradiol and 3 mg drospirenone (an antimineralocorticoid spironolactone analog) with a 4-day hormone-free interval have been approved for the treatment of emotional and physical symptoms of PMDD. Studies using this agent have shown efficacy for reduced mood, physical, and behavioral symptoms of PMDD, including a 48% improved response with this agent compared with a 36% response using placebo (P = .015).[103] Side effects occurring in at least 10% of patients treated with this medication included intermenstrual bleeding, headache, nausea, breast pain, and upper respiratory infection. Another COC approved for PMDD contains 20 µg of ethinylestradiol, 3 mg of drospirenone, and 0.451 mg of levomefolate calcium. In a systematic review of five randomized controlled trials comparing COCs containing drospirenone to placebo or other COCs for effect on premenstrual symptoms, the authors concluded that drospirenone 3 mg plus ethinylestradiol 20 µg may help treat PMDD better than placebo.[104] They were unable to determine if this combination would help patients with less severe symptoms or would be more effective than

other COCs. For patients desiring contraception, these particular agents have only been evaluated for efficacy in PMDD when used for up to three cycles and may be best for mild-to-moderate symptoms because COCs could worsen PMS/PMDD symptoms in some cases.[92]

GONADOTROPIN-RELEASING HORMONE AGONISTS

Treatment with GnRH agonists has been used for the physical and psychological symptoms of PMS. Their use may be considered when PMS symptoms are severe or life threatening and not responsive to SSRI therapy.[92] These agents are not typically used for long periods of time, however, because of vasomotor symptoms and the potential for negative long-term effects on bone. They also have to be administered by injection or nasal spray which may affect adherence. This treatment is reserved for patients with very severe PMDD who do not respond to other treatments.

M.P. has PMDD and does not need contraception. Mood symptoms predominate and are impairing her functionality. An SSRI should be started in either a continuous or intermittent manner. M.P. appears to be a good candidate for intermittent therapy because she can adhere to the regimen and does not have a concurrent depression or anxiety disorder. An appropriate initial treatment regimen is fluoxetine 20 mg orally daily for the last 2 weeks of the menstrual cycle. Her response rate should be assessed after two to three cycles of treatment.

The Transition Through Menopause

Louise Parent-Stevens and Trisha LaPointe

CORE PRINCIPLES		CHAPTER CASES
1	Menopause, the natural progression of reproductive aging in females, is characterized by declining ovarian function and decreased synthesis of sex hormones.	**Case 51-1 (Question 1), Figure 51-1**
2	Management of females who experience distressing symptoms associated with menopause, including hot flushes and genitourinary atrophy, is targeted at relieving symptoms while minimizing risks.	**Case 51-1 (Questions 1–6)** **Case 51-2 (Questions 1, 2), Figure 51-2**
3	Estrogen therapy (ET), the most effective treatment for menopausal symptoms, is associated with significant	**Case 51-1 (Questions 3, 5), Table 51-1**

	risks, including thromboembolic disease (TED) and breast and endometrial cancer. Progestogens are added to systemic estrogen therapy (EPT) to provide endometrial protection in patients with an intact uterus. Females must be adequately counseled so that they can make educated decisions about treatment.	
4	Selection of appropriate hormone therapy (HT) regimens (ET or EPT), including route, dose, and duration, is necessary to optimize outcomes. Based on current knowledge, systemic HT use should be limited to the management of menopausal symptoms.	**Case 51-1 (Questions 4, 5), Table 51-2, 51-3**
5	Risk for cardiovascular disease (CVD) is not increased when HT is initiated within 10 years of menopause and before age 60 years but is increased if started after this age and time frame.	**Case 51-1 (Question 3)**
6	Nonhormonal drugs, including serotonergic antidepressants and gabapentinoids, are alternatives in females who are unable or unwilling to take HT. Although commonly used, efficacy and safety data on herbal medicines for menopausal symptoms are limited.	**Case 51-1 (Questions 2, 6)** **Case 51-2 (Question 2), Table 51-4**
7	Genitourinary syndrome of menopause (GSM) does not wane with time after	**Case 51-2 (Questions 1, 2)**

menopause; long-term use of low-dose vaginal estrogen can be recommended.

INTRODUCTION

The perimenopausal or climacteric phase in the female aging process (ie, the time between the reproductive and nonreproductive years) is distinguished by waning ovarian function and irregular menstrual cycles. Menopause, the last spontaneous episode of physiologic uterine bleeding, is identified retrospectively after 12 months of amenorrhea and typically occurs 4 to 5 years after the onset of perimenopause. In females younger than 45 years, menopause can be confirmed by two elevated follicle-stimulating hormone (FSH) levels >4 weeks apart. Postmenopause is characterized by significantly decreased hormone levels that may contribute to an increased risk of disease. While life expectancy has increased, the average age of females at menopause has remained relatively constant at 51 years.[1] Females today may spend one-third of their lives in the postmenopausal state. Approximately 35% of the female population in the United States is older than 50 years and at risk for menopause-related health issues.[2] Age at menopause is determined primarily by genetics but may be decreased by low body weight and poor health status. Cigarette smoking decreases age at menopause by 1 to 2 years.[3] Higher socioeconomic status and prior oral contraceptive use may increase the age at menopause.[3] Cytotoxic drugs and radiotherapy may induce ovarian failure, and bilateral oophorectomy results in surgically induced menopause. Onset of menopause before age 40 is termed *premature ovarian insufficiency*.

PATHOPHYSIOLOGY

Perimenopause results from an age-related acceleration in oocyte (immature female egg) degeneration and ovarian resistance to gonadotropins. The aging follicles produce less inhibin, which triggers increased production of FSH (**Fig. 51-1**).[4,5] Despite this increase in FSH levels, the declining ovary is unable to consistently produce mature follicles, resulting in frequent anovulatory cycles during the years approaching menopause. However, spontaneous ovulation can still occur, and contraception should be used if pregnancy is not desired. When all ovarian follicles have been depleted, menopause occurs. This corresponds with an increase in FSH and luteinizing hormone levels, which peak 1 to 3 years after menopause.[5]

Figure 51-1 Perimenopausal changes in hypothalamus–pituitary–ovary axis. *Dashed line* indicates inhibitory effect, *solid line* stimulatory effect, and *wider line* more pronounced effect. FSH,

follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Postmenopausal estrogen production is ~10% of premenopausal levels.[6] After menopause, circulating estrogen is largely estrone, whereas the more potent estradiol is the primary estrogen during the reproductive years.[7]

Unlike the reproductive years, estrogen levels postmenopausally do not vary in a cyclic pattern. The source of postmenopausal estrogen is androstenedione, an androgen converted to estrogen by an aromatase enzyme found predominantly in fat, liver, and skin. Enzyme levels increase with age and body weight, resulting in higher estrogen levels in females with greater body fat.[7,8] As the failed ovary no longer produces progesterone, levels after menopause are roughly one-third of premenopausal levels and are derived from the adrenal gland.[7] Androgen production declines by ~50% with normal aging; however, owing to the greater drop in estrogen levels, the androgen-to-estrogen ratio increases markedly after menopause, often resulting in mild symptoms of androgenism, such as hirsutism.[7]

CLINICAL PRESENTATION

The decrease in estrogen production associated with menopause can result in clinical symptoms, such as hot flushes and genitourinary symptoms. Risk for cardiovascular disease (CVD), the leading cause of death in postmenopausal females, appears to be amplified by estrogen deficiency.[9] Postmenopausal osteoporosis may result from estrogen deficiency (see Chapter 110, Osteoporosis). Loss of estrogen has also been associated with adverse effects on cognition, neurologic functioning, well-being, and sexual health.[10] Other consequences of menopause may not yet be elucidated.

Signs and Symptoms

HOT FLUSHES

CASE 51-1

QUESTION 1: L.K., a 50-year-old female, is having sudden feelings of warmth accompanied by flushing of her skin and increased sweating for the past month. These symptoms often wake her at night. Her menses have recently been irregular (five menses in the past 12 months). Her physical examination is normal for a 50-year-old female. Her last mammogram 6 months ago was normal. She does not smoke, and her body mass index is 24 kg/m^2. She has hypertension that is controlled with hydrochlorothiazide and migraine headaches without aura, which she treats with oral sumatriptan as needed. Her family history is positive for osteoporosis but negative for CVD and breast cancer.

Which of L.K.'s current symptoms are consistent with menopause?

It appears that L.K. is having hot flushes, a vasomotor symptom (VMS) experienced by up to 80% of females during the menopause transition.[11] The onset of VMS may precede the last menstrual period, but the prevalence peaks 1 to 2 years after menopause and declines with time since menopause.[11] Frequent symptoms persist an average of 7 years; up to 30% of females may experience symptoms for >10 years.[11] Obesity and surgically induced menopause are risk factors for more frequent or severe hot flushes.[10,12] Symptoms include a feeling of warmth in the chest, neck, and facial areas that may be accompanied by visible flushing and increased sweating. Nocturnal hot flushes (night sweats) cause nighttime awakening and may lead to insomnia and sleep deprivation. Hot flushes average ~4 minutes in duration and are characteristically episodic rather than continuous but may occur hourly in females with severe symptoms.[11]

The specific etiology of hot flushes is unknown, but they are clearly associated with the declining estrogen concentrations that occur during menopause. It is postulated that the drop in estrogen leads to alterations in serotonergic and noradrenergic activity. These hormones are involved in temperature regulation; fluctuations in

levels trigger an inappropriate activation of the body's heat-release mechanisms, leading to cutaneous vasodilation and sweating seen with hot flushes.[11,13]

Cognitive and mood changes, including depression, are not uniformly associated with menopause but are reported more frequently in females during the perimenopausal period.[10,14] Genitourinary syndrome of menopause (GSM) is also associated with menopause (see Case 51-2, Question 1).[15]

Overview of Therapy

The goal of drug therapy in a symptomatic female is to relieve symptoms and improve quality of life without increasing the risk of serious adverse effects related to therapy.

TREATMENT

Case 51-1, Question 2: L.K. is seeking relief for her hot flushes but is not sure that she wants to use medications for this problem. What nonmedication therapies are appropriate for the management of L.K.'s hot flushes?

Lifestyle modifications

First-line treatment for hot flushes is lifestyle modification, including avoidance of known triggers (eg, hot beverages, alcohol, warm environments), wearing layered clothing, and the use of personal cooling devices. However, there is limited evidence for the efficacy of these interventions.[16] Weight loss in overweight females, cognitive–behavioral therapy, and clinical hypnosis may improve VMS, whereas regular exercise, yoga, and acupuncture have not demonstrated benefit.[16,17] If the patient continues to experience bothersome symptoms, drug therapy should be considered. It is noteworthy that placebo responses of 20% to 60% have been seen in clinical trials evaluating interventions for hot flushes.[16]

Black cohosh

Black cohosh (*Cimicifuga racemose*), an herbal product derived from a plant in the buttercup family, has a long tradition of use for the management of VMSs. It does not appear to have estrogenic effects but may exert a serotonergic effect.[18] Overall data do not support use; however, studies using standardized extracts have demonstrated efficacy.[19] Black cohosh is generally well tolerated, but use beyond 12 months has not been evaluated. The most common adverse effects are gastrointestinal upset and rash. There have been case reports of hepatotoxicity that cannot be directly attributed to black cohosh.[18,19]

Phytoestrogens

Phytoestrogens, including isoflavones and lignans, are plant-based substances that exhibit mild estrogenic effects. A meta-analysis of randomized, placebo-controlled trials concluded that phytoestrogens may modestly improve VMS.[20] However, further data are needed regarding optimal agent and dose. In general, isoflavones are well tolerated; the most commonly reported side effect is gastrointestinal intolerance.[19] Endometrial stimulation appears to be rare.[19] Data are limited on the safety of phytoestrogens in females with a history of estrogen-dependent disease.

L.K. does not have any estrogen-dependent diseases and, therefore, could try either black cohosh or phytoestrogens for her hot flushes if lifestyle modifications do not provide adequate benefit. She should be counseled that these products have mixed data supporting their benefits and that phytoestrogens could potentially have side effects similar to hormone therapy (HT).

Hormone therapy

Case 51-1, Question 3: L.K. returns to clinic after 2 months. She initiated lifestyle modifications and tried black cohosh but has noted worsening of her flushes, awakening multiple times at night due to night sweats, which is causing

daytime fatigue and irritability. She asks about HT to control her hot flushes. Is L.K. a candidate for hormone therapy?

HT has received a great deal of scientific and media attention during the past decades. The Women's Health Initiative (WHI), a large, prospective study of estrogen therapy (ET) and estrogen/progestogen therapy (EPT) in postmenopausal females, and several large cohort studies have provided a great deal of data, some of it conflicting, on the risks and benefits of hormone use after menopause. Before selecting a treatment option, patients should be evaluated for contraindications to HT and counseled about its possible risks and benefits (**Table 51-1**).

Table 51-1
Benefits and Risks of Postmenopausal Hormone Therapy

	Evidence	Indications/Contraindications Pacienc Considerations	Ref
Established Benefits*			
VMS	Systemlc (oral or TD) ET/EPT is most effective therapy for hot flushes. There may be a dose–response reiatlonshlp.	This is the pnmary indication foi the use of systemic hormone therapy	21.25
Osteoporosis	Numerous clinical trials support reduced risk of vertebral and hip fractures with the use of estrogen	Provides bone protection during use of ET/EPT for menopausal symptoms.	23
Vaginal atrophy	Numerous studies show both local and systemic estrogens reverse the atrophy Induced by menopause	Locallzed therapy should be used for patients with only genitourinary syndrome of menopause.	15
Cardiovascular dlsease (CVD)	No increased risk or possible decreased risk when initiated before age 60 and within 10 years of menopause (see also established risk)	Prevention of CVD is not a primary Indication for use: this information can reassure patient needing HT for menopause symptoms or replacement for females with premature ovarian failure	24–26
Unconfirmed Benefits*			
Allcause mortallty	Several systematic reviews noted reduced or no change in all-cause mortality in females starting HT early after menopause	This information can be used to reassure females that timely HT use is associated with overall low risk.	26.32
Colorectal cancer	Decreased risk is seen with EPT, but not With ET	May be secondary benefit In females using for hot flushes.	55
Recurrent UTIs and Incontinence	Low-dose locallzed estrogen treatment can decrease the risk for recurrent UTIs and incontinence	May be secondary benefit in females using localIzed theiapy for vaginal atrophy	56,57
Diabetes mellitus (DM)	Decreased Incldence of new-onset diabetes in females taking EPT or ET.	This suggests that DM is not a contraindication r0r females who wish to use EPT/ET	55
Cognitive effects	Some studies showed reduced risk for the development of Alzheimer dementia or cognitive deficits when HT was initiated within 5 years of menopause.	This suggests potentiai protective effects on cognition in females who Inltiate HT early after menopause	25.58
Established Risks*			
Thromboernbolic disease	Increased risk of DVT and PE, greatest within the first 1–2 years of use. risk with EPT possibly higher than with ET. TD estrogen has lower risk than oral estrogen.	**Absolute contraindication:** Current tobacco use. history of thrombosis. **Relative contraindication:** obesity, females age 65 years and older Therapy should be dlscontinued before surgery or anticipated period of immobilization.	25.32
Breast cancer	Risk increased ~25%–50% after 5 years of use, increases with contlnued use. Risk is higher with EPT vs ET.	**Absolute contraindication:** peisonal hisrory of breast cancer **Relative contraindication:** strong family history of breast cancer.	28–31
Cardiovascular disease	Increased risk of MI, when started >10 years after menopause or in females age 60 years or older (see also unconfirmed benefit).	**Relative contraindication:** age 60 years or older, >10 years since menopause	24.26,37
Endometrial cancer	Risk reiated to dose and duration of use Addition of adequate progestogen reduces or eliminates risk.	**Absolute contraindication:** undlagnosed postrnenopausal vaginal bleeding, prior history of endometrial cancer Rationale for the use of concomitant progestogen In patients with an Intact uterus	27
Ischemic stroke	30%–50% Increased risk for ischemic stroke seen Dose-related risk seen with both ET and EPT may tv ivv. with nonoral touie Risk higher with mcreasing age (because of underlying age-related risk of stroke). HT does not affect risk of hemorrhagic stroke.	**Absolute contraindication:** history of suoke or iransienr ischemic atcacks, current tobacco use **Relative contraindication:** obesiiy, uncomroiled hypertension, unconrrolled diabetes.	26, 32

Gallbladder disease	~60% Increased risk of cholecystitls, cholelithiasis seen wlth ET and EPT. less risk wlth nonoral route.	**Relative contraindication:** history of gallbladdtr dlsease.	55
Hypertriglyceridemia	Oral estrogen increases triglycerides Nonoral route has less effeet. EPT may have less effect than ET alone owing to attenuating effect of progestogen.	**Relative contraindication:** hypemiely eiidemia If estrogen is to be used in female wirh elevated TG, select transdermal route and monitor TG levels.	59
Estrogen sensitive conditions	5ystemic therapy with ET/EPT may worsen these conditions.	**Absolute contraindication:** known/suspe :ed pregnancy **Relative contraindication:** utenne fil.vijlds, endometriosis, porphytia	49
Unconfirmed Risksb			
Ovarian cancer	Increased risk seen with ET/EPT, longer durations of treatment	**Relative contraindication:** strang family history of ovarian cancer.	60
Urinary incontinence	Systemic estrogen caused or worsened urinary incontinence, not seen with ultralow dose	Avoid systemic estrogen in females with urinary incontinence, monitor for new onset in females taking HT.	55
Cognltive effects	Studies report worsening of dementia in females with preexisting dementia; no improvement or protectlon In older females taking HT	**Absolute contraindication:** patients wiih evi- dence of dementia. Avoid use in females age 65 years or older	21.61
Migraine headaches	HI may cause worsening of migraine headaches, nonoral estrogen and continuous progestin are preferred	**Relative contraindication:** mlgrairie with/with- out aura. Monitor for changes in HT frequency	6?

DVT, deep venous thrombosis; EPT, estrogen/progestogen therapy; ET, estrogen therapy; HA, headache; HT, hormone therapy; MI, myocardial infarction; PE, pulmonary embolism; TD, transdermally; TED, thromboembolic disease; TG, triglycerides; UTI, urinary tract infection.

[a]Well-documented benefit or risk supported by multiple clinical studies.

[b]Possible benefit or risk shown in limited clinical trials, additional data needed to confirm.

Established benefits of hormone therapy

Vasomotor Symptoms

Systemic estrogen, with or without a progestogen, is well documented to reduce the frequency and severity of hot flushes. In females with hot flushes, HT has been shown to improve quality of life.[21] During perimenopause, combined hormonal contraceptives are effective in reducing VMS as well as preventing pregnancy.[22]

Osteoporosis

Systemic HT prevents postmenopausal bone loss associated in a dose-related manner, reducing the risk of osteoporotic hip and vertebral fractures by ~25%.[23] Many estrogen products are U.S. Food and Drug Administration (FDA) approved for the prevention (but not treatment) of osteoporosis (**Table 51-2**). HT may be used for

the prevention of osteoporosis in recently menopausal females, even in the absence of menopausal symptoms, if alternate osteoporosis therapies cannot be used. Fracture protection dissipates upon discontinuation of systemic estrogen (see Chapter 110, Osteoporosis).[21] Alternative therapies should be initiated when HT is stopped in females at risk for osteoporosis.

Table 51-2

Hormones for Treatment of Vasomotor Symptoms and/or GSM

Drug (Brand Name)	Route	Initial Dosage
Estrogens, Systemic[b]		
Conjugated estrogens (Premarin®)[a] Esterified estrogen (Menest®)[a]	PO	0.3 mg
Estradiol (Estrace®)[a,c]	PO	0.5 mg
Estradiol weekly patch (Climara®)[a,c]	TD	0.025 mg/24 hour
Estradiol twice-weekly patch (Lyllana, Minivelle, Vivelle-Dot®)[a,c]	TD	0.025 mg/24 hour
Estradiol acetate vaginal ring (Femring®)[c]	HDV	0.05 mg/24-hour ring
Estradiol topical emulsion/gel/solution (Divigel®, Elestrin®, Estrogel®/Evamist®)[c]	TD	0.0125–0.75 mg (product dependent)
Progestogens (Minimum Recommended Dose to Prevent Endometrial Hyperplasia)[34]		
Medroxyprogesterone acetate (Provera®)	PO	5 mg for sequential regimen; 2.5 mg for continuous regimen
Norethindrone acetate	PO	2.5 mg for sequential regimen; 1 mg for continuous regimen
Micronized progesterone (Prometrium®)[c]	PO	200 mg for sequential regimen; 100 mg for continuous regimes
Progesterone vaginal gel (Crinone®)[c]	V	One full applicator of 4% gel every other day

Drug (Brand Name)	Route	Initial Dosage
Progesterone vaginal suppository (First® Progesterone VGS)	V	200 mg/day for 12 days
Levonorgestrel-releasing IUD (Mirena®)	IU	0.02 mg/day
Examples of Estrogen and Progestogen Combination Products		
Prempro®[a]	PO	0.3 mg CE and 1.5 mg MPA
Premphase®[a]	PO	0.625 mg CEE and 0.625 mg CEE/5 mg MPA
Climara Pro®[a,c] weekly patch	TD	0.045 mg estradiol/0.015 mg levonorgestrel/24-hour
CombiPatch®[a,c] weekly patch	TD	0.05 mg estradiol/0.014 mg norethindrone/24-hour
Low-Dose Vaginal Estrogens (Localized Effect Only)		
Conjugated equine estrogen cream (Premarin®)	LDV	0.5–2 g cream (0.3125–1.25 mg CEE) daily
Estradiol cream (Estrace®)[c]	LDV	Initial: 2–4 g cream (0.2–0.4 mg estradiol) daily
Estradiol inserts (Imvexxy®)[c]	LDV	4 µg daily
Estradiol ring (Estring®)[c]	LDV	2-mg ring (7.5 mg/day)
Estradiol tablets (Vagifem®, Yuvafem®)	LDV	One tablet (10 µg) daily

CEE, conjugated equine estrogens; HDV, high-dose vaginal estrogen, sufficient absorption to produce systemic estrogenic effect (ie, for the treatment of hot flushes); IU, intrauterine; IUD, intrauterine device; LDV, low-dose vaginal estrogen, provides localized estrogenic effect (ie, for vaginal atrophy), owing to low-dose, minimal systemic absorption; MPA, medroxyprogesterone acetate; PO, orally; TD, transdermally; V, vaginal.

[a]Approved by the U.S. Food and Drug Administration for the prevention of osteoporosis.

[b]Requires addition of progestogen in females with an intact uterus.

[c]FDA-approved bioidentical hormone.

[d]Not FDA approved in the United States, available in Canada.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home

Cardiovascular Disease

Although the WHI trial was stopped early owing to evidence of increased heart disease in subjects receiving estrogen, further analysis of those data and results from other studies found no increased risk of coronary heart disease in females younger than 60 years who began therapy within 10 years of menopause. A possible reduced risk of CVD was seen in females initiating therapy before age 55 and within 2 to 3 years of menopause, whereas an increased risk was seen in females age 60 years and older who initiated HT >10 years after menopause.[24–26] In younger patients such as L.K. who initiate HT for VMS soon after the onset of menopause, the risk of CVD is not increased.

Other Possible Benefits

Less established benefits of systemic HT (see Table 51-1) include beneficial effects on diabetes mellitus and colorectal cancer.[15,21,25]

Established risks of hormone therapy

Cardiovascular Disease

As noted earlier, an increased risk of CVD has been noted in females older than 60 years who initiated HT >10 years postmenopause.[21,24,25]

Endometrial Cancer

In a patient with an intact uterus, the use of ET alone stimulates endometrial proliferation, resulting in hyperplasia and a twofold to fourfold increased risk of endometrial cancer.[25] Higher estrogen dose and longer duration of use are associated with higher risk; risk persists for several years after discontinuation of ET.[21] Addition of adequate progestogen significantly attenuates the increased risk of endometrial cancer; a progestogen should be added to ET in a patient with an intact uterus (see Case 51-1, Question 4).[21,27]

Breast Cancer

Studies demonstrate a 25% to 50% overall increased risk of invasive breast cancer with HT, with a higher risk with EPT compared to ET. Risk increases with longer duration of use and returns to baseline 5 to 10 years after HT is stopped.[28,29] There is no apparent relationship to estrogen route or dose; synthetic progestins may confer higher risk than natural agents.[30,31] A shorter interval between the onset of menopause and the initiation of HT is associated with higher risk compared with a longer interval.[28] Risk may be attenuated in females with obesity because of their baseline increased risk.[29]

Thromboembolic Disease

HT use increases the overall risk for venous thromboembolic disease (TED), including deep venous thrombosis and pulmonary embolism, approximately twofold.[21,25,32] This risk may be mediated by inhibition of hepatic synthesis of anticoagulant factors. Nonoral estrogen, which avoids the first-pass metabolic effects of oral therapy, appears to have a significantly lower risk than oral estrogen. Risk is highest within the first 2 years of treatment and decreases upon discontinuation of HT.[21,25] Observational data suggest that synthetic progesterone derivatives, but not bioidentical progesterone, further increase the risk of TED.[25] Females who are older, have a higher body mass index, or have a prothrombotic mutation are at additional risk. HT should be avoided in females with a history of or at high risk for TED.[21,25]

Other Possible Risks

Other risks of systemic HT include potential adverse effects on cognition and urinary tract function, an increased risk of stroke, and the development of ovarian cancer and gallbladder disease (see Table 51-1).[25]

Recommendations

Current guidelines on systemic HT recommend use only in females with moderate-to-severe hot flushes (**Fig. 51-2**).[21,25] For females with

premature ovarian failure, HT is recommended until the typical age of natural menopause to avoid early manifestations of estrogen deficiency.[33]

Figure 51-2 Algorithm for the management of symptomatic menopausal females. EPT, estrogen/progestogen therapy; ET, estrogen therapy; HT, hormone therapy.

As L.K. continues to experience severe hot flushes that are affecting her quality of life, as she is recently postmenopausal, and as she has no absolute contraindications to estrogen (see Table 51-1), a trial of HT is appropriate.

CASE 51-1, QUESTION 4: What is an appropriate HT regimen for the management of L.K.'s hot flushes?

SELECTION OF THERAPY

Estrogens

Multiple hormonal products are currently available for the management of VMS (Table 51-2). Oral and nonoral estrogens appear to be equally efficacious in treating VMS. Because it is associated with lower risk, nonoral estrogen is preferred in females at risk for TED, hypertension, migraine headaches, hypertriglyceridemia, or gallbladder disease.[21,25]

Current recommendations are to initiate estrogen at a low dose (eg, 0.3 mg of conjugated estrogens [CEs] or 0.025 mg of transdermal estradiol). If symptoms persist after 2 to 3 weeks of therapy, the dose of estrogen can be increased to the next available dosage strength for the product being used. Although better tolerated, ultralow-dose transdermal estradiol products (0.014 mg/24 hours) may have slower onset and lower efficacy than traditional doses.[34]

Bioidentical hormones

Bioidentical HT (BHT) is defined as having the same chemical structure as the hormones produced by the human reproductive system and includes estradiol, estrone, progesterone, and testosterone. Studies of commercially available BHT products demonstrate an efficacy and risk profile similar to synthetic hormones. Females desiring to use bioidentical products should be prescribed commercially available products (see Table 51-2); extemporaneously compounded BHT does not carry FDA-approved warnings and may be of inadequate quality.[35]

Progestogens

In patients with an intact uterus, such as L.K., a progestogen must be added to the regimen to minimize the risk of endometrial cancer (**Table 51-3**). Currently, there is no indication for the addition of a progestogen in patients without a uterus. Synthetic progestogens may be more effective at reducing risk than natural progestogens, and combined continuous regimens appear to provide better endometrial protection than sequential regimens (Table 51-3).[27,30] Although not FDA approved for this indication, progesterone vaginal

gel and progestogen-releasing intrauterine systems protect against endometrial hyperplasia from ET.[30,36]

Table 51-3
ET/EPT Regimens and Expected Vaginal Bleeding Patterns

Estrogen/Progestogen Dosing	Typical Bleeding Pattern
Combined Systemic Regimens (EPT) for Patient With Intact Uterus	
Sequential Regimens	
Estrogen: daily ***PLUS*** Progestogen: days 10–25 or 14–25 of each 28-day cycle (minimum of 10 days)	1–2 days after progestogen dosing ended[a], ~80% experience regular withdrawal bleeding throughout treatment[c] that persists throughout therapy, ~10% experience spotting[d]
Estrogen: daily ***PLUS*** Progestogen: daily for 3–5 days/week	~40% experience irregular bleeding/spotting
Continuous Regimen	
Estrogen: daily ***PLUS*** Progestogen: daily	~40% have irregular bleeding/ spotting for first 6–12 months[b] ~80% become amenorrheic within 12 months
Systemic Estrogen-only Regimens (ET) for Patients Without Uterus	
Continuous Regimen	
Estrogen (PO or TD): daily	None None

EPT, estrogen/progestogen therapy; ET, estrogen therapy; TD, transdermally.

[a]Bleeding earlier than 11 days after beginning of the progestogen suggests need for endometrial evaluation.

[b]Bleeding >6 months after initiation of therapy requires endometrial evaluation.

[c]Withdrawal bleeding is vaginal bleeding for multiple days (usually <10 days) that resembles menstrual period and requires use of a tampon or sanitary pad.

[d]Spotting is light bleeding that lasts <1 day.

Sources: Archer DF, Pickar JH, Bottiglioni F. Bleeding patterns in postmenopausal women taking continuous combined or sequential regimens of conjugated estrogens with medroxyprogesterone acetate. Menopause Study Group. *Obstet Gynecol*. 1994;83(5 Pt 1):686–692; Furness S, Roberts H, Marjoribanks J, Lethaby

A, Hickey M, Farquhar C. Hormone therapy in postmenopausal women and risk of endometrial hyperplasia. *Cochrane Database Syst Rev.* 2009;(2):CD000402; Kroft J, Klostermann NR, Moody JR, Taerk E, Wolfman W. A novel regimen of combination transdermal estrogen and intermittent vaginally administered progesterone for relief of menopausal symptoms. *Gynecol Endocrinol.* 2010;26(12):902–908.

EPT may result in resumption of uterine bleeding. The pattern and frequency of bleeding depend on the EPT regimen used (Table 51-3).[37] Lower doses of estrogen are associated with a lower risk of bleeding.[38] Bleeding is a common reason for regimen discontinuation; patient preference regarding bleeding patterns should be considered when selecting an EPT regimen.[39]

Progestogen monotherapy appears to be similar to estrogen in relieving the symptoms of VMS. Effective regimens include megestrol acetate 20 mg/day orally, micronized progesterone 300 mg/day orally, and medroxyprogesterone acetate (MPA) 10 mg/day orally.[21] Adverse effects of progestogens include vaginal bleeding, fluid retention, increased appetite, breast tenderness, acne, hirsutism, headaches, mood swings, fatigue, and depression. In the absence of ET, progestogens do not appear to increase the risk of TED.[40] However, data on long-term safety, especially in regard to breast cancer, are lacking. Progestogen monotherapy for the treatment of hot flushes is generally reserved for females with contraindications to estrogen use.

DURATION OF HORMONE THERAPY

As some risks of HT increase with longer use, use beyond 5 years has generally not been recommended. However, many females continue to have VMS beyond this time frame; a thorough risk-versus-benefit review is needed to determine the appropriate duration for each female.[41] Because hot flushes are self-limiting, it can be difficult to assess whether symptom relief is related to the treatment or natural resolution of symptoms. Six to 12 months after hot flushes are fully treated, discontinuation of EPT should be attempted. There are no specific guidelines for withdrawing therapy; typical taper regimens involve decreasing the daily estrogen dose to

the next available dosage strength or increasing the dosing interval. If symptoms recur during the taper, therapy can be resumed at the lowest effective dose and another taper can be attempted in 6 months.[42,43]

ADVERSE EFFECTS

Case 51-1, Question 5: To minimize the risks of TED, L.K. is prescribed a combined estrogen/progestogen patch. How should she be counseled about possible side effects of EPT?

In addition to being counseled about the serious risks of EPT, L.K. should be advised regarding nuisance side effects from HT. Most common are resumption of vaginal bleeding and breast tenderness.[44] Nausea, weight gain, edema, headache, premenstrual syndrome–like symptoms, and increased vaginal discharge have also been reported.[45] Skin irritation may occur with the use of transdermal products. Frequently, these side effects diminish with time or may respond to a change in dosage or product. Although ET and EPT have not been shown to consistently induce or worsen hypertension, patients with hypertension, such as L.K., should be monitored for increases in blood pressure.[45,46]

TISSUE-SELECTIVE ESTROGEN COMPLEX

The tissue-selective estrogen complex (TSEC) of CE and the selective estrogen receptor modulator (SERM), bazedoxifene (BZA), is FDA approved for the treatment of VMS and the prevention of osteoporosis in postmenopausal patients with an intact uterus. The estrogen component reduces VMS and prevents bone loss, whereas the estrogen-antagonistic properties of BZA in the breast and uterus mitigate the effects of estrogen on these tissues, eliminating the need for concurrent progestogen. Clinical trials have demonstrated that CE/BZA produces fewer bleeding events and breast symptoms than the traditional combination of CE/MPA and may improve

symptoms of vaginal atrophy.[44,47] This agent is an alternative for females who do not tolerate EPT because of adverse effects.

NONHORMONAL AGENTS

Case 51-1, Question 6: L.K. returns 3 months later. Her hot flushes and night sweats resolved with EPT, but she experienced worsening of her migraine headaches, so she discontinued HT. Her hot flushes recurred soon thereafter. What alternative therapies are available for the management of L.K.'s symptoms?

Nonhormonal regimens, recommended for females with preexisting hormone-dependent cancers or females unwilling or unable to take HT, are modestly effective in reducing hot flush frequency and severity.[48] Serotonergic antidepressants may exert this effect, regulating neurotransmitter levels in the thermoregulatory area of the hypothalamus (**Table 51-4**).[49] In clinical trials, relief of VMSs with serotonergic antidepressants was seen at lower doses and with a more rapid onset than is seen for their antidepressant effects.[16] Venlafaxine and paroxetine, the most studied agents for VMSs, are considered the drugs of choice; paroxetine mesylate, at a dose of 7.5 mg, is FDA approved for this indication. Other selective serotonin reuptake inhibitors and serotonin and norepinephrine reuptake inhibitors are considered the second-line agents.[16] Dosing should be initiated at the lowest effective dose (Table 51-4); this can be increased after 2 to 3 weeks if the patient has an inadequate response. To avoid withdrawal symptoms, patients should be advised not to discontinue therapy abruptly. Commonly seen side effects of nonhormonal agents are listed in Table 51-4. Paroxetine and fluoxetine are strong inhibitors of CYP2D6 and should be avoided in females taking tamoxifen because formation of its active metabolite may be reduced.[16]

Table 51-4
Nonhormonal Agents for the Management of Vasomotor Symptoms

Drug	Recommended Dosage	Common Adverse Reactions Reported
Serotonergic Antidepressants: SSRIs		
Citalopram (Celexa®) Escitalopram (Lexapro®) Fluoxetine Paroxetine hydrochloride (Paxil™, Paxil CR™) Paroxetine mesylate[a] (Brisdelle®)	10–20 mg 10–20 mg 10–20 mg 10–20 mg 12.5–25 mg (CR) 7.5 mg	Dizziness, drowsiness, headache, insomnia, diarrhea, sexual dysfunction, dry mouth, nausea
Serotonergic Antidepressants: SNRIs		
Desvenlafaxine (Pristiq®)	50–150 mg	Dizziness, drowsiness, insomnia, dry mouth, sexual dysfunction, nausea, constipation, possible increase in blood pressure at higher doses
Venlafaxine (Effexor®, Effexor® XR)	37.5–75 mg 37.5–150 mg XR	
Gabapentinoids		
Gabapentin (Neurontin®)	900–2400 mg	Somnolence, fatigue, dizziness, nausea
Pregabalin (Lyrica®)	150–300 mg	Dizziness, sleepiness, weight gain, coordination/cognitive difficulty
Antihypertensive Agents		
Clonidine	PO: 0.05–0.15 mg TD: 0.1 mg/24 hour	Headache, dry mouth, drowsiness Skin reaction/itching (patch only), risk of rebound hypertension if stopped abruptly

HTN, hypertension; PO, orally; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TD, transdermally.

[a]FDA approved for the management of vasomotor symptoms.

Sources: Nonhormonal management of menopause-associated vasomotor symptoms: 2015 position statement of The North American Menopause Society. *Menopause*. 2015;22(11):1155–1172; Shan D, Zou L, Liu X, Shen Y, Cai Y, Zhang J. Efficacy and safety of gabapentin and pregabalin in patients with vasomotor

symptoms: a systematic review and meta-analysis. *Am J Obstet Gynecol*. 2020;222(6):564–579.e12; Biglia N, Bounous VE, De Seta F, Lello S, Nappi RE, Paoletti AM. Non-hormonal strategies for managing menopausal symptoms in cancer survivors: an update. *Ecancermedicalscience*. 2019;13:909.

The antiepileptic drug gabapentin has been shown in multiple studies to decrease VMS through an unidentified mechanism. The therapeutic effect occurs at a dose of 900 mg/day with an onset within 4 weeks of starting treatment. To minimize side effects, dosing should be initiated at 300 mg daily and titrated up in 300-mg/day increments as tolerated. Although one study showed benefit with 2400 mg/day, the optimal dose of gabapentin for hot flushes is unknown.[50,51]

Paroxetine mesylate 7.5 mg daily can be tried in L.K. If her symptoms are not improved after 2 to 3 weeks, an alternate serotonergic agent can be tried with dose titration as needed.

Genitourinary Syndrome of Menopause

SIGNS AND SYMPTOMS

CASE 51-2

QUESTION 1: B.L., a 64-year-old female, presents with persistent vaginal dryness and irritation as well as pain associated with intercourse. She has tried vaginal lubricants, which help with intercourse-related pain but do not relieve her daily vaginal symptoms.

She experienced menopause at age 50, which was accompanied by moderate hot flushes for 2 to 3 years that have since resolved without intervention. She denies symptoms of urinary incontinence.

What is causing B.L.'s condition?

B.L. appears to be experiencing symptoms of GSM. Estrogen is the dominant hormone of the vagina and lower urinary tract. With the postmenopausal loss of estrogen production, the vagina decreases in size and loses its rugal pattern; the mucosa becomes pale, thin, and dry; and vaginal blood flow decreases. A decrease in *Lactobacillus* production of lactic acid leads to an increase in vaginal

pH to 5.0 or greater (compared with a premenopausal pH of 3.5–4.5).[15] These changes make the vagina more susceptible to infection from bacterial colonization and localized trauma secondary to intercourse. In the urinary tract, loss of estrogen is associated with changes to the bladder and pelvic floor.[52] Unlike hot flushes, GSM does not abate with time since menopause.

Symptoms of GSM include vaginal dryness, itching, pain, and dyspareunia (painful coitus) and recurrent urinary tract infections and stress or urge incontinence. In the United States, almost half of postmenopausal females experience symptoms of GSM; however, few report these symptoms to their health care provider.[15,52]

Case 51-2, Question 2: What would be an appropriate regimen for B.L. to decrease her vaginal symptoms?

TREATMENT

Nonhormonal treatment

Vaginal moisturizers, which are the first-line treatment, adhere to the vaginal mucosa and improve vaginal symptoms but do not reverse atrophy. Patients report symptom relief within 3 months of continuous treatment.[15] Personal lubricants can be used for dyspareunia related to GSM. Silicone and iso-osmolar water-based products are preferred to oil-based products to minimize adverse effects.[15,45] Nonhormonal treatments used for VMSs do not improve GSM symptoms.

Ospemifene (Osphena®) is an orally active vaginal tissue–specific estrogen agonist/antagonist. Ospemifene, 60 mg once daily by mouth, has shown significant improvement in dyspareunia and vaginal atrophy. Although ospemifene does not contain estrogen, it does have estrogen agonist effects, and postmenopausal females with an intact uterus should be considered for concomitant progestin therapy. Use in females with preexisting breast cancer has not been adequately studied. The most common side effect is hot flushes.[15,45]

Dehydroepiandrosterone (DHEA) (prasterone, Intrarosa®) is an FDA-approved vaginal insert for the treatment of dyspareunia in

postmenopausal females. Prasterone, an adrenal steroid metabolized to estrogen and androgen in the vaginal mucosa, has been shown to reduce symptoms of GSM. Prasterone does not induce endometrial proliferation. The most common side effects are vaginal discharge and abnormal Pap smear.[45,53] No data exist on its use in females with a history of estrogen-dependent cancer.

Localized estrogen treatment

ET reverses vaginal epithelial thinning, decreases the vaginal pH, and improves the symptoms of vaginal atrophy. For vaginal symptoms alone, low-dose vaginal estrogen is the preferred treatment. The available products (see Table 51-2) appear to be equivalent in restoring vaginal cytology and pH and in relieving symptoms of vaginal dryness, pruritus, and dyspareunia; product selection should be based on patient preference. Vaginal creams and tablets are initiated with once-daily dosing; after symptoms have resolved, the patient should be switched to maintenance dosing of once- or twice-weekly administration. The low-dose vaginal ring releases a constant dose of estrogen for 90 days.[15]

The most common adverse effects of vaginal estrogens are vaginal discharge and bleeding, vulvovaginal candidiasis, and breast tenderness. Based on limited studies, the risk of endometrial hyperplasia from low-dose vaginal estrogen is small, and the addition of a progestogen is generally considered unnecessary. In the absence of vaginal bleeding, endometrial surveillance is not needed during low-dose vaginal ET.[45] Low-dose vaginal estrogen does not appear to increase the risk for TED, CVD, or breast cancer.[15]

For females with a history of estrogen-dependent cancer, vaginal ET can be considered for the management of GSM unresponsive to nonhormonal treatments, provided that the patient is informed of the risks and benefits.[45,54]

Because B.L. has not had relief with non-HT, localized ET such as estradiol cream applied vaginally once daily is appropriate. After her

symptoms have resolved, the dose can be decreased to a maintenance regimen of twice-weekly administration.

Thyroid Disorders

Eric F. Schneider and Kamaria K. Brown

CORE PRINCIPLES		CHAPTER CASES
1	Thyroid function tests are essential to confirm the presence of thyroid disorders but can be altered by acute and chronic illness and certain drugs. Thyrotropin (TSH) is the most accurate indicator of euthyroidism.	**Case 52-1 (Questions 1, 2) Case 52-2 (Question 1) Case 52-3 (Question 1) Case 52-4 (Question 1) Case 52-5 (Question 5) Case 52-22 (Question 1) Case 52-23 (Question 1), Tables 52-1, 52-7, Figures 52-1, 52-2**
2	Thyroid hormone deficiency can cause a goiter and hypothyroid symptoms (eg, weight gain, constipation, cold intolerance), including myxedema coma, heart failure, and hyperlipidemia. The most common cause of hypothyroidism is Hashimoto thyroiditis.	**Case 52-5 (Question 1) Case 52-8 (Question 2) Case 52-9 (Question 1) Case 52-10 (Questions 1, 2) Case 52-11 (Question 1) Case 52-12 (Question 1) Case 52-17 (Question 1), Tables 52-2, 52-3**

3	Generic or branded L-thyroxine (levothyroxine) is the preparation of choice for optimal correction of hypothyroidism. Triiodothyronine (T_3) containing preparations are not necessary because thyroxine (T_4) is converted to T_3.	**Case 52-5 (Question 2) Case 52-6 (Question 1) Case 52-9 (Question 2), Tables 52-4, 52-8**
4	The signs and symptoms of hypothyroidism can be corrected by the administration of L-thyroxine on an empty stomach at average oral replacement dosages of 1.6 µg/kg/day or intravenously. Dosing is altered by weight, comorbidities, and drug interactions.	**Case 52-5 (Questions 3–5) Case 52-7 (Question 1) Case 52-8 (Question 1) Case 52-9 (Question 2) Case 52-10 (Question 3), Tables 52-4, 52-8, 52-9**
5	The signs and symptoms of hyperthyroidism mimic those of adrenergic excess (eg, tachycardia, tremors, thyroid storm), but symptoms in the elderly may be absent ("apathetic"). Graves disease, a common cause of hyperthyroidism, can be complicated by ophthalmopathy.	**Case 52-20 (Questions 1, 2) Case 52-13 (Question 1) Case 52-18 (Questions 1, 2) Case 52-19 (Questions 1, 2), Tables 52-5, 52-6**
6	Management of hyperthyroidism includes antithyroid drugs (ATDs), iodides, radioactive iodine, and surgery. β-Blockers can provide symptomatic relief of hyperthyroid symptoms.	**Case 52-13 (Questions 2–8) Case 52-14 (Question 1) Case 52-16 (Questions 1, 2) Case 52-17 (Question 1) Case 52-19 (Question 2), Table 52-10**
7	Of the thioamides, methimazole (MMI) is preferable to propylthiouracil (PTU)	**Case 52-13 (Questions 4–7, 9, 10)**

	except during the first trimester of pregnancy and during thyroid storm. Thioamide toxicity includes gastrointestinal symptoms, rash, agranulocytosis, and hepatitis.	**Case 52-15 (Question 1)**
8	Both hypothyroidism and hyperthyroidism can alter metabolism of coadministered medications (eg, warfarin).	**Case 52-20 (Questions 2)**
9	The management of subclinical hypothyroidism and hyperthyroidism should be individualized.	**Case 52-11 (Question 1) Case 52-21 (Question 1)**
10	Certain drugs (eg, amiodarone, interferon, lithium, tyrosine kinase inhibitors) can cause thyroid disorders.	**Case 52-22 (Question 1) Case 52-23 (Question 1), Tables 52-2, 52-5**

INTRODUCTION

Thyroid disease, including hypothyroidism, hyperthyroidism, and nodular disease, are common, affecting 5% to 15% of the general population. Females are affected three to four times more than males.[1,2] Triiodothyronine (T_3) and thyroxine (T_4) are the two biologically active thyroid hormones produced by the thyroid gland. The hypothalamic thyrotropin-releasing hormone (TRH) stimulates release of thyrotropin (thyroid-stimulating hormone [TSH]) from the pituitary in response to low circulating levels of thyroid hormone. TSH in turn promotes hormone synthesis and release by increasing thyroid activity. High-circulating thyroid hormone levels block further production by inhibiting TSH release (negative feedback). As the serum concentrations of thyroid hormone decrease, the

hypothalamic– pituitary centers again become responsive by releasing TRH and TSH (**Fig. 52-1**).

Figure 52-1 Regulation of thyroid hormone secretion. Release of thyroid hormones is controlled by the hypothalamic–pituitary–thyroid axis. Dashed lines represent negative feedback, rT_3, reverse triiodothyronine (inactive); T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone or thyrotropin.

T_3 is four times more potent than T_4, the major circulating hormone secreted by the thyroid. About 80% of the total daily T_3 production results from the peripheral deiodination of T_4 to T_3. Approximately 35% to 40% of secreted T_4 is converted peripherally to T_3; another 45% of secreted T_4 undergoes peripheral conversion to inactive reverse T_3 (rT_3). Certain drugs and diseases can modify the conversion rate of T_4 to T_3 and reduce the serum T_3 levels (**Table 52-1**[3,4]; see Case 52-1, Question 2).

Table 52-1

Factors That Can Significantly Alter Thyroid Function Tests in Patients Who Are Euthyroid

Factors	Drugs/Situations
Elevated TBG Binding Capacity	
Elevated TT_4	Estrogens,[3,4] tamoxifen,[71] raloxifene[70]
Elevated TT_3	Oral contraceptives[23]
Normal TSH	Heroin[69]
Normal FT_4I, FT_4	Methadone maintenance[69]
Normal FT_3I, FT_3	Genetic elevation in TBG
	Clofibrate
	Active hepatitis[47,48]
Decreased TBG Binding Capacity/Displacement T4 From Binding Sites	
Decreased TT_4	Androgens[23]
Decreased TT_3	Salicylates,[23,61,62] salsalate[62]
Normal TSH	High-dose furosemide
Normal FT_4I, FT_4	Decreased TBG synthesis-cirrhosis/hepatic failure
Normal FT_3I, FT_3	Nephrotic syndrome[23,47,48]
	Danazol[23,47,48]
	Glucocorticoids[23,47,48,73]
Decreased Peripheral T4 → T3 Conversion	

Factors	Drugs/Situations
Decreased TT_3	PTU
Normal TT_4	Propranolol[193]
Normal FT_4I, FT_4	Glucocorticoids[23,73,280]
Normal TSH	
Decreased Pituitary and Peripheral T4 → T3	
Decreased TT_3	Iodinated contrast media (eg, ipodate)[281-285]
Elevated TT_4	Amiodarone[5,14,19]
Elevated TSH (transient)	Nonthyroidal illness[53,55,286]
Elevated FT_4I	
Elevated T4 Clearance by Enzyme Induction/Elevated Fecal Loss[a]	
Decreased TT_4	Phenytoin[63,64]
Decreased FT_4I	Phenobarbital[63]
Normal or Decreased FT_4	Carbamazepine[63–68]
Normal or Decreased TT_3	Cholestyramine, colestipol[105]
Normal or elevated TSH	Rifampin[63]
	Bexarotene[22]
Decreased TSH Secretion	
	Dopamine,[23,47,48] dobutamine[287]
	Levodopa,[23] cabergoline[288]
	Glucocorticoids[23,49,73]
	Bromocriptine,[23] Pramipexole,[72,73] Ropinirole[72,73]
	Octreotide[50]
	Metformin[74,75]
	Bexarotene[12]
Elevated TSH Secretion	
	Metoclopramide[23,47]
	Domperidone[23,47]

FT_3, free triiodothyronine; FT_3I, free triiodothyronine index; FT_4, free thyroxine; FT_4I, free thyroxine index; PTU, propylthiouracil; T_3, triiodothyronine; T_4, thyroxine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine.

[a]Can also cause hypothyroidism in patients receiving L-thyroxine therapy.

T_4 exists in the circulation as 0.1% free (active) and 99.9% protein-bound (inactive), primarily to thyroxine-binding globulin (TBG) with a long half-life ($t_{1/2}$) of 7 days. T_3 is bound to plasma proteins (99.8%), with about 0.2% free and has a threefold greater metabolic potency and a shorter $t_{1/2}$ of 1.5 days.[2]

Hypothyroidism is a clinical syndrome that results from a deficiency of thyroid hormone. The prevalence of hypothyroidism is 1.4% to 2% in females and 0.1% to 0.2% in males and is increased to 6% of females and 2.5% of males in persons older than 60 years.[1] Hypothyroidism can be caused by either primary (thyroid gland) or, less commonly, by secondary (hypothalamic–pituitary) malfunction.

Hashimoto thyroiditis, an autoimmune disorder, is the most common cause of primary hypothyroidism and appears to have a strong genetic predisposition. The pathogenesis of Hashimoto thyroiditis results from an impaired immune surveillance, causing dysfunction of normal suppressor T lymphocytes and excessive production of thyroid antibodies by plasma cells (differentiated B lymphocytes). The destruction of thyroid cells by circulating thyroid antibodies produces an underlying defect or block in the intrathyroidal, organobinding of iodide. The typical presentation is hypothyroidism and goiter (thyroid gland enlargement), but patients can present with hypothyroidism and no goiter, with euthyroidism and goiter, or rarely (<5%) with hyperthyroidism (hashitoxicosis).

Other common causes of hypothyroidism, including drug-induced, are presented in **Table 52-2**.[5–27]

Table 52-2
Causes of Hypothyroidism

Primary Hypothyroidism (Dysfunction of the Gland)[136,289,290]

Autoimmune thyroiditis (Hashimoto thyroiditis)
Idiopathic atrophy
Iatrogenic destruction of thyroid (surgery, radioactive iodine therapy, x-ray therapy)
Iodine deficiency
Dyshormonogenesis: defect in hormone synthesis, transport, or action
Thyroiditis (subacute, postpartum, silent, destructive)
Congenital hypothyroidism (thyroid aplasia/hypoplasia, defective hormone synthesis)
Secondary Hypothyroidism[134,289,290]
Deficiency of TSH because of pituitary dysfunction (Sheehan syndrome)
Deficiency of TRH because of hypothalamic dysfunction
Drug-Induced
Aminoglutethimide[23]
Amiodarone[5,14,19]
Bexarotene[12,22]
Ethionamide[20]
Iodides and iodide-containing preparations[18]
Rifampin[24]
Tyrosine kinase inhibitors (eg, imatinib, sunitinib, sorafenib)[10,11,16,21]
Interleukin[13,25]
Interferon-α [8,9,17,26]
Lithium[6,7,15]
Thiocyanates, phenylbutazone, sulfonylureas[23]

TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

The clinical presentation, physical findings, and laboratory abnormalities of overt hypothyroidism are summarized in **Table 52-3**. Myxedema coma is a rarely occurring, often fatal medical emergency resulting from long-standing, uncorrected hypothyroidism (see Case 52-9). Patients with myxedema coma can present with hypothermia, confusion, coma, carbon dioxide retention, hypoglycemia, hyponatremia, and ileus. Hypothyroid symptoms increase with the severity of the hypothyroidism, except in older patients who often present with minimal or atypical symptoms. Patients with subclinical hypothyroidism might have few or no symptoms. Laboratory findings that are diagnostic for overt hypothyroidism include elevated TSH and low free thyroxine (FT_4) levels; for subclinical or early hypothyroidism, the findings are an elevated TSH and normal FT_4 levels. Despite the prevalence of asymptomatic subclinical disease, there is no universally agreed upon strategy for screening for thyroid disorders. Recommendations range from screening all adults over age 35 every 5 years (American Thyroid Association) to insufficient evidence for or against screening any specific population of patients (U.S. Preventive Task Force).[28–30]

Table 52-3

Clinical and Laboratory Findings of Primary Hypothyroidism

Symptoms	Physical Findings	Laboratory
General: weakness, tiredness, lethargy, fatigue	Thin and brittle nails	Decreased TT_4
Cold intolerance	Thinning of skin	Decreased FT_4I
Headache	Pallor	Decreased FT_4
Loss of taste/smell	Puffiness of face, eyelids	Decreased TT_3
Deafness	Yellowing of skin	Decreased FT_3I
Hoarseness	Thinning of outer eyebrows	Elevated TSH

Symptoms	Physical Findings	Laboratory
No sweating	Thickening of tongue	Positive antibodies (in Hashimoto)
Modest weight gain	Peripheral edema	Elevated cholesterol
Elevated cholesterol Muscle cramps, aches, pains	Pleural/peritoneal/pericardial effusions	Elevated CPK
Dyspnea	Decreased DTRs	Decreased Na
Slow speech	“Myxedema heart”	Elevated LDH
Constipation	Bradycardia (Decreased HR)	Elevated AST
Menorrhagia	Hypertension	Decreased Hct/Hgb
Galactorrhea	Goiter (primary hypothyroidism)	

AST, aspartate aminotransferase; CPK, creatinine phosphokinase; DTRs, deep tendon reflexes; Hct, hematocrit; Hgb, hemoglobin; HR, heart rate; LDH, lactate dehydrogenase; FT_3I, free triiodothyronine index; FT_4, free thyroxine; FT_4I, free thyroxine index; Na, sodium; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine.

L-Thyroxine, at an oral replacement dosage of 1.6 µg/kg/day administered on an empty stomach, is the preferred thyroid replacement preparation.[31,32] Several brand name and less costly generic preparations are interchangeable in most patients. Older patients, those with severe hypothyroidism, and those with cardiac

disease may require minute T_4 doses initially to avoid cardiac toxicity (**Table 52-4**); complete reversal of hypothyroidism might not be indicated or possible. In myxedema coma (see Case 52-9, Question 2), an intravenous (IV) L-thyroxine loading dose is necessary to reduce the high mortality rate. In subclinical hypothyroidism (see Case 52-11), T_4 replacement therapy is beneficial in those with TSH >10 milli-international units (IU)/mL (normal, 0.40–4.5 μIU/).

Table 52-4
Treatment of Hypothyroidism

Patient Type/Complications	Dose (L-Thyroxine)	Comment
Uncomplicated adult	1.6 μg/kg/day; 100–125 μg/day average replacement dose; usual increment 25 μg q6–8 wk	*Onset of action:* 2–3 weeks; *max effect:* 4–6 weeks. Reversal of skin and hair changes may take several months. An FT_4 and TSH should be checked 6–8 weeks after initiation of therapy because T_4 has a half-life of 7 days, and three to four half-lives are needed to achieve steady state. Levels obtained before steady state can be very misleading. Because 80% is bioavailable, adjust IV doses downward. Small changes can be made by varying dose schedule (eg, 150 μg daily except Sunday).
Elderly	50 μg/day	Initiate T_4 cautiously. Elderly may require less than younger patients. Sensitive to small dose changes. Patients older than 60 years may require ≤50 μg/day.
Cardiovascular disease (angina, CAD)	Start with 12.5–25 μg/day. Elevated by 12.5–25 μg/day q2–6 wk as tolerated	These patients are very sensitive to cardiovascular effects of T_4. Even subtherapeutic doses can precipitate severe angina, MI, or death. Replace thyroid deficit slowly, cautiously, and sometimes even suboptimally.

Patient Type/Complications	Dose (L-Thyroxine)	Comment
Long-standing hypothyroidism (>1 year)	Dose slowly. Start with 25 μg/day; elevated by 25 μg/day q4–6 wk as tolerated	Sensitive to cardiovascular effects of T_4. Steady state may be delayed because of Decreased clearance of T_4.[a] Correct replacement dose is a compromise between prevention of myxedema and avoidance of cardiac toxicity.
Pregnancy	Most will require 45% elevation in dose to ensure euthyroidism	Evaluate TSH, TT_4, and FT_4I. *Goal:* Normal TSH and TT_4/FT_4I in upper normal range to prevent fetal hypothyroidism. TSH should be no higher than 2.5 μIU/mL during the first trimester and 3.0 μIU/mL in the second and third trimesters.
Pediatric (0–3 months)	10–15 μg/kg/day	Hypothyroid infants can exhibit skin mottling, lethargy, hoarseness, poor feeding, delayed development, constipation, large tongue, neonatal jaundice, piglike facies, choking, respiratory difficulties, and delayed skeletal maturation (epiphyseal dysgenesis). The serum T_4 should be increased rapidly to minimize impaired cognitive function. In the healthy term infant, 37.5–50 μg/day of T_4 is appropriate. Dose decreases with age (Table 52-9).

CAD, coronary artery disease; FT_4, free thyroxine; FT_4I, free thyroxine index; IV, intravenous; MI, myocardial infarction; q, every; T_4, thyroxine; TSH, thyroid-stimulating hormone; TT_4, total thyroxine.

[a]In patients with severe myxedema, steady state may require ≥6 months. In patients who are clinically euthyroid but have Elevated TT_4 and FTI, use TT_3 and TSH as guide to dose adjustments.

The goal of therapy is to reverse the signs and symptoms of hypothyroidism and normalize the TSH and FT_4 levels without causing iatrogenic thyrotoxicosis.[32] Some improvement of hypothyroid symptoms is often evident within 2 to 3 weeks of starting T_4 therapy, before steady state is reached. Overreplacement of T_4 (ie, suppressed serum concentrations of TSH) is associated with osteoporosis and cardiac toxicity. The optimal T_4 replacement dosage must be administered for ~6 to 8 weeks to achieve steady-state levels. The list of medications that interfere with T_4 absorption is extensive (eg, iron, aluminum-containing products, some calcium preparations, cholesterol resin, phosphate binders, sucralfate, and bile acid sequestrants).[32] These agents should be separated by at least 4 hours from concomitant T_4 administration.[32]

Hyperthyroidism or thyrotoxicosis is the hypermetabolic syndrome that occurs from excessive thyroid hormone production. Hyperthyroidism affects about 1.3% of the U.S. population (0.5% clinical disease and 0.7% subclinical hyperthyroidism).[1] The condition is more prevalent in females and White patients and increases with age.[1]

The classic symptoms of hyperthyroidism are summarized in **Table 52-5**. The typical symptoms are often absent in the older patient, producing a masked or “apathetic” picture. Because of the atypical presentation in the older patient, occult hyperthyroidism always must be considered, especially in patients with new or worsening cardiac findings (eg, atrial fibrillation). Untreated hyperthyroidism can progress to thyroid storm, a life-threatening form of hyperthyroidism characterized by exaggerated symptoms of thyrotoxicosis and the acute onset of high fever. The diagnosis of

hyperthyroidism is confirmed by high serum concentrations of FT_4 and free T_3 (FT_3) or an undetectable TSH level. Positive thyroid antibodies confirm an autoimmune origin for the hyperthyroidism (eg, Graves disease).[33]

Table 52-5
Clinical and Laboratory Findings of Hyperthyroidism

Symptoms
Heat intolerance
Weight loss common, or weight gain caused by Elevated appetite
Palpitations
Pedal edema
Diarrhea/frequent bowel movements
Amenorrhea/light menses
Tremor
Weakness, fatigue
Nervousness, irritability, insomnia
Physical Findings
Hair loss
Proptosis, lid lag, lid retraction, stare, chemosis, conjunctivitis, periorbital edema, loss of extraocular movements
Diffusely enlarged goiter, bruits, thrills
Wide pulse pressure
Pretibial myxedema
Plummer nails[a]
Flushed, moist skin
Palmar erythema
Brisk DTRs
Laboratory Findings
Elevated TT_4
Elevated TT_3

Elevated FT_4I/FT_4
Elevated FT_3I/FT_3
Suppressed TSH
TSI present
TgAb present
TPOAb present
RAIU >50%
Decreased cholesterol
Elevated alkaline phosphatase
Elevated calcium
Elevated AST

AST, aspartate aminotransferase; DTRs, deep tendon reflexes; FT_3, free triiodothyronine; FT_3I, free triiodothyronine index; FT_4, free thyroxine; FT_4I, free thyroxine index; RAIU, radioactive iodine uptake; TgAb, thyroglobulin autoantibodies; TPOAb, thyroid peroxidase antibody; TSI, thyroid-stimulating immunoglobulin; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine.

[a]The fingernail separates from its matrix, but only one or two nails are generally affected.

Graves disease, an autoimmune disease, is the most common cause of hyperthyroidism. Characteristics include diffuse goiter, ophthalmopathy (exophthalmos), dermopathy (pretibial myxedema), and acropachy (thickening of fingers or toes). The production of excessive thyroid hormone is attributed to a circulating immunoglobulin G or thyroid receptor antibody (TRAb), which has a

TSH-like ability to stimulate hormone synthesis. The abnormal production of TRAb differentiated B lymphocytes results from a deficiency of suppressor T-cell lymphocytes. Other causes of hyperthyroidism, including iatrogenic, are outlined in **Table 52-6**.[5,13,14,17,19,23,26,34–38]

Table 52-6

Causes of Hyperthyroidism

Graves disease (toxic diffuse goiter); may be caused by polymorphisms in the TSH receptor
Toxic uninodular goiter (Plummer disease)
Toxic multinodular goiter
Nodular goiter with hyperthyroidism caused by exogenous iodine (Jod-Basedow)
Iatrogenic thyrotoxicosis (prescription of excessive thyroid hormone dosage)
Factitious hyperthyroidism (exogenous thyroid excess through self-administration)
Tumors (thyroid adenoma, follicular carcinoma, thyrotropin-secreting tumor of the pituitary, and hydatidiform mole with secretion of a thyroid-stimulating substance)
Drug-induced (iodides,[37] amiodarone,[5,14,19] interleukin,[13,23] interferon-α,[17,26] lithium[34,35])

Hyperthyroidism: diagnosis and treatment. *Am Fam Physician*. 2016;93(*5*):363–370.

Both Graves disease and Hashimoto thyroiditis share similar clinical features and can exist in the same gland: positive antibody titers, goiter with lymphocytic infiltration of the gland, familial

tendency, and predilection for females. Thyrotoxicosis can precede the onset of Hashimoto hypothyroidism, and the end result of Graves hyperthyroidism is often hypothyroidism.[39]

Effective treatment options for hyperthyroidism include thioamide antithyroid drugs (ATDs), radioiodine, and surgery. Therapy selection is influenced by the etiology of the hyperthyroidism, size of the goiter, presence of eye complications (ophthalmopathy), coexisting conditions (eg, angina, pregnancy), patient age, patient preference, and physician preference. Radioactive iodine (RAI) is preferred in older patients, those with coexisting cardiac disease, ophthalmopathy, and a toxic multinodular goiter, whereas surgery is appropriate if obstructive symptoms are present or concomitant malignancy is suspected. Pregnant patients can be managed with ATDs or surgery in the second trimester; RAI is absolutely contraindicated.[40,41]

The ATDs (eg, methimazole, propylthiouracil) primarily prevent hormone synthesis but do not affect existing stores of thyroid hormone. Therefore, hyperthyroid symptoms will continue for 4 to 6 weeks after beginning ATD therapy and initial treatment with β-blockers or iodides is often required for symptomatic relief. Methimazole (MMI), given once daily, is considered the ATD of choice versus propylthiouracil (PTU), which requires two to three times daily dosing and has been associated with severe and fatal hepatitis. PTU should be reserved for use during pregnancy, in thyroid storm, and in those experiencing adverse reactions to methimazole (other than agranulocytosis or hepatitis). The onset of action of PTU is more rapid than MMI in thyroid storm because PTU can also inhibit the peripheral conversion of T_4 to T_3. PTU is also preferred during the first trimester of pregnancy because congenital defects have been reported with MMI. Although both drugs are secreted in breast milk, no adverse effects have been reported in the exposed infants. The duration of treatment is empiric, and ATDs typically are prescribed for 12 to 18 months in hopes of long-term spontaneous remission once the drug is discontinued.[42] Although ATDs maintain euthyroidism, they do not change the natural course

of the disease and the likelihood of spontaneous remission once treatment is discontinued is about 60%. Major adverse effects from ATDs include skin rash, gastrointestinal (GI) symptoms (eg, nausea, upset stomach, and metallic taste), agranulocytosis, and hepatitis. Cross-sensitivity between the ATDs is not complete, and the alternative drug can be used if rash or GI symptoms do not resolve. This is not true for agranulocytosis and hepatitis where the alternative agent is not recommended.[43]

Nodular goiters, both multinodular and uninodular, are common thyroid problems that occur in 4% to 5% of the adult population. The nodular goiter is usually found on routine physical examination in patients who are asymptomatic and euthyroid. A *cold nodule* is a "hypofunctioning" area of the thyroid that fails to collect radioiodine. *Hot nodule* is a term used to describe a "hyperfunctioning" or iodine-concentrating area of the thyroid. The hyperfunctioning autonomous nodule typically suppresses activity in the remainder of the gland, but it need not produce clinical or chemical evidence of hyperthyroidism and may remain unchanged for years. Some nodules may develop into toxic goiters, causing overt symptoms of toxicosis. Most hot nodules are benign; malignancies are rarely reported.[44,45] Treatment options include surgery, RAI, or thyroid replacement therapy if hypothyroid. All goitrogens should be removed if possible. L-Thyroxine suppression therapy is no longer recommended because the dangers from supraphysiologic dosages of T_4 (eg, osteoporosis and the potential for cardiac arrhythmias) outweigh the benefits. Nontoxic multinodular goiter is a common finding in about 5% of the population.[44,45] In low-risk patients, long-standing asymptomatic nodules that have not exhibited recent growth are likely to be benign and can be followed or excised surgically for cosmetic reasons. If the patient develops symptoms (swallowing or respiratory difficulty), surgery is the treatment of choice. Observation with close follow-up is the preferred treatment option for most benign multinodular goiters.[44,45]

Malignancy must be considered if there is recent growth in a "cold" single or dominant nodule, a firm nodule clinically suspicious for

cancer on a physical examination, a history of thyroid irradiation, or a strong family history of medullary thyroid carcinoma. Most cold nodules turn out to be benign adenomas rather than cancers. The incidence of malignancy in a cold nodule varies between 10% and 20%.[44] A fine-needle aspiration (FNA) of the thyroid nodule can document an underlying malignancy. Surgery is indicated if malignancy is suspected or if any obstructive or respiratory symptoms are present. After a total thyroidectomy for thyroid cancer, RAI ablation is usually given to remove any remaining thyroid tissue. A yearly evaluation for detection of recurrence of some thyroid cancers requires the patient to be off T_4 for 4 to 6 weeks so that a repeat radioactive uptake and scan can be completed. An elevated TSH level is also necessary to allow thyroglobulin levels, a tumor marker, to rise if any malignant tissue is present.[44,46]

THYROID TESTS

The principal laboratory tests recommended in the initial evaluation of thyroid disorders are the TSH and the FT_4 levels.[47,48] Testing for thyroid disorders, whether it be for diagnosis in symptomatic patients or screening at risk populations, should begin with assessment of TSH. Where TSH is abnormal, assessment of free T_4 should occur to confirm the presence of clinical or subclinical disease.[28] Other tests are available to further evaluate function of the thyroid gland as well as thyroid disease etiology. The presence of thyroid antibodies indicates an autoimmune thyroid etiology. Adjuncts to the previous tests include the total T_3 (TT_3), free T_3 (FT_3) or FT_3 index (FT_3I), and TRAb (**Table 52-7**).[49] The relationship between laboratory tests and thyroid disorders is summarized in **Figure 52-2**.

Table 52-7
Common Thyroid Function Tests

Tests	Measures	Normal[a]	Assay Interference	Comments
Hypothalamlc–Pituitary–Thyroid Axis				
TSH	Pituttary TSH leve!	0.40–4.5 ¡IU/mL	Dopamlne, glucocorticoids, metoclopramide, thyroid hormone, amlodarone, metformln (Table 52-1), biotin	Most sensitive index for hyperthyroidism, hypothyroidism, and replacement therapy
Circulating Hormone Levels				
FT_4	Direct measurement of ftee thyroxine	0.8–1.8 ng/dL (10–23 pmol/L)	No interference by alterations in TBG, biotin may Interfere with assay	Most accurate determination of FT_4 levels: might be higher than normal in patients on thyroxine replacement
TjRU (THBR)	Measures the uptake of Tj by TBG	22K,–35%	Biotin	Indirect and redprocal estimate of the available binding sites on TBG
FT_4I	Calculated free thyroxine index $TT_4 \times$ TjRU	1.4–3.8	Nonthyroidal Illness (see Case 52-1, Question 2)	Estimates direct FT_4 measurement; compensates for alterations in TBG
TT_4	Total free and bound T_4	4 8–10 4 µg/dL (62–134 nmol/L)	Alterations in TBG (Table 52-1), biotin	Speclflc and sensitive test if no alterations in TBG
TTj	Total free and bound T_3	76–181 ng/dL (1.2–2.8nmol/L)	Alterations in TBG levels, T_4, to T_3 (Table 52-1). Nonthyroidal illness (see Case 52-1, Question 2), biotin	Useful in detecting early, relapsing, and Tj toxlcosis: not useful In evaluation of hypothyroidism
FT_3	Direct measurement of free T_3	2.3–4 2 pg/mL (S.5–6.5 pmol/L)	No interference by alterations in TBG, biotin may interfere with assay	Most accurate determination of FT_3 levels: might be lower than normal in patients on thyroxine replacement
FT_3I	Calculated free T_3 index	80–180	Nonthyroidal Illness (see Case 52-1, Question 2)	Estimates direct FT_3 measurement: compensates for alterations in TBG
Autoimmunity				
TgAb	Thyroglobulin autoantibodies	<1 IU/mL	Nonthyroidal autoimmune disorders	Present in autoimmune thyroid disease: undetectable during remission
TPOAb	Thyroid peroxidase antibodies	<9 IU/mL	Nonthyroidal autoimmune disorders	More sensitive of the two antibodies, titers detectable even after remission
TSI	Thyroid-stimulating antibody	<140%		Confirms Graves disease: deteets risk of neonatal Graves
TRAb	Thyroid receptor antibody	<2.0 IU/L		Confirms Graves disease: deteets risk of neonatal Graves

FT_3, free triiodothyronine; FT_3I, free triiodothyronine index; FT_4, free thyroxine; FT_4I, free thyroxine index; T_3, triiodothyronine; T_4, thyroxine; TBG, thyroxine-binding globulin; TgAb, thyroglobulin autoantibodies; TPOAb, thyroid peroxidase antibodies; TSI, thyroid receptor–stimulating or thyroid-stimulating antibodies; TRAb, thyroid receptor antibody; TSH, thyroid-stimulating hormone; TT_3, total triiodothyronine; TT_4, total thyroxine; T_3RU, triiodothyronine resin uptake; THBR, thyroid hormone–binding ratio.

Figure 52-2 Evaluation of thyroid function tests. FT_3, free triiodothyronine; FT_4, free thyroxine; FT_4I, free thyroxine index; TSH,

thyrotropin; TT_3, total triiodothyronine; TT_4, total thyroxine.

Hypothalamic–Pituitary–Thyroid Axis

THYROID-STIMULATING HORMONE

The serum TSH, also known as thyrotropin, is the most sensitive test to evaluate thyroid function.[47,48,50] TSH, secreted by the pituitary, is elevated in early or subclinical hypothyroidism (when thyroid hormone levels appear normal) and when thyroid hormone replacement therapy is inadequate. TSH can be abnormal even if the FT_4 remains within the normal range because the TSH is specific for each person's physiologic set point. Polymorphisms in the TSH receptor contribute to this interindividual variability.[36] Consequently, low-normal free hormone levels can stimulate the pituitary to synthesize increased amounts of TSH. TSH cannot differentiate between primary hypothyroidism (thyroid failure), which is characterized by elevated TSH levels and secondary (pituitary or hypothalamus failure) hypothyroidism where TSH levels may be low or normal. The TSH assay can quantitate the upper and lower limits of normal so that a suppressed TSH level is highly suggestive of hyperthyroidism or exogenous thyroid overreplacement. Of note, TSH is not entirely specific for thyroid disease because abnormal levels are observed in patients who are euthyroid with nonthyroidal illnesses and in patients receiving drugs that can interfere with TSH secretion (see Table 52-1). TSH secretion is increased at bedtime and is affected by lack of sleep and exercise.[51] TSH secretion is suppressed physiologically by dopamine that antagonizes the stimulatory effects of TRH. Therefore, both dopaminergic agonists and antagonists can alter TSH secretion (see Case 52-4). Whether the upper limits of normal for TSH should be lowered to 2.5 μIU/mL is controversial.[36,48,51]

Free and Total Serum Hormone Levels

FREE THYROXINE, FREE THYROXINE INDEX, FREE TRIIODOTHYRONINE, AND FREE TRIIODOTHYRONINE INDEX

The free thyroxine (FT_4) and free triiodothyronine (FT_3) are the most reliable tests for the evaluation of hormone concentrations, especially when thyroid hormone–binding abnormalities exist.[28,33] The FT_3 is most useful in hyperthyroidism but can be normal or low in hypothyroidism. If a direct measure of the free hormone levels is not available, the estimated free hormone indices (FT_4I, FT_3I) can provide comparable information. However, these indices do not correct for changes observed in patients with "euthyroid sick" nonthyroidal illnesses in whom TBG binding affinity is altered. In these circumstances, the FT_4 and FT_3 are preferable.[28,33]

TOTAL THYROXINE AND TOTAL TRIIODOTHYRONINE

The total thyroxine (TT_4) and total triiodothyronine (TT_3) measure both free and bound (total) serum T_4 and T_3. Because the bound fraction is the major fraction measured, situations that change the hormone's affinity for TBG or the TBG level will influence the results. For example, falsely elevated levels of TT_4 and TT_3 are common in the euthyroid pregnant female (see Case 52-3). In addition, the TT_3 is often low in older patients and in many acute and chronic nonthyroidal illnesses because the peripheral conversion of T_4 to T_3 is decreased (see Case 52-1, Question 2, and Case 52-2). Therefore, careful interpretation of these tests is necessary in situations that alter thyroid hormone binding, TBG levels, or T_4 to T_3 conversion (Table 52-1). The TT_3 (and FT_3) is particularly helpful in detecting early relapse of Graves disease and in confirming the diagnosis of hyperthyroidism despite normal TT_4 levels. Conversely, TT_3 and FT_3 are not good indicators of hypothyroidism because T_3 levels can be normal. Measurement of only the total hormone levels is less reliable than either the free or estimated free hormone levels when alterations in thyroid-binding globulin or nonthyroidal illnesses exist.[28,33]

Thyroid Gland Function

RADIOACTIVE IODINE UPTAKE

The radioactive iodine uptake (RAIU), a measure of iodine utilization by the gland, is an indirect measure of hormone synthesis. It is elevated in hyperthyroidism and in early hypothyroidism when the failing gland is trying to increase hormone synthesis. A low or undetectable RAIU occurs in hypothyroidism, thyrotoxicosis factitia, and subacute thyroiditis. Typically, RAIU is used to calculate the dose of RAI therapy for treatment of Graves disease and to determine the activity of one or several nodules in a gland. The RAIU is not necessary to diagnose classic Graves disease or hypothyroidism.[30,31,48]

A tracer dose of iodine-123 (^{123}I) is administered, and the radioactivity of the gland is measured at 5 and 24 hours after ingestion. It is necessary to measure both the 5- and 24-hour RAIU so that patients with rapid turnover of iodine will not be missed. In some patients who are hyperthyroid, the 5-hour uptake is elevated, but the 24-hour uptake can fall to normal or subnormal levels. The normal range of the RAIU (Table 52-7) is affected by any condition that alters iodine intake. Iodine depletion caused by rigorous diuretic therapy or an iodine-deficient diet increases uptake because of replenishment of depleted total iodide pools. Conversely, dilution of ^{123}I with exogenous iodide sources (eg, contrast dyes) decreases RAIU.[52]

IMAGING STUDIES

Thyroid scan

A scan of the gland is performed simultaneously with the RAIU or after ingestion of technetium (^{99m}Tc) pertechnetate. The scan provides information concerning gland size and shape and identifies hypermetabolic (“hot”) and hypometabolic (“cold”) areas. The possibility of carcinoma must be considered if cold areas are present. A scan is often obtained in the evaluation of a patient with nodular thyroid disease.[30,31,42]

Thyroid ultrasound

A thyroid ultrasound can provide information about gland size and number of clinically palpable or nonpalpable nodules or cysts in the thyroid gland.[31]

Autoimmunity

THYROID PEROXIDASE AND ANTITHYROGLOBULIN ANTIBODIES

Thyroid peroxidase antibodies (TPOAb) and thyroglobulin autoantibodies (TgAb) to the thyroid gland indicate an autoimmune process.[47,48] About 50% to 90% of patients with Graves disease and nearly 100% of patients with Hashimoto thyroiditis have positive antibodies to both thyroid antigens.[48] Positive antibodies alone do not indicate thyroid disease because 5% to 10% of asymptomatic patients, as well as patients with other nonthyroidal autoimmune disorders, have positive antibodies.[48]

Clinically, the TPOAb is more specific than TgAb in assessing disease activity. Although both antibodies are elevated during acute flares of the disease, lower titers of TPOAb remain positive during quiescent periods of the disease, while TgAb levels revert to negative.[47,48]

THYROID RECEPTOR–STIMULATING ANTIBODIES OR THYROID-STIMULATING IMMUNOGLOBULIN

Thyroid receptor–stimulating antibodies (TRAb) or thyroid-stimulating immunoglobulin (TSI) are IgG immunoglobulins that are present in virtually all patients with Graves disease.[47,48] Like TSH, these immunoglobulins can stimulate the thyroid gland to produce thyroid hormones. In addition to aiding in the diagnosis of hyperthyroidism, TRAb titers are useful in predicting remission when discontinuing antithyroid drugs.[48] High titers of TSI are useful in diagnosing otherwise asymptomatic Graves disease (ie, ophthalmopathy), in predicting the risk of relapse of Graves disease after discontinuing medication, and in predicting the risk of neonatal hyperthyroidism in

utero through transplacental passage of TSI from the pregnant mother.[30,33] Otherwise, TSI measurement is expensive and offers no additional information in the patient with a typical Graves disease presentation.

Clinical Application and Interpretation

EUTHYROIDISM AND NONTHYROIDAL ILLNESS SYNDROME

CASE 52-1

QUESTION 1: R.K., an obese 42-year-old female, is admitted to the hospital because of increasing fatigue, sluggishness, shortness of breath (SOB), and pitting edema of the legs during the past 3 weeks. Bilateral pleural effusions found on her chest radiograph indicate a worsening of her heart failure with reduced ejection fraction (HFrEF). Her other medical problems include cirrhosis of the liver, type 2 diabetes, and chronic bronchitis, for which she takes glipizide 10 mg every day and an iodine-containing herbal supplement three times a day (tid).

Pertinent physical findings include a palpable but normal-size thyroid, bibasilar rales, cardiomegaly, hepatomegaly, 4+ pitting edema, and normal deep tendon reflexes (DTRs). A diagnosis of worsening HFrEF secondary to hypothyroidism is suspected based on the following laboratory findings:

Cholesterol, 385 mg/dL
RAIU at 24 hours, 13% (normal, 5–35*)
Scan, normal-size gland with homogenous uptake
TT_4, 1.4 µg/dL (normal, 4.8–10.4)
TT_3, 22 ng/dL (normal, 62–134)
TSH, 4 µIU/mL (normal, 0.40–4.5 µIU/mL)
FT_4, 1.0 ng/dL (normal, 0.8–1.8)
TPOAb, 3 IU/mL (normal, <9)
TgAb, 0.3 IU/mL (normal, <1)

Based on her clinical and laboratory findings, what is R.K.'s thyroid status?

*Please note that the normal values used in this chapter are those reported by Quest Diagnostics. Normal values at other locations may differ based on assay method used.

Although low-output failure can be a presenting sign of hypothyroidism, the normal TSH and FT_4 indicates that R.K. is euthyroid, despite the confusing results of her other thyroid function tests. The depressed RAIU is consistent with her history of iodide ingestion and dilution of the ^{131}I. The low TT_4 and TT_3 may be explained by her cirrhosis and nonthyroidal illness syndrome (see Case 52-1, Question 1). The negative thyroid antibodies, the normal scan, and normal DTRs further substantiate the diagnosis of euthyroidism.

Case 52-1, Question 2: What is the significance of R.K.'s TT_4, FT_4I, and TT_3 values?

R.K.'s thyroid function test results are consistent with the nonthyroidal illness syndrome. Abnormal thyroid function tests are commonly found in patients who are euthyroid with various serious systemic diseases including starvation, infections, sepsis, acute psychiatric disorders, human immunodeficiency virus (HIV) infection, myocardial infarction (MI), bone marrow transplantation, and severe chronic cardiac, pulmonary, renal, hepatic, and neoplastic diseases.[23,47,48,53–58]

This "euthyroid sick" syndrome occurs in around 45% of chronically ill or hospitalized patients and must be recognized. In general, the more sick the patient, the greater the degree of abnormal thyroid function findings, even though the patient has no thyroid disease.[55]

The most common finding is a low TT_3 (eg, 15–20 ng/dL) and high inactive reverse T_3 levels (rT_3). Other typical changes include a normal or low TT_4 and a suppressed or normal TSH level. A borderline high TSH may occur as patients recover from nonthyroidal illness.[59] In more serious illness, the TT_4, FT_4I, and FT_3 are often low. Free hormone levels (eg, FT_4, FT_3) are often normal or slightly low. However, these inconsistent findings fuel the controversy over whether thyroid hormone therapy is beneficial or detrimental. These

findings are believed to be explained by a central hypothyroidism caused by reduction in hypothalamic TRH because of increased hypothalamic T_3, increased peripheral metabolism of T_3, or by a reduction in serum thyroid hormone–binding proteins.[54] Impaired protein synthesis of thyroid-binding prealbumin (TBPA) and an increase in the proportion of a lower-binding-capacity form of TBG might account for the lower bound hormone levels, but the concomitant increase in the free hormone concentrations would maintain a euthyroid state. Furthermore, circulating substances that inhibit the binding of T_4 and T_3 to the serum-binding proteins might also be present.

Less common changes include a modestly elevated TT_4 and FT_4I in patients with acute viral hepatitis, psychiatric disorders, renal failure, and advanced HIV infection. The TT_3 is usually normal but can be low in critically ill patients. Modest elevations in hormonal binding affinity and increased synthesis of TBG explain these findings.[54]

Several studies have shown a strong inverse correlation between mortality and total serum T_4, T_3, and rT_3 levels.[55–57] Of 86 hospitalized, intensive care patients, 84% of those with a serum T_4 of <3 μg/dL died, whereas 85% of those with a serum T_4 of >5 μg/dL survived.[56] In 331 patients with acute MI, rT_3 levels >0.41 nmol/L were significantly associated with a greater risk of death at 1 year.[57] During recovery, TSH levels increase and hormone levels start to normalize. Therefore, a favorable outcome is associated with reversal of the hormone indices.

Thyroid experts are divided about whether nonthyroidal illness should be treated, and few randomized studies are available to guide therapeutic decisions.[53–58] The few available studies found no survival benefits or favorable clinical outcomes from hormone therapy, although cardiac hemodynamics improved. The benefits of hormone replacement are unproven and might be detrimental. In one trial, the mortality of patients with acute renal failure treated with T_4 was 43% versus 13% in the control group.[58] Other small trials have

shown thyroid hormones to be well-tolerated and safe.[60] Opponents argue that T_4 therapy, by inhibiting TSH, may interfere with normal thyroid recovery and is preferentially converted to inactive rT3.[59,60] Conversely, proponents argue that there may be cardiovascular benefits and there is no clear evidence that therapy is toxic.[59]

In summary, T_4 and T_3 measurements are not helpful in the diagnosis of thyroid dysfunction in patients with significant nonthyroidal illness. A normal or near-normal TSH is necessary to establish euthyroidism in sick patients with nonthyroidal illness. The available data are not supportive of starting thyroid hormone treatment. The abnormal laboratory findings should reverse with correction of R.K.'s nonthyroidal illness. To confirm euthyroidism, the slightly elevated TSH should be repeated once R.K.'s medical condition improves.[54]

Drug Interference With Thyroid Hormone Concentrations

CASE 52-2

Question 1: J.R., a 45-year-old male, describes symptoms of fatigue, dry skin, and constipation. His other medical problems include alcoholism for 10 years, cirrhosis, generalized tonic-clonic seizures treated with phenytoin (Dilantin®) 300 mg/day and phenobarbital 90 mg at night, and rheumatoid arthritis for which he takes celecoxib 200 mg twice daily.

The results of his thyroid function tests are as follows:

TT_4, 4.2 µg/dL (normal, 4.8–10.4)
FT_4, 0.6 ng/dL (normal, 0.8–1.8)
TSH, 2.5 µIU/mL (normal, 0.40–4.5)

How should these laboratory findings be interpreted? What factors are responsible for the observed changes?

Despite symptoms that could be consistent with hypothyroidism (eg, fatigue, dry skin, constipation) and findings of low serum hormone values, J.R. is euthyroid, as evidenced by the normal TSH

level. Secondary hypothyroidism is unlikely at this age without a history of central nervous system (CNS) trauma or tumor. Some nonthyroidal factors could account for J.R.'s low TT_4 and FT_4 values.[23] Anti-inflammatory doses of salicylates >2 g/day and salicylate derivatives can displace T_4 from both TBG and TBPA, causing these abnormal findings.[23,61,62] Elevation in free T_4 levels and suppression of TSH below normal occur transiently (ie, no longer than first 3 weeks of administration) but normalize with chronic administration. Cirrhosis, stress, severe infections, and hereditary factors can also decrease TBG and TBPA synthesis to produce similar TT_4 findings. A medication history for drugs such as androgens or glucocorticoids that can lower TBG levels, and therefore TT_4 levels, should be elicited (Table 52-1).[23]

Enzyme inducers, such as rifampin and anticonvulsants (phenytoin, phenobarbital, valproic acid, carbamazepine), can alter serum thyroid hormone levels.[23,63–68] A 40% to 60% reduction in total T_4 serum concentrations results from an increase in the metabolism of T_4 and from hormone displacement in patients receiving chronic anticonvulsant therapy. Serum T_3 levels are normal or slightly decreased. In addition, therapeutic levels of phenytoin and carbamazepine interfere with the FT_4 assay, causing a 20% to 40% lower FT_4 than would be expected in persons who are euthyroid.[64] TSH levels remain normal and patients are euthyroid; however, those who previously required T_4 therapy may need a dosage increase to maintain euthyroidism.[67,68] Valproic acid is reported to have similar but less potent effects on thyroid function.[63,65] Phenobarbital can increase T_4 uptake by the liver and increase the fecal excretion of T_4. Serum binding of thyroid hormones is unaffected by phenobarbital.[23]

In summary, J.R. is taking several drugs that can further compromise the already low serum T_4 levels resulting from his liver disease. FT_4 remains subnormal in persons who are euthyroid

receiving phenytoin. For J.R., the normal TSH confirms euthyroidism and no thyroid replacement is warranted.

CASE 52-3

QUESTION 1: S.T., a 23-year-old, sexually active female whose only medication is birth control pills, comes to the clinic with symptoms of extreme nervousness, diaphoresis, and scanty menstrual periods. Although she appears healthy, the possibility of hyperthyroidism is considered based on the following laboratory values:

TT_4, 16 μg/dL (normal, 4.8–10.4)
FT_4, 1.2 ng/dL (normal, 0.8–1.8)
TSH, 1.2 μIU/mL (normal, 0.40–4.5)

Based on this information, what would be a reasonable assessment of S.T.'s thyroid status?

The normal FT_4 and TSH confirm that S.T. is not hyperthyroid. The elevated TT_4 is consistent with increased TBG levels observed in patients with acute hepatitis; in pregnancy; and in persons taking estrogens, estrogen-containing contraceptives, tamoxifen, raloxifene, heroin, or methadone.[3,4,23,69–71] Because TBG and therefore bound T_4 levels are increased by estrogens in S.T., total serum T_4 measurements are falsely elevated but free thyroxine levels remain normal. In patients requiring L-thyroxine, the use of estrogens can increase requirements of hormone replacement because the increased pituitary secretion of TSH cannot increase thyroid production needed to offset the increased binding of T_4.[3] Thyroid function tests should return to normal within 4 weeks after estrogen-containing contraceptives are discontinued.

CASE 52-4

QUESTION 1: J.P., a 55-year-old female, reports 3 months of progressive tremors, dizziness, and ataxia. Two months ago, she had a silent MI complicated by malignant ventricular ectopy that was responsive only to amiodarone therapy. Her other medical problems include Parkinsonism, type 2 diabetes, and diabetic gastroparesis. Her current medications include

amiodarone, insulin glargine, metformin, metoclopramide, pramipexole and levodopa/carbidopa. Physical examination of the thyroid was unremarkable. Thyroid function tests yielded the following results:

TT_4, 14.5 μg/dL (normal, 4.8–10.4)
FT_4, 2.3 ng/dL (normal, 0.8–1.8)
TSH, 3.8 μIU/mL (normal, 0.40–4.5)
TT_3, 40 ng/dL (normal, 62–134)
TPOAb, 4 IU/mL (normal, <9)

How should J.P.'s laboratory values be interpreted?

Although the symptoms of tremors, dizziness, and weight loss are suggestive of hyperthyroidism, the low TT_3, negative antibodies, normal TSH, and normal thyroid examination make this diagnosis unlikely. Her drug therapy could also explain her laboratory findings.

The drugs J.P. is taking—pramipexole, levodopa, metformin, and metoclopramide—may add to the diagnostic confusion. Although these drugs do not affect the actual circulating hormone levels, they affect the dopaminergic system that controls both TSH and TRH secretion.[23,50,72] Infusions of dopamine and dobutamine can decrease both TSH secretion and the TSH response to TRH in patients who are euthyroid and hypothyroid.[23,50,73] Therefore, dopamine agonists such as pramipexole, cabergoline, and levodopa can blunt the normal TSH response.[23,50,72,73] In addition, metformin after 1 year of therapy can cause significant TSH suppression without changes in free thyroxine levels by as yet an unknown mechanism of action.[74,75] Conversely, dopamine antagonists such as metoclopramide or domperidone can elevate TSH levels.[23,50] Fortunately, the alterations in TSH caused by these agents are usually not substantial enough to completely obscure the true thyroid abnormality; however, doses of thyroid drugs should be adjusted to maintain patients in a euthyroid state. See Table 52-2 and Cases 52-23 and 52-24 for more information about drug effects on thyroid function.

J.P.'s thyroid tests present a confusing picture; however, the presence of a TSH within the normal range indicates euthyroidism.

J.P. should be continued on her current regimen with follow-up monitoring of thyroid tests.

HYPOTHYROIDISM

Clinical Presentation

CASE 52-5

Question 1: M.W., a 2.20-pound (70-kg), 23-year-old voice student, thinks that her neck has become "fatter" over the past 3 to 4 months. She has gained 22.05 pounds (10 kg), feels mentally sluggish, tires easily, and finds that she can no longer hit high notes. Physical examination reveals puffy facies, yellowish skin, delayed DTRs, and a firm, enlarged thyroid gland. Laboratory data include the following results:

FT_4, 0.6 ng/dL (normal, 0.8–1.8)
TSH, 60 μIU/mL (normal, 0.40–4.5)
TPOAb, 136 IU/mL units (normal, <9)

What is M.W.'s thyroid status based on her clinical and laboratory findings?

M.W. presents with many of the clinical features of hypothyroidism as presented in Table 52-3. These include weight gain, mental sluggishness, easy fatigability, lowering of the voice pitch, puffy facies, yellowish tint of the skin, delayed DTRs, and enlarged thyroid.[76] The diagnosis of hypothyroidism is confirmed by her laboratory findings of a low FT_4, an elevated TSH value, and positive TPOAb.

A firm goiter, thyroid antibodies, and clinical symptoms of hypothyroidism strongly suggest Hashimoto thyroiditis.[28] She has no history of prior antithyroid drug use, surgery, or RAI treatment, which are common causes of iatrogenic hypothyroidism. She is also not taking any goitrogens or drugs known to cause hypothyroidism (Table 52-2).

Treatment With Thyroid Hormones

THYROID HORMONE PRODUCTS

CASE 52-5, QUESTION 2: What thyroid preparation should be used to treat M.W.'s hypothyroidism? Are differences, advantages, or disadvantages significant among the various generic and brand name formulations of thyroid hormones?

The principal goals of thyroid hormone therapy are to attain and maintain a euthyroid state. Thyroid preparations (**Table 52-8**)[31,77–79] are synthetic (L-thyroxine, L-triiodothyronine) or natural (desiccated thyroid). The latter comes from animal tissues.

Table 52-8
Thyroid Preparations

Drug/Dosage Forms	Composition	Dosage Equivalent	Comments
Thyroid USP (Armour®) *Tab:* 15, 30, 60, 90, 120, 180, 240, and 300 mg	Desiccated hog, beef, or sheep thyroid gland	60–100 μg[a]	Unpredictable T_4:T_3 ratio; supraphysiologic elevations in T_3 levels might produce toxic symptoms; Armour brand preferred
L-Thyroxine (Levoxyl®, Levothroid®, Synthroid®, Unithroid®, various) *Tab:* 13, 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, 200, and 300 μg. *Inj:* 200 and 500 μg	Synthetic T_4	60 μg[a]	Stable, predictable potency; well-absorbed; more potent than desiccated thyroid. When changing from >2 gr desiccated thyroid to L-T_4, a lower dosage of L-T_4 might be needed to avoid toxicity. Weight should be considered in dosing (1.6 μg/kg/day). L-T_4 absorption can be impaired by iron, aluminum-containing products (eg, antacids, sucralfate), Kayexalate, calcium preparations, proton-pump inhibitors, cholesterol resin and phosphate binders, raloxifene, soy, bran, coffee, fiber enriched foods. L-T_4 metabolism increased by anticonvulsants, rifampin, imatinib, bexarotene, and pregnancy
Triiodothyronine (Cytomel®) *Tab:* 5, 25, and 50 μg *Inj:* 10 μg/mL (Triostat®)	Synthetic T_3	25–37.5 μg	Complete absorption; requires multiple daily dosing; toxicity similar to all T_3-containing products; see desiccated thyroid comments

Inj, injection; L-T_4, L-thyroxine; T_3, triiodothyronine; T_4, thyroxine; Tab, tablet; USP, United States Pharmacopeia.

[a]Historically, 60 mg (1 g) of desiccated thyroid = 60 μg of T_4.[79] This conversion was determined with older TSH assays, without direct measurement of FT_4 and has been challenged. The conversion is now typically reported as equivalent to 80 μg,[77] 88 μg,[78] or 100 μg,[32] of T_4 per 60 mg of desiccated thyroid. The T_3 component of desiccated thyroid is an additional factor to consider when converting from one to the other and an exact equivalent dose has not been determined.

Desiccated thyroid

Desiccated thyroid is obtained from dried powdered pork thyroid glands that have had connective tissue and fat removed. Today, starting patients on desiccated thyroid is not justified. The United States Pharmacopeia (USP) requires thyroid content to be 90% to 110% of the labeled 38 µg T_4 and 9 µg T_3 for each 65 mg of the desiccated compound.[80] Advocates of desiccated thyroid use cite the inclusion of metabolically active components (eg, diiodothyronine) and the inclusion of both T_4 and T_3 in the preparation. However, the 4.2:1 ratio of T_4:T_3 is lower than the human 14:1 ratio, potentially resulting in toxic amounts of T_3.[32] The lack of conclusive and long-term evidence combined with the potential for toxicity makes routine use of desiccated thyroid products unwarranted.[32] Clinicians should be aware that some patients may oppose the use of animal-derived products on religious or social grounds.

Allergic reactions to the animal protein are another concern. In addition, desiccated thyroid suffers from two problems inherent to all T_3-containing preparations. Because T_3 is absorbed more rapidly than T_4, supraphysiologic elevations in plasma T_3 levels occur after oral ingestion, which can produce mild thyrotoxic symptoms in some patients. FT_4 levels are low during T_3 administration and, if misinterpreted, can result in the erroneous administration of more hormone. These problems with T_3 are easily missed unless T_3 levels are routinely monitored. Because significant amounts of T_4 are converted to T_3 peripherally, oral administration of T_3 offers no advantage and is not usually needed[32,81,82] (see Triiodothyronine section).

Patients maintained on desiccated thyroid should be encouraged to change to L-thyroxine (T_4). Although 65 mg (1 g) of desiccated thyroid is theoretically equal in potency to 75 to 100 µg of T_4,[79] this equivalency may not hold true if the desiccated thyroid preparation is less active than its labeled content. The patient's weight also should be considered when switching therapy (see Case 52-5, Question 3).

L-Thyroxine (Levothyroxine)

L-Thyroxine, also known as levothyroxine, is the thyroid replacement of choice.[28,32,83] Its advantages include stability, uniform potency, relatively low cost, and lack of allergenic foreign protein content. The mean absorption of a commonly used branded preparation is 81%.[84] Absorption is optimal on an empty stomach.[85] Current guidelines recommend taking L-thyroxine either 60 minutes before breakfast or 3 to 4 hours after the evening meal for consistent absorption.[28,32] Several medications can also impair L-thyroxine absorption.

Concerns about generic and branded L-thyroxine tablet stability and potency, bioavailability, and product interchangeability have caused confusion in the management of thyroid disorders. Several Food and Drug Administration (FDA)–approved brand and generic formulations exist. Raising concerns about the methodology the FDA used to determine bioequivalence, the American Thyroid Association, the Endocrine Society, and the American Association of Clinical Endocrinologists issued joint position statements expressing their displeasure with the FDA's conclusions of interchangeability.[87] Although this issue remains controversial, the preponderance of the evidence supports the FDA ratings and suggests that these preparations are likely to be interchangeable in the majority of patients.[28,32,87–90] Current guidelines recommend maintaining therapy with products of a consistent manufacturer, particularly in high-risk, frail, or elderly patients in whom fluctuations are most critical.[32] In the event of a L-thyroxine manufacturer change, TSH should be monitored when the patient achieves steady state on the new product.[86]

Triiodothyronine

T_3 (Cytomel®) is not recommended for routine thyroid hormone replacement because of the problems identified earlier with T_3 administration (see Desiccated Thyroid section). Although T_3 is well-absorbed, it has a relatively short half-life (1.5 days), necessitating multiple daily dosing to ensure a uniform response. Proposed

advantages of T_3 include beneficial effects on weight and lipids; however, more studies are required to establish whether a clinical benefit exists.[32] Further, a longer-acting form of T_3 would be needed to make this a practical therapeutic option. Other disadvantages include higher expense and a greater potential for cardiotoxicity.[32] Its primary use is for patients who require short-term hormone replacement therapy and rarely in those in whom T_4 conversion to T_3 might be impaired. Proponents favoring thyroid treatment of the "euthyroid sick" syndrome identify T_3 as the hormone replacement of choice. T_3 therapy should be monitored using the TSH and TT_3 or FT_3 levels.

Several randomized studies now conclude that routine replacement with combination T_4 and small dosages of T_3 offer no consistent advantage to T_4 alone. However, there is evidence of improved cognitive performance and mood changes in some patients, and some trials indicate a patient preference in favor of the T_4/T_3 combination.[32,81,82] One proposed explanation for why some people report a cognitive benefit relates to polymorphism in deiodinase enzymes that convert T_4 to T_3 resulting in local tissue hypothyroidism and potentially leading to decreased brain concentrations of T_3.[91] The short half-life of T_3 and the need for multiple doses per day to prevent symptoms of toxicity further complicates the potential use in combination with T_4. Until high-quality, long-term controlled trials exist to prove if a specific subset of patients with hypothyroidism would benefit from combination therapy, the standard of care remains long-term treatment with L-thyroxine.[32]

L-THYROXINE

Dosage and administration

CASE 52-5, QUESTION 3: What would you recommend as appropriate starting and maintenance dosages of T_4 for M.W.?

The maintenance dosage for M.W. can be estimated from her weight. Average replacement doses of 1.6 μg/kg/day (eg, 100–125 μg) are sufficient in most patients to normalize the TSH.[32] L-Thyroxine dosages that suppress TSH levels to below normal or undetectable levels (subclinical hyperthyroidism) should be avoided to prevent osteoporosis and cardiac toxicity.[83,92–96] Excessive L-thyroxine can cause tachycardia, atrial arrhythmias, impaired ventricular relaxation, reduced exercise performance, and increased risk of cardiac mortality.[92] These considerations are especially important in older patients who might require less T_4 than their younger counterparts and who are particularly sensitive to minute changes in T_4 doses (see Table 52-4). As patients age, the dosage should be evaluated yearly and, if necessary, decreased to maintain a normal TSH level.[97]

How rapidly T_4 replacement can proceed depends on the likelihood of invoking cardiac toxicity in susceptible patients. Minute doses of T_4 (eg, <75 μg) can increase heart rate, stroke volume, oxygen consumption, and cardiac workload before euthyroidism occurs. One double-blind study compared the clinical outcome between starting full replacement doses versus gradual 25-μg incremental doses in relatively young hypothyroid subjects with asymptomatic cardiac disease and concluded that those receiving full doses normalized thyroid function tests more rapidly (4 weeks) and without any toxicity.[98] Because M.W. has no identifiable risk factors (see Case 52-10, Question 3) for cardiotoxicity that require careful dosage titration (eg, old age, cardiac disease, long duration of hypothyroidism), she can be started on an estimated full replacement dose of 125 μg daily of L-thyroxine (70 kg × 1.6 μg/kg/day = 112 μg).[28,32] An alternative conservative approach would be to start with 100 μg/day, check the FT_4 or FT_4I and TSH tests after 6 to 8 weeks of therapy, and if the TSH is still elevated without any symptoms of toxicity, increase the dosage to 112 μg/day. The appropriate replacement dose will produce a TSH of 1 to 2 μIU/mL, normalize FT_4 or FT_4I levels, and reverse clinical symptoms of

hypothyroidism. Generally, doses should not be adjusted more frequently than once a month and should not exceed increments of 12.5 to 25 µg/day. Even in the absence of overt coronary disease, patients older than 50 to 60 years should be started on a lower dose of L-thyroxine (50 µg/day) and titrated.[28]

L-Thyroxine bioavailability is improved when it is taken on an empty stomach and at night.[83,85,99,100] Simultaneous coadministration of T_4 with soy proteins, coffee, or high-fiber diets (eg, oat bran, soybean) should be avoided because T_4's absorption can be impaired.[101–103] Estrogen therapy can increase T_4 requirements by increasing TBG to increase T_4 binding.[3] Cholestyramine, colestipol, iron sulfate, antacids, sucralfate, calcium preparations, particularly the carbonate salt, and raloxifene can impair thyroid absorption if these medications are administered at the same time.[83,104–111] Cholesterol-lowering agents (eg, HMG-CoA reductase inhibitors, bile acid sequestrants) and phosphate binders are also reported to interfere with thyroid absorption.[107,112] Aluminum-containing products (ie, antacids, sucralfate) should also be avoided because separating the administration from T_4 does not consistently correct this interaction.[108,109] Data are conflicting as to whether proton-pump inhibitors (eg, omeprazole) reduce T_4 absorption; therefore, addition or deletion of a proton-pump inhibitor warrants additional monitoring.[113,114]

Monitoring therapy

Case 52-5, Question 4: Ten days after starting L-thyroxine therapy, M.W. continues to experience of tiredness, fatigue, and difficulty singing despite excellent adherence. Thyroid function tests show a TT_4 of 4 µg/dL (normal, 4.8–10.4), an FT_4 of 0.5 ng/dL (normal, 0.8–1.8), and a TSH of 40 µIU/mL (normal, 0.40–4.5). What therapeutic options are available? How should M.W.'s thyroid function tests be interpreted?

Clinical improvement in the signs and symptoms of hypothyroidism and normalization of laboratory parameters are appropriate therapeutic end points. If the replacement dose is sufficient, some correction of her symptoms should occur after 2 to 3 weeks, but maximal effects will not be evident for 4 to 6 weeks. Typically, improvement of anemia and hair and skin changes is delayed and requires several months of treatment before resolution.[74,79]

In patients with severe myxedema, a transiently elevated T_4 level might occur at 6 weeks because the metabolic clearance of T_4 is decreased by the hypometabolic state associated with hypothyroidism.

FT_4 or FT_4I and TSH should be checked about 6 to 8 weeks after the initiation of therapy because T_4 has a half-life of 7 days, and three to four half-lives are needed to reach steady-state levels. Levels obtained before this time (as in M.W.) may be misleading and should be interpreted cautiously. No change in her L-thyroxine dosage should be attempted at this time.

Case 52-5, Question 5: Eight weeks later, on a routine follow-up visit, M.W. still feels tired and not back to her normal self. She denies any symptoms of hyperthyroidism. Her thyroid function tests show a TT_4 of 14 μg/dL (normal, 4.8–10.4), a TT_3 of 100 ng/dL (normal, 62–134), FT_4 of 1.9 ng/dL (normal, 0.8–1.8), and a TSH of 3.5 μIU/mL (normal, 0.40–4.5). How should M.W.'s thyroid function tests be interpreted? What changes, if any, should be recommended in her therapeutic regimen?

Patients treated with L-thyroxine may develop an elevated TT_4 concentration and FT_4 without overt clinical signs of hyperthyroidism.[115,116] Despite these elevated levels, patients are euthyroid, as evidenced by a normal TSH. Because T_3 is not being released from the nonfunctioning thyroid gland, a higher concentration of T_4 is necessary to increase the amount of T_3 obtained from peripheral conversion. Jonklaas et al reported that the mean FT_4 was significantly higher (1.34 ng/dL) in patients receiving

L-thyroxine postoperatively compared to their euthyroid levels before thyroidectomy (FT_4, 1.06 ng/dL).[116] T_3 levels on L-thyroxine replacement were also comparable after surgery to pre-surgery levels. However, lower T_3 levels were noted only in those in whom TSH levels were >4.5 μIU/mL, indicating that low T_3 levels are likely a result of suboptimal L-thyroxine replacement. Thus, the TSH appears to be the best indicator of euthyroidism in patients treated with L-thyroxine.

Another possibility is that the elevated thyroid levels may only be an artifact of the laboratory collection time. Before any changes in her dosing regimen are made, M.W. should be asked about the time she takes the drug and its relationship to the time of her blood drawn. Random sampling of FT_4 and TSH levels can be significantly different when compared with trough levels.[117,118] In one study, the FT_4 level was 12% higher, and the TSH level 19% lower when obtained from random samples compared with trough samples.[118] Transient elevations in FT_4 levels were detected for 9 hours after ingestion of the oral L-thyroxine.

The symptoms of fatigue that M.W. is experiencing are likely not because of her hypothyroidism. Patients may continue to have symptoms of hypothyroidism despite normalization of the TSH value.[32] Although some have suggested that the goal TSH be titrated to 1 to 2 μIU/mL or lower for replacement therapy to improve well-being, this is controversial. One study found that changes in T_4 dosing to achieve TSH concentrations of 2 to 4.8 μIU/mL, 0.3 to 1.9 μIU/mL, or <0.3 μIU/mL in patients who are hypothyroid did not result in improvements in well-being, psychological, or hypothyroid symptoms, or quality of life.[119] Data justifying the safety of higher T_4 replacement doses found that achievement of a low but detectable TSH level (0.04–0.4 μIU/mL) was not associated with an increased risk of cardiovascular disease or fractures compared to those with suppressed (<0.03 μIU/mL) or elevated (>4 μIU/mL) TSH levels.[120]

In conclusion, if an elevated TT_4 and FT_4 are noted without any symptoms of thyrotoxicosis (as in M.W.), the dosage should not be

decreased; rather, a trough FT_4 and TSH level should be obtained to eliminate excessive dosing or any laboratory artifacts. Alternatively, obtaining a level at least 9 hours after L-thyroxine administration also seems appropriate. Repeat values should be in the normal range if the dosing is correct. An excessively suppressed TSH confirms a dosage that is too high. In M.W., the lack of hyperthyroid symptoms suggests euthyroidism, and no changes in her therapeutic regimen should be attempted until trough levels are available. Evaluation for other causes of fatigue should be explored.

TRIIODOTHYRONINE

CASE 52-6

QUESTION 1: C.B., a 65-year-old female, is currently experiencing fatigue and vague muscle aches and pains that she attributes to insufficient thyroid medication. On physical examination, the thyroid gland is palpable but not enlarged and DTRs are 2 plus and brisk. Her dose of T_3 was increased from 25 µg tid to 50 µg tid about 2 weeks ago based on the results of a recent FT_4 of 0.5 ng/dL (normal, 0.8–1.8). She denies taking any other medications.

Is C.B.'s thyroid hormone replacement appropriate?

As noted previously, T_3 is not the drug of choice for thyroid replacement. The use of L-thyroxine would simplify her dosing regimen and facilitate monitoring.

The low FT_4 did not justify increasing C.B.'s T_3 dose. Because she is receiving T_3, the FT_4, which is a measure of free T_4, will always be low and will never reach normal levels. In fact, her vague symptoms may be related to hyperthyroidism because she is receiving the equivalent of ~450 µg of L-thyroxine daily (based on a pharmacodynamic study showing an equivalent T_3 :T_4 ratio of 1:3).[121] TSH and FT_3 levels are most useful in monitoring patients receiving T_3 therapy. A TSH level should be obtained to evaluate her thyroid function. A suppressed TSH and an elevated FT_3 would indicate hyperthyroidism. It is important to remember that in an older patient,

hyperthyroidism might not always produce symptoms because of an "apathetic" sympathetic system.

L-thyroxine should be initiated cautiously in older patients to avoid exacerbating any preexisting arteriosclerotic heart disease that might be masked by the hypothyroidism (see Case 52-10, Questions 2 and 3). In general, older patients require smaller replacement dosages (approximately ≤1.6 μg/kg/day of T_4) than their younger counterparts.[97,122,123] Dosages of <50 μg/day of T_4 are common in patients older than 60 years. However, this lower T_4 dosage is not universal for all older subjects.[123] The reason that older patients need lower dosages is unclear, but it has been suggested that the lower requirements result from an age-related decrease in T_4 degradation rates. Because dosage requirements change with age, patients should be reassessed annually to determine whether the original dosage prescribed is still appropriate.[97,124]

In C.B., who had been on T_3 without any evidence of cardiac toxicity, a less cautious approach in changing to T_4 can be attempted. An empiric L-thyroxine dosage of 68 μg/day (40 kg × 1.6 μg/kg/day) is an approximate dosing end point for C.B. The T_3 should be discontinued and T_4 should be initiated in a dose of 50 μg/day; this dosage can be adjusted as needed based on C.B.'s symptoms and thyroid function tests. After T_3 therapy is discontinued, its effects will disappear over 3 to 5 days. In contrast, T_4 levels rise slowly over 4 to 5 days, so no overlap in T_3 administration is necessary to prevent hypothyroidism.

Parenteral dosing

CASE 52-7

QUESTION 1: G.F., a 70-year-old male with long-standing hypothyroidism, has been receiving L-thyroxine 100 μg/day. Currently, he is in the hospital with a stroke and paralysis that prohibits him from swallowing oral medications. His last thyroid function tests were normal.

What is a reasonable method of administering thyroid hormone to G.F.?

Because L-thyroxine has a half-life of 7 days, administration can be delayed for up to 1 week (assuming G.F. can resume oral intake at that time). However, if parenteral administration is required, L-thyroxine is available as an intramuscular (IM) or IV injection. The IV route is preferred because IM absorption may be slow and unpredictable, particularly if the circulation is compromised. Because the oral absorption of T_4 is ~80%,[84] parenteral doses should be decreased. Once IV L-thyroxine replacement is successful, maintenance with a once-weekly IM injection can be continued if oral ingestion is not feasible.[125]

HYPOTHYROIDISM IN PREGNANCY

CASE 52-8

QUESTION 1: P.K. is a 35-year-old female with Hashimoto thyroiditis who is 6 weeks' pregnant. Laboratory test results showed TT_4 5 μg/dL (first trimester normal, 6.4–15.2) and FT_4 0.7 ng/dL (first trimester normal, 0.9–2.0). She takes her medications in the morning, which include L-thyroxine 100 μg/day and a prenatal vitamin enriched with iron and calcium.

What dosing adjustments are required because of P.K.'s pregnancy?

Inadequately treated or undiagnosed maternal hypothyroidism can be detrimental to the mother and the developing fetus.[126,127] Miscarriage, spontaneous abortion, hypertension, preeclampsia, and higher rates of cesarean sections and stillbirths have been reported with maternal hypothyroidism.[128] Congenital defects, congenital hypothyroidism (see Case 52-8, Question 2), abnormal fetal development, and impaired cognitive development in the newborn have been attributed to maternal hypothyroidism.[129] Measurement of TPOAb is recommended in patients with recurrent miscarriage because of an association with elevated levels and miscarriage after the first trimester.[48] The IQ scores of children born to mothers with undiagnosed hypothyroidism during pregnancy averaged 7 points

lower than children born to euthyroid mothers.[126] A delay in both mental and motor development has been observed in children ages 1 to 2 years old who were born to mothers with hypothyroxinemia but normal TSH levels during the first trimester of pregnancy.[127] Children born to mothers with untreated hypothyroidism are also more likely to have learning and attention deficit disorders and are at a higher risk of being born with unilateral spastic cerebral palsy.[130,131] Data such as these have led to the conclusion that normal maternal thyroid function is essential during early fetal development. However, a 2018 cohort study showed that children born to mothers with TSH and T_4 abnormalities in the first trimester had no clinically important impairment in educational achievement.[132] Fetal thyroid hormone production begins by the end of the first trimester, with the fetus relying on maternal thyroid hormones until that time. Transfer of maternal thyroid hormones is under the control of the placenta.[133] There is a small risk of congenital hypothyroidism if maternal antibodies from Hashimoto thyroiditis cross the fetal circulation. The infant's cord blood should be assayed at birth to ensure that TSH is normal and that the child is euthyroid.

The majority of females with primary hypothyroidism will require a 30% to 50% increase in the prepregnancy T_4 dosage to maintain euthyroidism during the first trimester of pregnancy.[41,133–135] The only evidence of increased T_4 demands is an elevated TSH level (eg, subclinical hypothyroidism) that occurs between weeks 5 (but can be as early as 3) and 16 of gestation. Often, no clinical symptoms of hypothyroidism are evident and the FT_4 and the index are normal. Because of the adverse consequences associated with maternal hypothyroidism, it is reasonable to evaluate TSH in all pregnant females[136] as well as empirically increase the prepregnancy T_4 dosage by 30% (extra two pills/week) as soon as pregnancy is confirmed.[135] Because there is a physiologic decrease in TSH during pregnancy caused by the TSH-like activity of human chorionic gonadotropin (HCG), the upper limit of the normal TSH range should be adjusted for pregnancy.[128,133] Where possible, population-based trimester-specific TSH reference ranges should be used. In the

absence of available data, first trimester lower and upper reference ranges can be reduced by 0.4 and 0.5 μIU/mL, respectively beginning weeks 7 to 12.[128] Reference ranges gradually return toward normal, nonpregnant ranges in the second and third trimesters. For a treatment goal, the lower half of the trimester-specific reference range (or <2.5 μIU/mL if reference range is unavailable) should be used.[128]

Physiologic explanations for the increase in thyroid hormone requirements include the twofold increase in TBPA caused by high estrogen levels, increased volume of distribution of thyroid hormones, and maternal transport of T_4.[41,133] Rising HCG concentrations result in increased production of thyroid hormones.[133] Changes in serum proteins cause direct immunoassay of FT_4 to yield incorrect results. A newer assay has been shown to produce reliable trimester-specific reference ranges for FT_4; however, these assays are not universally available.[40] In the absence of trimester-specific reference ranges for FT_4, the FT_4 index or TT_4 should be used to evaluate thyroxine production.[28,128] It is important to recognize that coadministration of iron- and calcium-containing prenatal vitamins reduces T_4 absorption (see Case 52-5, Question 3) and that these drug interactions may affect dosage requirements. When prenatal vitamins with iron and calcium were separated by 4 hours from T_4 administration, only 31% of females required an increase in T_4 dose.[137] Females should be followed closely during pregnancy with monthly monitoring during the first half of pregnancy and at least once between gestation weeks 26 and 32. If necessary, the T_4 dosage should be adjusted to maintain a TSH in pregnancy-adjusted ranges and an ultrafiltrate measured FT_4, FT_4I, or TT_4 in the upper limits of normal based on adjusted normal ranges. When the TT_4 is used, reference ranges should be increased by 50%.[28,40] Combination therapy with T_4 and T_3 or desiccated thyroid should not be given to pregnant females or those planning pregnancy.[28,31,128]

P.K.'s low TT_4 and FT_4 are concerning. The TT_4 should be much higher because of pregnancy-associated increases in TBG. The TSH

level should be obtained, and the daily dosage of T_4 should be increased to 125 µg after eliminating the possibility of patient nonadherence and drug interactions. Ingestion of the prenatal vitamins with iron and calcium should be separated by at least 4 hours from T_4. P.K. could also be instructed to take the T_4 at night for better absorption.[85] The TSH should be repeated in 6 weeks, and the dosage should be adjusted as needed to keep the TSH in the range as above. After delivery, the dosage should be reduced to prepregnancy levels and the FT_4 and TSH rechecked to ensure euthyroidism.

CONGENITAL HYPOTHYROIDISM

Case 52-8, Question 2: P.K. delivered a healthy baby, T.K., at term without difficulty. T.K.'s postpartum screening serum T_4 level was 5 µg/dL (normal, 4.8–10.4), and TSH was 35 µIU/mL (normal, 0.40–4.5). At home, T.K. became lethargic, had a weak cry, sucked poorly, and failed to thrive. Assess the situation (including a treatment plan and prognosis). How is mental development affected?

T.K.'s symptoms are suggestive of congenital hypothyroidism, although in most infants the clinical signs and symptoms are so subtle and nonspecific that they are easily missed until the child is several months old. The early clinical findings include prolonged jaundice, skin mottling (cutis marmorata), lethargy, poor feeding, constipation, hypothermia, hoarse cry, large fontanels, distended abdomen, hypotonia, slow reflexes, and piglike facies.[138] Respiratory difficulties, delayed skeletal maturation, and choking (but not palpable goiter) may be present. These infants are also at risk for additional congenital defects or complications.[138] Mass neonatal screening programs have been successful in detecting congenital hypothyroidism within the first few weeks of life before clinical manifestations are apparent and before irreversible changes occur.[138]

The postpartum low serum T_4 concentration and elevated TSH level (>20 μIU/mL) in T.K. are of concern and should be verified. Transient hypothyroidism can result from intrauterine exposure to ATDs or excess iodides, or from transplacental passage of TRAb from the mother. Thyroid function tests often normalize without treatment in 3 to 6 months as the TRAb is cleared by the infant.[138] The diagnosis of hypothyroidism should be confirmed by a low serum T_4, a low FT_4, and an elevated TSH concentration during the next few weeks. Serum T_3 concentrations are often in the normal range and are not helpful. Normal serum T_4 concentrations are higher in the first few weeks of life and gradually return to normal by 2 to 4 months of life. The FT_4I may also be elevated. Because of these confusing changes, thyroid serum levels should be compared with the normal range for the approximate postnatal age.

Thyroid hormones play a critical role in normal growth and development, particularly of the CNS, during the first 3 years of life. If untreated, dwarfism and irreversible mental retardation occur. T.K.'s normal mental (IQ) and physical development will be determined by the age at which treatment is started, the initial dosage of T_4, the serum T_4 level attained during therapy, the adequacy with which treatment is maintained, and the cause and severity of the initial deficiency.[139–145] There is an inverse relationship between the amount of time to reach a euthyroid state and the likelihood of impaired neurologic development.[138]

Sodium L-thyroxine is the preparation of choice for replacement.[138] T_4 tablets can be crushed and mixed with breast milk or formula; suspensions are not stable and should not be used. T_4 tablets should not be mixed with soy-based formulas because decreased absorption and longer time to reach a TSH <10 μIU/mL may occur. If a soy-based formula is required, the dosage of T_4 should be administered halfway between feeds.[138] T_3 is less desirable because its short half-life causes a greater fluctuation in plasma levels (Table 52-8). The initial replacement dose of T_4 should raise the serum T_4

as rapidly as possible to minimize the consequences of hypothyroidism on cognitive function. A delay in starting therapy of even a few days has resulted in a poorer IQ outcome.[140,141,145] A minimum T_4 dosage of 10 to 15 µg/kg/day is recommended to raise the serum T_4 to >10 µg/dL (129 nmol/L) by 7 days.[139] However, some suggest that higher than previously recommended dosages of 12 to 17 µg/kg/day might be more effective, but concern about negative neurologic outcomes exists.[138,140,141] In the full-term healthy infant, full initial replacement T_4 doses are appropriate.[138,146] In these infants, reduced doses of T_4 (~25%–33% of the recommended dose) can be started and increased gradually by similar increments until the therapeutic dose is achieved. The recommended replacement dose decreases with age and is shown in **Tables** 52-4 and **52-9**.[147]

Table 52-9

T_4 Recommended Replacement Dose

Age	Daily µg/kg/day T_4
Newborn–3 months	10–15
3–6 months	8–10
6–12 months	6–8
1–5 years	5–6
6–12 years	4–5
>12 years	2–3
Adolescent/post puberty	Adult dose (1.6)

T_4, thyroxine.

Mental development and attainment of normal growth are not severely impaired if adequate T_4 treatment is initiated before 3 months of age to achieve a T_4 level >10 µg/dL (129 nmol/L).[138–141,143]

Children with the most severe congenital hypothyroidism had IQs lower than their siblings.[141] Young adults 20 years after congenital hypothyroidism showed impaired motor and intellectual outcomes after suboptimal T_4 (<7.8 μg/kg/day) therapy compared to sibling controls.[143] However, those receiving optimal therapy still had some memory, attention, and behavior deficits.[148] Newborns starting L-thyroxine during the first 4 to 6 weeks of life have mean IQs similar to controls. The IQ drops if treatment is delayed until 6 weeks and 3 months (mean IQ, 95), or until 3 and 6 months (mean IQ, 75). When treatment is delayed until 6 months to 1 year of age, normal mental development is impaired despite subsequent treatment. Higher IQs also were found in children who received T_4 dosages >10 μg/kg/day and achieved a mean T_4 level >14 μg/dL (181 nmol/L) in the first month of therapy.[138,140,141,145,149] Neurologic deficits were also more likely to occur in infants whose thyroid replacement was delayed or inadequate (T_4 <8 μg/dL [103 nmol/L] within 30 days of therapy and or had delayed TSH normalization [18–24 months]). Additional risk factors for low IQs and poor motor and speech skills despite adequate therapy include clinical signs of hypothyroidism during fetal life, T_4 <2 μg/dL at birth, thyroid aplasia, and retarded bone age.[138,139,141]

The goal of therapy is a T_4 in the upper normal range (eg, 10–18 μg/dL) and/or an FT_4 of 2 to 5 ng/dL during the first 2 weeks of therapy, and then a lower target thereafter: a T_4 of 10 to 16 μg/dL (and/or an FT_4 of 1.6–2.2 ng/dL). IQs are improved if TSH levels are normalized within the first month of therapy, but no later than 3 months.[140,141,145,149] Thyroid function tests should be routinely monitored 2 to 4 weeks after starting therapy, then every 1 to 2 months during the first 6 months of life, every 3 to 4 months until age 3, and finally, every 6 to 12 months until growth is complete.[138] Although TSH suppression is the most reliable index of adequate replacement in older children, normalization of the TSH should not be used as the sole monitoring parameter in infants because the TSH may lag behind correction of the T_4 and/or FT_4 levels.

Overtreatment should be avoided to prevent brain dysfunction, acceleration of bone age, and craniosynostosis (premature closure of the cranial sutures).[138,146] Normal growth and development should also be a treatment goal. Other clinical end points include an improvement in activity level, skin color, temperature, facial appearance, and reversal of other symptoms and signs of hypothyroidism. The child will require lifelong replacement therapy.

Myxedema Coma

CLINICAL PRESENTATION

CASE 52-9

Question 1: R.B., a 65-year-old, agitated female arrived at the emergency department with chest pain unrelieved by nitroglycerin (NTG). Her medical problems include alcoholic cardiomyopathy, angina, and hypothyroidism. Although she has been advised repeatedly to take her T_4 regularly, she continues to take it sporadically. An FT_4 drawn 4 months ago was 0.5 ng/dL (normal, 0.7–1.9). Haloperidol 2 mg IM and morphine sulfate 10 mg IM were given for the agitation. After the injection, the nurse noticed mental depression, lethargy, and shallow breathing. R.B.'s oral temperature was 94.1 °F (34.5 °C), and she exhibited chills and shakes.

What is your assessment of R.B.'s subjective and objective data?

R.B. has several symptoms consistent with myxedema coma.[150] The classic features are hypothermia, delayed DTRs, and an altered sensorium that ranges from stupor to coma. Other predominant features include hypoxia, carbon dioxide retention, severe hypoglycemia, hyponatremia, and paranoid psychosis.[150] Typical physical findings (see Table 52-3) include a puffy face and eyelids, a yellowish discoloration of the skin, and loss of the lateral eyebrows. Pleural and pericardial effusions and cardiomegaly may be present. Because myxedema coma frequently occurs in older females, it is often difficult to distinguish the signs and symptoms from dementia or other disease states, as illustrated by R.B. Precipitating factors include cold weather or hypothermia, stress (eg, surgery, infection,

trauma); coexisting disease states such as MI, diabetes, hypoglycemia, or fluid and electrolyte abnormalities (especially hyponatremia); and medications such as sedatives, narcotic analgesics, antidepressants, and other respiratory depressants and diuretics.[150–152]

Haloperidol and morphine might be responsible for what appears to be impending myxedema coma in R.B. In patients with severe myxedema, respiratory depressants (anesthetics, narcotic analgesics, sedative hypnotics) alone or in combination with the hypothermic effects of the phenothiazines can aggravate the preexisting hypothermia and carbon dioxide retention to precipitate myxedema coma.[150,151] Tranquilizers such as haloperidol should not be given; small doses of less depressive sedative hypnotics such as the benzodiazepines should be used only when necessary. Patients with myxedema are also inherently sensitive to the respiratory depressant effects of narcotic analgesics, especially morphine. A dose as small as 10 mg may induce coma in a patient who are hypothyroid or cause death in a patient who is already comatose.[150–152] If morphine is required, the dose should be decreased to one-third to one-half the usual analgesic dose and the respiratory rate should be monitored closely.

TREATMENT

Case 52-9, Question 2: What would be a reasonable therapeutic plan for the management of R.B.'s myxedema coma?

Emergency treatment, usually in the intensive care unit, of myxedema coma is directed toward thyroid replacement, maintenance of vital functions, and elimination of precipitating factors. Despite immediate and aggressive therapy with large replacement doses of thyroid, mortality rates of 60% to 70% are common.[150]

Whether T_4 or T_3 is the drug of choice in myxedema coma is controversial because no comparative trials have been conducted.

Although T_3 is potentially more cardiotoxic, it has been recommended because its more rapid onset might reverse coma faster and the peripheral conversion from T_4 to the biologically active T_3 might be inhibited in severe systemic disease.[151–155] T_4 alone, T_3 alone, and a combination of the two have all been used successfully to treat myxedema coma.[150,152,156] However, L-thyroxine is generally regarded as the hormone of choice because of greater clinical experience with T_4 than with T_3. Also, mortality has occurred despite the higher T_3 levels achieved after T_3 administration.[152] T_3 might be considered after failure of T_4 or if concomitant systemic illness (eg, heart failure) is likely to impair conversion of T_4 to T_3.[150] Supraphysiologic elevations in T_3 levels occur only after oral administration but are not seen after IV T_3 infusion. Factors associated with a higher mortality 1 month after therapy include older age, cardiac complications, and T_4 replacement ≥500 μg/day or T_3 replacement >75 μg/day.[151,152] If T_3 is used, it should be administered concurrently with T_4 and not as monotherapy to avoid the need for high doses associated with increased mortality.[32]

L-Thyroxine 200 to 400 μg should be given IV initially in patients younger than 55 years without cardiac disease to saturate empty TBG sites and raise the serum T_4 level to 6 to 7 μg/dL.[32,150,156] A maintenance dose of 1.2 μg/kg/day IV or 1.6 μg/kg/day orally should follow the initial dose. The initial dose can be adjusted based on the patient's weight and other restrictive factors (eg, age, cardiac disease). The initial T_4 dosage for R.B. should be 200 μg/day to avoid worsening her angina. If the proper dosage is given, consciousness, restoration of vital signs, and decreased TSH levels should occur within 24 hours. If T_3 is to be coadministered, the dose is 5 to 20 μg IV, followed by a maintenance dose of 2.5 to 10 μg every 8 hours.[32] Dosage of 10 μg every 4 hours for the first 24 hours and then 10 μg every 6 hours for a few days until oral therapy can be started.[150]

Maintenance doses should be titrated to the patient's clinical response. Because myxedema can impair oral absorption, the IV route is preferred to ensure adequate drug concentrations. Oral administration is permitted once GI function returns to normal.[150,156]

Supportive measures include assisted ventilation, glucose for hypoglycemia, restriction of fluids for hyponatremia, and the use of blood or plasma expanders to prevent circulatory collapse and to maintain blood pressure. The use of blankets to treat R.B.'s hypothermia is not advised because vasodilation will occur and further compromise the cardiovascular components of shock. Although steroids have not been shown to be clearly beneficial in primary myxedema, they may be lifesaving in patients with hypopituitarism masquerading as myxedema coma. Because it is difficult to distinguish between primary and secondary myxedema, hydrocortisone 50 to 100 mg every 6 hours should be given empirically, beginning before the first dose of thyroid hormones.[32,150]

Appropriate measures should be taken to relieve R.B.'s chest pain while ruling out the possibility of an MI. The use of a narcotic antagonist such as naloxone may be beneficial in this instance because it can reverse the effects of the morphine. Naloxone can also arouse comatose patients intoxicated with alcohol.

Hypothyroidism With Cardiac Disease

CLINICAL PRESENTATION

CASE 52-10

Question 1: E.B., a 45-year-old female, is admitted with chest pain, SOB, dyspnea on exertion, and orthopnea suggestive of heart failure. Significant past medical history reveals exertional angina and Graves disease, treated with RAI ablation 10 years ago. Testing and physical examination reveal cardiomegaly, diastolic hypertension, obesity, facial edema and puffiness, delayed DTRs, and nonpitting pretibial edema. Pertinent laboratory findings include the following results:

FT_4, 0.2 ng/dL (normal, 0.8–1.8)
TSH, 100 μIU/mL (normal, 0.40–4.5)

Brain natriuretic peptide, 550 pg/mL (normal, <100 pg/mL)

A chest radiograph reveals cardiomegaly and pericardial effusions, and an electrocardiogram (ECG) shows bradycardia and flattened T waves with ST depression. Left ventricular ejection fraction was 25% on echocardiography. Furosemide, nitrates, metoprolol, and lisinopril are started. E.B.'s symptoms improve, but her cardiac abnormalities are not reversed.

Why do these clinical findings suggest hypothyroidism?

E.B.'s abnormal thyroid function tests, symptoms, physical findings, and history of RAI therapy are consistent with severe hypothyroidism. "Myxedema heart" can be confused with HFrEF because the signs and symptoms are similar: cardiomegaly, dyspnea, edema, pericardial effusions, elevated brain natriuretic peptide (BNP) and abnormal ECG.[150,157] Therefore, hypothyroidism should be ruled out as a reversible cause in all patients with new or worsening symptoms of cardiovascular disease (eg, angina, arrhythmia).

TREATMENT

Case 52-10, Question 2: What might be the effect of hypothyroidism on the cardiac treatment and status of E.B.?

If E.B.'s cardiac abnormalities are caused by hypothyroidism, adequate doses of T_4 will restore the heart size, normalize the diastolic blood pressure, reverse the ECG findings, and normalize the serum enzyme elevations within 2 to 4 weeks.

Angina or premature beats can develop or worsen with the institution of T_4 therapy, so doses should be titrated carefully (see Case 52-10, Question 3).[158–160] Nitrates may precipitate hypotension and/or syncope in patients who are hypothyroid because these patients have a low circulating blood volume and their response to vasodilation can be exaggerated. Furthermore, if β-blockers are required, the cardioselective β-blockers are preferred. The non–cardioselective β-blockers have produced coronary spasm by

exacerbating the compensatory increase in norepinephrine levels and α-adrenergic tone found in hypothyroidism.[159–161]

Case 52-10, Question 3: How aggressively should thyroid hormone therapy be initiated in a patient like E.B. who has angina? What is the hormone replacement of choice in patients with cardiac disease?

Patients with long-standing hypothyroidism, arteriosclerotic cardiac disease, or advanced age tend to be extremely sensitive to the cardiac effects of thyroid hormone. Initiation of normal or even subtherapeutic doses might produce severe angina, MI, supra- and ventricular premature beats, cardiac failure, or sudden death and underscore the need to replace thyroid cautiously, and sometimes suboptimally, to avoid cardiac toxicity.[158–161] The angina and cardiac status should be controlled before initiating T_4 therapy. In the patient with poorly controlled angina, cardiac catheterization is warranted to assess the coronary artery status before starting hormone therapy.

For E.B., 12.5 to 25 μg daily of T_4 should be initiated cautiously and increased as tolerated by similar increments of T_4 every 4 to 6 weeks until a therapeutic dosage is reached. The rapidity with which the increments can proceed is determined by how well each increased dose is tolerated. If cardiac toxicity occurs, therapy should be stopped immediately. Once symptoms resolve, therapy can be restarted using smaller dosage increments and longer intervals between dosage adjustments. If cardiac symptoms recur, further T_4 therapy should be stopped pending cardiac evaluation. In patients with severe cardiac sensitivity, complete euthyroidism may be difficult to achieve; however, revascularization procedures (coronary artery stenting or bypass grafting) may allow full T_4 replacement therapy.[32] E.B.'s clinical status and ECG should be monitored closely during the titration period. T_4 should be discontinued or decreased at the first sign of cardiac deterioration. It is not necessary to monitor thyroid function tests (eg, TSH or FT_4) during the titration period because the results will remain abnormal until adequate replacement

is achieved. Thyroid function tests should be obtained once maximally tolerated or estimated euthyroid dosages are achieved.

Subclinical Hypothyroidism

CASE 52-11

Question 1: M.P., a healthy 53-year-old female, comes in for her regular checkup. She denies any symptoms of hypothyroidism and feels well. She has no other medical problems, takes no medications, and has no known allergies. Her physical examination is within normal limits. Routine screening laboratory tests are normal except for an FT_4 of 1.2 ng/dL (normal, 0.8–1.8) and a TSH of 8 μIU/mL (normal, 0.40–4.5).

Does M.P. require thyroid treatment, based on her clinical presentation and laboratory findings?

M.P.'s free thyroid levels are normal, but her TSH level is elevated, indicating subclinical hypothyroidism (SH). The prevalence of SH ranges from 4% to 10% and increases to 26% in the elderly population, particularly females.[94,95] It is unclear whether SH represents the early stages of thyroid failure. The estimated risk of developing overt hypothyroidism after 10 years in untreated patients by Kaplan–Meier curves was 0% for a TSH level of 4 to 6 μIU/mL, 42.8% for a TSH level of 6 to 12 μIU/mL, and 76.9% for a TSH level >12 μIU/mL. This risk increased in patients with positive thyroid antibodies.[162] Because the most common clinical scenarios involve asymptomatic patients with TSH levels <10 μIU/mL, negative thyroid antibodies, and no history of prior thyroid disease, routine thyroid screening has been recommended, particularly in elderly females.[95]

Mild symptoms of hypothyroidism, including psychiatric and cognitive abnormalities, are found in ~30% of patients with SH, but the average TSH level usually exceeds 11 μIU/mL. Cardiac dysfunction, including impaired left ventricular diastolic function at rest, systolic dysfunction with exercise, atherosclerosis, heart failure, and MI has been reported.[92,95,163–165] Data showing an increased risk of coronary artery disease (CAD) are conflicting and influenced by

the severity of SH, study design, and length of follow-up. A meta-analysis noted a 1.6 times increased risk of CAD,[166] a cross-sectional analysis noted an odds ratio of 2.2 only in those with TSH levels of ≥10 μIU/mL, whereas a 20-year longitudinal analysis found a significant risk (hazard ratio [HR] of 1.7) regardless of the degree of TSH elevation.[167] However, a large prospective cohort study found no significant association with atherosclerotic disease or cardiac mortality but observed an increase in all-cause mortality at 10 years of follow-up.[168] Compelling data reported from 11 large prospective cohorts with a median follow-up of 2.5 to 20 years involving 3450 subjects with SH found an increased risk of CAD (HR 1.89) and mortality (HR 1.5) but not total mortality only in those with TSH level >10 μIU/mL after adjustment for traditional cardiovascular factors. No increased CAD or CAD mortality was noted with more minimal TSH elevations.[169]

Other atypical and nonspecific signs and symptoms reflecting dysfunction of any part of the body may occur, primarily in the elderly. Failure to thrive, mental confusion, weight loss with poor appetite, incontinence, depression, inability to walk, carpal tunnel syndrome, deafness, ileus, anemia, hypercholesterolemia, and hyponatremia have been reported.[94,95,163–165]

Treatment of SH with T_4 is controversial because study results are conflicting. Potential benefits of treatment include (a) preventing progression to hypothyroidism, (b) improving the lipid profile and reducing cardiac risks, and (c) reversing symptoms of hypothyroidism. Patients with higher TSH levels (eg, >10 μIU/mL), a history of previously diagnosed thyroid disease, elevated lipid levels, or evidence of positive thyroid antibodies gained the most benefit from L-thyroxine therapy.[92,95,162,165,170] L-thyroxine significantly reduced total cholesterol by 7.9 to 15.8 mg/dL and low-density cholesterol concentrations by 10 mg/dL; serum high-density lipoprotein (HDL) cholesterol and triglyceride concentrations remain unchanged.[95,164,165,170] Improvement of elevated intraocular pressures, memory, mood, somatic symptoms, and diastolic dysfunction has also been reported after T_4 replacement.[162,164,165,170]

Conversely, a meta-analysis published in 2018 indicated that treatment of SH does not improve general quality of life or thyroid symptoms.[171] Recent guidelines suggest that T_4 therapy should be reserved for females who are attempting pregnancy, patients with TSH levels >20 μIU/mL, and in those with severe symptoms despite normal thyroxine levels.[172]

Treatment of older patients requires an assessment of the risks versus benefits of therapy. Thyroid therapy carries the risk of unmasking underlying cardiac disease in older patients. Nevertheless, thyroid replacement appears reasonable in asymptomatic patients with TSH levels >10 μIU/mL and especially those with symptoms of mild hypothyroidism, dyslipidemia, laboratory abnormalities, or end-organ alterations.[94,95,162,164,170] Patients with mild SH (TSH 6–10 μIU/mL) may benefit from therapy with L-thyroxine 25–75 μg/day when there is evidence of cardiovascular risk (eg, diastolic dysfunction, risk of atherosclerotic disease, diabetes) or clinical indicators suggestive of hypothyroidism (eg, goiter, antibodies).[95] There is no evidence supporting the treatment of mild subclinical disease in patients older than 80 years.[95] Conversely, patients with asymptomatic SH and a TSH level <10 μIU/mL do not warrant immediate therapy, but close follow-up is recommended.

Because M.P. is asymptomatic and has a TSH level <10 μIU/mL, it is reasonable to delay therapy and recheck the TSH in a few months.

Secondary Hypothyroidism

CASE 52-12

Question 1: J.R. is a 65-year-old female who is currently experiencing fatigue, cold intolerance, dry skin, and weight gain for the past several months. Her thyroid examination and DTRs are within normal limits. Her TSH level was 0.5 μIU/mL (normal, 0.40–4.5). She denies taking any other medications. J.R. is started empirically on a 3-month trial of L-thyroxine.

How should the TSH level be interpreted? Is T_4 therapy indicated, based on her presenting findings?

Despite symptoms that could be consistent with hypothyroidism (eg, fatigue, cold intolerance, dry skin, weight gain), the normal TSH level implies that J.P. is euthyroid. However, because a diagnosis of hypopituitarism (ie, TSH level could be normal or low) cannot be ruled out, a FT_4 level should be obtained. A low FT_4 would increase the likelihood of hypopituitarism and the presence of secondary hypothyroidism. Some argue that hypopituitarism is underdiagnosed and would advocate adding FT_4 to the primary screening tests.[173]

If the FT_4 level is normal, indicating euthyroidism, then hypopituitarism is unlikely and L-thyroxine therapy is not indicated. A randomized, double-blind, placebo-controlled crossover trial found that T_4 supplementation in patients with hypothyroid symptoms and normal thyroid function tests was not more effective than placebo in improving cognitive function or psychological well-being despite changes in the TSH and FT_4 levels.[174,175]

HYPERTHYROIDISM

Clinical Presentation

CASE 52-13

Question 1: C.R., a 47-year-old female, has a 3-month history of intermittent heat intolerance, sweats, tremor, and severe muscle weakness, which has limited her ability to climb stairs. Her weight has increased because of increased appetite. She is also bothered by the pounding of her heart and some minor difficulty in swallowing. There is a family history of thyroid disease, but she denies taking any thyroid medications or any history of radiation to her neck. C.R. previously received iodide drops with symptomatic improvement, but her disease recurred despite its continued administration. Her other medical problems include type 2 diabetes controlled by diet, and osteoarthritis treated

with acetaminophen 650 mg PO q6h. She has a history of noncompliance with her clinic visits.

Physical examination reveals a thin, flushed, hyperkinetic, nervous female. Blood pressure (BP) is 180/90 mm Hg; pulse is 130 beats/minute, irregularly irregular; respiratory rate is 30 breaths/minute; and temperature is 99.5 °F (37.5 °C). Other pertinent findings include a lid lag with stare, proptosis with tearing, decreased visual acuity, a diffusely enlarged thyroid gland without nodules, a bruit in the left lobe of the thyroid, positive jugular venous distension (JVD), bibasilar rales, warm moist skin with multiple bruises, new-onset atrial fibrillation (AF), slight diarrhea, hepatomegaly, acropachy, 2+ pitting edema, a fine tremor, proximal muscle weakness, and irregular scant menses.

Laboratory data include the following:

FT_4, 2.9 ng/dL (normal, 0.8–1.8)
TSH, <0.5 μIU/mL (normal, 0.40–4.5)
RAIU at 24 hours, 80% (normal, 5%–35%)
International normalized ratio (INR) 4.8 (normal, 1; therapeutic, 2–3)
TRAb, 2.3 IU/L (normal, <2)
Fasting blood glucose, 350 mg/dL

What do you make of these subjective and objective data?

C.R. presents with many of the clinical and laboratory features[176] associated with an increased metabolic state resulting from excessive thyroid hormones (Table 52-5). Her ocular symptoms are consistent with Graves disease and include lid lag (lid falls behind the movement of the eye and a narrow white rim of sclera becomes visible between the upper lid and cornea, producing a “staring” appearance), ophthalmopathy (protrusion of the eyeball), and decreased visual acuity. The thyroid bruit, palpitations, exertional dyspnea, heart failure signs (JVD, bibasilar rales, edema, hepatomegaly), diarrhea, irregular scant menses, nervousness, tremor, muscle weakness, increased perspiration, and flushing of the skin are consistent with a hypermetabolic state.[176,177] Although sinus tachycardia is the most common arrhythmia in hyperthyroidism, new-onset AF is the presenting symptom in 5% to 20% of patients with hyperthyroidism, particularly in those older than 70 years.[178] Together with C.R.’s symptoms, a diagnosis of Graves disease is confirmed by an elevated FT_4 level, an undetectable TSH level, an

increased RAIU, positive TRAb, and a diffusely enlarged goiter (Table 52-6 lists the causes of hyperthyroidism).

Iodides

Case 52-13, Question 2: Why were the iodide drops initially effective in improving C.R.'s symptoms and later ineffective? When are iodides indicated? What is their mechanism of action?

Iodides have several effects: They inhibit thyroid hormone release, they block iodotyrosine and iodothyronine synthesis by blocking organification, and they decrease the vascularity of the thyroid gland.[179] However, large doses may accentuate hyperthyroidism because they provide a significant increase in available substrate for hormone synthesis (see Case 52-23).[37,179]

The inhibitory effect of exogenous iodides on the intrathyroidal organification of iodides is known as the Wolff–Chaikoff effect. This is an inherent autoregulatory function of the normal gland to prevent excessive hormone synthesis in the event of a large iodide load. The Wolff–Chaikoff effect occurs when intrathyroidal concentrations of iodides reach a critical level, and this is not overcome by TSH stimulation. However, as illustrated by C.R., the gland can "escape" from this block even with continued iodide use. The gland escapes by decreasing iodide transport or by leaking iodide. Both mechanisms decrease the critical intrathyroidal iodide level, thereby decreasing the block to organification.[18,37,179] This effect is illustrated in C.R. Therefore, iodides should not be used as primary therapy for Graves disease.

The most important pharmacologic effect of iodides is their ability to promptly inhibit thyroid hormone release when dosages of 6 mg/day are given.[18,179] The mechanism is unknown, but it is not related to the Wolff–Chaikoff effect, which may take several weeks to manifest. Unlike the Wolff–Chaikoff effect, this effect can be overcome partially by an increase in TSH secretion. Thus, the normal gland can escape in 7 to 14 days because inhibition of

thyroid hormone release stimulates a reflex increase in TSH secretion. Because patients with hyperthyroidism experience an improvement in symptoms within 2 to 7 days of initiation of therapy, inhibition of hormone release must be the predominant mechanism of action for the iodides. This rapid onset is the reason iodides are used in the treatment of thyroid storm and as an ameliorative measure while awaiting the onset of the therapeutic effects of ATDs or RAI.[180]

Large doses of iodides are also used 2 weeks before thyroid surgery to increase the firmness of the thyroid gland by decreasing its size, vascularity, and friability. Iodides facilitate a smoother, less complicated surgery and reduce the risk of postoperative complications by inducing a euthyroid state.[179]

Stable iodine can be administered orally either as an unpleasant-tasting Lugol solution (5% iodine and 10% potassium iodide), containing 8 mg/drop of iodide, or as the more palatable saturated solution of potassium iodide (SSKI), containing 50 mg/drop of iodide. The minimum effective daily dose is 6 mg,[179] although larger doses (eg, 5–10 drops qid of SSKI) are often administered.

The advantages of iodide therapy are that it is simple, inexpensive, and relatively nontoxic and involves no glandular destruction. Disadvantages include "escape," accentuation of thyrotoxicosis, allergic reactions, relapse after discontinuation of treatment, and subsequent interference with RAI if used before therapy.[18,33,179]

Treatment Modalities

Case 52-13, Question 3: What are the advantages and disadvantages of the different treatment modalities available for C.R.?

The three major treatment modalities for Graves-related hyperthyroidism are the ATDs, RAI, and surgery (**Table 52-10**).[176] In most cases, any of these three modalities can be used, and there is controversy as to which is the most effective therapy. Often the final

decision is empiric, depending on the clinician's available resources and the patient's desires. A review of treatment guidelines published by the major endocrine organizations found that RAI is the most common treatment, while surgery is the least common.[181] Patients who are older and those with cardiac disease, concomitant ophthalmopathy, and hyperthyroidism caused by a toxic multinodular goiter are treated best with RAI.[33] Surgery is the preferred therapy for pregnant females who are drug-intolerant, when obstructive symptoms are present, or if malignancy is suspected.[33,128]

Table 52-10
Treatment for Hyperthyroidism

Modality	Drug/Dosage	Mechanism of Action	Toxicity	Indication
Primary Treatment				
Antithyroid Drugs				
Methimazole (Tapazole®) 5–10 mg tablet; rectal suppositories can be made[189]	30–40 mg PO daily or in two divided doses (*max:* 60 mg/day) for 6–8 weeks or until euthyroid, then maintenance of 5–10 mg/day PO × 12–18 months	Blocks organification of hormone synthesis, does not block conversion of T_4 to T_3	Skin rashes, GI symptoms, arthralgias, cholestatic jaundice, agranulocytosis, aplasia cutis, and embryopathy syndrome in pregnancy (MMI only)	DOC in adults/children except in thyroid storm and first trimester of pregnancy (see PTU). Once-daily dosing can improve adherence.
PTU 50 mg tablet; rectal formulation can be made[187,188]	100–200 mg PO q6–8h (*max:* 1200 mg/day) for 6–8 weeks or until euthyroid; then maintenance of 50–150 mg daily PO × 12–18 months	Similar to methimazole, and blocks peripheral conversion of T_4 to T_3 (PTU only)	Hepatitis, some fatal. Similar to MMI	DOC in thyroid storm, first trimester of pregnancy
Surgery				
	Preoperative preparation with iodides, ATDs, or β-blockers before surgery; see specific operative agent	Near-total thyroidectomy	Hypothyroidism, cosmetic scarring, hypoparathyroidism, risks of surgery, and anesthesia, vocal cord damage	Obstruction, choking, malignancy, pregnancy in second trimester, contraindication to RAI or ATDs
RAI				
	^{131}I radioactive isotope; 80–100 μCi/g thyroid tissue. Average dose, ≈10 mCi; pretreatment with corticosteroids indicated in patients with ophthalmopathy	Destruction of the gland	Hypothyroidism; worsening of ophthalmopathy; fear of radiation-induced leukemia; genetic damage; malignancy; rarely, radiation sickness	Adults, older patients who are poor surgical risks or have cardiac disease; patients with a history of prior thyroid surgery; contraindications to ATD usage; increasingly used in kids

Adjuncts co Primary Usage				
lodides				
Lugol solution 8 mg/ drop (5% iodine. 10% potassium lodide; saturated [SSKII 50 mg/ drop)	5–10 drops tid PO for 1 0–14 days before surgery; minimum effective dose 6 mg/day	Decreased vascularity of gland and Elevated firmness; blocks reiease of thyrold hormone	Hypersensitivity reactions. skin rashes. mucous membrane uicers. anaphyiaxls. metallic taste, rfiinorrhea, parotid, and submaxillary swelllng, fetal goiters and death	Preoperative preparation before surgery; thyroid storm. provides symptomatic relief of symptoms *Do not use More RAI or chronically during prcgnancy*
P-*Blockers*				
Propranolol or equivalent p-blocker. *Avoid* those with ISA	Propranolol 10–40 mg PO q6h or PRN to control HR <100 beats/ minute; IV 0.5–1 mgslowly	Blocks effects of thyroid hormone peripherally, no effect on underlying dls-ease; blocks T_4 to T_3 conversion	Related to P blockade. bradycardia. HF. blocks hyperglycemic tesponse to hypoglycemla. bronchospasm. CNS symptoms at high doses; fetal bradycardia	Symptomatic relief while awaiting onset of ATDs. RAI: preoperative preparation Tor surgery: thyroid storm
Calcium Channel Blockers				
	Diltiazem 120 mg PO tid-qid or verapamil 80–120 mg PO tid–qid PRN to control HR <100 beats/minute	Blocks effects of thyroid hormone peripherally, no effect on underlying disease	Bradycardia. peripheral edema. HF. headache. flushing. hypotension. dlzziness	Alternative for sympto-matic relief of hyper-thyroid symptoms In patients who cannot tolerate P-blockers
Corticosteroids				
	Prednisone or equivalent corti-costeroids 50–140 mg PO daily in divided doses; IV hydrocorti-sone 50–100 mg q6h or equiv-alent for thyroid storm	Decreased T5I. suppression of in-flammatory process; blocks T_4 to T_3 conversion	Complications of steroid therapy	Ophthalmopathy. thy-roid storm (use IV steroid), pretibial myxedema. pretreat-ment before RAI ther-apy in patients with ophthalmopathy

CNS, central nervous system; DOC, drug of choice; GI, gastrointestinal; HF, congestive heart failure; HR, heart rate; ISA, intrinsic sympathomimetic activity; IV, intravenous; mCi, millicurie; MMI, methimazole; PO, orally (by mouth); PRN, as needed; PTU, propylthiouracil; q, every; qid, four times a day; RAI, radioactive iodine; SSKI, saturated solution of potassium iodide; T_3, triiodothyronine; T_4, thyroxine; tid, three times a day; TSI, thyroid receptor–stimulating or thyroid-stimulating immunoglobulin; µCi, microcurie.

ANTITHYROID DRUGS

The ATDs are the preferred treatment for children, pregnant females, and young adults with uncomplicated Graves disease.[176,182,183] This is the only treatment that leaves the thyroid gland intact and does not carry the added risk of permanent hypothyroidism often associated with RAI or surgery.

Because the thyrotoxicosis of Graves disease might be self-limiting, ATDs are used to control the symptoms until spontaneous remission occurs. Thioamides should also be given before treatment with RAI or surgery to deplete the gland of stored thyroid hormone, which prevents subsequent thyroid storm. Although hyperthyroidism from toxic nodules will also respond to ATDs, more definitive therapy (surgery or RAI) is needed because these conditions do not undergo spontaneous remission.[33,44]

Disadvantages of ATD therapy include the numerous tablets required, patient adherence, possible drug toxicity, the long duration of treatment, and the low remission rates after discontinuation of therapy (see Case 52-14).

The use of ATDs in C.R. has several potential drawbacks. Her relatively large gland and severe disease make the prognosis for spontaneous remission somewhat less favorable. A delay in the onset of ATD effect may be expected if intraglandular stores of thyroid have been increased by her prior iodide therapy. Furthermore, her nonadherence and difficulty swallowing may necessitate another means of treatment. Thioamides may also be prepared for administration by the rectal routes.[184–186]

SURGERY

Surgery is considered the treatment of choice[176,187–189] when (a) malignancy is suspected; (b) esophageal obstruction, evidenced by difficulty swallowing, is present; (c) respiratory difficulties are

present; (d) contraindications to the use of ATDs (eg, allergy) or RAI (eg, pregnancy) exist; (e) a large goiter that regresses poorly on RAI or ATD therapy is present; or (f) it is the patient's preference. Some argue that surgery is underused in the treatment of Graves disease, especially with Graves disease complicated by ophthalmopathy.[187,190] In a prospective, randomized trial comparing the three treatment modalities, surgery produced euthyroidism more quickly and was associated with a lower relapse rate than either RAI or ATDs.[188] A meta-analysis of 35 studies encompassing 7241 patients with Graves disease found that thyroidectomy was successful in 92% of patients with a low recurrence (7.2%) of hyperthyroidism.[191] If C.R.'s minor difficulty in swallowing persists because of poor regression of goiter size with drug therapy, then surgery is a reasonable alternative. If surgery is contemplated, C.R. must be brought to surgery in a euthyroid state to prevent rapid postoperative rises in T_4 levels and subsequent thyroid storm (see Case 52-19, Question 1). A total or near-total rather than a subtotal thyroidectomy is the procedure of choice when performed by an experienced surgeon.[187,189,191] Although subtotal thyroidectomy theoretically avoids the predictable risk of hypothyroidism from total thyroidectomy, the likelihood of recurrent hyperthyroidism increases in proportion to the amount of residual thyroid tissue remaining.[187,188] Recurrent thyrotoxicosis following a subtotal thyroidectomy should be treated with RAI because the incidence of surgical complications increases with a second surgery.[33]

Patients should be in a euthyroid state at the time of surgery to avoid precipitation of thyroid storm and morbidity. Generally, iodides (see Case 52-13, Question 2), ATDs, or propranolol can be used.[33,179,192] The combination of iodides and propranolol is more effective than either used alone.[193] Propranolol used alone has been associated with thyroid crisis postoperatively and may be less effective than iodides in decreasing gland friability and vascularity.[193]

Surgical complication rates are low when the procedure is performed by a competent surgeon and when the patient is adequately prepared for surgery. Postoperative complications

include hypoparathyroidism, adhesions, laryngeal nerve damage, bleeding, infection, and poor wound healing.[189,190,194] Complications are also higher if a total rather than a subtotal thyroidectomy is performed, but there is a lower risk of recurrent hyperthyroidism. Development of hypothyroidism, especially SH, is greatest during the first year after surgery, with an insidious rise in incidence over the next 10 years. Permanent hypothyroidism following surgery is inversely related to the amount of remnant thyroid tissue left behind and varies widely (rates ranging from below 10% to as high as 80% are reported).[195] Thyroid function tests should be monitored annually after surgery. When total thyroidectomy is performed, postoperative L-thyroxine should be initiated at a dose of 1.6 μg/kg/day.[33] Inadvertent parathyroidectomy can result in life-threatening hypocalcemia. Patients receiving total thyroidectomy should have postoperative measurement of serum calcium and/or intact parathyroid hormone concentrations.[33,190]

The disadvantages of surgery are expense, hospitalization, hypothyroidism, the small risk of postoperative complications, and the patient's fear of surgery.[187,188,191]

RADIOACTIVE IODINE

RAI, the most common treatment modality in the United States, is the preferred treatment for (a) debilitated, cardiac, or older patients who are poor surgical candidates; (b) patients who fail to respond to drug therapy or who experience adverse drug reactions; and (c) patients who develop recurrent hyperthyroidism after surgery.[176,181,188,196]

Pregnancy is an absolute contraindication to RAI therapy. Previously, the use of RAI was restricted to adults older than an arbitrary age of 20 to 35 years because it was feared that RAI could result in genetic damage or neoplasia. However, its use in adolescents is increasing after more than 50 years of clinical experience with RAI showing that it is safe and effective.[196–199] There is no reported evidence of genetic damage after ^{131}I ingestion and the dose of radiation to the gonads is <3 rads, which is comparable

to other radiographic diagnostic tests (eg, barium enemas).[200] The incidence of leukemia or malignancy is no higher in recipients of ^{131}I than in patients who are thyrotoxic treated with drugs or surgery.[197,201] In a retrospective review of 98 adolescents followed for 36 years after receiving ^{131}I, no cancers of the thyroid or leukemia were reported.[199] One interesting finding is that patients receiving RAI should be warned that they can set off radiation detectors at airport screening terminals for up to 12 weeks after RAI and that they should carry documentation of their treatment.[202,203]

RAI is painless, effective, economical, and quick, but unsubstantiated fears about radiation and malignancy, as well as the high incidence of hypothyroidism, may deter its use.[33,204,205] RAI could be used safely in this nonpregnant young patient. However, C.R.'s prior use of iodides will dilute the ^{131}I pool. Thus, it will be impossible to achieve therapeutic thyroid concentrations of RAI for as long as 3 to 6 months.

Treatment With Antithyroid Drugs

PROPYLTHIOURACIL VERSUS METHIMAZOLE

Case 52-13, Question 4: C.R. is started on MMI 15 mg twice daily after baseline FT_4 and TSH levels have been obtained. Three weeks later, she angrily states that the medication is not working because her symptoms are worse; however, she reluctantly admits to missing doses because of difficulty swallowing, nausea, vomiting, diarrhea, fatigue, a cough, and a sore throat. What are the advantages of using either PTU or MMI in the treatment of hyperthyroidism?

Both ATDs are effective in treating hyperthyroidism. The antithyroid effectiveness of the ATDs primarily depends on their ability to block the organification of iodides, thereby inhibiting thyroid hormone synthesis.[182,183] Thyroid autoantibody synthesis may also be suppressed. In most hyperthyroid adults and children, MMI should be considered the ATD of choice because of increasing reports of hepatitis, some fatal, from PTU.[50] PTU should be reserved

for use in thyroid storm, during the first trimester of pregnancy because of rare teratogenicity from MMI, and in those allergic to MMI (except agranulocytosis and hepatitis) who are not candidates for RAI or surgery.[44,206]

Dosing and administration

Methimazole is effective when administered initially as a single-dose compared with the multiple-dose regimen required with PTU to achieve a euthyroid state.[182,183] Although a single-dose regimen of PTU has been tried acutely, it is most effective when given in divided doses. Compared to PTU, MMI is also less hepatotoxic, less expensive, requires daily ingestion of fewer numbers of tablets, and is not associated with a bitter tablet taste.[50,183] However, PTU is preferred in thyroid storm because, unlike MMI, it also blocks the peripheral conversion of T_4 to T_3.[192] Within 24 to 48 hours after PTU administration, a 25% to 40% reduction in peripheral T_3 production is seen, which contributes to PTU's rapid onset. A significantly greater fall in T_3 concentration and the T_3:T_4 ratio can be demonstrated in patients who are hyperthyroid treated acutely with PTU and iodine than with MMI and iodides. Lastly, PTU is preferred over MMI during the first trimester of pregnancy (see Case 52-15).[40]

Monitoring therapy

Case 52-13, Question 5: What additional objective baseline data should be obtained to monitor both the efficacy and toxicity of ATDs?

Before ATDs are administered, a baseline FT_4 and TSH should be obtained. A baseline white blood cell (WBC) count with differential can also help differentiate the leukopenia associated with hyperthyroidism from drug-induced leukopenia and/or agranulocytosis (see Case 52-13, Question 10). Baseline liver function tests can assist in the evaluation of ATD-induced hepatotoxicity (see Case 52-13, Question 9). A repeat FT_4 and TSH

should be obtained after 4 to 6 weeks on therapy and 4 to 6 weeks after any change in the dosing regimen. Once the patient is euthyroid on maintenance dosages, thyroid function tests can be obtained every 3 to 6 months.

Duration of therapy

Case 52-13, Question 6: How long should C.R. be continued on ATD treatment?

Traditionally, ATD therapy is continued for 1 to 2 years despite the lack of data regarding the optimal treatment period.[176,182,183] The goal of treatment is to control the symptoms of Graves disease until spontaneous remission occurs. Graves disease remits spontaneously in about 30% to 50% of patients but relapse is high.[207] Because it is unknown when or if remission will occur, it is understandable why the optimal duration of therapy is unclear. Short-term therapy (ie, <6 months) has been advocated to save time and money and improve adherence because earlier studies suggested remission rates comparable to a longer course of therapy. However, short-term therapy is not recommended because longer follow-ups of patients receiving short-term therapy have noted poorer remission rates.[182,183]

Most data support a 12- to 18-month course of treatment to achieve remission rates of ~60%.[182,183] Two prospective randomized trials found that extending treatment from 6 to 18 months was beneficial but that 42 months of therapy was not significantly better than 18 months.[208] A retrospective study of 211 patients determined that therapy for more than 24 months independently predicted long-term remission.[209] A 2017 meta-analysis also concluded that long-term ATD treatment is safe and effective in adults.[210] However, one retrospective study of patients treated for >12 months observed remission rates of only 17.5%.[211] These conflicting results underscore the fact that determining the optimal treatment period is confounded by the large variability that exists with regard to

spontaneous remission. Nevertheless, treatment periods of 1 to 2 years are justifiable in adherent patients. Therapy can be reinstituted if hyperthyroidism reappears shortly after therapy is discontinued. Methimazole can also be continued indefinitely if there are no side effects and treatment with either RAI or surgery is not desired. In C.R., this goal might not be achievable, given her history of nonadherence.

PRECAUTIONS

Case 52-13, Question 7: Can ATD therapy affect any of C.R.'s preexisting medical conditions?

Thyrotoxicosis can activate or intensify diabetes, primarily by increasing the basal hepatic glucose production and the metabolism of insulin.[212] Therefore, effective therapy with ATDs may restore control of C.R.'s type 2 diabetes.

C.R.'s arthritis should not be affected, although ATDs have been associated with the development of systemic lupus erythematosus (SLE), lupus-like syndromes, and vasculitis.[182,213] These adverse drug reactions are rare; the incidence is <0.1%. Lupus-like syndromes include skin ulcers, splenomegaly, migratory polyarthritis, pleuritis and pericarditis, periarteritis, and renal abnormalities.[33,213] Serologic abnormalities may also occur with these connective tissue disorders and include hyperglobulinemia, positive SLE preparations, and positive antinuclear antibodies. Recovery occurs with adequate steroid therapy and withdrawal of the ATD. Because cross-reaction between MMI and PTU is likely to occur, patients exhibiting these reactions should be treated with surgery or RAI. C.R.'s treatment should be monitored with this lupus-like adverse effect in mind, but the occurrence of this syndrome is so uncommon that a trouble-free course of therapy can be anticipated.[213]

ADJUNCTIVE THERAPY

Case 52-13, Question 8: What adjunctive therapy might help alleviate some of C.R.'s symptoms while awaiting the onset of the ATD's effects?

****

Iodides (see Case 13, Question 2), β-adrenergic blocking agents without intrinsic sympathomimetic activity, or calcium channel blockers can be used acutely to ameliorate some of C.R.'s symptoms.[193,214] Because iodides were previously ineffective in C.R., a β-blocker should be tried.

β-Adrenergic blocking agents rapidly decrease the nervousness, palpitations, fatigue, weight loss, diaphoresis, heat intolerance, and tremor associated with thyrotoxicosis, probably because many of the signs and symptoms mimic sympathetic overactivity.[176,193] An increase in the number of β-adrenergic receptors rather than an elevation in catecholamine levels is probably responsible for this overactivity. Because the underlying disease process and thyroid hormone levels are not affected significantly by β-blockers, patients generally remain mildly symptomatic and fail to gain weight. For this reason, they should not be used as the sole treatment for thyrotoxicosis.

All β-blockers without intrinsic sympathetic activity (eg, atenolol, metoprolol, propranolol) are effective in alleviating the hyperthyroid symptoms, but propranolol and nadolol are the only β-blockers that may inhibit peripheral conversion of T_4 to T_3 at high doses.[33] Thyroid function tests are generally not affected except for a mild decrease in the T_3 level.

In summary, β-blockers are (a) effective adjuncts in the management of thyroid storm, (b) useful to prepare patients for surgery, and (c) useful in the short-term management of thyrotoxicosis during pregnancy.[33,187,192] Surprisingly, propranolol also improves many of the neuromuscular manifestations of hyperthyroidism, including thyrotoxic periodic paralysis. Current guidelines recommend elderly patients, those with concomitant heart disease, and those with a resting heart rate over 90 beats/minute receive adjunctive therapy with β-blockers.[33,215]

Diltiazem or verapamil are effective alternatives when β-blockers are contraindicated.[214] Diltiazem 120 mg tid or qid can be tried. The dihydropyridine calcium channel blockers are unlikely to be effective.

Because of C.R.'s history of diabetes, the effects of β-adrenergic blocking drugs in patients with diabetes must be considered (see Chapter 53, Diabetes Mellitus). If β-blockers are instituted, a cardioselective β-blocker would be a better choice for patients on therapy that can cause hypoglycemia because of lower risk of hypoglycemia unawareness.[216] The appropriate dosage should be based on clinical and objective improvement of hyperthyroid symptoms, such as a reduction in heart rate. Metoprolol 25 to 50 mg bid can be started initially, and the dosage titrated to maintain the heart rate at <90 beats/minute. Otherwise, diltiazem, verapamil, or a retrial of iodides is warranted.[193,214,215]

ADVERSE EFFECTS

Case 52-13, Question 9: A pruritic area over the pretibial aspects of both legs, as well as several maculopapular erythematous patches and abdominal tenderness, were noticed during C.R.'s physical examination. Do these reactions require the discontinuation of her PTU?

Antithyroid drug rash

Although C.R. may be experiencing a drug rash from PTU, pretibial myxedema or the dermopathy of Graves disease may also be possibilities because of the location of the pruritic area. About 4% of patients with Graves disease who exhibit infiltrative exophthalmos also have dermatologic changes.[177] The skin is thickened, erythematous, and nonpitting because of mucopolysaccharide infiltration and accentuation of hair follicles. Pruritus or pain may be present. Treatment includes topical corticosteroids, control of the Graves disease, and reassurance.[177]

Thioamides can produce a maculopapular pruritic rash in 5% to 6% of treated patients.[183] The rash can occur at any time but is more common early in therapy. If the rash is mild, drug therapy can be

continued while the patient's symptoms are treated with an antihistamine and a topical steroid; such rashes generally subside spontaneously. Alternatively, another ATD can be substituted because cross-sensitivity to this side effect is uncommon. Antithyroid drugs should be stopped if the rash is urticarial in nature or associated with systemic manifestations (eg, fever, arthralgias).

Hepatitis

C.R.'s symptoms of nausea, vomiting, diarrhea, fatigue, and abdominal tenderness require further evaluation. Her symptoms could be consistent with mild GI side effects from her PTU therapy, impending thyroid storm from nonadherence (see Case 52-19, Question 1) or more seriously, PTU-induced hepatitis. PTU has been associated with 0.1% severe hepatotoxicity, leading to liver transplants and fatalities primarily in children.[44,206,217,218] Although usually hepatocellular in nature, cholestasis, hepatic necrosis, and fulminant hepatic failures have been reported.[183,219,220] Transient elevations in transaminases occur in ~30% of asymptomatic patients within the first 2 months of PTU therapy and may not require drug discontinuation.[219] Liver enzymes usually normalize within 3 months of reducing the PTU to maintenance dosages despite drug continuation. However, PTU should be stopped immediately in patients with clinical symptoms of hepatitis to ensure complete recovery. The mechanism of PTU-induced hepatotoxicity appears to be autoimmune because circulating autoantibodies and in-vitro peripheral lymphocyte sensitization to PTU have been detected.[220] Overt hepatitis typically occurs during the first 2 months of PTU therapy and is not dose-related. In contrast, MMI rarely produces a cholestatic jaundice picture that might be more common in older patients and in those receiving higher dosages (ie, >40 mg/day).[221] In patients with ATD-induced hepatitis, changing to the alternative ATD is not recommended because fatalities have been reported on rechallenge. In such patients, either radioactive therapy or surgery should be used.[177]

In C.R., PTU should be stopped while awaiting results of thyroid function tests, transaminases, and bilirubin. Routine monitoring of liver function tests is not recommended during ATD therapy because patients can be asymptomatic. However, routine monitoring might be reasonable in patients with a history of liver disease and risk factors for hepatitis (eg, alcohol use). All patients receiving ATDs should be questioned closely during the first 2 months of therapy for symptoms of hepatitis, and hepatic function tests should be obtained if appropriate.

Agranulocytosis

Case 52-13, Question 10: What is your assessment of C.R.'s symptoms of sore throat and cough?

C.R.'s symptoms should not be dismissed casually because they might indicate PTU-induced agranulocytosis. Agranulocytosis (<500/mm^3 of neutrophils) is the most severe adverse hematologic reaction associated with the ATDs and should be considered strongly in C.R.[183,222] An accurate history should be obtained from C.R. The clinician should be particularly alert for a temperature of 101 °F (38.33 °C) for 2 or more days, malaise, or other flu-like findings that appeared temporally with her sore throat. If subjective or objective data are consistent with agranulocytosis, the PTU should be discontinued immediately until the results of a repeat WBC count with a differential are obtained. Traditionally, routine serial determinations of WBC counts are not recommended for monitoring the development of agranulocytosis because the onset is so abrupt. Instead, patients should be instructed to immediately report rash, fever, sore throat, or any flu-like symptoms. However, one study suggested that weekly monitoring of the WBC count with a differential during the first 3 months of antithyroid therapy might identify asymptomatic patients with agranulocytosis before infection occurs.[222]

The prevalence of agranulocytosis is about 0.5% but ranges from 0.5% to 6%.[183,222] The risk factors for agranulocytosis are unknown. There is no predilection for either gender, and the reaction may be idiosyncratic or dose-related. Some reports suggest that patients older than 40 years and those taking high dosages of MMI (eg, >40 mg/day) might be more susceptible than those on any dosage of PTU. Although controversial, patients receiving low dosages of MMI (eg, <40 mg/day) might be at less risk than those receiving high or conventional dosages of PTU.[183,222]

Agranulocytosis typically develops within the first 3 months of treatment, although it can occur at any time and as late as 12 months after starting ATD therapy.[183] A delayed reaction is more common with MMI therapy than with PTU. In 55 patients who developed agranulocytosis while taking ATDs, the duration of PTU therapy (17.7 ± 9.7 days) was significantly shorter than for MMI therapy (36.9 ± 14.5 days).[222] The mechanism of ATD-induced agranulocytosis is unknown. Both allergic (idiosyncratic) and toxic-type (dose-related) reactions have been suggested. An autoimmune reaction with circulating antineutrophil antibodies and lymphocyte sensitization to antithyroid drugs has been demonstrated.[223] Death usually results from overwhelming infection.

If agranulocytosis is diagnosed, the drug should be discontinued, the patient monitored for signs of infection, and antibiotics instituted if necessary. Granulocyte colony-stimulating factors may shorten the recovery period.[183,224] If the patient recovers, granulocytes begin to reappear in the periphery within a few days to 3 weeks; a normal granulocyte count occurs shortly thereafter.[222,224]

Although some cases of granulocytopenia have resolved with substitution or continuation of ATDs, the risks of drug rechallenge clearly outweigh the benefits, and other treatments should be instituted. Changing to an alternative ATD should also be avoided because of possible cross-sensitivity between these agents.[183]

In summary, all patients receiving ATD therapy should be well educated regarding the signs and symptoms of agranulocytosis. If these symptoms develop, they should be advised to contact their physician or pharmacist. If they cannot reach their own physician,

patients should inform the emergency physician that they are taking ATDs, and a WBC count with differential should be obtained. Routine monitoring of a WBC and differential is not recommended until further studies justify that it is indicated and cost-effective.

REMISSION RATES WITH THIOAMIDES

CASE 52-14

QUESTION 1: B.D., a 30-year-old female, has been maintained on MMI 5 mg daily for >2 years. Her MMI has been discontinued twice in the past, and each time her hyperthyroidism recurred. She refuses either surgery or RAI therapy. Although she is clinically euthyroid on MMI, her gland is larger than her usual size and has never decreased with therapy. Recent laboratory tests showed an FT_4 of 1 ng/dL (normal, 0.8–1.8) and a TSH level of 6.5 μIU/mL (normal, 0.40–4.5).

What is responsible for the enlarging gland? What subjective or objective data in B.D. would influence her remission rate and justify a longer course of ATD therapy? Would the addition of T_4 be helpful?

The high TSH level suggests that TSH stimulation caused by excessive suppression of hormone synthesis by MMI is contributing to the enlarging thyroid gland.[225] The easiest solution to this problem is to decrease the maintenance dose of MMI to 2.5 mg daily to normalize the TSH value and minimize gland stimulation.

Long-term remission rates achieved with the ATDs are disappointing. Remission rates within 6 years after discontinuing therapy average 50% (range, 14%–75%),[182,183,208,211,226] although relapse rates are as high as 80%. The rate of permanent remission is usually <25% if the follow-up period is long enough.[182,183,227] Why some patients remain in remission while others relapse once ATDs are discontinued is unclear, although patients who remain euthyroid for >10 to 15 years after discontinuing therapy probably do so because of disease progression to Hashimoto thyroiditis rather than as a direct result of treatment.[176] In other words, the natural course of Graves hyperthyroidism might be eventual hypothyroidism regardless of the treatment modality used. Several factors have a

limited role in predicting relapse and remission and have been used to guide therapy.

A longer duration of ATD treatment (see Case 52-13, Question 6) improves the remission rate by changing the basic underlying abnormality of Graves disease.[182,208,211,226] Numerous studies show that titers of antithyroid receptor (TSI) and antimicrosomal antibodies fall during ATD therapy but are unchanged during therapy with placebo or β-blockers.[182,183,208,228] Patients with low or undetectable TSI titers at the end of 12 to 24 months of ATD therapy had a 45% chance of remission compared to <10% chance of remission for those with higher titers within 1 to 5 years after completing therapy.[227–230] The best response was obtained in those with smaller goiters, less severe disease, and nonsmokers. A higher ATD dose did not improve the remission rate but resulted in more toxicity, including agranulocytosis, arthralgias, dermatitis, gastritis, and hepatotoxicity.[182,226,227]

Certain clinical features have been associated with a greater chance of disease remission and might help clinicians identify patients who deserve a longer ATD trial before changing to RAI or surgery. These clinical features include smaller goiter, mild symptoms of short duration, a reduction in goiter size during treatment, nonsmokers, absence of ophthalmopathy, and undetectable or low TSI levels.[183,227,228] Smokers should be advised to discontinue smoking to increase the chance of remission (see Chapter 91, Tobacco Use and Dependence).[231]

In a preliminary study, the addition of L-thyroxine to maintenance doses of ATDs for 1 year, followed by an additional year of L-thyroxine alone, significantly reduced the risk of relapse after stopping ATDs.[230] Those receiving the T_4–MMI combination experienced significant reductions in TSH receptor antibody titers compared to those taking MMI alone. At 3 years, the combination-treated patients had a lower rate of recurrence after stopping therapy (1.7%) than those receiving MMI alone (recurrence rate, 34.7%). Unfortunately, several prospective studies evaluating the addition of T_4 to ATDs have not validated these initial favorable

results.[227,229,232,233] Support for this therapeutic approach has waned, and the addition of T_4 to existing ATD therapy is not recommended.

B.D.'s large goiter reduces her chance of remission with longer therapy.[234] Although ATD therapy can be continued indefinitely if well-tolerated, surgery or RAI therapy should seriously be considered for B.D., who already has received MMI for >2 years. Alternative therapy is especially crucial if she plans to become pregnant within the next few years (see Case 52-15).

Hyperthyroidism in Pregnancy

CASE 52-15

Question 1: N.N., a 32-year-old female who is 3 months pregnant, is referred for management of her Graves disease.

What are the therapeutic ramifications of managing thyrotoxicosis during pregnancy?

Hyperthyroidism develops in ~0.2% of pregnant females and often precedes conception.[129] Symptoms of thyrotoxicosis are typically ameliorated during the second and third trimesters and exacerbated early in the postpartum period. Treatment is crucial to prevent damage to the fetus and to maintain the pregnancy. RAI, chronic iodide therapy, and iodine-containing compounds are contraindicated during pregnancy because they will cross the placenta to produce fetal goiter and athyreosis.[235–237] If rapid control of hyperthyroid symptoms is required, short-term use (<1–4 weeks) of propranolol is safe.[41,129,134] Iodide use in pregnancy should be limited to transient preoperative use prior to thyroidectomy or in the management of thyroid storm.[41,238]

Either surgery or ATD is the treatment of choice for pregnant patients who are hyperthyroid. Surgery is safe during the second trimester with adequate preoperative preparation. PTU is preferable during the first trimester (through week 16) because of rare reports of teratogenicity from MMI.[128,239] Females taking MMI should be

switched to PTU at a dose of 1:20 as soon as possible after confirmation of pregnancy.[128] Both ATDs are equally efficacious,[240] demonstrate similar placental crossing properties,[241] and produce similar thyroid hormone concentrations in fetal umbilical cord blood samples.[242] Methimazole has been associated with anecdotal reports of congenital scalp defects (eg, aplasia cutis) and an embryopathy syndrome (esophageal and choanal atresia).[243–246] However, the risks of reversible aplasia cutis were not greater in females receiving MMI (eg, 2.7%) compared to PTU (eg, 3%) or hyperthyroid controls (eg, 6%).[240,243,244] Therefore, MMI can be considered throughout pregnancy if there is intolerance or nonadherence to PTU[235,236,240] (see Chapter 49, Obstetric Drug Therapy).

Fetal hypothyroidism and goiter can develop when large doses of ATDs are administered to the mother, even if the mother is still hyperthyroid.[235,236] Therefore, to avoid goiter and suppression of the fetal thyroid gland, which begins to function at about 12 to 14 weeks of gestation, the lowest effective ATD dose should be given. Normal FT_4 levels occur in >90% of neonates when maternal FT_4 is maintained in the upper third of the normal range (1.5–1.9 ng/L).[41,238] Conversely, over 30% of neonates exhibit a low FT_4 when maternal levels are maintained in the lower two-thirds of the normal range.[41] Complete control of maternal hyperthyroidism increases the risk of fetal hypothyroidism. Current guidelines recommend maintaining the T_4/FT_4 at or just above the upper limit of the normal range and monitoring every four weeks.[128] Start PTU (eg, maximum of 300 mg/day in three divided doses) or MMI if after gestational week 16 (eg, maximum of 20–30 mg given once daily) until control is achieved, then taper to the lowest effective dose. Consideration can be given to changing PTU to MMI after the first trimester; however, there is risk of over/under-treating the condition and lack of evidence supporting the change.[128] In many patients, remission of Graves disease occurs during pregnancy and some patients can discontinue ATDs in the second half of pregnancy.[235] Measurement of TRAb levels between weeks 18 and 22 of gestation can be useful, because disappearance of TRAb is an indication that ATD therapy my no

longer be necessary. If TRAb remains elevated in the second trimester, it should be measured again near term, between weeks 30 and 34. Presence of sustained high TRAb concentrations (>5 IU/L or three times the upper limit of normal) indicate the need for neonatal monitoring. The neonate will clear the ATD faster than antibodies passed through the placenta, resulting in neonatal hyperthyroidism.[128]

Although transient fetal or neonatal hypothyroidism does not appear to be a major threat to the baby, it is advisable to maintain the mother in a mildly hyperthyroid state.[235,236] Mild maternal hyperthyroidism appears to be well-tolerated, but maternal hypothyroidism is poorly tolerated by both the mother and the fetus (see Case 52-8, Question 1). T_4 levels should be maintained at or just above the upper limit of the normal range to decrease the risk of fetal hypothyroidism.[128] The goal of therapy is a measurable, but suppressed maternal TSH level (0.1–0.4 μIU/mL) because complete correction of maternal hyperthyroidism increases the risk of fetal hypothyroidism.[33,133]

Both ATDs can be safely used in the lactating mother if the maximal dose of MMI does not exceed 10 to 20 mg daily or less preferably, if PTU does not exceed 200 mg/day (up to 750 mg/day in one report).[247,248] Iodides are secreted in breast milk, and transient SH may occur in breastfed infants; therefore, they should be used with caution in breast feeding females (see Chapter 49 Obstetric Drug Therapy).[249,250]

Treatment With Radioactive Iodine

PRETREATMENT

CASE 52-16

Question 1: B.J., a 35-year-old female, has newly diagnosed Graves disease complicated by HFrEF and angina. After a few days of treatment with MMI 30 mg daily and Lugol solution, 5 drops/day, B.J. received RAI therapy. Six months later, she is still symptomatic.

What is the influence of B.J.'s pretreatment therapy on the efficacy of her RAI therapy?

Older or debilitated patients with severe hyperthyroidism and/or concomitant cardiac disease should receive antithyroid pretreatment before RAI therapy to deplete stored thyroid hormone and minimize post-RAI hyperthyroidism (occurring in the first 10 days after ^{131}I administration) and thyroid storm caused by leakage of hormones from the damaged thyroid gland.[183,192,205] Other patients who are hyperthyroid can receive RAI safely without pre-therapy.

Lugol solution or other iodides should not be given before RAI because iodides decrease the gland's uptake of RAI and its effectiveness. This effect of iodides persists for several weeks. Iodides can be given after RAI treatment if needed to rapidly control symptoms of hyperthyroidism.[33,42]

Prior to RAI, ATDs achieve a euthyroid state, but pretreatment may lower the cure rate and increase the need for subsequent RAI.[183,196,251] A meta-analysis of 14 trials found that use of ATDs (PTU, MMI, carbimazole [not available in the United States]) before and after RAI was associated with an increased risk of treatment failure (relative risk of 1.28; 95% CI, 1.07–1.52) and a 32% reduced risk of hypothyroidism regardless of the ATD used.[196] To facilitate optimal uptake and retention of 131RAI by the gland, ATDs should be stopped at least 2 to 3 days, before RAI administration.[251–253] If necessary, ATDs can be restarted 3 to 7 days after RAI administration without impairing its efficacy. β-Adrenergic blocking agents can be used before, during, and after RAI therapy without interfering with its uptake.

B.J. remains symptomatic because MMI and iodides decreased RAI's efficacy. Propranolol should be given to B.J. before RAI therapy to relieve hyperthyroid symptoms because only a short course of ATD was given. Iodides might be preferable to propranolol following RAI therapy if B.J.'s HFrEF worsens. For subsequent RAI doses, MMI pretreatment should be stopped 2 to 3 days before RAI, thereby allowing a shorter duration of hyperthyroidism.

ONSET OF EFFECTS

CASE 52-16, QUESTION 2: B.J. still is symptomatic 2 weeks after a second dose of RAI. When can she expect to experience the therapeutic effects of RAI therapy? What educational precautions about radiation safety should B.J. receive?

Although some benefits from RAI therapy are evident within 1 month, a period of 6 to 18 weeks is generally required for maximal effects.[176,196,205] Euthyroidism or, more commonly, hypothyroidism occurs in ~85% to 95% of patients treated with a single nonablative dose of RAI; the remaining 5% to 15% become euthyroid or hypothyroid after two or more doses.[42] This slow onset is a disadvantage, but symptomatic control can be obtained quickly by administration of a β-adrenergic blocking agent or iodides starting 1 to 14 days after the ^{131}I dose. Iodides are less preferable if a second dose of RAI is necessary. Antithyroid drugs can also be given, although their therapeutic effects are delayed for 3 to 4 weeks.

Most patients become hypothyroid 2 to 3 months after receiving RAI; however, some require longer. For this reason, at least 6 months should elapse before a second dose of RAI is administered, unless the patient remains severely thyrotoxic.[33,42] It is inadvisable to give a second dose before the major effects of the first dose have become apparent. Although the use of iodides before RAI in B.J. may have decreased the amount of ^{131}I retained by her thyroid, it still is advisable to wait at least 6 months before a second dose is given.

Safety precautions to reduce radiation exposure to family members and members of the public are not universal and vary across the United States depending on the dose of RAI administered.[196] B.J. should avoid close contact (eg, 6 feet) with children for 5 days, with pregnant females for 10 days, and intimate contact with body fluids for 5 days. B.J. should avoid airplane travels, public transportation, and work if contact with others during these activities last more than 2 hours. Other recommendations include sole use of bathroom facilities; sitting while urinating to avoid splashing, and to flush the toilet twice with the lid down.[196,254]

IATROGENIC HYPOTHYROIDISM

CASE 52-17

QUESTION 1: S.D., a 54-year-old female, returns to the thyroid clinic after being lost to follow-up for 6 months. She initially received RAI 3 years ago but required a repeat dose of RAI one year ago. She has no other medical problems and is not taking any medications. She is a mildly obese, puffy-faced female wearing several layers of clothing who reports of fatigue and lack of energy. Her reflexes are delayed, and her skin is cool and dry.

What is a likely explanation for her symptoms?

S.D.'s clinical presentation and history are compatible with hypothyroidism secondary to RAI therapy. An FT_4 and a TSH level would confirm this diagnosis. Iatrogenic hypothyroidism is the major complication of RAI therapy, although transient hypothyroidism can occur in the first 3 to 6 weeks after therapy.[176] The incidence of iatrogenic myxedema is often reported as 7% to 8%, but it increases at a constant rate of 2.5% per year. The reported prevalence of this complication ranges from 26% to 70% after 1 to 14 years.[205]

The best predictor of eventual hypothyroidism is the total dose of RAI administered. Prevention of iatrogenic hypothyroidism is directed toward calculation of a dose that will produce neither recurrent hyperthyroidism nor hypothyroidism. Unfortunately, when lower doses of RAI were used to avoid hypothyroidism, the cure rate was reduced but the incidence of hypothyroidism was unaffected.[255] Thus, the appearance of iatrogenic hypothyroidism may be inevitable with time. However, hypothyroidism is managed easily and is an acceptable therapeutic end point. Because hypothyroidism after RAI therapy is latent and often insidious, patients should be informed of this and monitored closely at monthly intervals for subsequent hypothyroidism. Awareness of a transient hypothyroidism soon after RAI therapy should minimize the institution of unnecessary hormone replacement.

Ophthalmopathy

CLINICAL PRESENTATION

CASE 52-18

QUESTION 1: H.R., a 50-year-old male, first developed "large eyes with stare," weakness, diaphoresis, and thyroid enlargement when he was diagnosed with Graves disease. RAI therapy caused some worsening of his eye symptoms. Although he is clinically euthyroid, physical examination reveals severe bilateral conjunctival edema and injection, proptosis of the right eye, incomplete lid closure, and decreased visual acuity. He reports of photophobia, tearing, and extreme irritation, which is worse after smoking cigarettes. His other medical problems include type 2 diabetes treated with metformin and pioglitazone.

What is the association of H.R.'s ocular changes with Graves disease?

H.R. presents with symptoms consistent with the infiltrative ophthalmopathy of Graves disease.[256–258] The eye signs of Graves disease are the most striking abnormality of this disorder. Rarely, ophthalmopathy can occur without any evidence of hyperthyroidism. Fortunately, severe ophthalmopathy occurs in only 3% to 5% of patients, whereas 25% to 50% have some eye findings. Eye disease is more severe in older patients and in males than females. Smokers often have higher levels of TSI and more severe ophthalmopathy.[231,257,259]

It is unknown why the eye and its muscles are attacked in Graves disease but is likely related to the presence of TSH receptor antibodies along with other immunoglobulins that activate both thyrotropin and insulin-like growth factor 1 (IGF-1) receptors on orbital fibroblasts.[258,260,261] Histologic examination reveals lymphocytic infiltration, increased mucopolysaccharides, fat (because of increased adipogenesis and glycosaminoglycans), and water in all retrobulbar tissue. Ocular symptoms include edema, chemosis, excessive lacrimation, photophobia, corneal protrusion (proptosis), scarring, ulceration, extraocular muscle paralysis with loss of eye movements, and blindness from retinal and optic nerve damage.[177]

The eye involvement can occur at any time and is usually bilateral. The ocular symptoms usually subside or remain stable once the

patient is euthyroid; however, some cases will progress if patients become hypothyroid and are left untreated following RAI treatment (see Question 2).[215] Pioglitazone has been associated with a 1- to 2-mm increase in eye protrusion by stimulating adipogenesis and increasing retrobulbar fat production.[262] Although eye changes were more common in people with a history of thyroid disorders, the overall incidence of eye changes associated with pioglitazone is unknown.[262]

MANAGEMENT OF EYE SYMPTOMS

Case 52-18, Question 2: Was previous treatment of H.R.'s hyperthyroidism appropriate? How should his current ocular symptoms be managed?

The optimal treatment of hyperthyroidism and its effect on the course of ophthalmopathy remain controversial.[256,257,263] ATDs might improve eye symptoms through an immunosuppressive mechanism of action and control of the hyperthyroidism or exert a neutral effect.[256] Many clinicians believe that RAI ablation or surgical removal is preferable because it removes the antigen source and prevents progression of the ophthalmopathy.[187,256] However, several studies have confirmed development or worsening of eye symptoms immediately after RAI therapy.[259,263] Concomitant use of 0.4 to 0.5 mg/kg of prednisone begun 1 to 3 days post-RAI continued for 1 month and tapered over 2 months may be used in patients with mild active eye disease to prevent progression of eye symptoms.[33,259] Lower-dose, shorter-duration prednisone therapy (0.2 mg/kg/day for 6 weeks) may be as effective as conventionally used doses.[264] Patients with active moderate-to-severe or sight threatening ophthalmopathy at the time of treatment should be treated with surgery or ATDs instead of RAI.[33,215] Regardless of the treatment used, control of the hyperthyroidism often improves most eye findings, except for proptosis.

In H.R., prednisone 40 to 60 mg/day should have been started after his RAI treatment and continued for 2 to 3 months until the eye

symptoms improved. Because the pathophysiology of the ophthalmopathy is unclear, treatment is limited to symptomatic and empiric measures once the patient is euthyroid.[256,257] H.R. should also be encouraged to stop smoking to prevent progression of the ophthalmopathy.[231] His pioglitazone should be discontinued, in case this is contributing to his ophthalmopathy. Although it is too late for steroids to mitigate RAI-induced worsening of ophthalmopathy, there is evidence that corticosteroids reduce orbital inflammation and congestion and are useful in the management of the disease.[177,265] H.R. could be considered for a course of corticosteroids; however, this must be weighed against the potential for worsening his glycemic control (see Chapter 53, Diabetes Mellitus).

Because periorbital edema and chemosis are worse in the morning after being in the horizontal position, elevating the head of the bed, diuretics, and restricting salt intake may be helpful. Protective glasses can relieve photophobia and external irritation. Topical corticosteroid drops are effective in decreasing local irritation, but they should be used cautiously because they increase the risk of infection. Ocular irritants such as smoke and dust should be avoided. Bothersome symptoms (eg, dry eye, redness, tearing) caused by eyelid retraction can be relieved by artificial tears and lubricants.[256] Incomplete lid closure predisposes to corneal scarring and ulceration, so lubricant eye drops should be applied several times daily and at night to keep the bulbs moist. Taping the eyelids shut at night prevents drying and scarring. Lateral surgical closure of the lids (tarsorrhaphy) may be required to improve lid closure.[177]

With severe and progressive ophthalmopathy, an aggressive approach is necessary. Systemic corticosteroids can produce either dramatic or marginal results in the emergency treatment of progressive exophthalmos associated with decreasing visual acuity. Prednisone at dosages of 35 to 80 mg/day is often effective, although dosages as high as 100 to 140 mg/day may be necessary.[256,257] Pain, irritation, tearing, and other subjective symptoms often respond within 24 hours of administration. Therapy for about 3 months is necessary to improve eye muscle and optic nerve function disturbances. Initial large doses should be tapered

rapidly once the desired response is obtained to minimize adverse effects. Subconjunctival and retrobulbar injections of steroids are not as effective.

Orbital x-ray therapy also relieves congestive and inflammatory symptoms.[256] The combination of orbital irradiation and systemic steroids may be required to achieve maximal benefits. Plasmapheresis and immunosuppressive agents, such as cyclophosphamide, azathioprine, cyclosporine, and methotrexate, combined with steroids have also been used with limited success. Similarly, the plasma B cell–depleting agent rituximab has resulted in improvement in eye disease.[266] Clinical trials with an IGF-I receptor inhibitor, teprotumumab, administered every 3 weeks for 21 weeks resulted in significant improvement in the clinical activity score used to assess severity of ophthalmopathy as well as the degree of proptosis.[261,267] Future investigations are focusing on anti-TNF and anti-interleukin receptor antibodies agents that may neutralize some of the inflammatory reactions in the eye.[256,258]

When the previous measures and thyroid ablation fail to arrest the progression of visual loss and exophthalmos, then surgical orbital decompression should be considered.[176]

Thyroid Storm

CLINICAL PRESENTATION

CASE 52-19

Question 1: H.L., a 48-year-old female, is admitted to the hospital with a 3-week history of fatigue, weakness, dyspnea on exertion, SOB, palpitations, and inability to keep food and liquids down. One year before admission, she began noticing a preference for cold weather and an increase in nervousness and emotional lability. After her husband died a few days ago, she experienced increased nausea and vomiting, irritability, insomnia, tremor, and a 104 °F (40 °C) fever, which she attributed to an upper respiratory tract infection. She denies taking any current medications. Her laboratory data obtained on admission included an FT_4 of 4.65 ng/dL (normal, 0.8–1.8) and an undetectable TSH level.

What is your assessment of H.L.'s subjective and objective data?

The presentation is consistent with thyroid storm, a life-threatening medical emergency that might have been precipitated by the stress associated with the death of her husband. The clinical manifestations of thyroid storm[192] include the acute onset of high fever, tachycardia, and tachypnea, and involvement of the following organ systems: cardiovascular (tachycardia, pulmonary edema, hypertension, shock), CNS (tremor, emotional lability, confusion, psychosis, apathy, stupor, coma), and GI (diarrhea, abdominal pain, nausea and vomiting, liver enlargement, jaundice, nonspecific elevations of bilirubin and prothrombin time).

Thyroid storm develops in about 2% to 8% of patients who are hyperthyroid. The pathogenesis of thyroid storm is not well understood, but the condition can be described as an "exaggerated" or decompensated form of thyrotoxicosis. The term *decompensated* implies failure of body systems to adequately resist the effects of thyrotoxicosis. It is not attributed solely to the release of massive quantities of hormones, which can occur after surgery or RAI therapy. Catecholamines also play an important role; the increased quantities of thyroid hormone in conjunction with increased sympathetic and adrenal output contribute to many of the manifestations of thyroid storm. Although thyroid hormones exert an independent effect, many of the symptoms of hyperthyroidism are ameliorated by catecholamine-blocking agents such as β-blockers and calcium channel blockers (eg, diltiazem, verapamil).[180,268]

TREATMENT

Case 52-19, Question 2: What treatment plan (including route of administration) should be initiated promptly in H.L.?

Intensive, continuous, and immediate treatment can significantly reduce the mortality of thyroid storm. Mortality rates in thyroid storm are high, ranging between 20% and 30%.[192] Treatment of thyroid

storm should be directed against four major areas discussed in the following sections.[192]

Decrease in synthesis and release of hormones

High dosages of ATDs, preferably PTU 500 to 1000 mg/day or MMI 60 to 80 mg/day, should be given orally in four divided doses. If H.L. cannot take oral doses, a rectal formulation of PTU (better bioavailability with enema than suppository) or MMI, which is as effective as the oral route, can be administered.[33,184] No commercial parenteral preparation is available for either drug, limiting their use by the IV route. PTU is the ATD of choice because it acts more rapidly than MMI by blocking the peripheral conversion of T_4 to T_3, a dominant source of the hormone.[180]

Iodides, which rapidly block further release of intraglandular stores of T_4, should be given at least 1 hour after ATD administration. Given in this way, the substrate for hormone synthesis is not increased, and the therapeutic effect of ATD is not blocked. The addition of iodides (eg, Lugol solution 15–30 drops/day orally in divided doses) to the ATDs ameliorates symptoms rapidly and may restore T_4 concentrations to near-normal levels in 4 to 5 days.[180,215]

Lithium interferes with production of T_3 and T_4 and may decrease release of thyroid hormones from the thyroid gland and can be used in doses of 300 mg every 6 to 8 hours in patients where iodine administration is not possible.[180] Lithium is a narrow therapeutic index drug, and its use must be weighed against the risk of toxicity in a patient who is already critically ill. Cholestyramine 4 g orally (PO) qid may assist in lowering hormone levels by interfering with enterohepatic recirculation of thyroid hormones, but should be administered apart from other agents to prevent inhibiting their absorption.[180,269] Other effective modalities include plasmapheresis, charcoal hemoperfusion, and plasma exchange.[180,192]

Reversal of the peripheral effects of hormones and catecholamines

β-Adrenergic blocking drugs are the preferred agents to decrease the tachycardia, agitation, tremulousness, and other symptoms of excessive adrenergic stimulation seen in thyroid storm. Propranolol is the β-blocker of choice because its clinical efficacy in storm is well documented and it inhibits the peripheral conversion of T_4 to T_3.[192,193] If rapid effects are necessary, propranolol 1 mg by slow IV push can be given every 5 minutes to lower the heart rate to ~90 beats/minute. A 5- to 10-mg/hour IV infusion can maintain the desired heart rate. IV esmolol 50 to 100 µg/kg/minute can also be given. If perfusion is maintained, oral β-blockers (eg, propranolol, 40 mg every 6 hours; atenolol, 50–100 mg bid; metoprolol, 50–100 mg daily; nadolol, 40–80 mg daily), titrated to response, can also be given.[180,215]

Supportive treatment of vital functions

This may include sedation, oxygen, IV glucose, vitamins, treatment of infections with antibiotics, rehydration, and treatment of hyperpyrexia with cooling blankets, sponge baths, and the judicious use of antipyretics.[180,192] Because hypoadrenalism is often suspected, hydrocortisone should be given empirically IV with a 300-mg loading dose followed by 100 mg every 8 hours.[33] Because pharmacologic doses of steroids offer a beneficial effect in storm by acutely depressing serum T_3 levels and inhibiting conversion of T_4 to T_3, their routine use is recommended.[180,215]

Elimination of precipitating causes of storm

Precipitating causes of thyroid storm include infection (most common), trauma, inadequate preparation before thyroidectomy, surgical operations, stress, diabetic ketoacidosis, pregnancy, emboli, discontinuation or withdrawal of antithyroid medications, drug therapy, and RAI therapy.[192]

T_3 Thyrotoxicosis: Clinical Presentation

CASE 52-20

QUESTION 1: S.K., a 48-year-old female, is admitted to the hospital for a possible MI. Her symptoms include chest pain that is unrelieved by NTG, increasing SOB with exercise, nervousness, palpitations, muscle weakness, weight loss despite an increased appetite, and epistaxis; she also bruises easily. She has a history of deep venous thrombosis treated with warfarin 5 mg/day; her last INR was 2.8 (normal, 1; therapeutic, 2–3). She has angina, treated with NTG 0.4 mg, and HF, treated with lisinopril 20 mg/day.

Pertinent physical findings include a BP of 180/90 mm Hg, a pulse of 110 beats/minute, hyperreflexia, lid lag, and a diffusely enlarged thyroid gland that is about four times normal (about 100 g).

Laboratory data include the following results:

TT_4, 6 μg/dL (normal, 4.8–10.4)
FT_4, 2 ng/dL (normal, 0.8–1.8)
TSH, <0.01 μIU/mL (normal, 0.40–4.5)
TPOAb, 35 IU/mL (normal, <9)
TRAb, 3.2 IU/L (normal, <2)
Alkaline phosphatase, 200 units/L
Total bilirubin, 1.1 mg/dL
An RAI scan shows a diffusely enlarged gland, three to four times the normal size.

What subjective and objective data are suggestive of hyperthyroidism in S.K.?

S.K.'s laboratory findings of positive TRAb and TPOAb with elevated thyroid hormone levels verify an autoimmune hyperthyroid state. However, the serum FT_4 is elevated only slightly and is disproportionately low relative to the severity of her symptoms, the undetectable TSH level, and her other laboratory findings. The low-normal TT_4 could be explained by displacement of T_4 from TBG by aspirin (see Case 52-2). The possibility of a variant type of hyperthyroidism known as T_3 toxicosis should be considered. The clinical features include signs and symptoms of thyrotoxicosis, normal or borderline high FT_4, an undetectable TSH level, and elevated T_3 levels. The latter occurs through preferential secretion and peripheral conversion of T_4 to T_3. A T_3 level should be obtained to establish the diagnosis.[270]

Asymptomatic elevations of T_3 levels often precede elevation of T_4 levels and the development of overt hyperthyroidism. T_3 toxicosis probably represents an early stage of classic T_4 toxicosis and is useful for early diagnosis or as an early indicator of relapse after discontinuation of ATD therapy.

Together with S.K.'s symptoms, laboratory results support a diagnosis of Graves disease. Her cardiac status and other medical problems are aggravated by the hyperthyroidism.

Effects on Clotting and Warfarin Metabolism

Case 52-20, Question 2: What factors contribute to S.K.'s hypoprothrombinemia? What effect could this have on her subsequent drug treatment?

The easy bruising and bleeding observed in S.K. are most likely related to an exaggerated response to warfarin. This may be related to a decrease in the hepatic metabolism of warfarin (secondary to hepatic congestion), but it is more likely that S.K.'s findings are because of the combined effects of hyperthyroidism and warfarin on vitamin K–dependent clotting factors.

Warfarin metabolism and the metabolism of vitamin K–dependent clotting factors can be altered by thyroid status.[14] Net circulating levels of vitamin K–dependent clotting factors are generally not altered in patients who are hyperthyroid because both the synthesis and catabolism of these clotting factors are increased. However, an enhanced anticoagulant response occurs when the warfarin-induced decrease in clotting factor synthesis is combined with the hyperthyroidism-induced increase in clotting factor catabolism.[14,271] This may explain S.K.'s elevated INR, bruising, and history of epistaxis.

The opposite occurs in hypothyroidism, in which a decrease in both the metabolism and synthesis of clotting factors occurs. In patients who are hypothyroid, the response to oral anticoagulants is

delayed because the clotting factors are eliminated more slowly.[14,271] Therefore, patients who are hyperthyroid need less warfarin, whereas patients who are hypothyroid require more warfarin to achieve the same anticoagulant response. The anticoagulant response to warfarin should be monitored carefully in patients with thyroid abnormalities, and the dosage adjusted as the thyroid status changes.

Subclinical Hyperthyroidism

CASE 52-21

QUESTION 1: J.C. is a 68-year-old male who is found to have a TSH level of 0.15 μIU/mL (normal, 0.40–4.5) with normal FT_4 and FT_3 hormone levels on routine blood tests. He is otherwise healthy and denies any symptoms of thyroid dysfunction. On physical examination, his thyroid gland is normal. He denies any family history of thyroid disease and is taking no medications.

How should these tests be interpreted? How should J.C. be managed?

J.C.'s laboratory findings of a suppressed TSH value below the limits of normal and normal free thyroid hormone levels are consistent with subclinical hyperthyroidism (SHyper)[94–96] Other unlikely causes of a suppressed TSH in J.C. include medications (eg, metformin, bexarotene, glucocorticoids) (Table 52-1), pituitary hypothyroidism, and nonthyroidal illness (see Case 52-1, Questions 1 and 2).[12,74] Because of age-dependent decline in TSH secretion, a low TSH may also be a normal finding in healthy elderly patients.[272]

The dangers of SHyper are similar to those of overt hyperthyroidism and include cardiac findings (eg, atrial and ventricular premature beats, AF, left ventricular hypertrophy, diastolic dysfunction), loss of bone mass, higher fracture rates, especially in postmenopausal females, and if present, subtle symptoms of hyperthyroidism.[92–96] In elderly patients, hyperthyroid symptoms, even if overtly hyperthyroid, may be "apathetic" unapparent because of impaired sympathetic nervous system responsiveness.[272] A significant relationship between AF and degree of SHyper is clear,

whereas an association with increased atherosclerotic heart disease or mortality is weak.[168] The relative risk of AF in SHyper may be as high as 5.2 and increased by older age, male gender, higher FT_4 levels, and degree of TSH suppression. In two cohorts followed for 10 to 13 years, the relative risk of AF ranged from 1.6 to 3.1, depending on the degree of TSH suppression.[168,273] The likelihood a patient with endogenous SHyper will progress to overt hyperthyroidism is not clear. Patients may spontaneously revert to euthyroidism, progress to hyperthyroidism, or continue with SHyper. Individuals with undetectable TSH concentrations appear most likely to progress, and overall the rate of progression to overt disease is 1% to 5% annually.[95] A study of 2024 patients with 7-year follow-up of SHyper importantly found 36% reverted back to normal within 7 years, especially those with TSH levels between 0.1 and 0.4 μIU/mL.[274]

The management of subclinical hyperthyroidism is controversial, especially in asymptomatic patients because of limited treatment outcomes evidence.[94–96] Current guidelines recommend treatment of subclinical hyperthyroidism (TSH levels <0.1 μIU/mL) in patients older than 65 years, postmenopausal female not taking antiresorptive therapy (see Chapter 110, Osteoporosis), and those with cardiac disease and osteoporosis.[33,94,95] For patients with TSH levels of 0.1 to 0.45 μIU/mL, treatment of patients older than 65 years and those with cardiovascular disease or hyperthyroid symptoms can be considered.[33,215] A 2010 review recommends RAI or ATD therapy only if the TSH level is <0.1 μIU/mL in postmenopausal females, in those age 60 years and older, and in patients with a history of heart disease, osteoporosis, or hyperthyroid symptoms.[96] For patients with TSH levels of 0.1 to 0.4 μIU/mL, treatment can be considered if they are in the aforementioned groups; otherwise, therapy is not recommended because TSH normalization may occur.[95,215]

In J.C., his thyroid function tests should be repeated. An RAIU and scan should be obtained to detect any hyperactive areas or nodules that might be responsible for the suppressed TSH. Because J.C. is

generally healthy, treatment can be considered if there are concerns about cardiac disease or bone loss; otherwise, no therapy is also reasonable based on the available evidence. Close monitoring of thyroid function tests is recommended every 6 months to a year. If hyperthyroid symptoms or changes in cardiac or bone function occur, then RAI therapy is recommended.

DRUG-INDUCED THYROID DISEASE

Lithium

CASE 52-22

QUESTION 1: D.A., a 56-year-old male, reports of sluggishness, cold intolerance, fatigue, and a "rundown" feeling, which doctors attribute to the depressive phase of his bipolar affective illness. He previously had been well controlled with sertraline 100 mg/day, but lithium carbonate 900 mg/day was added 4 months ago because of unreasonable mirthfulness and uncontrollable gift-buying tendencies. Physical examination reveals a puffy face and a large goiter.

What is a reasonable assessment of these subjective and objective data?

Thyroid function tests (ie, TSH, FT_4) and a thyroid ultrasound should be obtained to evaluate the possibility of lithium- and possibly sertraline-induced hypothyroidism and goiter.[6,7,15,275] If the TSH is elevated, T_4 should be initiated and lithium continued if necessary. Although the incidence of goiter and hypothyroidism in the manic-depressive population is unknown, the 10% incidence of baseline elevated TSH appears higher than in the general population.

The exact mechanism of lithium's antithyroid effect on the gland is unclear, although it is highly concentrated by the gland. Like the iodides, chronic lithium therapy inhibits the release of thyroid hormone from the gland. The fall in serum T_4 and T_3 hormone levels

leads to a compensatory and transient increase in serum TSH levels until a new steady state is achieved.[6,7,15]

Elevated TSH levels are reported in ~19% of patients on chronic lithium therapy.[15] Typically, the serum thyroid hormone levels decrease and the TSH levels increase during the first few months of treatment, returning to pretreatment levels after 1 year.[15] Normalization of the TSH level is less likely to occur in patients with preexisting positive thyroid antibodies before lithium therapy.[6,15] Induction of thyroid antibodies and increases in baseline antibody titers also occur after chronic lithium therapy. Because abnormal thyroid function tests can be transient, a longer period of observation is justified before starting thyroid therapy in patients with SH.

Overt hypothyroidism appears in a small percentage of the population after 5 months to 2 years of therapy; one 15-year study found an incidence of 1.5% but an 8.4 relative risk in females with antibody positivity compared to negative subjects.[6,7,15] Lithium-induced goiter with or without hypothyroidism is common after weeks to months of therapy. Although incidences of <6% have been reported, higher rates of 40% to 60% are observed if the goiter is diagnosed using more specific imaging techniques (eg, ultrasound).[6,7,15] A direct goitrogenic effect of lithium on inducing cell proliferation might explain the occurrence of euthyroid goiter. The goiters respond to discontinuation of lithium or to suppression with thyroid hormone despite continuation of lithium therapy.[7,15] Surgical removal of the goiter is required if there are local obstructive symptoms. In D.A.'s case, sertraline could be exerting an additive or synergistic antithyroid effect with lithium because antithyroid effects have also been associated with this drug.[275]

Most patients with lithium-induced thyroid abnormalities are females older than 50 years, have a prior history of compromised thyroid function (eg, Hashimoto thyroiditis), positive thyroid antibodies before lithium therapy, or a strong family history of thyroid disease.[6,7,15] Therefore, baseline thyroid function tests (ie, FT_4, TSH), antibodies, and thyroid ultrasound should be obtained before starting lithium therapy, and levels should be checked annually thereafter or

more frequently if clinically indicated. Patients should also be questioned about a positive history or family history for thyroid disease and the concurrent use of other, potentially goitrogenic medications (eg, tricyclic antidepressants, iodides, iodinated expectorants/herbals).

Iodides and Amiodarone

CASE 52-23

QUESTION 1: C.Y., a 54-year-old male with chronic AF presents with a 6-month history of weakness, fatigue, tremor, heat intolerance, and increased palpitations, previously controlled for the last 2 years on amiodarone 200 mg/day. Physical examination reveals a 50-g multinodular gland, which C.Y. says has "been there forever." He denies any family history of thyroid disease or ingestion of any thyroid medication. His current symptoms began after a magnetic resonance imaging (MRI) procedure with iodinated radiocontrast media.

What might be responsible for C.Y.'s hyperthyroid symptoms?

The iodine load from the MRI or the amiodarone could be responsible for C.Y.'s hyperthyroid symptoms.[33,179,276] Iodine-induced hyperthyroidism, or Jod-Basedow phenomenon, was first described in the 1800s when patients residing in iodide-deficient areas became toxic when given adequate iodide supplementation.[277] Both T_3 toxicosis and classic T_4 toxicosis have been reported following iodide ingestion or injection of iodinated contrast media.[277]

Although it is presumed that both iodide deficiency and a multinodular goiter, as in C.Y., are required to invoke the Jod-Basedow phenomenon, iodine-induced disease has been reported in patients residing in iodide-sufficient areas as well as in patients who are euthyroid with normal glands and no apparent risk factors (eg, family history).[37,179] Iodine-induced hyperthyroidism is rare in iodine-sufficient populations and generally subclinical and self-limiting when it does occur.[33] In the event iodine-induced hyperthyroidism persists, it can be managed with ATDs.[215]

Amiodarone can cause hypo- or hyperthyroidism in susceptible patients because of its high iodine content.[33,179,276] Patients beginning therapy with amiodarone should have thyroid testing before treatment is begun, within the first three months, and then at 3- to 6-month intervals thereafter.[33] Twelve milligrams (37%) of free iodine is released per 400-mg dose of amiodarone. Patients with multinodular goiters who lose the ability to turn off iodide organification from increased iodide loads (Wolff–Chaikoff effect) are most likely to develop iodide-induced thyrotoxicosis. Conversely, patients with positive antibodies or with underlying Hashimoto thyroiditis who cannot escape from the Wolff–Chaikoff block are most likely to develop hypothyroidism.[5]

Amiodarone-induced hypothyroidism may occur at any time during therapy and does not appear to be related to the cumulative dose. A low-normal or low FT_4 and a persistently elevated TSH (see Case 52-4) are consistent with amiodarone-induced hypothyroidism, which occurs in up to 14% of long-term users.[278] The hypothyroidism responds readily to T_4 therapy, even if the amiodarone is continued.[5,19,276] Amiodarone-induced hypothyroidism typically resolves after stopping the drug but resolution may be delayed because of its long half-life.[5,276]

In contrast, amiodarone-induced thyrotoxicosis, which occurs in up to 6% of long-term users in iodine-sufficient areas (with a higher prevalence in areas of iodine deficiency).[33] Elevated hormone levels, an undetectable TSH level, and clinical symptoms consistent with hyperthyroidism are the best indicators of amiodarone-induced thyrotoxicosis.

Amiodarone-induced hyperthyroidism can be classified as either type I or type II.[33,276] Type I occurs in patients with underlying thyroid disease (eg, multinodular goiter, Graves disease, autonomous nodules) and is related to the iodine load. The formation of large amounts of preformed hormone from the massive iodine load produces a protracted course of hyperthyroidism, which is challenging to manage. Type II amiodarone-induced hyperthyroidism is because of an inflammatory destructive thyroiditis, with excessive

release of thyroid hormone into the systemic circulation.[33] This occurs most often in patients with normal thyroid glands. Unique laboratory findings include a low RAIU and elevated interleukin-6 levels.[5,276]

The management of amiodarone-induced thyrotoxicosis is complicated because it is not always possible to identify the type of hyperthyroidism and a mixture of the two types can occur. Stopping amiodarone alone does not immediately improve the hyperthyroidism because of the drug's long half-life (22–55 days) and its sequestration in fat. RAI ablation is rarely effective because the high iodine load from amiodarone will suppress RAI uptake.[276] Methimazole is the treatment of choice for type I hyperthyroidism.[5,14,179,276] In patients with type II hyperthyroidism, corticosteroids are the most appropriate choice.[33] In the case of hemodynamic instability or poor clinical improvement, ATD therapy can be added to corticosteroid therapy.[33] A total thyroidectomy can rapidly control the thyrotoxicosis, permitting continued therapy with amiodarone if necessary; however, in a case series of 34 patients there was a 9% mortality rate with an overall complication rate of 29%.[279] Changing amiodarone to dronedarone, which is devoid of iodine and lacks the undesirable thyroid effects, should be strongly considered in C.Y.[276]

Large doses of iodides should be avoided in patients with nontoxic multinodular goiters who are predisposed to thyrotoxicosis (see Case 52-4 and Case 52-13, Question 2).

Diabetes Mellitus

Jennifer D. Goldman, Nikhil A. Sangave, and David Schnee

CORE PRINCIPLES		CHAPTER CASES
1	A glycated hemoglobin (A_{1c}) level can be used to diagnose diabetes, in addition to a fasting plasma glucose (FPG) or oral glucose tolerance test (OGTT). Each test must be confirmed on a subsequent day.	**Case 53-1 (Questions 1, 2) Case 53-2 (Question 1) Case 53-11 (Question 1) Case 53-17 (Question 1)**
2	The primary metabolic goals for diabetes are an A_{1c} <7%, a systolic blood pressure <140 mm Hg, and statin therapy for most patients older than age 40. Management of cholesterol should include a statin drug, and management of hypertension should include an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker.	**Case 53-2 (Question 2) Case 53-11 (Question 2)**
3	Glycemic treatment goals should be	**Case 53-2 (Question 2) Case 53-4**

	individualized. For patients with a short duration of diabetes, long life expectancy, and no significant vascular disease, more stringent goals can be considered, if it can be achieved without increasing hypoglycemia. For patients with existing vascular disease, other significant macrovascular or microvascular disease, a history of hypoglycemia, or limited life expectancy, or for those with long-standing diabetes who have difficulty lowering their A_{1c}, a less stringent A_{1c} goal should be considered.	**(Question 2) Case 53-11 (Question 2) Case 53-17 (Question 3) Case 53-18 (Question 3)**
4	Medical nutrition therapy (MNT) and physical activity are cornerstones to the treatment of diabetes.	**Case 53-2 (Questions 11, 12) Case 53-11 (Question 3) Case 53-17 (Question 4) Case 53-18 (Question 4)**
5	Self-monitoring of blood glucose (SMBG) or continuous glucose monitoring (CGM) should be performed by all patients with type 1 diabetes and most patients with type 2 diabetes, particularly those on antidiabetic therapy that can cause hypoglycemia or those engaged in self-management. The key to SMBG is to educate patients on how to respond to their blood glucose (BG) levels.	**Case 53-2 (Questions 9–11, 17) Case 53-4 (Questions 1, 5, 7) Case 53-8 (Question 2) Case 53-11 (Question 6) Case 53-21 (Question 1) Case 53-22 (Question 1)**
6	The avoidance of hyperglycemic and hypoglycemic emergencies is critical. Basal-bolus insulin regimens should be	**Case 53-2 (Questions 3-8, 13-16) Case 53-3 (Question 1) Case 53-4 (Question 3, 4, 6)**

	used for patients with type 1 diabetes. These can be administered either by multiple daily injections or by an insulin pump. Basal-bolus insulin regimens are also effective for patients with type 2 diabetes who no longer are able to achieve A_{1c} goals with noninsulin therapies.	**Case 53-5 (Question 1) Case 53-6 (Question 1) Case 53-8 (Questions 1, 3) Case 53-9 (Question 1) Case 53-10 (Questions 1-5) Case 53-13 (Question 5) Case 53-17 (Question 2)**
7	Metformin is the first-line therapy for type 2 diabetes unless a patient has a contraindication to its use or is unable to tolerate this agent. It should be added at diagnosis along with lifestyle changes.	**Case 53-11 (Questions 3–5)**
8	After monotherapy, a second antidiabetic agent should be added to the regimen. Factors to consider include the patient's current comorbidities (history of atherosclerotic cardiovascular disease [ASCVD], chronic kidney disease [CKD], congestive heart failure [CHF], or obesity), A_{1c} goal, the amount of reduction in A_{1c} required, the patient's kidney and liver function, medication side effects, risk of hypoglycemia and cost of therapy.	**Case 53-11 (Questions 7, 8) Case 53-12 (Question 1) Case 53-13 (Questions 1-3, 7) Case 53-14 (Question 1) Case 53-15 (Questions 1, 2) Case 53-16 (Question 1) Case 53-17 (Question 5)**
9	In type 2 diabetes, insulin therapy should be considered any time there are symptoms of hyperglycemia, evidence of catabolism, when A_{1c} is >10% or evidence of high BG levels >300 mg/dL.	**Case 53-11 (Question 7) Case 53-12 (Question 1) Case 53-13 (Question 4)**
10	Owing to concerns about the effects of hypoglycemia and new trials indicating a	**Case 53-7 (Question 1)**

	lack of benefit of very tight glucose control in acutely ill patients, the current-recommended goal BG in hospitalized patients is 140 to 180 mg/dL.	
11	Although acute hyperglycemic crises can occur in patients with diabetes, most morbidity and mortality occur over the course of years and can be classified as either microvascular (nephropathy, neuropathy, and retinopathy) or macrovascular (coronary heart disease [CHD], stroke, and peripheral vascular disease).	**Case 53-18 (Questions 1, 2, 5) Case 53-19 (Questions 1–3) Case 53-20 (Questions 1)**
12	Aspirin therapy may be considered as a primary prevention strategy in those with diabetes who are at increased cardiovascular risk, after a comprehensive discussion with the patient on the benefits versus the comparable increased risk of bleeding.	**Case 53-18 (Question 6)**
13	The incidence and severity of microvascular complications has a strong correlation with long-term glycemic control as measured by A_{1c}. Macrovascular complications are influenced by glycemic control but are more dependent on multiple etiologic factors including dyslipidemia, hypertension, and smoking.	**Case 53-11 (Question 2)**

INTRODUCTION

An estimated 34.2 million people, just over 1 in 10, or 13% of the U.S. population, currently have diabetes. This total includes 7.3 million adults who are not yet diagnosed.[1] Prediabetes can be found in 88 million American adults, ~1 in 3. In 2018, there were 1.5 million new cases in adults diagnosed.[1] New cases diagnosed in adults decreased between 2008 and 2018, but new diagnosed cases of type 1 and type 2 have increased among youth in the United States. Racial and ethnic minorities continue to develop type 2 diabetes at higher rates.[1] Globally, the prevalence of diabetes in 2019 is 9.3% (463 million people) and expected to rise to 10.2% (578 million) by 2030 and 10.9% (700 million) by 2045.[2] The incidence of type 2 diabetes is epidemic. This is directly related to obesity, decreased physical activity levels, and also the fact that people with diabetes are living longer.[1] Additional individual factors include a genetic predisposition for increased insulin resistance and progressive β-cell failure. Clinical studies have affirmed that type 2 diabetes can be delayed or prevented in patients with prediabetes when significant lifestyle changes are implemented with or without medications.[3]

DEFINITION, CLASSIFICATION, AND EPIDEMIOLOGY

Diabetes is a chronic condition caused by an absolute lack of insulin or a relative lack of insulin as a result of impaired insulin secretion and action. Its hallmark clinical characteristics are symptomatic glucose intolerance resulting in hyperglycemia and alterations in lipid and protein metabolism. In the long term, these metabolic abnormalities contribute to the development of complications such as cardiovascular disease (CVD), retinopathy, nephropathy, and neuropathy and a higher risk of cancer.[4–7]

Genetically, etiologically, and clinically, diabetes is a heterogeneous group of disorders. Nevertheless, most cases of diabetes mellitus (DM) can be assigned to type 1 or type 2 diabetes

(**Table 53-1**). The term gestational diabetes mellitus (GDM) is used to describe glucose intolerance that has its onset during pregnancy. Glucose intolerance that cannot be ascribed to causes consistent with these three classifications includes specific genetic defects in β-cell function or insulin action (usually genetically defective insulin receptors); diseases of the exocrine pancreas; endocrinopathies; drug- or chemical-induced; infections; and other genetic syndromes. Early glucose intolerance or "prediabetes" is identified as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT), and they are considered risk factors for the future development of diabetes and are associated with obesity, hypertriglyceridemia, and/or low high-density lipoprotein (HDL) cholesterol and hypertension.[4,5]

Table 53-1

Type 1 and Type 2 Diabetes

Characteristics	Type 1	Type 2
Other names	Previously, type I; insulin-dependent diabetes mellitus (IDDM); juvenile-onset diabetes mellitus	Previously, type II; non–insulin-dependent diabetes mellitus (NIDDM); adult-onset diabetes mellitus
Percentage of diabetic population	5%–10%	90%
Age at onset	Usually <30 years; peaks at 12–14 years; rare before 6 months; some adults develop type 1 during the fifth decade.	Usually >40 years, but increasing prevalence among obese children
Pancreatic function	Usually none, although some residual C-peptide can sometimes be detected at diagnosis, especially in adults	Insulin present in low, "normal," or high amounts
Pathogenesis	Associated with certain HLA types; presence of islet cell antibodies suggests autoimmune process.	Defect in insulin secretion; tissue resistance to insulin; ↑ hepatic glucose output

Characteristics	Type 1	Type 2
Family history	Generally not strong	Strong
Obesity	Uncommon	Common (60%–90%)
History of ketoacidosis	Often present	Rare, except in circumstances of unusual stress (eg, infection)
Clinical presentation	Moderate-to-severe symptoms that generally progress relatively rapidly (days to weeks): polyuria, polydipsia, fatigue, weight loss, ketoacidosis	Mild polyuria, fatigue; often diagnosed on routine physical or dental examination
Treatment	MNT	MNT
	Physical activity	Physical activity
	Insulin Amylin mimetic (pramlintide)	Antidiabetic agents (biguanides, glinides, sulfonylureas, thiazolidinediones, α-glucosidase inhibitors, incretin mimetics/analogs, DPP-4 inhibitors, SGLT-2 inhibitors)
	Insulin	Insulin
Amylin mimetic (pramlintide)		Amylin mimetic (pramlintide)

DPP-4, dipeptidyl peptidase-4; HLA, human leukocyte antigen; MNT, medical nutrition therapy; SGLT2, sodium–glucose transporter 2.

Approximately 5% to 10% of the diagnosed diabetic population has type 1 diabetes, which usually results from autoimmune destruction of the pancreatic β cells. At clinical presentation, these patients have little or no pancreatic reserve, have a tendency to develop ketoacidosis, and require exogenous insulin to sustain life. The incidence of autoimmune-mediated type 1 diabetes peaks during childhood and adolescence, but it can occur at any age. A minority of patients diagnosed with type 1 diabetes, mostly of African or Asian ancestry, can have no evidence of autoimmunity; the etiology is, therefore, unknown. In these individuals, the rate of pancreatic destruction seems to occur more slowly, leading to a later onset and less acute presentation.[4]

Most people with diabetes have type 2 diabetes, a heterogeneous disorder that is characterized by obesity, β-cell dysfunction, resistance to insulin action, and increased hepatic glucose production. Both the incidence and prevalence of diabetes increase dramatically with age, obesity, and lack of physical activity.[4] In the United States, the percentage of patients with diagnosed or undiagnosed diabetes in those ages 18 to 44 years is 4.1%. This increases to 26.8% in those 65 and older.[1] The prevalence of type 2 diabetes also differs among adult ethnic populations. Relative to non-Hispanic Whites (7.9%), the prevalence of diagnosed diabetes is higher in Asian Americans (11.3%), Hispanics (13.7%), African Americans (11.7%), and American Indians and Alaskan Natives (14.7%).[1] Diabetes is a serious condition that places people at risk for greater morbidity and mortality relative to the nondiabetic population. Diabetes is the seventh leading cause of death in the United States, although deaths attributed to diabetes and its complications are likely to be underreported. Compared with the general population, the mortality rate for people with diabetes is about twice that for people without diabetes.[1]

Medical management of people with diabetes is costly. In 2017, the total cost of diabetes in the United States was estimated to be $327.2 billion, with 1 of 4 health care dollars being spent on people with diabetes.[8] The average health care expenditures for people with diabetes were ~2.3 times higher than those for individuals without diabetes. The majority (56%) of all health care expenditures attributed to diabetes are used by people ages 65 years and older. Hospital inpatient costs, nursing facility resources, home care, physician visits, and medications (not just diabetes agents) made up the majority of these expenditures. Because many expenditures are related to the treatment of long-term complications, considerable effort has been directed toward early diagnosis and metabolic control of patients with diabetes.[8]

CARBOHYDRATE METABOLISM

An understanding of the signs and symptoms associated with diabetes is based on a knowledge of glucose metabolism and the metabolic effects of insulin in nondiabetic subjects and in subjects with diabetes during the fed (postprandial) and fasting (postabsorptive) states.[9] Homeostatic mechanisms maintain plasma glucose concentrations between 55 and 140 mg/dL. A minimum concentration of 40 to 60 mg/dL is required to provide adequate fuel for the central nervous system, which uses glucose as its primary energy source and is independent of insulin for glucose utilization. When BG concentrations exceed the reabsorptive capacity of the proximal tubule in the kidneys (~180 mg/dL), glucose spills into the urine (glucosuria), resulting in a loss of calories and water. Muscle and fat, which use glucose as a major source of energy, require insulin for glucose uptake. If glucose is unavailable, these tissues are able to use other substrates such as amino acids and fatty acids for fuel.[9]

Postprandial Glucose and Lipid Metabolism in the Nondiabetic Individual

After food is ingested, BG concentrations rise and stimulate insulin release. Insulin is the key to efficient glucose utilization. It promotes the uptake of glucose, fatty acids, and amino acids, and their conversion to storage forms in most tissues. Insulin also inhibits hepatic glucose production by suppressing glucagon and its effects. In muscle, insulin promotes the uptake of glucose and its storage as glycogen. It also stimulates the uptake of amino acids and their conversion to protein. In adipose tissue, glucose is converted to free fatty acids and stored as triglycerides. Insulin also prevents a breakdown of these triglycerides to free fatty acids, a form that may be transported to other tissues for utilization. The liver does not require insulin for glucose transport, but insulin facilitates the conversion of glucose to glycogen and free fatty acids.[9,10]

Free fatty acids are esterified to triglycerides, which are transported by very-low-density lipoproteins (VLDLs) to adipose and

muscle tissue. Normal insulin signaling suppresses VLDL secretion by reducing the production of fatty acids in the liver.[10] Once secreted by the liver, VLDL is acted on primarily by hepatic lipase in the liver and by lipoprotein lipase on endothelial cells.[10] Acting through apolipoprotein (apo) CII on the surface of the VLDL particle, these lipases remove free fatty acids from the lipoprotein and convert VLDL to intermediate-density lipoprotein (IDL) and then IDL to low-density lipoprotein (LDL). Insulin plays a role in stimulating apoCII expression, which partly explains the hypertriglyceridemia that occurs in type 2 diabetes.[10]

Fasting Glucose Metabolism in the Nondiabetic Individual

As BG concentrations drop toward normal during the fasting state, insulin release is inhibited. Simultaneously, a number of counterregulatory hormones that oppose the effect of insulin and promote an increase in blood sugar are released (eg, glucagon, epinephrine, growth hormone, and cortisol). As a result, several processes maintain a minimum BG concentration for the central nervous system. Glycogen in the liver is broken down into glucose (glycogenolysis). Amino acids are transported from muscle to liver, where they are converted to glucose through gluconeogenesis. Uptake of glucose by insulin-dependent tissues is diminished to conserve glucose for the brain. Finally, triglycerides are broken down into free fatty acids, which are used as alternative fuel sources.[9,10]

TYPE 1 DIABETES

Pathogenesis

The loss of insulin secretion in type 1 DM results from autoimmune destruction of the insulin-producing β cells in the pancreas, which is thought to be triggered by environmental factors, such as viruses or

toxins, in genetically susceptible individuals.[4,11] This form of diabetes is associated closely with histocompatibility antigens (human leukocyte antigen [HLA]-DR3 or HLA-DR4) and the presence of circulating antibodies, including insulin autoantibodies, glutamic acid decarboxylase (GAD65) autoantibodies, islet cell autoantibodies (ICAs), and autoantibodies to tyrosine phosphatases (eg, ICA 512). The capacity of normal pancreatic β cells to secrete insulin far exceeds the normal amounts needed to control carbohydrate, fat, and protein metabolism. As a result, the clinical onset of type 1 diabetes is preceded by an extensive asymptomatic period during which β cells are destroyed (**Fig. 53-1**). β-cell destruction may occur rapidly but is more likely to take place over a period of weeks, months, or even years. The earliest detectable abnormality in insulin secretion is a progressive reduction of immediate or first-phase plasma insulin response. However, this initial impairment has few detrimental effects on overall glucose homeostasis, and plasma glucose concentrations remain normal. Most affected individuals have circulating antibodies to islet cells or to their own insulin at this stage of the disease. These represent markers of an ongoing autoimmune process that culminates in type 1 diabetes. Fasting hyperglycemia occurs when the β-cell mass is reduced by 80% to 90%. One or more of these autoantibodies is usually present in 85% to 90% of individuals at this point. Initially, only postprandial hyperglycemia occurs, but as insulin secretion becomes further compromised, progressive fasting hyperglycemia is seen. Within 8 to 10 years of clinical presentation, β-cell loss is complete and insulin deficiency is absolute.[4,11]

Timing of trigger in relation to immunologic abnormalities is unknown. Note that overt diabetes is not apparent until insulin secretory reserves are <10%–20% of normal.

Figure 53-1 Pathogenesis of type 1 diabetes. In an individual with a genetic predisposition, an event (such as a virus or toxin) triggers autoimmune destruction of the pancreatic β cells, probably during a period of several years. When the number of β cells diminishes to ~250,000, the pancreas is unable to secrete sufficient insulin, and intolerance to glucose ensues. At this point, a stressful event, such as a viral infection, can produce acute symptoms of hyperglycemia and ketoacidosis. Once the acute event has passed, the pancreas temporarily recovers, leading to a remission (honeymoon period). Continued destruction of the β cell ultimately leads to an insulin-dependent state.

Clinical Presentation

Although the onset of type 1 diabetes seems to be abrupt, evidence now exists for an extended preclinical period that can precede obvious symptoms by several years. Because insulin secretion becomes compromised, progressive fasting hyperglycemia occurs. Glucosuria, which occurs when BG levels exceed the renal threshold, results in an osmotic diuresis, producing the classic symptoms of polyuria with compensatory polydipsia. If symptoms are untreated, weight loss occurs because glucose calories are lost in the urine, and body fat and protein stores are broken down owing to increased rates of lipolysis and proteolysis. Muscle begins to metabolize its own glycogen stores and fatty acids for fuel, and the liver begins to metabolize free fatty acids that are released in response to epinephrine and low insulin concentrations. An absolute lack of insulin may cause excessive mobilization of free fatty acids to the liver, where they are metabolized to ketones. This can result in ketonemia, ketonuria, and, ultimately, ketoacidosis. Patients present with fatigue, significant weight loss, polyuria, and polydipsia. A significant elevation in A_{1c} confirms weeks or months of preceding hyperglycemia.

Because glucose provides an excellent medium for microorganisms, patients may present also with recurrent respiratory, vaginal, and other infections. Patients also may experience blurred vision secondary to osmotically induced changes in the lens of the eye. Treatment with insulin is essential to prevent severe dehydration, ketoacidosis, and death.[4,7,11]

Honeymoon Period

Within days or weeks of the initial diagnosis and implementing treatment, many patients with type 1 diabetes experience an apparent remission, which is reflected by decreased BG concentrations and markedly decreased insulin requirements. This is called the *honeymoon period* because it may last for only a few weeks to months. Once hyperglycemia, metabolic acidosis, and ketosis resolve, endogenous insulin secretion recovers temporarily

(Fig. 53-1). Although the honeymoon period may last for up to a year, increasing exogenous insulin requirements are inevitable and should be anticipated. During this time, patients should be maintained on insulin even if the dose is very low because interrupted treatment is associated with a greater incidence of resistance and allergy to insulin.[12]

TYPE 2 DIABETES

Pathogenesis

Type 2 diabetes is characterized by impaired insulin secretion and resistance to insulin action. In the presence of insulin resistance, glucose utilization by tissues is impaired, hepatic glucose and free fatty acid production is increased, and excess glucose accumulates in the circulation. This hyperglycemia stimulates the pancreas to produce more insulin in an attempt to overcome insulin resistance. The simultaneous elevation of both glucose and insulin levels is strongly suggestive of insulin resistance. Genetic predisposition may play a role in the development of type 2 diabetes. People with type 2 diabetes have a stronger family history of diabetes than do those with type 1. There is no association with HLA types, however, and circulating ICAs are absent.[13,14] People with type 2 diabetes also exhibit varying degrees of tissue resistance to insulin, impaired insulin secretion, and increased basal hepatic glucose production. Finally, environmental factors such as obesity and a sedentary lifestyle also contribute to the development of insulin resistance.

Despite being the most common form of diabetes, the exact pathogenesis of type 2 is less well understood. Basal insulin levels are typically normal or elevated at diagnosis. First- or early-phase insulin release in response to glucose often is reduced, and pulsatile insulin secretion is absent, resulting in postprandial hyperglycemia. The effects of other insulinotropic substances such as incretin hormones, which contribute to meal-stimulated insulin release, are

also altered.[15] With time, β cells lose their ability to respond to elevated glucose concentrations, leading to increased loss of glucose control. In patients with severe hyperglycemia, the amount of insulin secreted in response to glucose is diminished, and insulin resistance is worsened (glucose toxicity).

Most individuals with type 2 exhibit decreased tissue responsiveness to insulin.[13] Excess weight or hyperglycemia may contribute to hyperinsulinemia, which in time may lead to a decrease in or downregulation of the number of insulin receptors on the surface of target tissues and organs. Evidence suggests that decreased peripheral glucose uptake and utilization in muscle is the primary site of insulin resistance and results in prolonged postprandial hyperglycemia. Resistance may be secondary to decreased numbers of insulin receptors on the cell surface, decreased affinity of receptors for insulin, or defects in insulin signaling and action that follows receptor binding. Defects in insulin signaling and action are referred to as *postreceptor* or *postbinding defects* and are likely to be the primary sites of insulin resistance.

Patients with type 2 diabetes also exhibit increased hepatic glucose production (glycogenolysis and gluconeogenesis) reflected by an elevated fasting plasma or BG concentration.[13] As noted, hepatic glucose production is the primary source of glucose in the fasting state. In patients with type 2 diabetes, altered hepatic glucose production may also contribute to or cause postprandial hyperglycemia. Glucagon, produced by the α-cells in the pancreatic islets and secreted in response to low BG, stimulates hepatic glucose production.[16] Its production is inhibited by insulin. Glucagon response to carbohydrate ingestion is altered in patients with type 2 diabetes who have a defective or absent early insulin response secondary to β-cell dysfunction or failure. For patients with type 2 diabetes, untreated fasting and postprandial hyperglycemia caused by decreased glucose uptake and increased hepatic glucose production, hyperinsulinemia, and insulin resistance lead to a vicious cycle that inflicts ongoing damage to tissues and organs. Type 2 diabetes is a multifactorial disease and eight core defects were first described and called the *Ominous Octet*.[17] These eight defects

include (1) decreased insulin secretion, (2) decreased incretin effect, (3) increased lipolysis, (4) increased glucose reabsorption, (5) decreased glucose uptake, (6) neurotransmitter dysfunction, (7) increased hepatic glucose production, and (8) increased glucagon secretion.[17] The Ominous Octet was followed by the "Egregious Eleven," which further expanded on these eight pathophysiologic defects and added three more: (9) systemic low-grade inflammation, (10) changes in gut microbiota, and (11) reduction in amylin production.[18] Various drug therapies impact one or multiple of these defects.

Patients with type 2 diabetes are often subclassified based on weight. Obese individuals account for >80% of patients with type 2 diabetes.[13] Patients with type 2 diabetes who are not obese often have increased body fat distributed in the abdominal area. Nonobese individuals account for about 10% of the type 2 population. Typically, they develop a mild form of diabetes during childhood, adolescence, or as young adults (usually before age 25), and their insulin levels are low in response to a glucose challenge. Included in this group are patients who have maturity-onset diabetes of the young (MODY).[4,13] MODY is associated with a strong family history that suggests an autosomal dominant transmission. The underlying defect is heterogeneous, and multiple abnormalities at loci on different chromosomes have been discovered. More common defects include those for hepatic transcription factors and glucokinase (the "glucose sensor" in β cells). Patients with MODY may present with moderate-to-severe symptoms with or without ketosis. Unlike type 1 diabetes, however, the disease generally is mild and controlled with diet, oral agents, or low doses of insulin. With the increasing prevalence of obesity and type 2 diabetes in children and adolescents, it is important to distinguish between a youth with type 2 diabetes and one who really has autoimmune type 1 diabetes and is also obese.[19]

Type 2 diabetes is associated with a variety of comorbid disorders, including dyslipidemia, hypertension, and premature atherosclerosis (**Fig. 53-2**). Currently termed the *metabolic syndrome*, this triad of clinical findings (hypertension, elevated fasting glucose, and

dyslipidemia) is proposed to derive from insulin resistance itself and the resulting compensatory hyperinsulinemia.[20] The labeling of this triad as a separate “syndrome” remains the subject of considerable debate, partly because it appears to have little diagnostic utility beyond its component parts.[21] Metabolic syndrome is common in the United States. Utilizing the National Health and Nutrition Examination Survey (NHANES) data from 2003 to 2013, it was estimated that nearly 35% of all adults and 50% of those older than age 60 have metabolic syndrome.[22] Metabolic syndrome is highly correlated with cardiovascular (CV) events.[23] Not all individuals with the metabolic syndrome progress to IGT or diabetes, but those who do may be genetically predisposed to β-cell dysfunction. **Figure 53-3** depicts the typical dyslipidemia pattern seen in diabetes and how insulin resistance affects normal lipoprotein metabolism.[20,21]

Figure 53-2 Metabolic syndrome. Genetic and environmental factors (visceral obesity, sedentary lifestyle, and aging) predispose some individuals to insulin resistance. To overcome the resistance, the pancreas secretes more insulin, leading to hyperinsulinemia. People with insulin resistance and hyperinsulinemia commonly develop a cluster of medical problems and biochemical abnormalities: cardiovascular disease, hypertension, dyslipidemia, hyperuricemia, and type 2 diabetes mellitus. Only those individuals

who are further genetically predisposed to β-cell failure go on to develop IGT, IFG, and type 2 diabetes. Many people with type 2 diabetes already have evidence of cardiovascular disease at the time of diabetes diagnosis. The cause-and-effect relationship between insulin resistance or hyperinsulinemia and these clinical conditions has not been clarified. See text for expanded discussion. HTN, hypertension; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

Figure 53-3 Changes in lipoprotein metabolism are a direct consequence of insulin resistance and are present before the onset of overt diabetes. Apo, apolipoprotein; CE, cholesteryl esters; CETP, cholesteryl ester transfer protein; FFA, free fatty acid; HDL, high-density lipoprotein; HDL-C, high-density lipoprotein cholesterol; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; TG, triglyceride; VLDL, very-low-density lipoprotein.

Clinical Presentation

Type 2 diabetes is typically diagnosed incidentally during a routine physical examination or when the patient seeks other medical attention. Because symptoms are mild in their onset, patients will rarely report symptoms of fatigue, polyuria, and polydipsia, but may admit to them during clinical examination. Because these patients have sufficient insulin concentrations to prevent lipolysis, there is usually no history of ketosis except in situations of unusual stress (eg, infections and trauma). Weight loss is therefore uncommon because relatively high endogenous insulin levels promote lipogenesis. Macrovascular disease is typically evident at diagnosis. Microvascular complications at diagnosis suggest the presence of undiagnosed or subclinical diabetes for 7 to 10 years. Because patients with type 2 diabetes retain some pancreatic reserve at the time of diagnosis, they generally can be treated with MNT, physical activity, and noninsulin antidiabetic medications for several years. Nevertheless, many eventually require insulin for control of their symptoms.[24]

Screening

The American Diabetes Association (ADA) advises that adults without risk factors should be screened starting at age 45.[4] Repeat testing should take place every 3 years if results are normal or yearly if they have prediabetes. Adults may be tested at a younger age and more frequently if they are overweight (body mass index [BMI] ≥25 or 23 kg/m^2 in Asian Americans) and have one or more of the risk factors listed in **Table 53-2**. An FPG or A_{1c} is preferred over the OGTT to test for diabetes, because they are much less cumbersome, although all are equally appropriate for diagnosis. Asymptomatic children who are age 10 or who experience the onset of puberty before age 10 should be screened for type 2 diabetes if they are overweight (BMI ≥85th percentile) or obesity (BMI ≥95th percentile) for age and sex and have one or more risk factors listed in Table 53-2.[4]

Table 53-2

Risk Factors for Type 2 Diabetes Mellitus

Adults	Children[a]
Overweight (≥25 kg/m^2 or (≥23 kg/m^2 in Asian Americans))	Overweight (BMI >85th percentile for age and sex; or weight >120% of ideal for height)
Family history of diabetes (first-degree relative)	Family history of diabetes (first- or second-degree relative)
Physical inactivity	
Ethnic predisposition[b]	Ethnic predisposition[b]
Previous IFG, IGT, or A_{1c} ≥5.7%	
History of PCOS, GDM, or macrosomia	Maternal history of diabetes (including GDM)
Clinical conditions associated with insulin resistance (eg, severe obesity and acanthosis nigricans)	Signs of insulin resistance (eg, acanthosis nigricans)
Hypertension (≥140/90 mm Hg or on antihypertensive therapy)	Conditions associated with insulin resistance (eg, hypertension, dyslipidemia, or PCOS)
Dyslipidemia	
HDL-C <35 mg/dL (0.90 mmol/L)	
Triglyceride >250 mg/dL (2.82 mmol/L)	
Cardiovascular disease	

A_{1c}, glycated hemoglobin; BMI, body mass index; GDM, gestational diabetes mellitus; HDL-C, high-density lipoprotein cholesterol; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; PCOS, polycystic ovarian syndrome.

[a]Children are younger than age 18 years.

[b]Ethnic predisposition includes individuals of African American, Latino, Native American, Asian, or Pacific Islander descent.

Source: American Diabetes Association. 2. Classification and diagnosis of diabetes: *Standards of Medical Care in Diabetes—2021*. *Diabetes Care*. 2021;44(suppl 1):S15–S33. doi:10.2337/dc21-S002.

GESTATIONAL DIABETES MELLITUS

GDM affects about 7% of all pregnancies and is defined as "any carbohydrate intolerance with onset or first recognition during pregnancy."[4,25] The onset of diabetes during pregnancy and its duration affects the prognosis for a good obstetric and perinatal outcome (see Chapter 49, Obstetric Drug Therapy).

Diagnostic Criteria

The categories for normal diabetic plasma glucose levels, increased risk for diabetes, and diabetic plasma glucose levels for FPG, A_{1c}, and the OGTT are listed in **Table 53-3**.[26] The Expert Committee of the ADA has established the diagnostic criteria for diabetes for nonpregnant individuals of any age. For these individuals, a diagnosis of diabetes can be made when one of the following is present[4]:

Table 53-3

Diagnostic Criteria for Prediabetes and Diabetes

	FPG (in mg/dL [mmol/L])	A_{1c}	OGTT (in mg/dL [mmol/L])
Normal	<100 (5.6)	≤5.6%	<140 (7.8)
Prediabetes (ie, IFG, IGT)	100–125 (5.6–6.9)	≥5.7%–6.4%	140–199 (7.8–11.0)
Diabetes (nonpregnant adult)	≥126 (7.0)	≥6.5%	≥200 (11.1)

Equivalent venous whole-blood glucose concentrations are ~12%–15% lower. Arterial samples are higher than venous samples postprandially because glucose has not yet been removed from peripheral tissues. Capillary whole-blood samples contain a mixture of arterial and venous blood. Fasting levels are equivalent to whole-blood venous samples.

A_{1c}, glycated hemoglobin; FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

Sources: American Diabetes Association. 6. Glycemic targets: *Standards of Medical Care in Diabetes—2021*. *Diabetes Care*. 2021;44(suppl 1):S73–S84. doi:10.2337/dc21-S006.

1. An A_{1c} of ≥6.5%: The test must be performed in a laboratory (not with a point-of-care test). It should be performed using a method

certified by the National Glycohemoglobin Standardization Program.

2. An FPG of ≥126 mg/dL: *Fasting* means no caloric intake for at least 8 hours.
3. Classic signs and symptoms of diabetes (polyuria, polydipsia, ketonuria, and unexplained weight loss) combined with a random plasma glucose of ≥200 mg/dL.
4. After a standard OGTT (75 g of glucose for an adult or 1.75 g/kg for a child), the venous plasma glucose concentration is ≥200 mg/dL at 2 hours.[4]

The diagnosis must be confirmed by repeating the test, preferably the same test in the absence of unequivocal hyperglycemia. If two different tests are performed (eg, FPG and A_{1c}), and both are above the diagnostic threshold, then diabetes is confirmed. If only one test's value is above the diagnostic cut point, the test that is above the diagnostic cut point should be repeated. The diagnosis is made based on the results of the confirmed test.[4]

At times, it may be difficult to classify patients as having type 1 or type 2 DM. Type 1 is more likely when a patient is younger than age 30 years, lean, and has an elevated FPG and signs and symptoms of diabetes. The presence of moderate ketonuria with hyperglycemia in an otherwise unstressed patient also strongly supports a diagnosis of type 1 diabetes. Absence of ketonuria, however, is not of diagnostic value. The presence of autoantibodies to insulin or islet cell components may also indicate the need for eventual insulin therapy.[4,27] Relatively, lean older adults believed to have type 2 diabetes because they are initially responsive to oral agents or low doses of insulin may be subsequently diagnosed with type 1 diabetes. In addition, clinicians are beginning to observe more cases of type 2 diabetes in obese children and adolescents.[4,25] Individuals with A_{1c}, FPG, or OGTT values that are intermediate between normal and those considered diagnostic of diabetes are considered to have prediabetes. The terms IFG and IGT should not be used interchangeably because each results from somewhat different

physiologic processes. It is important to interpret the categories listed in Table 53-3 as a continuum of increased risk for diabetes, rather than focus on the absolute cutoff points for prediabetes or diabetes.

Many factors can impair glucose tolerance or increase plasma glucose. These must be excluded before a definitive diagnosis is made. For example, an individual who has not fasted for a minimum of 8 hours may have an elevated FPG. Patients who are tested for glucose tolerance during, or very soon after, an acute illness (eg, a myocardial infarction [MI]) or who are on corticosteroids (eg, prednisone and dexamethasone) may be misdiagnosed because of the presence of high concentrations of counterregulatory hormones that increase glucose concentrations. Glucose tolerance often returns to normal in these individuals.[28]

LONG-TERM COMPLICATIONS

Although acute hyperglycemic crises can occur in patients with diabetes, the long-term sequelae of diabetes account for most of the morbidity and mortality in the diabetic population. Complications are typically designated as microvascular or macrovascular in nature. Glucose toxicity contributes most to the development and progression of microvascular complications (retinopathy, nephropathy, and neuropathy) owing to the particular susceptibility of these cell systems to elevated glucose.[7] Diabetes is the leading cause of new cases of adult blindness and kidney failure in the United States.[1] About 60% to 70% of people with diabetes also have some manifestation of peripheral or autonomic neuropathy. Severe peripheral neuropathy coupled with abnormalities in immune function likely contributes to the high rate of lower extremity amputations among patients with diabetes.[1,7] Finally, poor glucose control promotes the development of dental and oral complications and increases the risk of complications during pregnancy for both mother and fetus.[25,29] Macrovascular complications are multifactorial in their

etiology and less dependent on hyperglycemia. DM itself is a well-known risk factor for macrovascular disease (peripheral vascular disease, CVD, and stroke). Despite a significant decline in all diabetes-related complications over the course of time, patients with diabetes have an eight times greater risk of acute MI and a 6.7 times greater risk of stroke when looking at the data for the 2010 time point.[30] An assessment of patients enrolled in the Framingham Heart Study showed that those with diabetes are at a three times greater risk of CVD-related mortality than are those without diabetes.[31] Thus, although tight glycemic control (A_{1c} <7.0%) will dramatically reduce the risk of microvascular disease, its relationship to macrovascular disease is still under intense debate.

RELATIONSHIP OF GLYCEMIC CONTROL TO MICROVASCULAR AND MACROVASCULAR DISEASE

Although epidemiologic studies have shown a general relationship between glucose control and CV events, recent randomized trials have failed to confirm a benefit of tight glucose control compared with standard control, which highlights the multifactorial nature of macrovascular disease.[32] However, the clear relationship between microvascular events and glycemic control is well established from randomized, clinical trials. The Diabetes Control and Complications Trial (DCCT), which included patients with T1DM, and the open-label follow-up trial, DCCT-EDIC (Diabetes Control and Complications Trial-Epidemiology of Diabetes Interventions and Complications), established the benefits of intensive glycemic control on microvascular end points.[33,34] In the DCCT, intensive treatment (A_{1c} 7.1% vs 9.0%) reduced the risk of clinically meaningful retinopathy, nephropathy, and neuropathy by ~60%. The Epidemiology of Diabetes Interventions and Complications (EDIC) study was followed as an open-label extension of the DCCT cohorts. Patients originally

assigned to the intensive treatment group were shown to have a persistently lower incidence of microvascular complications even after the glucose control reached parity between the two study groups after the end of the randomized portion of the trial.[34,35] The EDIC study also showed a significant reduction in CV complications among patients previously assigned to the intensive therapy DCCT arm.[36] See **Table 53-4** for the glycemic goals of intensive insulin therapy (herein called *physiologic* or *basal-bolus therapy*). This persistence of the microvascular benefits of glycemic control has also been demonstrated in patients with type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS) (see Case 53-11, Question 2).[37]

Table 53-4

Goals of Physiologic (Basal-Bolus) Insulin Therapy

Monitoring Parameter	Adults (mg/dL)	School Age (6–12 years) (mg/dL)	Adolescents and Young Adults (13–29 years) (mg/dL)	Pregnancy (mg/dL)
Premeals	80–130	90–130	90–130	60–99
2-Hour postprandial plasma glucose	<180	Not routinely recommended	Not routinely recommended	100–129
Bedtime/overnight (2:00–4:00 AM) plasma glucose	>70	90–150	90–150	60–99
A_{1C}[a]	<7.0%[b]	<7.5%[c]	<7.5%[c]	<6%
Urine ketones[d]	Absent to rare	Absent to rare	Absent to rare	Rare

See Case 53-2, Question 2, and Case 53-4, Question 2, for discussion. Basal-bolus insulin therapy is a complete therapeutic program of diabetes management and requires a team approach.

[a]A_{1c}, glycated hemoglobin, referenced to a nondiabetic range of 4% to 6% using a Diabetes Control and Complications Trial (DCCT)-based assay.

[b]Acceptable values should be individualized to levels that are attainable without creating undue risk for hypoglycemia. These results are similar to the results achieved in the DCCT trial. The American Diabetes Association recommends consideration for a lower goal (eg, <6%) in individuals with a short duration of diabetes, long life expectancy, and no significant cardiovascular disease. Less stringent goals may be appropriate for patients with hypoglycemic unawareness, history of severe hypoglycemia, counterregulatory insufficiency, advanced microvascular or macrovascular complications, or other complicating features (Table 53-10).

[c]A lower goal (<7%) is reasonable if it can be achieved without creating excessive risk of hypoglycemia.

[d]Does not apply to patients with type 2 diabetes.

Sources: American Diabetes Association. 6. Glycemic targets: *Standards of Medical Care in Diabetes—2021*. *Diabetes Care*. 2021;44(suppl 1):S73–S84. doi:10.2337/dc21-S006. The relationship between glycemic control and macrovascular disease has always been less clear. Evidence of early atherosclerosis in patients with type 1 diabetes in whom dyslipidemia and hypertension are typically absent argues strongly for a role of hyperglycemia itself in the development or progression of macrovascular disease.[38] The UKPDS trial was the first to report the benefit of tight BG control on CV complications in type 2 diabetes.[39] Although the microvascular benefits were clear, the 21% relative risk reduction for fatal and nonfatal MI and sudden cardiac death failed to reach statistical significance (P = .052). However, in a planned 10-year follow-up of patients enrolled in the trial, a significant 15% reduction was seen in the risk of MI (P = .01).[37] A similar finding for macrovascular benefit was reported in a 17-year follow-up of the DCCT-EDIC study.[36] Thus, although glycemic control benefited macrovascular disease, it took more than a decade to see the benefit. Reducing macrovascular risk in patients with diabetes thus takes a more comprehensive approach than does just glycemic control. In a trial of multiple risk factor control in type 2 diabetes, the STENO-2 trial found a significant 53% reduction in macrovascular events, with modest control of hypertension, dyslipidemia, and glycemia simultaneously.[40] Control of all major CVD risk factors is highlighted by the ADA for its importance in reducing macrovascular disease risk.[5] See **Table 53-5** for the metabolic goals for adults with diabetes.[41,42]

American Diabetes Association Metabolic Goals for Adults With

Diabetes Mellitus

Glycemic goals	
A_{1c}	<7.0% (normal, 4%–6%)[a]
Preprandial plasma glucose	80–130 mg/dL (3.9–7.2 mmol/L)[b]
Postprandial plasma glucose	<180 mg/dL (<10.0 mmol/L)[c]
Blood pressure	<140/90 mm Hg (Refer to Chapter 9, Essential Hypertension.)
Lipids	Refer to Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease.

Goals must be individualized to the patient. See Case 53-2, Question 2, for a broader discussion.[64]

A_{1c}, glycated hemoglobin.

[a]More stringent goals (ie, <6%) can be considered for select individuals. The American Association of Clinical Endocrinologists/American College of Endocrinology recommends an A_{1c} goal of ≤6.5%.[64]

[b]The American Association of Clinical Endocrinologists recommends a fasting blood glucose goal of <110 mg/dL (6.1 mmol/L).[64]

[c]The American Association of Clinical Endocrinologists/American College of Endocrinology recommends a goal of <140 mg/L (7.8 mmol/L).[100,101]

Source: American Diabetes Association. 6. Glycemic targets: *Standards of Medical Care in Diabetes—2021*. *Diabetes Care*. 2021;44(suppl 1):S73–S84. doi:10.2337/dc21-S006.

Three trials published in 2008 and 2009 have raised new questions about tight glycemic control in patients with type 2 diabetes. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, a higher rate of mortality was seen in the intensive treatment arm, which achieved an A_{1c} of 6.4% compared with the standard arm, which achieved 7.5%.[43] The ACCORD study was a National Heart, Lung, and Blood Institute study of >10,000 patients with type 2 diabetes with known heart disease or multiple CV risk factors. The intensively treated group had an excess of 3 deaths per 1000 participants per year compared with the standard group during

an average of 4 years on treatment (257 vs 203 deaths). The higher mortality rate was not attributable to a specific drug therapy or to severe hypoglycemia.[44] A second trial, the Action in Diabetes and Vascular Disease a Controlled Evaluation (ADVANCE), was an even larger study of >11,000 patients, which had findings different from that of ACCORD. In ADVANCE, there was an insignificant trend for reduced CV mortality and reduced overall mortality with tight glycemic control (A_{1c} of 6.3% compared with 7.0%).[45] Lastly, in the smaller Veterans Affairs Diabetes Trial (VADT), nearly 2000 patients were studied and found to have an insignificant 12% relative risk reduction in macrovascular end points but a 7% relative increase in overall mortality (95 vs 102 deaths). Neither finding was statistically significant.[46] After the ~10-year follow-up to the VADT trial, the study found one fewer CV event/116 person-years without a reduction in mortality. The intensive arm of this study had a mean A_{1c} of 6.9%, not <6.5%.[47]

In the face of these new data, the ADA, along with the American Heart Association (AHA) and the American College of Cardiology (ACC), issued a position statement in 2009.[48] Although acknowledging the findings of the ACCORD trial, the persistent trend for reductions in macrovascular events in all three trials was found to be reassuring. The position of the committee (which continues to be the official position of the ADA in the 2015 guidelines) is that although intensive glycemic control did not improve macrovascular outcomes, a goal of <7% is still reasonable based on microvascular benefits and a clear lack of harm across the trials of intensive versus standard glycemic control.[41] However, the ADA does acknowledge that there is room to individualize the A_{1c} goal and that achieving an A_{1c} of <7% has limited macrovascular benefit compared with A_{1c} values of 7% to 8%. Patients with type 2 diabetes and CVD or multiple risk factors for CVD should discuss their treatment goals with their providers. In these patients, a less intensive goal may be appropriate, particularly for patients who have difficulty achieving the goal of <7%.[41]

PREVENTION OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

Because the clinical symptoms of type 1 DM are the overt expression of an insidious pathogenic process that begins years earlier, investigators are focusing attention on strategies that alter the natural history of the disease (Fig. 53-1). First-degree relatives of individuals with type 1 DM have an increased risk of developing diabetes and can be identified by the presence of immune markers that may herald the disease by many years.[11] This has led to attempts at immune intervention at the prediabetes stage (primary prevention) or after the development of islet antibodies (secondary prevention). Most immunotherapy trials are tertiary prevention after diagnosis of type 1 diabetes. Results have not been extraordinary, but will be areas of future study. For primary prevention, vaccines, and secondary prevention, immunomodulatory agents will continue to be an area of research.[49] The Diabetes Prevention Program Research Group studied a diverse group of 3234 individuals at high risk for developing diabetes to determine whether lifestyle interventions or metformin (850 mg by mouth [PO] twice a day [bid]) would prevent or delay the onset of type 2 diabetes.[50] After 3 years, the incidence of diabetes was reduced by 58% and 31% in the intensive lifestyle and metformin groups, respectively, compared with the control group. Diabetes incidence during 10 years of follow-up was persistently lower in the groups originally treated with lifestyle (34% reduction) and metformin (18% reduction) interventions compared with the control group.[51] Other studies have confirmed the value of lifestyle intervention and other drugs (acarbose, orlistat, and various thiazolidinediones [TZDs]) in the prevention of type 2 diabetes, but the strongest evidence is with metformin.[3] Lifelong medication therapy, however, is not without its own risks and complications. Current recommendations regarding the treatment for individuals with prediabetes include lifestyle modification (5%–10% weight loss and 150 minutes/week of moderately intense physical

activity).[52] Metformin, although less effective than are lifestyle changes, can be considered for very high-risk individuals.[53]

CASE 53-1

QUESTION 1: R.P. is a 43-year-old African American female visiting a primary care clinic to obtain a routine physical examination for her new job. Her past medical history is significant for GDM. She was told during her two pregnancies (last child born 3 years ago) that she had "borderline diabetes," which resolved each time after giving birth. Her family history is significant for type 2 diabetes (mother, maternal grandmother, and older first cousin), hypertension, and CVD. She denies tobacco or alcohol use. She states that she tries to walk 15 minutes twice a week. Physical examination is significant for moderate central obesity (64 inches [162.56 cm]; 160 pounds [72.57 kg]; BMI, 30.2 kg/m^2, and blood pressure [BP] 145/85 mm Hg). R.P. denies any symptoms of polyphagia, polyuria, or lethargy. On checking her electronic medical record, she has documented hypertension and an FPG value of 119 mg/dL, measured 2 months prior.

What features of R.P.'s history and examination are consistent with an increased risk of developing type 2 diabetes?

The features of R.P.'s history that are consistent with an increased risk of developing type 2 diabetes include her age, ethnicity, weight, family history of diabetes, history of GDM, and a documented IFG. In addition, type 2 diabetes is also often associated with other disorders such as hypertension. The fact that R.P. has hypertension that is not well controlled and has a family history of hypertension and CVD may indicate that she is predisposed to insulin resistance, further putting her at risk for developing type 2 diabetes.

CASE 53-1, QUESTION 2: The physician orders an A_{1c} for R.P., which comes back at 6.1%. How should R.P. be managed at this time?

Both the A_{1c} and FPG values are in the prediabetes range. R.P. should be educated about her risk of developing type 2 diabetes. Working with her health care providers, R.P. should be encouraged and educated on how to institute lifestyle modifications (MNT and physical activity) that will help her lose weight, improve her CV

health, and decrease her risk of developing type 2 diabetes. A weight loss goal of 5% to 10% during the next 6 to 12 months should be recommended, and she should increase her level of moderate physical activity to at least 150 minutes/week. Her hypertension should be managed. At this time, the use of pharmacologic agents (ie, metformin) to prevent the development of type 2 diabetes is not recommended.

TREATMENT

There are three major components to the treatment of diabetes: diet, drugs (insulin and antidiabetic agents [oral and injectable]), and exercise. Each of these components interacts with the others to the extent that no assessment and modification of one can be made without knowledge of the other two.

Medical Nutrition Therapy

PRINCIPLES

MNT plays a crucial role in the therapy for all individuals with diabetes.[52,54] Unfortunately, patient acceptance and adherence to diet and meal planning are often poor, but revised evidence-based recommendations that are more flexible than are the previous approaches offer new opportunities to increase the effectiveness of nutrition therapy.

Nutrition therapy is designed to help patients achieve appropriate metabolic and physiologic goals (eg, glucose, lipids, BP, proteinuria, and weight), select healthy foods, and take into consideration personal and cultural preferences. Appropriate levels and types of physical activity to achieve a healthier status are incorporated into the nutrition plan.[52,55-57]

NUTRITION THERAPY AND TYPE 1 DIABETES MELLITUS

For patients with type 1 diabetes taking fixed doses of insulin, a meal plan is designed to provide adequate carbohydrates timed to match the peak action of exogenously administered mealtime insulin. Regularly scheduled meals and snacks should contain consistent carbohydrate amounts, which are required to prevent hypoglycemic reactions. Fortunately, newer insulins and insulin regimens provide much more flexibility in the amount and timing of food intake. Patients who are taught to count carbohydrates can inject rapid- or short-acting insulin doses designed to match their anticipated intake. Integration of food intake, physical activity, and insulin dose is critical and discussed extensively in the cases that follow.[52,55-57]

NUTRITION THERAPY AND TYPE 2 DIABETES MELLITUS

For patients with type 2 diabetes, meal plans emphasize normalizing plasma glucose and lipid levels as well as maintaining a normal BP to prevent or mitigate CV morbidity. Although weight loss reduces insulin resistance and improves glycemic control, traditional dietary strategies incorporating hypocaloric diets have not been effective in achieving long-term weight loss. A sustainable weight loss can be achieved within structured programs that emphasize lifestyle changes, physical activity, and food intake that modestly reduces caloric and fat intake.[52,55-57]

SPECIFIC NUTRITION COMPONENTS

MNT is an integral and critical component of diabetes care. For a more extensive discussion of the principles underlying nutrition therapy, the reader is directed to other sources. A few key principles are briefly noted subsequently because they are common sources of misunderstanding.[52,55-57]

Carbohydrates and artificial sweeteners

Carbohydrates include sugar (sucrose), starch, and fiber, and are liberally incorporated into the diet of a person with diabetes. In fact, the amount of dietary carbohydrate is the main determinant of insulin demand and is commonly used to determine the premeal insulin

dose. Furthermore, patients using fixed doses of insulin or antihyperglycemic medications (eg, sulfonylureas) must eat meals containing consistent amounts of carbohydrates to avoid hypoglycemia. Because isocaloric amounts of sucrose and starch produce the same degree of glycemia, sucrose can be substituted for a portion of the total carbohydrate intake and should be incorporated into an otherwise healthful diet.

Whole grains, fruits, and vegetables high in fiber are recommended for people with diabetes because they are for the general population. There is no evidence that larger amounts produce a differential metabolic benefit with regard to plasma glucose and lipid levels. Nonnutritive sweeteners (saccharin, aspartame, neotame, acesulfame potassium, and sucralose) and sugar alcohols have been rigorously tested by the U.S. Food and Drug Administration (FDA) for safety in people with diabetes and are safe at approved daily intakes. Fructose and the reduced-calorie sweeteners called *sugar alcohols* produce lower postprandial glucose responses than do sucrose, glucose, and starch. When sugar alcohols (eg, sorbitol, mannitol, lactitol, xylitol, and maltitol) are consumed, it is recommended to subtract half of their grams from the total carbohydrate amount because their effect on BG is less. Patients should be advised that when these sweeteners are used in foods labeled “dietetic” or “sugar free,” they still add to the carbohydrate content and provide substantial calories (2 cal/g). Furthermore, excessive intake of sorbitol-sweetened foods (eg, 30–50 g/day) can induce an osmotic diarrhea, and excessive amounts of fructose can increase total and low-density lipoprotein cholesterol (LDL-C).[58]

Counting carbohydrates

When patients are taught to estimate the grams of carbohydrate in a meal, they are given the following guideline: One carbohydrate serving—1 starch or 1 fruit or 1 cup milk—15 g carbohydrate. Patients vary with regard to their insulin-to-carbohydrate ratio

throughout time and throughout the day; however, a typical starting point is 1 unit/15 g carbohydrate.[52,55-57]

Fat

CVD is a major cause of morbidity and mortality in patients with diabetes. Therefore, saturated fats should be limited to <7% of calories. The intake of *trans* fat should also be minimized. The recommended cholesterol intake is <200 mg/day for patients with diabetes. Two or more servings/week of fish to provide *n*-3 polyunsaturated fatty acids and ω-3 fatty acids are advised.[52,55-57]

Protein

Data are insufficient to support special dietary protein recommendations for persons with diabetes if kidney function is normal. Generally, 15% to 20% of the daily caloric intake comes from animal and vegetable protein sources in the U.S. diet. This amount may be liberalized in pregnant and lactating females or in elderly people. With the onset of nephropathy, a lower protein intake of 0.8 to 1.0 g/kg/day is considered sufficiently restrictive. For patients in later stages of nephropathy, reduction of protein intake to 0.8 g/kg/day is recommended. High-protein diets are not recommended as a long-term method for weight loss, because the effects on kidney function are not known.[52,55-57]

Sodium

The ADA recommends a reduced sodium intake of <2300 mg/day in normotensive and hypertensive individuals. For patients with diabetes and symptomatic heart failure (HF), sodium should be further restricted to <2000 mg/day to help reduce symptoms. For all other patients, the ADA has no particular restrictions on sodium intake but recommends individualizing amounts based on the patient's sensitivity to salt and concurrent conditions such as hypertension or nephropathy.[55-57]

Alcohol

The ADA's recommendation for alcohol is consistent with general recommendations of no more than two alcoholic drinks/day for males or one drink/day for females. A drink is equivalent to 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of distilled spirits (each contains about 15 g of carbohydrate). Nevertheless, its caloric contribution must be considered (1 alcoholic beverage = 2 fat exchanges), and it should always be taken with food to minimize its hypoglycemic effect. In people with diabetes, light-to-moderate alcohol intake (one to two drinks/day) is associated with a decreased risk of CVD. A note of caution: Evening consumption of alcohol may increase the risk of nocturnal and fasting hypoglycemia, particularly in people with type 1 diabetes.[52,55-57,59,60]

PHYSICAL ACTIVITY

Physical activity is a key factor in the treatment of diabetes, particularly in type 2 diabetes, because obesity and inactivity contribute to the development of glucose intolerance in genetically predisposed individuals. Regular exercise reduces cholesterol levels, raises high-density lipoprotein cholesterol (HDL-C), lowers BP, augments weight reduction diets, reduces the dose requirements or need for insulin or antihyperglycemic agents, enhances insulin sensitivity, and improves psychological well-being by reducing stress. Exercise increases glucose utilization, which is provided initially from the breakdown of muscle glycogen and, subsequently, from hepatic glycogenolysis and gluconeogenesis. These effects are mediated through norepinephrine, epinephrine, growth hormone, cortisol, and glucagon, along with the suppression of insulin secretion. In patients using insulin, hyperglycemia, normoglycemia, or hypoglycemia can occur secondary to exercise depending on the degree of control, recent administration of rapid-acting insulin, and food intake. Exercise in patients taking insulin must be tempered by increased food intake, potential delay in insulin administration, decreased doses of insulin, or a combination of these actions to minimize hypoglycemia.[61]

In patients with type 2 diabetes, plasma glucose concentrations usually decrease in response to exercise, but symptomatic hypoglycemia is uncommon. The vascular benefits of exercise are particularly helpful in patients with diabetes given their predisposition to CVD. In general, exercise that produces moderate exertion (increase in heart rate of 20%–40% from resting baseline) is recommended with a starting goal of 150 minutes/week. The eventual goal is for patients to be able to achieve 50% to 70% of their age-adjusted maximal heart rate.[59]

Resistance exercise has been shown to improve insulin sensitivity. Therefore, in the absence of any contraindications, people with type 2 diabetes are encouraged to perform resistance training three times per week. Patients with conditions that may preclude certain types of physical activity (eg, coronary artery disease, uncontrolled hypertension, severe autonomic neuropathy, severe peripheral neuropathy or history of foot lesions, and advanced retinopathy in which retinal detachment may occur) should be carefully evaluated before starting an exercise regimen.[62]

Pharmacologic Treatment

Insulin, along with diet, is crucial to the survival of individuals with type 1 diabetes and plays a major role in the therapy for people with type 2 diabetes when their symptoms cannot be controlled with diet or noninsulin antidiabetic agents. Insulin also is used for people with type 2 diabetes during periods of intercurrent illness or stress (eg, surgery and pregnancy). The use of other antidiabetic agents is primarily reserved for the treatment of patients with type 2 diabetes. The ADA recommends a patient-centered approach to the use of pharmacologic agents. Comorbidities of patients should be considered when choosing drug therapy. These include the presence of atherosclerotic cardiovascular disease (ASCVD) or who are at high risk, established chronic kidney disease (CKD) and congestive heart failure. Additional considerations include the risk of hypoglycemia, the impact on weight, the risk of side effects, cost,

and patient preferences.[63] The clinical use of these agents and the complications associated with their use are discussed later in this chapter.

Overall Goals of Therapy

The overall goal of diabetes management is to prevent acute and chronic complications. Periodic assessments of A_{1c} coupled with regular measurement of fasting, preprandial, and postprandial glucose levels should be used to assess therapy. The following overall goals of therapy are agreed on by most endocrinologists:

1. Landmark randomized, prospective trials of various interventional therapies in patients with both type 1 and type 2 diabetes have clearly demonstrated that reductions in hyperglycemia significantly decrease microvascular complications. In both the UKPDS and the DCCT follow-up studies, significant reductions in macrovascular complications were also observed. Recent trials of specific agents have also shown a reduction in major adverse CV events (MACE) and a reduction in CKD and hospitalizations and deaths owing to HF. Target BG goals may need to be adjusted for patients with frequent, severe hypoglycemia or hypoglycemia unawareness (see Case 53-8, Questions 1–3, and Case 53-9), or with CVD. In addition, established renal insufficiency, proliferative retinopathy, severe neuropathy, and other advanced complications are not likely to be improved by tight glucose control. See Table 53-5 for the ADA glycemic goals.[64] The American Association of Clinical Endocrinologists (AACE) and the American College of Endocrinology established glycemic goals as well (Table 53-5).[14,63] The ADA guidelines will be discussed throughout this chapter.
2. Try to keep patients free of symptoms associated with hyperglycemia (polyuria, polydipsia, weight loss, fatigue, recurrent infection, and ketoacidosis) or hypoglycemia (hunger, anxiety, palpitations, and sweatiness).

3. Maintain normal growth and development in children. Intensive therapy is not recommended across any age group with a goal A_{1c} of <7.5%. Goals can be individualized, targeting <7% if it can be done so safely with minimum hypoglycemia (see Case 53-4, Questions 2 and 3).
4. Eliminate or minimize all other CV risk factors (obesity, hypertension, tobacco use, and hyperlipidemia; see Table 53-5 for glycemic and BP goals).
5. Try to integrate the patient into the health care team through intensive education. The patient's knowledge and understanding of this disease can favorably influence its outcomes (see Table 53-14).

Methods of Monitoring Glycemic Control

In addition to monitoring signs and symptoms associated with hyperglycemia, hypoglycemia, and the long-term complications of diabetes, an ongoing assessment of metabolic control is an integral component of diabetes management. Ideally, SMBG results combined with laboratory measures of acute and chronic glycemia can be used to evaluate and adjust therapy.[14,63] SMBG and A_{1c} levels continue to be the two primary methods used to access glycemic control. Continuous glucose monitoring (CGM) of interstitial fluid is also available for people with diabetes. CGM is currently recommended for consideration, along with SMBG, for patients with type 1 diabetes and patients with type 2 diabetes utilizing insulin, especially those with hypoglycemic unawareness.[63]

KETONE TESTING

Ketone testing is recommended for patients with gestational and type 1 diabetes. Urine ketones (acetoacetic acid) should be evaluated when glucose concentrations consistently exceed 300 mg/dL or during acute illness.[14] There are several commercially available meters available that either test both BG and ketones or blood ketones alone. Persistently high glucose concentrations of this

magnitude signal insulin deficiency that can, in turn, lead to lipolysis and ketoacidosis. A positive test may indicate impending or established ketoacidosis and demands a more extensive diagnostic workup. Testing also is recommended during pregnancy and if the patient has symptoms of ketoacidosis. Although there are generally no ketones in the urine, they may be present in people who are on extremely low-caloric diets and in the first morning sample of females who are pregnant. Also, see discussions of sick day management and ketoacidosis in other sections of this chapter (Cases 53-7 and 53-13).

PLASMA GLUCOSE

FPG concentrations are commonly used to assess glycemic control in the fasting state because this is when glucose concentrations are most reproducible. FPG concentrations generally reflect glucose derived from hepatic glucose production because this is the primary source of glucose in the postabsorptive state. The FPG is the most frequent test performed by patients when self-monitoring. Postprandial glucose concentrations (1–2 hours after the start of the meal) also are used to assess glycemic control when fasting glucose concentrations are within normal limits or when there is a need to assess the effects of food or drugs (eg, rapid-acting insulins and glinides) on meal-related glycemia. In individuals without diabetes, glucose concentrations generally return to <140 mg/dL within 2 hours of a meal. One- to 2-hour postprandial concentrations primarily reflect the efficiency of insulin-mediated glucose uptake by peripheral tissue.

Because glucose concentrations are affected by various factors (eg, meals, medications, and stress), single time point measurements cannot be used to assess a patient's overall control. Most laboratories measure plasma glucose concentrations rather than whole blood because these values are not subject to changes in the hematocrit. The majority of glucose monitors report plasma-referenced glucose concentrations. Whole BG concentrations are

~10% to 15% lower than are plasma glucose concentrations because glucose is not distributed into red blood cells (RBCs).[14]

SELF-MONITORING OF BLOOD GLUCOSE

SMBG has made euglycemia, both preprandially and postprandially, an achievable goal. Patients and their health care providers can use SMBG and/or CGM to assess directly the effects of drug dose changes, meals, exercise, and illness on BG concentrations. With improved technology, decreasing costs, and increased coverage by health plans, either SMBG or CGM is an option for all patients with diabetes. However, SMBG and CGM remain expensive for patients without health insurance; and when using SMBG, insurance carriers will often limit how often a patient can check their BG levels. Furthermore, to achieve maximal benefit from SMBG, both the clinician and patient must be motivated and willing to spend the time required to interpret the data and modify therapy to improve glycemic control. Selection and use of SMBG testing materials are discussed in Case 53-2, Questions 9 and 10. Patients in whom SMBG and/or CGM is particularly valuable include the following[14,63]:

- *Patients with type 1 diabetes*: Frequent BG measurements help the patient correlate meals, exercise, and insulin dose with BG concentrations. This instant feedback gives the patient an increased sense of control and motivation, leading to improved glucose control.
- *Pregnant patients*: Infant morbidity and mortality are associated with the mother's overall glucose control. Using SMBG and/or CGM, the mother with diabetes who achieves normoglycemia before conception and throughout pregnancy improves her chances of delivering a live, healthy infant.
- *Patients having difficulty recognizing hypoglycemia*: With time, patients with diabetes can develop a sluggish counterregulatory response to hypoglycemia, whereby hypoglycemic symptoms are blunted or even absent. This is often referred to as *hypoglycemic unawareness*. Routine SMBG and/or CGM to detect asymptomatic hypoglycemia is essential in these individuals. In addition, acute

anxiety attacks or signs and symptoms associated with a rapidly falling BG concentration may mimic a true hypoglycemic reaction. This can be evaluated easily by measuring a finger stick BG concentration.

- *Patients who are using physiologic (eg, basal-bolus) insulin therapy*: Individuals who are on multiple daily doses of insulin or those using an insulin pump should perform SMBG and/or CGM to evaluate the effectiveness of their insulin regimens and meal plans and to check for hypoglycemic or hyperglycemic reactions (see Case 53-2, Question 10). Knowledge of preprandial, postprandial, bedtime, and nocturnal (eg, 2:00 AM) BG concentrations is essential in determining basal and preprandial insulin requirements.
- *Patients with type 2 diabetes who are on therapy that can cause hypoglycemia*: Individuals taking glinides, a sulfonylurea, or insulin therapy should know how to perform SMBG and/or CGM to detect hypoglycemia when experiencing symptoms consistent with hypoglycemia.
- *Patients with type 2 diabetes who are engaged in self-management of their diabetes*: Even individuals using noninsulin therapies can benefit from SMBG to evaluate the impact of food, exercise, and antidiabetic medications on their BG.

CONTINUOUS GLUCOSE MONITORING

As with SMBG, CGM provides real-time information on glucose concentrations. However, the difference is that the CMG system automatically detects glucose concentrations (subcutaneous [SC] interstitial fluid glucose concentrations) on a continual basis. CGM systems use electrochemical sensors that are inserted into the skin. Sensor probe length varies as does the duration that the sensor can remain in the skin up to 14 days depending on the sensor. The sensors transmit a signal to a receiver (wired or wireless), which records and displays the data every 1 to 5 minutes. The sensors require a warmup or initialization period and may have calibration requirements. Calibration is performed by using a BG monitor.

Interstitial glucose levels lag behind plasma or BG levels by 8 to 18 minutes, depending on the glucose rate of change.[14] Therefore, if a person's glucose is low, or trending downward, SMBG is required. Some CGM systems have alarms that can go off at certain high and low glucose thresholds. The ability to detect hypoglycemia during the night with these alarms has been a very attractive reason for using CGM. Another key feature is the ability to follow trends and rates of change in BG levels. Any acute treatment changes still require SMBG. Small, short-term studies have demonstrated modest improvements in A_{1c} (0.3%–0.6% reductions) in adults and children with type 1 diabetes.[65] Just as for SMBG with a glucose meter, use of CGM requires a person to actively assess and react to their readings for this self-management tool to have an impact on A_{1c}. The ambulatory glucose profile (AGP) is created from all available CGMs and provides data on time in range, percentage above and below range, and variability.[66] Pharmacists in clinical practice can integrate CGM into their clinical services utilizing both professional and personal use monitors. This can facilitate the drug therapy management and aid in collaborative data interpretation, documentation, and billing.[67]

GLYCATED HEMOGLOBIN

The glycated hemoglobin, or A_{1c}, has become the gold standard for measuring chronic glycemia and is the clinical marker for predicting long-term complications, particularly microvascular complications. A_{1c} is most commonly measured because it comprises the majority of A_{1c} and is the least affected by recent fluctuations in BG. A_{1c} measures the percentage of hemoglobin A that has been irreversibly glycated at the *N*-terminal amino group of the β-chain; the plasma glucose level and the life span of an RBC (~120 days) determine its value. Thus, A_{1c} is an indicator of glycemic control during the preceding 2 to 3 months. In patients without diabetes, A_{1c} comprises ~4% to 6% of the total hemoglobin. Values may be three times this level in patients with diabetes.[63,68]

The following formula was developed to convert an A_{1c} into an average glucose: $28.7 \times A_{1c} - 46.7 = eAG$ (estimated average glucose). A formula that approximates (not exact) this very closely and is much easier to use in practice is $(A_{1c} - 2) \times 30$. The ADA now recommends reporting an eAG (units, mg/dL or mmol/L) along with the A_{1c}. An eAG calculator is available on their website to do this conversion (https://professional.diabetes.org/diapro/glucose_calc). The correlation between A_{1c} and eAG is shown in the following table with 95% confidence intervals (CIs) in parentheses.[4,63,69,70]

A_{1c} (%)	Estimated Average Plasma Glucose (mg/dL)
5	97 (76–120)
6	126 (100–152)
7	154 (123–185)
8	183 (147–217)
9	212 (170–249)
10	240 (193–282)
11	269 (217–314)
12	298 (240–347)

Hemoglobinopathies, such as sickle cell trait or chemically modified derivatives of hemoglobin as seen in uremia, in which hemoglobin becomes carbamylated, or acetylated hemoglobin with high-dose aspirin, can affect A_{1c} values (increase or decrease depending on the assay), resulting in inaccurate indications of glycemic control. Alterations in RBC survival or turnover, seen in hemolytic anemia and acute blood loss, can falsely lower the A_{1c}. Also, a recent blood transfusion or use of intravenous (IV) iron therapy or erythropoietin-stimulating agents in patients with CKD can falsely lower A_{1c} values. A glycated serum protein (fructosamine) should be considered for these patients. Antioxidants such as vitamins C and E also may interfere with the glycosylation process.[71]

A_{1c} can be measured without any special patient preparation (eg, fasting), and generally is not subject to acute changes in insulin dosing, exercise, or diet. A_{1c} values can be used as an adjunct to assess overall glycemic control in patients with diabetes or to diagnose diabetes and prediabetes.[63] Normalization can indicate whether euglycemia has been achieved. However, A_{1c} does not replace the day-to-day monitoring of BG concentrations, which is essential for evaluating acute changes in BG concentrations. These values are needed to adjust the meal plan or medication doses. Sometimes, an A_{1c} is used to verify clinical impressions related to glucose control and patient adherence. It should be measured quarterly in patients who do not meet treatment goals and at least semiannually in stable patients who are meeting treatment goals.[72]

GLYCATED SERUM PROTEIN, GLYCATED SERUM ALBUMIN, AND FRUCTOSAMINE

Assays for glycated serum proteins reflect the extent of glycosylation of a variety of serum proteins, including glycated serum albumin.[63] The fructosamine assay is one of the most widely used methods to measure glycated proteins (normal, 2–2.8 mmol/L). Because the half-life of albumin is ~14 to 20 days, fructosamine provides an indication of glycemic control during a shorter time frame (1–2 weeks) than does the A_{1c}. The ADA does not consider measurement of fructosamine equivalent to that of A_{1c}, although it correlates well with this value. Fructosamine levels may be useful as an adjunct to A_{1c} in determining whether a patient is improving or worsening in the short term (eg, a patient on insulin therapy undergoing multiple dosage adjustments; for females with type 2 diabetes during pregnancy or gestational diabetes) or in patients with conditions such as hemolytic anemia in whom the A_{1c} test is inaccurate.[73,74]

INSULIN

Insulin is a hormone secreted from the pancreatic β cell in response to glucose and other stimulants (eg, amino acids, free fatty acids, gastric hormones, parasympathetic stimulation, and β-adrenergic stimulation).[73] The hormone is made up of two polypeptide chains (a 21-amino acid A chain and a 30-amino acid B chain), which are connected by two disulfide bonds. Proinsulin, the precursor of insulin, is a single-chain 86-amino acid polypeptide that is processed in the Golgi apparatus of β cells and then packaged into granules.[75–80] In the storage granule, the connecting or C-peptide is cleaved from proinsulin to produce equimolar amounts of insulin and C-peptide. Insulin and C-peptide are cosecreted; thus, measurable C-peptide levels indicate the presence of endogenously produced insulin and functioning β cells. Insulin is crucial to the survival of individuals with type 1 diabetes, whose β cells have been destroyed. It also plays a major role in the therapy for many individuals with type 2 diabetes in combination with antidiabetic agents. Insulin also is used in patients with type 2 diabetes during pregnancy or periods of illness or stress (eg, surgery).

Commercially available insulin products differ in their physical and chemical properties as well as in the pharmacokinetics of their action. Prior issues with immunogenicity have been eliminated through modern manufacturing processes and the cessation of use of animal-derived insulin products. Consequently, immunologically mediated sequelae, such as lipodystrophy, hypersensitivity, and insulin resistance caused by “blocking” antibodies, are extremely rare.

Pharmacokinetics: Absorption, Distribution, and Elimination

The route of administration for insulin is primarily via SC injection. Regular insulin, a solution, can be administered by any parenteral route: IV, intramuscular (IM), or SC, and all injectable rapid-acting insulins may be administered by either SC injection or IV infusion.[81] Afrezza® (insulin human) is the only insulin currently available as a

powder for inhalation.[82] Other routes for insulin administration have been studied, including dermal, nasal, buccal, and oral; however, these formulations are not currently approved for use in the United States.

After SC injection, insulin is absorbed directly into the bloodstream, bypassing the lymphatic system. The rate-limiting step of insulin activity after SC administration is the absorption of insulin from the injection site, which depends on a multitude of factors such as type of insulin administered, injection site utilized, and patient technique. Variations in SC absorption can occur, primarily related to changes in blood flow around the injection site.[73]

Endogenous insulin is secreted directly into the portal circulation and is primarily cleared by the liver in nondiabetic individuals (60%), with the kidneys removing only 35% to 40% of it.[83] Exogenous insulin is degraded at both renal and extrarenal (liver and muscle) sites. Degradation also takes place at the cellular level after internalization of the insulin–receptor complex. In contrast to endogenously secreted insulin, up to 60% of exogenous insulin is cleared from the systemic circulation by the kidneys, with the liver accounting for only 30% to 40% of its clearance. Insulin is filtered by glomerular capillaries, but >99% is reabsorbed by the proximal tubules. The insulin is then degraded in glomerular capillary cells and postglomerular peritubular cells.[74,84] See Case 53-6 for changes in insulin requirement in renal dysfunction.

Pharmacodynamics

Clinically, the most important differences among insulin products relate to their onset, peak, and duration of action (not the actual insulin levels, which is pharmacokinetics). Current insulin products can be categorized as rapid-acting, short-acting, intermediate-acting, long-acting, and ultralong-acting insulin. Products available in the United States are listed in **Table 53-6**, and the onset of action, peak effect, and durations of action of each insulin category are listed in **Table 53-7**. However, these data are derived primarily from studies

in normal, healthy volunteers in the fasting state or in well-controlled patients with diabetes stabilized in a metabolic ward. In reality, intersubject and intrasubject variations in response to insulin can be substantial because an individual pattern of response to insulin can be affected by numerous factors (eg, the formation of insulin hexamers, the presence of insulin-binding antibodies, dose, exercise, site of injection, massage of the injection site, ambient temperature, and interactions between insulins that have been mixed together; see **Table 53-8** and Case 53-2, Question 14).[62] Nevertheless, knowledge of when one might expect the various insulins to exert their effects is absolutely essential to the rational adjustment of insulin dosages.

Table 53-6
Insulins Available in the United States

Type/Duration of Action	Brand Name	Manufacturer
Ultrarapid Acting		
Insulin aspart	Fiasp®	Novo Nordisk
Insulin lispro-aabc	Lyumjev®	Eli Lilly
Rapid Acting		
Insulin lispro	Humalog® Insulin lispro	Eli Lilly
	Admelog®	Sanofi Aventis
Insulin aspart	NovoLog®	Novo Nordisk
Insulin glulisine	Apidra®	Sanofi Aventis
Short Acting		
Regular	Humulin® R[a]	Eli Lilly
	Novolin® R	Novo Nordisk
Intermediate Acting		
NPH (isophane insulin suspension)	Humulin® N	Eli Lilly
	Novolin® N	Novo Nordisk

Type/Duration of Action	Brand Name	Manufacturer
Long Acting		
Insulin glargine	Lantus®	Sanofi Aventis
	Toujeo® (U-300)	Sanofi Aventis
	Semglee®	Viatris
	Basaglar®	Eli Lilly
Insulin detemir	Levemir®	Novo Nordisk
Insulin degludec	Tresiba® (U-100 and U-200)	Novo Nordisk
Premixed Insulins		
NPH/regular (70%/30%)	Humulin® 70/30	Eli Lilly
	Novolin® 70/30	Novo Nordisk
Insulin aspart protamine suspension/insulin aspart (70%/30%)	NovoLog® Mix 70/30™	Novo Nordisk
Insulin lispro protamine suspension/insulin lispro (75%/25%)	Humalog® Mix 75/25™	Eli Lilly
Insulin lispro protamine suspension/insulin lispro (50%/50%)	Humalog® Mix 50/50™	Eli Lilly
Inhaled Insulin		
Regular insulin	Afrezza®	MannKind

Insulin is made through recombinant DNA technology. Only regular and neutral protamine Hagedorn (NPH) are human insulin. All other insulins are human insulin analogs. All insulins available in the United States have a concentration of 100 units/mL (U-100), except as noted.

[a]A U-500 concentration is available for use in rare circumstances in patients with severe insulin resistance requiring very large insulin doses.

Table 53-8
Factors Altering Onset and Duration of Insulin Action

Factor	Comments

Factor	Comments	
Route of administration	Onset of action more rapid and duration of action shorter for IV > IM > SC	
	Intrapulmonary insulin has onset and duration comparable to SC rapid-acting insulins.	
Factors altering clearance		
Renal function	Renal failure lowers insulin clearance; may prolong and intensify action of exogenous and endogenous insulin.[366]	
Insulin antibodies	IgG antibodies bind insulin as it is absorbed and release it slowly, thereby delaying or prolonging its effect.	
Thyroid function	Hyperthyroidism increases clearance, but also increases insulin action, making control difficult; patients stabilize as they become euthyroid.	
Factors altering SC absorption	Factors that raise SC blood flow ↑ absorption rates of regular insulin; effect on intermediate- and long-acting insulins are minimal.	
Site of injection	Rate of absorption is fastest from the abdomen, intermediate from the arm, and slowest from the thigh. Less variation is observed in patients with type 2 diabetes; less variation is observed with current rapid-acting and long-acting insulins.	
	Site	*Half-life absorption (minutes)*
	Abdomen	87 ± 12
	Arm	141 ± 23
	Hip	153 ± 28
	Thigh	164 ± 15
Exercise of injected area	Strenuous exercise of an injected area within 1 hour of injection can increase absorption rate; rate of absorption of regular insulin is increased, but little effect on intermediate-acting insulin.	
Ambient temperature	Heat (eg, hot weather, hot bath, and sauna) increases absorption rate; cold has opposite effect.	
Local massage	Massaging injected area for 30 minutes substantially increases absorption rate of regular insulin as well as longer-acting insulins.	
Smoking	Controversial; vasoconstriction may decrease absorption rate.	

Factor	Comments
Jet injectors	Insulin absorption is more rapid, probably secondary to increases in surface area for absorption.
Lipohypertrophy	Insulin absorption is delayed from lipohypertrophic sites.
Insulin preparation	More soluble forms of insulin are absorbed more rapidly and have shorter durations of action (see Table 53-7 and text); human insulin may have shorter action than does animal insulin.
Insulin mixtures	The short-acting properties of rapid-acting insulins may be blunted if mixed with NPH insulin (see Case 53-2, Question 15).
Insulin concentration	More dilute solutions (eg, U-40, U-10) are absorbed more rapidly than are the more concentrated forms (U-100, U-500).
Insulin dose	Lower doses are absorbed more rapidly and have a shorter duration of action than do larger doses.

IgG, immunoglobulin G; IM, intramuscular; IV, intravenous; NPH, neutral protamine Hagedorn; SC, subcutaneous.

BASAL INSULIN

Basal insulin is required for all patients with type 1 DM and some patients with type 2 DM. The primary purpose of basal insulin is to suppress hepatic glucose production and maintain normal glucose levels in the fasting state and in between meals.[62] There are multiple

basal insulin products available including neutral protamine Hagedorn (NPH) insulin, insulin glargine (U-100 and U-300), insulin detemir, and insulin degludec (U-100 and U-200), which all differ based on the onset and duration of action. If used appropriately, all basal insulins can adequately manage a patient's fasting and in-between-meal glucose levels. However, the newer basal insulin analogs (insulin detemir, glargine, and degludec) have displayed an added benefit over NPH insulin with a longer duration of action with a more constant plasma concentration. It is these features that minimize the likelihood of hypoglycemia.[85] NPH insulin may be used once daily; however, often twice-daily dosing is required to achieve appropriate glucose control. Insulin detemir and glargine have demonstrated a decreased risk of nocturnal hypoglycemia in some patients, and may also be dosed once daily. Insulin detemir and insulin glargine U-100 are typically dosed once daily; however, because insulin detemir's duration is dose dependent and insulin glargine's duration of action averages between 18 and 24 hours, patients may require twice-daily dosing for these agents.[86–90] The newer, even longer-acting basal insulins (glargine U-300 and degludec U-100 and U-200) provide the patient with the convenience of once-daily dosing, and have a decreased risk of hypoglycemia compared to the other basal insulin options for patients with both type 1 and 2 diabetes.[91] A consideration, however, that must be made when choosing any insulin product is the out-of-pocket cost to the patient. Although the cost of all insulin products has risen significantly in recent years, follow-on products (specifically for insulin glargine U-100) have been approved by the FDA (Basaglar® and Semglee®), which provide the patient with a similar effect at a potentially lower cost to the patient.[92]

BOLUS/MEALTIME INSULIN

Similar to basal insulin, bolus/mealtime insulin is required for use in all patients with type 1 DM and for some patients with type 2 DM. There are many bolus/mealtime insulins available, which are classified as short-acting (regular insulin), rapid-acting (insulin

aspart, lispro, glulisine), ultrarapid-acting (insulin lispro-aabc (brand name Lyumjev®), faster-acting insulin aspart (brand name Fiasp®), and inhaled human insulin (brand name Afrezza®), all of which differ based on their onset and duration of action. Of all the bolus/mealtime insulin products, regular insulin has the longest onset and duration of action compared to the newer rapid-acting insulins, which have both a faster onset and shorter duration of action. Because they can be injected shortly before eating (0–15 minutes), all rapid-acting insulins provide patients greater flexibility in lifestyle compared to using regular insulin, and are available in vials and various insulin pens. Rapid-acting insulins also lower postprandial BG levels and can decrease the risk of late postprandial and nocturnal hypoglycemia compared with regular insulin formulations.[75,93] Insulin aspart is the only rapid-acting insulin available as brand name only. Recently, insulin lispro has become available both as a generic product (marketed by Eli Lilly) and a follow-on product (marketed under the name Admelog®) providing this particular rapid-acting insulin at a decreased cost to patients.[94–96] The ultrarapid-acting insulins may provide a benefit in some patients because they have been shown to potentially improve postprandial glucose control over the rapid-acting insulins.[81] Lastly, insulin human powder for inhalation (Afrezza®) is indicated for postprandial coverage in patients with type 1 or type 2 diabetes with a pharmacodynamic profile similar to that of rapid-acting insulin.[97] Inhaled insulin offers a patient the unique ability to administer mealtime insulin without the need to inject, and may also decrease the risk of hypoglycemia in some patients.[98] Insulin human powder for inhalation is available as prefilled inhalers containing 4, 8, or 12 units of rapid-acting insulin to be used at the beginning of a meal. It is contraindicated for use in patients with chronic lung disease such as asthma and chronic obstructive lung disease as well as current smokers. Because all mealtime insulins are comparable in efficacy for postprandial BG reduction, cost and patient preference must be taken into consideration when choosing the optimal product.

U-500 CONCENTRATED REGULAR INSULIN

Regular insulin U-500 (500 units/mL) is a concentrated insulin that is indicated for SC use in insulin-resistant patients requiring >200 units of insulin per day. Because this product is five times more potent than the 100 units/mL formulation, its usefulness is that a large insulin dose may be administered in a smaller volume. Its onset of action is ~30 minutes and peaks similar to regular insulin U-100. Regular insulin U-500, however, has a longer duration of action (up to 24 hours) compared to the U-100 formulation and is therefore recommended to be administered between two and three times daily.[99] A U-500 syringe is required to draw up and administer a dose with this product to avoid dosing errors. The manufacturer of U-500 regular insulin has incorporated multiple differences in packaging between regular insulin U-100 and U-500 to decrease the risk of dispensing errors. Specifically, the regular insulin U-500 vial contains 20 mL compared to the U-100 vial, which contains only 10 mL. The U-500 insulin vial is also marked with a band of diagonal brown stripes to distinguish it from the U-100 vial, which contains no stripes.[4] The U-500 insulin pen (Humulin® R U-500 KwikPen®) approved by the FDA in 2016 may help eliminate many of these issues.

PREMIXED INSULIN

Products that contain premixed NPH and regular insulin in a fixed ratio of 70:30 are available from Lilly (Indianapolis, Indiana) as Humulin® 70/30 and from Novo Nordisk (Bagsværd, Denmark) as Novolin® 70/30. Additional premixed formulations are available in which both insulin lispro and insulin aspart have been cocrystallized with protamine to create an intermediate-acting insulin similar to NPH. Humalog® Mix 75/25™ and Humalog® Mix 50/50™ (Lilly) are products with lispro protamine and insulin lispro in a fixed ratio of 75:25 and 50:50, respectively. NovoLog® Mix 70/30™ (Novo Nordisk) is aspart protamine and insulin aspart in a fixed ratio of 70:30. These premixed insulins are useful for patients who have difficulty measuring and mixing insulins and are dosed twice daily. These insulins are compatible when mixed together and retain their

individual pharmacodynamic profiles. Each of these mixed insulin combinations is available as both vials and insulin pens, with the exception of Novolin® 70/30, which is available in insulin vials only (see Table 53-19 later in this chapter and Case 53-2, Question 15).

TREATMENT OF TYPE 1 DIABETES: CLINICAL USE OF INSULIN

Clinical Presentation of Type 1 Diabetes

CASE 53-2

QUESTION 1: A.H., a slender, 18-year-old female who was recently discharged from the hospital for severe dehydration and mild ketoacidosis, is referred to the Diabetes Clinic from the University Student Health Service (no records available). A fasting and a random plasma glucose ordered subsequently were 190 and 250 mg/dL. Approximately 4 weeks before she was hospitalized, A.H. had moved across the country to attend college—her first time away from home. In retrospect, she remembers that she had symptoms of polydipsia, nocturia (six times a night), fatigue, and a 12-pounds (5.44-kg) weight loss during this period, which she attributed to the anxiety associated with her move away from home and adjustment to her new environment. Her medical history is remarkable for recurrent upper respiratory infections and three cases of vaginal moniliasis in the past 6 months. Her family history is negative for diabetes, and she takes no medications.

Physical examination is within normal limits. She weighs 110.23 pounds (50 kg) and is 64 inches (162.56 cm) tall. Laboratory results are as follows: FPG, 280 mg/dL; A_{1c}, 14%; and trace urine ketones as measured by Keto-Diastix®.

On the basis of her history and laboratory findings, the presumptive diagnosis is type 1 diabetes.

Which findings are consistent with this diagnosis in A.H.?

A.H. meets several of the diagnostic criteria for diabetes. She has classic symptoms of type 1 diabetes (polyuria, polydipsia, weight loss, fatigue, and recurrent infections), a random plasma glucose >200 mg/dL, and an FPG >126 mg/dL on at least two occasions as well as an A_{1c} >6.5%[4] (Tables 53-1 and 53-3). Features of A.H.'s

history that are consistent with type 1 diabetes, in particular, include the relatively acute onset of symptoms in association with a major life event (moving away from home), ketones in the urine, negative family history, and a relatively young age at onset.[33,34]

Treatment Goals

Case 53-2, Question 2: A.H. will be started on insulin therapy on this visit. What are the goals of therapy? Will normoglycemia prevent the development or progression of long-term complications?

The goal of diabetes management is the prevention of acute and chronic complications. The results of the DCCT and DCCT-EDIC studies convincingly demonstrated that lowering BG concentrations through intensive insulin therapy in persons with type 1 diabetes slows or prevents the development of microvascular complications.[26] The ADA recommends an A_{1c} goal of <7% for most patients, and an individual goal as close to normal as possible (<6.5%) if it can be achieved without significant hypoglycemia. For children and adolescents, the ADA recommends an A_{1c} goal of <7.5%, and an individualized goal of <7% if achievable without significant hypoglycemia.[100,101]

It is important to understand that physiologic or basal-bolus insulin therapy involves a *complete* program of diabetes management that includes a balanced meal plan, physical activity, frequent SMBG, and insulin adjustments based on these factors (Table 53-4).

In summary, A.H. is a patient newly diagnosed with type 1 diabetes who has not yet developed any signs or symptoms of long-term complications. Therefore, she is an ideal candidate for basal-bolus insulin therapy, and if she is willing and motivated, normoglycemia with rare hypoglycemic episodes is a reasonable long-term goal. This goal should be achieved gradually over the course of several months with insulin therapy, diet, education, and strong clinical support. A desirable goal is an A_{1c} value as close to

the normal range as possible with minimal episodes of hypoglycemia.

Basal-Bolus (Physiologic) Insulin Therapy

Case 53-2, Question 3: What methods of insulin administration are available to achieve optimal glucose control?

A physiologic insulin regimen is designed to mimic normal insulin secretion as closely as possible. Problems with insulin delivery include factors that affect the SC absorption of insulin (Table 53-8).[102] Before the development of the rapid-acting insulin analogs and basal insulins, previous insulins lacked pharmacodynamic profiles that allowed one to closely simulate normal pancreatic release of the hormone. In the nondiabetic individual, the pancreas secretes boluses of insulin in response to food. Between meals and throughout the night, the pancreas secretes small amounts of insulin that are sufficient to suppress lipolysis and hepatic glucose output (basal insulin). Clinicians now have more tools to mimic this basal-bolus model. Two methods have been used to achieve this pattern of insulin release: (a) insulin pump therapy (previously referred to as continuous SC infusion of insulin) and (b) basal-bolus insulin regimens consisting of once- or twice-daily doses of basal insulin coupled with premeal doses of rapid-acting insulin (see Case 53-2, Questions 3–5).

CONTINUOUS SUBCUTANEOUS INSULIN INJECTION

The use of continuous subcutaneous insulin infusion (CSII), commonly known as *insulin pumps*, is currently the most precise way to mimic normal insulin secretion. This consists of a battery-operated pump and a device that can program the pump to deliver predetermined amounts of rapid-acting insulin (ie, lispro, aspart, or glulisine) from a reservoir to an SC inserted catheter or needle.[89,90] One systematic review found that insulin pump therapy had a

modest A_{1c} reduction (−0.30% [95% CI, −0.58 to −0.02]) and reduction in severe hypoglycemia rates in children and adults (ADA section 7). In addition, older patients with type 1 diabetes may confer benefit from CSII. It has also shown to be beneficial in pediatric patients with type 1 diabetes in reducing diabetic ketoacidosis (DKA), neuropathy, and retinopathy. These systems are designed to deliver preset levels of insulin throughout the day to mimic basal insulin secretion, and can also be programmed to deliver meal-related boluses as needed. Most patients using an insulin pump use a rapid-acting insulin, rather than regular insulin. For meal coverage, the rapid-acting insulin can be given 0 to 15 minutes before eating. The delivery of the bolus can be adjusted based on the carbohydrate content of the meal.

If CSII delivery is interrupted, check for rise in glucose and urine ketones after 2 to 3 hours. CSII may also lead to lipohypertrophy and, in some instances, lipoatrophy. Most patients with diabetes discontinue CSII because of high costs, poor glycemic control, or discomfort from the device physically and emotionally (ie, depression and anxiety).

The preferred meal-planning approach for patients using an insulin pump is carbohydrate counting. The insulin-to-carbohydrate ratio, or how much carbohydrate is covered by 1 unit of insulin, must be determined. One method is to use the “500 rule.” The number 500 (or 450 for regular insulin) is divided by the total daily dose (TDD) of insulin the patient is using to determine the insulin-to-carbohydrate ratio (see Case 53-2, Question 11). Insulin pumps are capable of delivering many basal insulin rates. The basal insulin infusion rate may be adjusted depending on the situation. Many patients find it advantageous to decrease the basal rate during the middle of the night when nocturnal hypoglycemia is most likely to occur. The basal rate also may be increased before awakening to avoid hyperglycemia secondary to the “dawn phenomenon” or adjusted when physically active adjustments that are not possible when using SC basal insulin injections.

Several new CSII devices that allow a patient to manage their diabetes have emerged. One such device attaches on the skin like a patch and releases a set amount of insulin throughout the day while mealtime insulin can be released in 2-unit increments as needed. Features of the current pump models include bolus dose calculators based on preset carbohydrate-to-insulin ratios and correction factors, carbohydrate counts for selected foods, and an "insulin-on-board" feature, which helps avoid excessive dosing of insulin by indicating how much insulin from a previously administered dose should still be acting. Sensor-augmented pumps have effectively suspended insulin when glucose was low or predicted to go low in 30 minutes. One study showed that nocturnal hypoglycemia was significantly reduced with these types of systems Automation to Simulate Pancreatic Insulin REsponse (ASPIRE). Many of these systems have been FDA approved, and the most recent ones have been shown to effectively administer insulin if BG is either high or low, only requiring the patient to record meals and exercise. This has been called the *hybrid closed-loop approach* and is one step closer to a truly automated process for diabetes management.

Most insurance plans provide coverage for insulin pumps for patients with type 1 diabetes and for some patients with type 2 diabetes. Factors to consider when choosing a pump include safety features, durability, ability of the manufacturer to provide service, availability of training, clinically desirable features, CGM compatibility, and cosmetic attractiveness for the user.[90,103,104] The ADA website (www.diabetes.org) contains helpful information about insulin pumps for patients under the section on Living with Diabetes.

MULTIPLE DAILY INJECTIONS

Case 53-2, Question 4: How can insulin be administered to A.H. to model physiologic release of insulin from the pancreas?

There are a variety of insulin regimens that are intended to mimic the natural release of insulin from the pancreas.[105–107] Examples of

these are displayed and illustrated in **Figure 53-4**. A TDD of insulin is estimated empirically (eg, 0.3–0.5 units/kg/day for patients with type 1 diabetes) or according to guidelines listed in **Table 53-9**. The TDD of insulin then is split into several doses. In general, the basal dose comprises ~40% to 50% of the TDD, and the other bolus doses comprise the remaining 50%. If a patient eats three meals a day, the bolus dose would then be divided by three to calculate the number of units of bolus insulin required to cover each meal.

Figure 53-4 Theoretic insulin effect provided by various insulin regimens. A, Two daily injections of rapid-acting (insulin aspart, glulisine, or lispro), short-acting (regular), and intermediate-acting insulin (neutral protamine Hagedorn [NPH]). B, Morning injection of rapid-acting or short-acting insulin and intermediate-acting insulin, a predinner injection of rapid-acting or short-acting insulin, and a bedtime injection of intermediate-acting insulin. Suggested for patients with early morning hypoglycemia, and also those who have early morning hyperglycemia (owing to rebound phenomenon from hypoglycemia). C, Premeal injections of rapid-acting or short-acting insulin and long-acting (eg, insulin glargine or detemir) or intermediate-acting insulin (NPH) at bedtime. D, Continuous subcutaneous insulin infusion, showing an example with bolus given for a bedtime snack. BR, breakfast; Bed, bedtime; DI, dinner; LU, lunch. Arrows indicate time of insulin injection (<15 minutes before

meals for rapid-acting insulin and 30 minutes before meals for short-acting insulin).

Table 53-9
Empiric Insulin Doses

Estimating Total Daily Insulin Requirements	
These are initial doses only; they must be adjusted using SMBG results. Patients may be particularly resistant to insulin if their blood glucose concentrations are high (glucose toxicity); once glucose concentrations begin to drop, insulin requirements often decrease precipitously. The weight used is actual body weight. Insulin dose requirements can change dramatically with time depending on circumstances (eg, a growth spurt, modest weight gain or loss, changes in physical activity, stress, or illness).	
Type 1 diabetes	
Initial dose	0.3–0.5 units/kg
Honeymoon phase	0.2–0.5 units/kg
With ketosis, during illness, during growth	1.0–1.5 units/kg
Type 2 diabetes	
With insulin resistance	0.7–1.5 units/kg
Estimating Basal Insulin Requirements	
These are empiric doses only and should be adjusted using appropriate SMBG results (fasting or premeal). Basal requirements vary throughout the day, often increasing during the early morning hours. The basal requirement also is influenced by the presence of endogenous insulin, the degree of insulin resistance, and body weight. Basal requirements are ~50% of total daily insulin needs. Thus, basal insulin dose is ~50% of TDD. A conservative approach is to reduce the calculated 50% basal dose by 20% to avoid hypoglycemia.[63]	
Estimating Premeal Insulin Requirements	
The premeal insulin requirements are ~50% of the TDD, usually divided equally into three doses initially, taken with each meal (ie, breakfast, lunch, and dinner), and then each premeal dose is individually adjusted based on BG readings. The “500 rule” estimates the number of grams of carbohydrate that will be covered by 1 unit of rapid-acting insulin. The rule is modified to the “450 rule” if using regular insulin.	
500/TDD of insulin—number of grams covered	
Example: For a patient using 50 units/day, 500/50 = 10. Therefore, 10 g of	

carbohydrate would be covered by 1 unit of insulin lispro, glulisine, or aspart. This equation works very well for patients with type 1 diabetes in estimating their premeal insulin requirements. Because patients with type 2 diabetes have insulin resistance, the rule may underestimate their insulin requirements.
Determining the "Correction Factor"
Supplemental doses of rapid-acting insulin are administered to acutely lower glucose concentrations that exceed the target glucose concentration. These doses must be individualized for each patient and again are based on the degree of sensitivity to insulin action. For example, if the premeal blood glucose target is 120 mg/dL and the patient's value is 190 mg/dL, additional units of rapid-acting insulin could be added to the premeal dose. The correction factor determines how far the blood glucose drops per unit of insulin given and is known as the "1700 rule." For regular insulin, the rule is modified to the "1500 rule." The equation is as follows:
1700/TDD = point drop in blood glucose per unit of insulin
Example: If a patient uses 28 units/day of insulin, their correction factor (or insulin sensitivity) would be 1700/28 = 60 mg/dL. Therefore, the patient can expect a 60-mg/dL drop for every unit of rapid-acting insulin administered. Patients with a higher sensitivity factor have lower insulin requirements. Individuals with a lower sensitivity factor (higher insulin requirements) typically achieve a smaller reduction in blood glucose per unit of insulin

SMBG, self-monitored blood glucose; TDD, total daily dose.

Outpatient insulin therapy in type 1 and type 2 diabetes mellitus: scientific review. *JAMA*. 2003;289(17):2254–2264. doi:10.1001/jama.289.17.2254; Walsh J, Roberts R. *Pumping Insulin: Everything You Need for Success on a Smart Insulin Pump*. 4th ed. Torrey Pines Press; 2006; Walsh J, Roberts R, Bailey T, Varma CB. *Using Insulin: Everything You Need for Success With Insulin*. Torrey Pine Press; 2003.

A regimen much less commonly used in patients with type 1 diabetes involves injecting a mixture of intermediate-acting and regular or rapid-acting insulin twice daily, before breakfast and before dinner (Fig. 53-4A). The morning dose of regular or rapid-acting insulin is intended to cover the increase in BG due to the breakfast meal; the morning dose of NPH covers the noon meal and provides basal insulin throughout the day; the evening dose of regular or rapid-acting insulin covers the evening meal; and the evening dose of NPH provides basal insulin levels during the night and covers any evening snack that is ingested. Because NPH is an intermediate-acting insulin and has a peak effect, it does not provide

true basal insulin coverage. When NPH is injected in the morning, the patient must eat lunch on time because of this peak effect; otherwise, he/she will experience hypoglycemia. Also, when NPH is taken with mealtime insulin before dinner, the patient is at risk for nocturnal hypoglycemia from the peak effect of the evening dose of NPH. The advantage of using a rapid-acting insulin (eg, insulin lispro, insulin aspart, or insulin glulisine) instead of regular insulin in this regimen is to facilitate the patient being able to take insulin doses immediately before a meal. However, the peak effect of the NPH component in this combined dose still presents the same problems. Although this type of regimen may decrease the overall total number of injections per day, it does not mimic physiologic insulin release.

Figure 53-4B depicts a variation of this method. It is the same except that the evening dose of NPH is given as a third injection at bedtime. This shifts the time of peak effect from ~2:00 to 3:00 AM to ~7:00 AM. By administering NPH at bedtime, nocturnal hypoglycemia is reduced, and peak insulin activity occurs when the patient is more likely to be awake and ingesting food. This method may be useful for patients in whom nocturnal hypoglycemia and fasting hyperglycemia are particularly troublesome; however, this regimen also does not mimic physiologic insulin release.

The regimen that most closely mimics physiologic insulin release besides the use of an insulin pump is the use of a once-daily basal insulin such as insulin glargine, detemir, or degludec to provide basal insulin levels throughout the day, along with doses of a rapid-acting insulin (preferred) or regular insulin before meals (Fig. 53-4C depicts the long-acting insulin given at bedtime, but it may alternatively be given in the morning). When smaller doses are used, twice-daily insulin detemir and possibly U-100 insulin glargine will be required for 24-hour coverage.[108,109] Insulins U-100 and U-200 degludec and U-300 glargine will last 24 hours with once-daily dosing. This method theoretically provides insulin similar to the insulin pump: constant basal levels plus small boluses for meals and snacks. In doing so, it offers some of the same advantages of the pump in that it permits

some degree of flexibility in the patient's lifestyle. For example, if a patient with diabetes chooses to skip a meal, they omit a premeal bolus; if the patient chooses to eat a larger meal than usual, they increase the premeal bolus. Similar dose adjustments can be made to accommodate snacks, exercise patterns, and acute illnesses. Alternatives to this regimen are depicted in Table 53-4, where the long-acting insulin is replaced with intermediate-acting insulin for basal coverage and or the rapid-acting insulin is replaced with short-acting insulin for bolus coverage. These options, however, are not preferred because they do not as closely mimic normal physiologic insulin release.

Case 53-2, Question 5: Should A.H. use an insulin pump or multiple daily insulin injections?

Indications for basal-bolus insulin therapy are listed in **Table 53-10**. Patients with type 1 diabetes should be placed on a basal-bolus insulin regimen. A.H. is an ideal candidate to strive for an A_{1c} goal of <6.5%. She is newly diagnosed, has not yet developed the long-term complications of diabetes, and should derive the benefits of normoglycemia. Assuming A.H. will be able to manage a basal-bolus insulin regimen, individualized target BG levels that strive for the best level of glucose control possible without placing her at undue risk for hypoglycemia should be prescribed. She must be willing to test her BG concentrations four or more times daily or utilize a continuous BG monitor and inject herself four or more times daily or learn about the use and care of an insulin pump. She also must be willing to keep detailed BG and food records and participate in an extensive education program that enables her to adjust her insulin doses based on BG concentrations, physical activity, and the carbohydrate content of her snacks and meals.

Table 53-10

Basal-Bolus (Physiologic) Insulin Therapy: Indications and Precautions

Patient Selection Criteria
Type 1 diabetes, otherwise healthy patients (age >7 years) who are highly motivated, engaged in diabetes self-management, and are able to adhere to a complex insulin regimen. Must be willing to test blood glucose concentrations multiple times daily and inject four doses of insulin daily, on average
Females with diabetes who plan to conceive
Pregnant patients with diabetes (preexisting)
Patients poorly controlled on conventional therapy, 2–3 injections daily (includes patients with type 2 diabetes)
Technical ability to test blood glucose concentrations
Intellectual ability to interpret blood glucose concentrations and adjust insulin doses appropriately
Access to trained and skilled medical staff to direct treatment program and provide close supervision
Avoid or Use Cautiously in Patients Who Are Predisposed to Severe Hypoglycemic Reactions or in Whom Such Reactions Could Be Fatal
Patients with counterregulatory insufficiency
β-Adrenergic blocker therapy
Autonomic insufficiency
Adrenal or pituitary insufficiency
Patients with coronary or cerebral vascular disease
(*Note:* Counterregulatory hormones released in response to hypoglycemia may have adverse effects in these individuals.)
Unreliable, nonadherent individuals, including those who abuse alcohol or drugs and those with psychiatric disorders

Transition to an insulin pump is facilitated by patients being able to attain these skills using multiple daily SC insulin injections before insulin pump initiation. The ADA recommends that the use of insulin pumps be limited to highly motivated individuals under the guidance of a health care team trained and knowledgeable in their use. Pumps offer the patient the ability to use multiple basal rates during the 24-hour period and assist with the calculation of bolus and correction insulin doses. Most studies have shown that pump therapy provides

equivalent and sometimes better glycemic control than does intensive management with multiple injections.[102,110]

Insulin pumps are particularly useful in patients with frequent, unpredictable hypoglycemia, or marked dawn phenomena (see Case 53-3). Others have described the methods by which insulin doses are established and altered in patients using the insulin pump.[111] Because A.H. has just been diagnosed, she should be initiated on a basal-bolus SC insulin therapy. Once she has acquired these skills, she may be considered for pump therapy.

Clinical Use of Insulin

INITIATING INSULIN THERAPY

Case 53-2, Question 6: How should multiple daily insulin injections be initiated in A.H.?

A conservative TDD of insulin is estimated empirically or according to guidelines similar to those listed in Table 53-9 in newly diagnosed patients and will differ in patients with type 1 and type 2 diabetes. Many weight-based empiric dose calculations have been proposed, as listed in Table 53-9, for patients with both type 1 and type 2 diabetes; however, these regimens are mostly beneficial for patients with type 1 diabetes because these patients are completely insulin deficient. For patients with type 2 diabetes, initial basal insulin doses that are weight based or a starting dose of ~10 units daily are appropriate options based on patient-specific information. Insulin doses would then be adjusted based on home blood glucose (HBG) levels.[76,111]

For a basal-bolus insulin regimen, insulin glargine, insulin detemir, or insulin degludec could ideally be used as the basal insulin with bolus doses of a rapid- or short-acting insulin (insulin lispro, insulin aspart, or insulin glulisine) given at mealtime. During the initial visit, A.H. needs to learn how to inject her insulin (see Case 53-2, Question 8), how to test her BG (**Table 53-11**), how and when to test

for ketones (either urine or blood), and how to recognize and treat hypoglycemia (**Table 53-12**). She also needs to understand the importance of meal planning and the relationship between carbohydrate intake and insulin action (**Table 53-13**). It is very important not to overwhelm A.H. with information on the first visit. One should be particularly sensitive to the psychological impact of this diagnosis on A.H., address her major concerns, and provide only the information that is absolutely essential before the next visit. Between visits, she should be assessed and provided information on an as-needed basis by phone. **Table 53-14** lists important areas of patient education.

Table 53-11

Self-Monitored Blood Glucose Testing: Areas of Patient Education

When and How Often to Test
Technique
How and when to calibrate the glucose monitor
Review all “buttons” and their purposes. Identify battery type. Review cleaning procedures, if applicable.
Preparation
1. Calibrate monitor/set code for batch of test strips, if required. 2. Insert test strip to turn machine on (some meters require user to turn machine on). 3. Prepare all materials: tissue, strip, and lancet. 4. Remember to close the lid of the strip container immediately. Strips exposed to air and moisture deteriorate rapidly. 5. Wash hands with warm water. *Dry thoroughly.* A wet finger causes blood to spread rather than form a drop. Milk the finger from the base to ensure an adequate flow of blood. 6. Lance the tip of the finger. Avoid the pads of the finger where nerve endings are concentrated. 7. Hold the finger *below* the heart with the lanced area pointing toward the floor. 8. Once a sufficient amount of blood is available, *quickly* apply blood to designated area of the test strip. Depending on the strip type, the blood sample is placed in an area on the surface of the strip, or it is applied to the side of the strip where it is taken up by capillary action.

Record Results in a Log Book and Bring to All Clinician Visits. Include relevant information regarding diet or exercise.
How to Use Results to Achieve Glycemic Targets; Educate Patients on What to Do With Their Blood Glucose Readings (eg, adjust their insulin dose; modify their carbohydrate content).

Table 53-12
Hypoglycemia

Definition
Level 1: Blood glucose concentration <70 mg/dL, but <54 mg/dL: Patient may or may not be symptomatic (tremors, palpitations, sweating, intense hunger); patients are able to self-treat.
Level 2: Blood glucose <54 mg/dL: Patient is generally symptomatic; patient may be neuroglycopenic (experience autonomic symptoms: headache, mood changes, decreased attention, drowsiness). Patients may require assistance in treating.
Level 3: No designated blood glucose: Severe hypoglycemia associated with altered mental status and physical function; patient may become unconscious, unresponsive, or have convulsions. Patients require assistance for appropriate treatment.
Common Signs and Symptoms of Hypoglycemia
Blurred vision, sweaty palms, generalized sweating, tremulousness, hunger, confusion, anxiety, circumoral tingling, and numbness. Patients vary with regard to their symptoms. Behavior can be confused with alcohol inebriation. Patients become combative and use poor judgment.
Nocturnal hypoglycemia: nightmares, restless sleep, profuse sweating, morning headache, morning “hangover.” Not all patients have symptoms during nocturnal hypoglycemia.
Clinical Considerations
Irregular eating patterns
↑ Physical exercise
Gastroparesis (delayed gastric emptying)
Defective counterregulatory responses
Excessive dose of insulin or insulin secretagogues (sulfonylureas, glinides)
Alcohol ingestion
Drugs

Treatment	
Ingest 10–20 g of rapidly absorbed carbohydrate. Repeat in 15–20 minutes if glucose concentration remains <70 mg/dL or if patient is symptomatic. Follow with complex carbohydrate/protein snack if mealtime is not imminent.	
The following are examples of food sources that provide 15 g of carbohydrate:	
Orange, grapefruit, or apple juice; regular, non-diet soda	1/2 cup
Fat-free milk	1 cup
Grape juice, cranberry juice cocktail	1/3 cup
Sugar	1 tbsp or 3 cubes
Lifesavers	5–6 pieces
Glucose tablets	3–4 tablets
If patient is unconscious, the following measures should be initiated:	
Glucagon 1 mg intranasal, SC, IM, or IV (generally administered IM in outpatient setting; mean response time, 6.5 minutes)	
Glucose 25 g IV (dextrose 50%, 50 mL; mean response time, 4 minutes)	

IM, intramuscular; IV, intravenous; SC, subcutaneous.

Table 53-13
Interpreting Self-Monitored Blood Glucose Concentrations

Test Time	Target Insulin Dose	Target Meal/Snack
Prebreakfast (fasting)	Predinner/bedtime intermediate-acting or basal insulin	Dinner or bedtime snack
Prelunch	Prebreakfast regular or rapid-acting insulin	Breakfast or midmorning snack
Predinner	Prebreakfast intermediate-acting insulin or prelunch regular or rapid-acting insulin	Lunch or midafternoon snack
Bedtime	Predinner regular or rapid-acting insulin	Dinner
2-hour postprandial	Premeal regular or rapid-acting insulin	Preceding meal or snack

Test Time	Target Insulin Dose	Target Meal/Snack
2:00–3:00 AM or later	Predinner intermediate-acting insulin or basal insulin if given in AM	Dinner or bedtime snack

Considerations: (a) Assumes a regular meal pattern. For patients who travel, have odd working or sleeping hours, or have irregular meal patterns, these guidelines may not apply. (b) Assumes administration of regular insulin 30 to 60 minutes before meals or rapid-acting insulin 0 to 15 minutes before meals and a normal pattern of insulin response (see Table 53-8 for factors that can alter insulin absorption and response). (c) If prebreakfast concentrations are high, rule out reactive hyperglycemia (Somogyi reaction or posthypoglycemic hyperglycemia). Consider contribution of dawn phenomenon as well. Whenever blood glucose concentrations are high, consider reactive hyperglycemia (excessive insulin doses). (d) Consider accuracy of reported test results: (i) Do they correlate with the glycated hemoglobin (A_{1c}) and patient's signs and symptoms? (ii) What is the patient's medication adherence? Could results be fabricated? (iii) Is the patient's technique appropriate? Check timing, adequate blood sample, machine, strips, and calibration (Table 53-11). (iv) Are insulin kinetics altered? (v) What is the carbohydrate content, quality, and regularity of meals?

Hypoglycemia: Signs, symptoms, and appropriate treatment (Table 53-12)
Exercise: Effect on blood glucose concentrations and insulin dose (Table 53-19)
Diet: See text. Emphasis placed on carbohydrate counting because the carbohydrate is responsible for 90% of the rise in blood glucose after a meal
Insulins
Injection technique
Types of insulin
Time of action profiles (onset, peak, and duration)
Storage
Stability (look for crystallization and precipitation with NPH insulin)
Therapeutic goals: A_{1c}, fasting, preprandial, and postprandial blood glucose

levels, cholesterol, triglyceride, blood pressure (refer to Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; and Chapter 9, Essential Hypertension)
SMBG testing: Table 53-13
Interpretation of SMBG testing results
Foot care: Inspect feet daily; wear well-fitted shoes; avoid self-care of ingrown toenails, corns, or athlete's foot; see a podiatrist.
Sick day management: Table 53-20
Cardiovascular risk factors: Tobacco use, high blood pressure, obesity, elevated cholesterol
Importance of annual ophthalmologic examinations; tests for microalbuminuria; keeping up to date with immunizations

A_{1C}, glycated hemoglobin; NPH, neutral protamine Hagedorn; SMBG, self-monitored blood glucose.

A reasonable first approach for A.H. is to provide a TDD of 24 units of insulin (~0.5 units/kg). Because 50% of the daily dose should be given as basal insulin and the remainder given as rapid-acting insulin divided into three doses, A.H. would take the following: 12 units of basal insulin (either insulin glargine or insulin degludec) once daily (morning or bedtime) with 4 units of rapid-acting insulin (insulin aspart or lispro) given ~5 to 10 minutes before each meal.[111] Alternatively, if insulin detemir is used, the dose would generally be split twice daily (6 units bid) because the duration of action of insulin detemir is typically <24 hours when given at such a small dose. Caveat: As A.H.'s glucose concentration returns to normal; glucose toxicity will recede, and she may require less insulin.

SELECTING AN INSULIN DELIVERY DEVICE

CASE 53-2, QUESTION 7: What kind of insulin delivery device should be prescribed for A.H.?

Insulin delivery is achieved utilizing syringes, prefilled insulin delivery devices (pens), or through oral inhalation. Insulin syringes are plastic, disposable syringes with needles that are extremely fine

(typically 30–31 gauge), sharp, and well lubricated to ease insertion. Pen needles and syringes have been improved so that insulin injections are relatively painless if proper technique is used. The lengths of needles are 15/64 inch (6 mm), 5/16 inch (8 mm), or ½ inch (12.7 mm).[112] Research has shown that there is no medical reason why a patient would require use of a needle longer than 4 to 6 mm for insulin administration because skin thickness does not vary between different demographics. Previous thoughts that larger or obese patients require longer needle length for proper insulin administration have been disproven. Manufacturers produce 1-, 0.5-, and 0.3-mL syringes for U-100 insulin. For patients such as A.H., using fewer than 30 units of insulin per injection, the 0.3-mL syringe is preferred for ease of reading the dose markings on the syringe. Insulin syringes are available in 1-unit increments or 0.5-unit increments. One-half-unit increments are useful for pediatric patients and for patients who count carbohydrates because mealtime insulin doses can be rounded to the 0.5 unit.[112,113]

Insulin pen devices are also available for injecting insulin. Pen devices may increase dosing accuracy and are often preferred because they make insulin administration much easier, especially for patients who need to take their insulin doses away from home.[114–116] The pens are particularly useful for patients with (a) regimens consisting of multiple daily doses of rapid- or short-acting insulin before meals and snacks (such as A.H.), (b) a fear of needles, (c) impaired visual or dexterity problems, (d) hectic work schedules or lifestyle, or (e) a need to train alternative individuals who administer insulin (eg, school nurses or siblings). In addition, studies have shown that use of insulin pen devices versus vial and syringe insulin administration may result in fewer discontinuations of insulin therapy and improve overall adherence to an insulin regimen.[117]

Pens eliminate the need to draw insulin up in a syringe because the insulin dose is dialed up on the device. Pen devices are available as a disposable prefilled pen or a durable pen in which an insulin cartridge is replaced. Most typically used are the prefilled pens that contain a built-in, single-use insulin cartridge. Most U-100 formulations contain 300 units of insulin, whereas concentrated

insulins will contain more units in each device. Pen devices are available to dose insulin in 1-unit (most) and 0.5-unit increments. Pen needles are available in 29-, 30-, 31-, and 32-gauge needles and 5/32 inch (4 mm), 3/16 inch (5 mm), 1/4 inch (6 mm), 5/16 inch (8 mm) lengths, and ½ inch (12.7 mm), but there is no medical rationale to use needles longer than 6 mm. Patients are advised to use a new disposable needle for each injection. Unfortunately, limited health insurance coverage and higher copays may deter pen use.[112]

For insulin delivery using an insulin pump, see Case 53-2, Questions 3 and 5.

If she elected to use a syringe, a 0.3-mL U-100 insulin syringe with a short needle length should be prescribed for A.H. Subjectively, patients can "feel" the difference between different brands, or they may prefer the "ease of bubble removal," physical characteristics, or packaging of one syringe over another. If she elected to use an insulin pen, a prefilled pen for insulin glargine and insulin aspart or insulin lispro are available. The shortest possible needle length (4 mm for pen needles and 6 mm for syringes) should be prescribed for A.H.

MEASURING AND INJECTING INSULIN

Injection

Case 53-2, Question 8: How should A.H. be instructed to administer her insulin injections?

A.H. should prepare an area for injection. Alcohol swabs may be used to clean the rubber stopper of the insulin vial (or pen device). To inject the insulin SC, A.H. should be instructed to firmly pinch up the area to be injected (this creates a firm surface for the injection) and to quickly insert the needle perpendicularly (90° angle) into the center of this area. Note, however, that pinching is only necessary when A.H. is using a syringe that is ≥6 mm.[112] The syringe should be held toward the middle or back of the barrel, like a pencil. Anxious

patients have a tendency to “choke” the hub of the syringe, and this prevents proper needle insertion. A 45° angle of injection may be used for infants and very thin individuals who have little SC fat, especially in the thigh area.[112] The site should not be massaged, because this may accelerate the absorption and onset of action of insulin (Table 53-8). When using an insulin pen, the needle should be embedded within the skin for about 5 to 10 seconds after depressing the dosing knob to ensure full delivery of the insulin dose.[112,118]

Rotating injection sites

The primary sites used for injecting insulin are the lateral thigh, abdomen (avoid the 2-inch radius around the navel), and upper arm (**Fig. 53-5**). The ADA and American Association of Diabetes Educators (AADE) recommend that insulin injections be rotated within the same anatomic region to decrease the chances of variability in insulin absorption.[82] The abdominal area is often the most recommended site of administration because this site has the most predictable absorption and is least affected by exercise.[119] Alternatively, A.H. can be instructed to rotate her morning injection within one region (eg, the abdomen) and her evening injection in another anatomic region. This minimizes the variables that can alter her response to insulin.

A

90° angle
A

B

Figure 53-5 Selecting insulin injection sites. A, Areas of the body most suitable for insulin injections. The actual point of injection should be varied each time within a chosen body area. Give injections at least 1 inch apart. Patients should consult with their provider or diabetes educator about which area is most appropriate for use. B, The site where insulin should be injected. Insulin is injected into the subcutaneous tissue (between the skin and the muscle layer). If the skin is pinched up and the needle is pushed all the way in, the needle will reach the proper space under the skin. (A, LifeART image © 2011. Lippincott Williams & Wilkins. All rights reserved; B, Adapted with permission from Springhouse. *Lippincott's Visual Encyclopedia of Clinical Skills*. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2009.)

Rotating injection sites is recommended to avoid the lipodystrophic effect of insulin (lipohypertrophy and lipoatrophy); however, because insulin has been purified, these complications are less common.[82,112] Nevertheless, repetitive use of the same site of injection may still result in lipohypertrophy, and it does toughen the skin, making needle penetration more difficult. Furthermore, insulin absorption from lipohypertrophic sites can be slowed.[112]

Agitation

A.H. does not need to agitate insulin glargine or aspart because these are clear insulins. For NPH insulin, which is a suspension, or a combination/mixed insulin, the vial or pen must be gently agitated before use. The vial should be rolled between the palms of the hands to minimize foaming. A pen device is inverted back and forth to mix the insulin. Agitation is only required for insulin suspensions (ie, insulin mixtures).

Measurement

First, A.H. should make sure her hands and the injection site are clean. She should withdraw the plunger to the level of insulin she intends to inject (eg, 12 units for her insulin glargine dose), then she should insert the needle into the vial, and inject the air to prevent creation of a vacuum within the vial. The vial then should be inverted with the syringe inserted, and 12 units of insulin glargine should be withdrawn. The bevel of the needle should be well below the surface of the insulin to avoid withdrawing air or bubbles into the syringe. Insulin glargine must not be mixed in the same syringe with her rapid-acting insulin, and it should be injected into a different site if it is injected at the same time as her glargine dose.[14]

The barrel of the syringe should be held at eye level to check for air bubbles and to allow accurate placement of the plunger tip at the 12-unit mark. If bubbles are present, they should be removed by tapping the syringe gently to coax the bubbles to the top of the barrel, where they can be injected back into the insulin vial. To remove air bubbles in an insulin pen, prime the pen with 2 units of insulin before each use (repeat until an insulin drop appears at tip of pen needle). Also, remove and discard the pen needle from the device in between uses to prevent air bubbles from accumulating.

Case 53-2, Question 9: How should A.H. be educated to self-monitor her BG? What types of self-monitoring BG tests are available, and what are the major differences among them? How accurate are results obtained from home BG testing? Should she begin CGM at the same time?

SELF-MONITORING OF BLOOD GLUCOSE

The ADA recommends that most individuals with diabetes should attempt to attain and achieve normoglycemia as safely as possible. SMBG is a tool to allow patients to safely achieve these goals. For patients with type 1 diabetes, this can be achieved by the routine use of SMBG. SMBG is also important in (a) pregnancy complicated by diabetes, (b) patients with unstable diabetes, (c) patients with a propensity for severe ketosis or hypoglycemia, (d) patients prone to

hypoglycemia who may not experience the usual warning symptoms, and (e) patients using an insulin pump. The technology in this area is changing rapidly, with new monitors with advanced features being introduced yearly.[14]

All monitors use test strips and are self-timing, requiring no patient action after the blood is placed on the strip. Several factors should be taken into account when evaluating a monitor and its appropriateness for an individual. The primary considerations are ease of use, accuracy relative to a reference standard, reliability, insurance coverage, and cost.[14]

Most monitors no longer require coding for the test strips, which simplifies the process for patients. Convenience factors include meter size, volume of blood required for testing, site to obtain sample (eg, finger vs alternative site such as forearm), capacity of the meter to store BG values (memory) and data such as comments, required testing time, ability to download BG values, general availability of strips, ability to turn off audible signals, audible readings and instructions for visually impaired, and availability of technical support. Some devices are less reliable for use in anemic patients (eg, patients undergoing renal transplant), and all function most reliably within certain temperature ranges (usually 60–95 °F [15.56–35 °C]) and humidity (generally <90%) conditions. Strips are sensitive to light, moisture, and temperature extremes and must be stored and handled with care. In recent years, CGMs have also become more readily available to the public, and offer a more convenient option for testing glucose levels compared to a traditional home BG monitor.

Patient education regarding any testing procedures, and, if needed, the importance of logging results in a diary, and test times is critical. Ultimately, A.H. should be taught how and when to check her BG levels to optimize her insulin regimen (**Table 53-15**).

Table 53-15

Guidelines for Dosing Insulin

Basic Insulin Doses

First, adjust the basic insulin dose (ie, the dose that the patient will be instructed to take daily).

Only adjust insulin doses if a *pattern* of response is observed under stable diet and exercise circumstances. That is, the same response to insulin is observed for ≥3 days, particularly for the basal insulin dose. It is important to verify the stability of diet and exercise. Consider adjusting these variables as well.

Unless all levels are >200 mg/dL, try to adjust one component of insulin therapy at a time.

Start with the insulin component affecting the FBG concentration. This glucose level often is the most difficult to control, and often affects all other glucose concentrations measured throughout the day. The basal insulin dose is often what is adjusted to control the FBG. However, if the dinner insulin dose (of rapid-acting or short-acting insulin) is not adequate, this can result in hyperglycemia that can persist into the morning. The basal dose is typically adjusted by 2–4 units, no sooner than every 3–4 days.

Prandial/mealtime insulin dose:

- For patients eating a set amount of carbohydrate at meals: typically adjust the basic insulin dose by 1–2 units at a time. The amount given is based on the individual patient's response to insulin. This can be determined by looking at the patient's TDD using the "500 rule" (see the following, and Table 53-9).
- For patients using the insulin-to-carbohydrate method (ie, 1 unit rapid-acting or short-acting insulin for every *x* g of carbohydrate), adjust the "ratio" based in the patient's response to insulin (eg, 1:8, 1:10, 1:12, 1:15, 1:18, 1:20).

General Principles

Assume that diet and physical activity are stable. Set a reasonable goal initially. This may mean the upper limits of the acceptable concentrations may be high initially (eg, <200 mg/dL). Move toward a more ideal goal slowly.

Supplementary Insulin Doses (with rapid-acting or short-acting insulin)

Once the basic dose of prandial insulin has been established, supplemental doses of rapid- or short-acting insulin can be prescribed to correct *preprandial* hyperglycemia. For example, if the goal is 140 mg/dL and the glucose value is 190 mg/dL, administer one additional unit. Supplemental doses also can be used when the patient is ill (Table 53-15).

Algorithms for correction doses are based on the patient's sensitivity to insulin using the "1500 or 1700 rule" (Table 53-9).

If premeal glucose concentrations are <70 mg/dL, the dose of aspart, glulisine, lispro, or regular insulin administered before the meal is ↓ by 1–2 units; insulin administration is delayed until just before the meal; the meal should include an extra 15 g of glucose if the value is <50 mg/dL.

If supplemental doses before a given meal are required for ≥3 days, the basic insulin dose should be adjusted appropriately. For example, if a patient taking lispro before meals requires an extra 2 units before lunch for ≥3 days, 2 units should be added to the prebreakfast dose, or the insulin-to-carbohydrate ratio at breakfast should be adjusted (eg, if patient was using a 1:15 ratio, a 1:12 ratio could be used). Rapid-acting insulin doses should be adjusted no more frequently than every 2–3 days.
Anticipatory Insulin Doses (With Rapid-Acting or Short-Acting Insulin)
The basic insulin dose is ↑ or ↓ based on the anticipated effects of diet or physical activity.
↑ Aspart/glulisine/lispro or regular insulin by 1 unit for each additional 15 g of carbohydrate ingested (eg, holiday meal) or ↓ the usual dose by 1–2 units if the meal is smaller than usual (Table 53-9).
See Table 53-19 for the recommended insulin adjustments for exercise.

FBG, fasting blood glucose; TDD, total daily dose.

Used properly, available monitors provide accurate results that can be used by patients to manage their diabetes. Problems with a monitor can be detected by performing a quality control test. **Table 53-16** lists factors that can affect results of SMBG test results. Any time SMBG values are inconsistent with the patient's symptoms or A_{1c} values, sources of error should be evaluated. A.H.'s technique should be reviewed periodically because clinical decisions are often based on the patient's BG testing record.

Table 53-16

Factors That Can Alter Self-Monitored Blood Glucose Test Results: Troubleshooting

Glucose monitor not coded for batch of test strips[a]
An inadequate amount of blood applied to test strip[b]
Improper storage of test strips (temperature and humidity)[a]
Dirty glucose monitor[a]
Low battery[a]
Test performed outside of altitude, temperature, and humidity operating conditions[a]

Low[c] or high[b] hematocrit
Dehydration[b]
Hyperosmolar, nonketotic state[b]
Lipemia[a]
Interfering substances
Nonglucose sugars (eg, maltose, xylose, galactose) in meters using GDH-PQQ test strips[118]
Large amounts of acetaminophen[c]
Large amounts of ascorbic acid or salicylates (rare)[b]

GDH-PQQ, glucose dehydrogenase pyrroloquinoline quinone.

[a]Effect unpredictable.

[b]Values tend to be lower.

[c]Values tend to be higher.

Because A.H. is just starting insulin therapy and SMBG, it would be reasonable to hold off on considering CGM until she becomes comfortable with these skills. Then, she and her practitioner could assess whether CGM would be useful.

TESTING FREQUENCY

Case 53-2, Question 10: How often should A.H. test her BG concentrations?

Although the exact frequency and timing of BG tests should be dictated by individualized patient goals, most patients with type 1 diabetes using an intensive basal-bolus insulin regimen should perform SMBG multiple times per day. This may include before meals and snacks, bedtime, 2 hours postprandially, and before exercise, when the patient suspects hypoglycemia, after treatment of hypoglycemia, or when the patient is performing a critical task such as driving.[14]

Because A.H. is being initiated on insulin therapy with the goal of normoglycemia, she should ideally self-monitor her BG four times/day (before meals and at bedtime) for 2 weeks until the pattern of blood sugar fluctuation can be assessed and adjustments to her insulin regimen can be made. Motivated patients may continue this degree of monitoring, but it may be reduced to twice daily for patients on long-term insulin who have achieved glycemic control. Varying the time of day in which testing is performed will allow the clinician and patient to make informed decisions on how to make adjustments. For those patients who are not using an intensive insulin regimen, such as patients with type 2 diabetes using insulin, there is insufficient evidence as to how often a patient should check their BG because of the decreased risk of hypoglycemia.[120,121] There is also insufficient evidence regarding the overall benefit of checking BG levels in patients with type 2 diabetes not using insulin therapy.[122] Instead, patients along with their providers should determine the appropriate frequency and timing to check BG levels to best optimize drug therapy and decrease the risk of hypoglycemia.[41]

The objective of ongoing, frequent BG testing is to determine whether normoglycemia is being achieved, assess effectiveness of drug therapy as well as the impact of meals, food, illness, or exercise on BG levels. Typical times to check BG may include before meals and snacks, 2 hours postprandial, at bedtime, and, occasionally, at 2:00 to 3:00 AM. However, it can be challenging for patients to adhere to such a rigorous regimen. A.H. should set her alarm for 3:00 AM two or three times/week and test her BG. BG concentrations measured before meals allow patients and clinicians to determine whether the rapid-acting insulin dose is appropriate for the amount of carbohydrate consumed; FPG levels are used to determine whether the basal insulin dose is adequate; and the 2:00 to 3:00 AM BG level is used to identify if the patient is experiencing nocturnal hypoglycemia. For example, the BG measured before dinner reflects the action of A.H.'s prelunch insulin aspart dose on food she has eaten for lunch, as well as hepatic glucose production between

meals. Increasingly, patients who use carbohydrate counting with rapid-acting insulins test 2-hour postprandial levels when initiating therapy to enhance proper dosage adjustment (Table 53-13).

The importance of frequent BG testing in patients newly diagnosed with type 1 diabetes cannot be overemphasized. When BG is tested less frequently than four times daily, it becomes difficult to adjust insulin doses based on infrequent readings or to assess patterns in glucose levels (ie, pattern management). If patients refuse to test four times daily, they should be encouraged to test four times daily on representative days of the week or to test at different times of the day each day so that a weekly profile can be developed. A.H. also should be encouraged to test her BG concentration any time she is feeling unusual, if she is experiencing hypoglycemic symptoms, or to evaluate the effect of unusual circumstances on her BG concentration (eg, increased physical exercise, a large holiday meal, final examinations, or a family crisis).[14] If a patient is unable or unwilling to check BG at these varying times, a CGM, which measures interstitial glucose levels, may be recommended. Monitors that either measure and display glucose levels continuously or ones that measure glucose levels continuously are available; however, they only display glucose values when swiped by a reader or smartphone.[123–126] Use of a CGM would allow the patient the ability to determine their glucose values easily at any point throughout the day. CGMs require more initial training and education; however, when used appropriately, they may be a useful tool to both decrease A_{1c} levels and the overall incidence of hypoglycemia.[63]

USING BLOOD GLUCOSE TEST RESULTS TO EVALUATE INSULIN DOSES

Case 53-2, Question 11: A.H. was instructed to inject herself with 12 units of insulin glargine each evening and to give 4 units of insulin aspart just before each meal. She was asked to test her BG four times daily (before meals and at bedtime), to record her results and other unusual events or symptoms during the day, and to bring her BG logbook to the clinic. A.H. was also instructed to track her food and record the number of carbohydrates she ingested at each

meal. The initial goal of therapy is to lower her BG to eliminate symptoms of hyperglycemia. The ultimate goal is to achieve an A_{1c} level of <7%, fasting glucose of 80 to 130 mg/dL, and postprandial values of <180 mg/dL.[72] One week later, trends in her BG concentrations were as follows:

Time	Glucose Concentration (mg/dL)
7:00 AM	160–200
Noon	220–260
5:00 PM	130–180
11:00 PM	140–180

Occasional 3:00 AM tests averaged 160 mg/dL, and A.H.'s urine is negative for ketones. She eats approximately four carbohydrate servings for breakfast (60 g) and two to four carbohydrate servings for lunch and dinner (30–60 g). Subjectively, A.H. feels a bit better, and her weight has stabilized, but she still urinates two to three times nightly. How would you interpret these results, and how should A.H.'s insulin doses be altered?

Values from SMBG appropriately form the basis for insulin adjustments. Ultimately, the goal is to move motivated patients toward being able to recognize their own glucose trends and make insulin adjustments accordingly based on recommendations between the patient and provider.[103] Before using A.H.'s BG results to adjust her insulin dose, it is important to observe and reassess her testing technique. One also should determine whether there were any unusual circumstances in her life such as acute illness, diet changes or excursions, drug therapy changes, or exercise patterns during the past week that may have affected her response to insulin. Once these have been ruled out as confounding factors, one can begin making adjustments in A.H.'s insulin dose, realizing that fine-tuning will be impossible until a consistent diet and exercise pattern have been instituted.

Several principles must be kept in mind whenever BG tests are used to adjust a patient's basic insulin dose (**Table 53-17**). Because many factors can alter a patient's response to insulin, it is important to review BG concentration *trends* measured for a minimum of 3

days to adjust the patient's standing insulin dose (ie, the dose the patient will use every day). The only exception to this rule is the use of supplemental insulin doses to correct exceptionally high glucose concentrations after A.H. has acquired sophisticated insulin adjustment skills (see Case 53-2, Question 16). SMBG results should always be evaluated in conjunction with A_{1c} values.

Table 53-17
Factors That Can Alter Blood Glucose Control

Diet
Insufficient calories (eg, alcoholism, eating disorders, anorexia, nausea, and vomiting)
Overeating (eg, during the holidays)
Irregularly spaced, skipped, or delayed meals
Dietary content (eg, fiber, carbohydrate content)
Physical Activity
See Table 53-19
Stress
Infection
Surgery/trauma
Psychological
Drugs
Certain medications can increase or decrease blood glucose levels. It is important to assess for potential effects on the blood glucose when starting new medications.
Hormonal Changes
Menstruation: Glucose concentrations may increase premenstrually and return to normal after menses.
Pregnancy
Puberty: hyperglycemia probably related to high growth hormone levels
Gastroparesis
Delays gastric emptying time. Peak insulin action and meal-related glucose excursions may become mismatched.

Altered Insulin Pharmacokinetics
See Table 53-8
Insulin Injection Technique
Measuring
Timing
Technique
Inactive Insulin
Outdated insulin
Improperly stored insulin (heat or cold)
Crystallized insulin

The daily dose of insulin glargine is inadequately controlling A.H.'s FPG and should be increased by 2 to 4 units. A more conservative approach would be to increase the dose to 14 units each evening (or a designated time of day that she will be able to do consistently) and further titrate as needed.[26] She is achieving some response from her lunchtime dose of insulin aspart, but there is room for improvement in her meal insulin coverage overall. The BG concentration of 160 mg/dL at 3:00 AM indicates that rebound hyperglycemia is an unlikely cause of her high fasting levels (see Case 53-2, Question 13, and Case 53-3). As an initial step toward control, A.H.'s daily dose of insulin glargine should be increased in an attempt to control her fasting hyperglycemia. However, this approach does not address A.H.'s elevated prelunch values. Her intake of carbohydrates also varies from meal to meal. Thus, a more appropriate method would be to calculate the insulin-to-carbohydrate ratio for A.H. and allow her to determine her premeal aspart dose based on the amounts of carbohydrates she will ingest at each meal. A typical starting point for the insulin-to-carbohydrate ratio is 1 unit to every 15 g of carbohydrate ingested. To calculate her insulin-to-carbohydrate ratio, the "500 rule" is used: Divide the number 500 by her TDD of insulin (14 units of insulin glargine plus 12 units of insulin aspart for meal coverage: total of 26 units):

$$500/26 = 19 \text{ g of carbohydrate covered by 1 unit of insulin} \quad \text{(Eq. 53-1)}$$

Because most single servings of carbohydrate contain 15 g, A.H. decides to start with a ratio of 1 unit for every 15 g or single serving of carbohydrates she consumes at each meal. If A.H. were using regular insulin for meal coverage, she could use the "450 rule": 450 divided by the total daily insulin dose yields grams of carbohydrate covered by 1 unit of insulin.

To evaluate the accuracy of her insulin-to-carbohydrate ratio, A.H. will need to check her BG values 2 hours after each meal (postprandial) to assess the appropriateness of her ratio. She agrees to test her BG level eight times/day and return in 2 weeks.

Case 53-2, Question 12: A.H. is getting more comfortable with carbohydrate counting and adjusting her insulin doses accordingly. A review of her food diary reveals that for the most part, she is able to determine the appropriate serving sizes for 15 g of carbohydrate. She admits to difficulty determining carbohydrate amounts when eating out. As a result, A.H. notices that her preprandial BG concentrations exceed her goal of 80 to 130 mg/dL on occasion.[127] Sometimes they are as high as 200 mg/dL. Evaluate A.H.'s BG trends. How should occasional preprandial glucose concentrations that exceed the desired goal of 80 to 130 mg/dL be managed?

Once the basal insulin dose and insulin-to-carbohydrate insulin dose have been established, one can begin to teach A.H. how to use a correction factor to adjust her dose of insulin when preprandial BG concentrations fall above or below the range of BG concentrations that have been established as her goal of therapy (80–130 mg/dL per the ADA; Table 53-15).

A correction insulin dose is used to compensate for unusually high BG concentrations (high-sugar correction). To reemphasize, this assumes there are no unusual changes in the patient's overall diet or exercise patterns (**Table 53-18** explains the effects of exercise on BG). Many clinicians favor rapid-acting insulin versus regular insulin because of their shorter duration of action, and patients do not have

to worry about residual effects 3 to 4 hours after its injection. This is particularly valuable when correctional doses of insulin are needed at bedtime.

Table 53-18
Exercise in Patients With Diabetes

1. Test blood glucose before, during, and after exercise.
2. For moderate exercise (eg, bicycling or jogging for 30–45 minutes), ↓ the preceding dose of regular or rapid-acting insulin by ~30%–50%. If glucose concentration is normal or low before exercise, supplement the diet with a snack containing 10–15 g of carbohydrate.
3. To avoid ↑ absorption of regular insulin by exercise, inject into the abdomen or exercise 30–60 minutes after injection. Avoid exercise when rapid-acting insulin is peaking.
4. Individuals with low glycogen stores may be predisposed to the hypoglycemic effects of exercise. Examples include alcoholics, fasted individuals, or patients on extremely hypocaloric (<800 calories), low-carbohydrate (<10 g/day) diets.
5. Patients taking insulin are more susceptible to hypoglycemia than are those taking oral insulin secretagogues (sulfonylureas, glinides). Patients with type 2 diabetes treated with diet are unlikely to develop hypoglycemia.
6. Watch for postexercise hypoglycemia. Individuals who have been exercising during the day will likely need to ↑ their carbohydrate intake and should test their blood glucose during the night to detect nocturnal hypoglycemia. Hypoglycemia can occur 8–15 hours after exercise.
7. If the glucose concentration is >240–300 mg/dL, the patient should not exercise. This indicates severe insulin deficiency. These patients are predisposed to hyperglycemia secondary to exercise.
8. Patients with severe proliferative retinopathy or retinal hemorrhage should avoid jarring exercise or exercise that involves moving the head below the waist.

The patient's sensitivity to insulin, as reflected by his/her TDD on a unit per kilogram basis, is a major determinant of any algorithm developed. A general approach is to give an additional 1 to 2 units of supplemental rapid-acting insulin for each 30- to 50-mg/dL elevation above the target level.[93] An alternative method of estimating the drop in a person's BG per unit of regular insulin is the "1500 Rule."[110] The derived value is referred to as the *sensitivity factor*: The rule was modified to the "1800 rule" for use with rapid-acting insulin (insulin

lispro, aspart, or glulisine). Because these insulins tend to drop the BG level faster and farther, 1500 turns out to be too aggressive. Others have recommended other numerators such as 1600, 1700, 2000, and 2200.[128] For this case, the "1700 rule" will be used. The calculation for A.H. would be as follows:

$$1700/24 = 70 \text{ mg/dL} \quad \text{(Eq. 53-2)}$$

Thus, 1 unit of insulin aspart for A.H. will drop her BG level by about 70 mg/dL. People with a lower sensitivity factor (higher insulin requirements) typically achieve a smaller reduction in BG per unit of insulin compared with those with a higher sensitivity factor (lower insulin requirement). Thus, an algorithm of 1 unit of insulin aspart for every 70-mg/dL excursion above her goal of 120 mg/dL is a reasonable place to begin. If this dose of insulin is insufficient, one can decrease the BG excursion required per unit of insulin dose (eg, 50 mg/dL). Correctional insulin doses also are used for sick day management (see Case 53-5). The following is an example of a high-sugar correction algorithm for A.H.:

Glucose Concentration (mg/dL)	Insulin Aspart
<80	1 unit less
80–120	Usual dose
120–190	1 unit extra
191–260	2 units extra
261–330[a]	3 units extra
331–400[a]	4 units extra

[a]Check urine or blood ketone levels. If ketones are positive and blood glucose (BG) concentrations remain >300 mg/dL for ≥12 hours, call the physician for directions.

EVALUATING FASTING HYPERGLYCEMIA

Case 53-2, Question 13: A.H. returns after 1 month. She is currently using 14 units of insulin glargine each evening, 1 unit of insulin aspart for each 15 g of carbohydrate ingested at mealtime, and a high-sugar correction factor of 1 unit

of insulin aspart for every 70 mg/dL above 130 mg/dL. Presuming that her diet is consistent, her SMBG results are as follows:

Time	Glucose Concentration (mg/dL)
7:00 AM	140–180
Noon	120–150
5:00 PM	90–130
11:00 PM	90–120
3:00 AM	60–90

Overall, A.H. feels her diabetes is in good control. Her energy level has returned to normal, and her nocturia has diminished, but she occasionally gets up one or two times nightly to urinate. A.H. has also noticed that nightmares or "sweats" sometimes awaken her. When this occurs, she generally has something to eat because she is "famished." She is able to get back to sleep but wakes up the next morning with a "splitting headache" and a "hungover" feeling. A.H.'s weight remains the same, and she has begun to develop some consistency in her dietary patterns with the help of a dietitian. She has been consistently correcting her prelunch and predinner insulin doses by adding or subtracting 2 units from her premeal insulin doses based on her premeal BG values. The A_{1c} from her last visit is 7.3%. Evaluate A.H.'s BG values. What are the possible causes of A.H.'s fasting hyperglycemia?

When evaluating morning hyperglycemia, several causes must be considered:

- An insufficient basal dose of insulin. If the basal dose is insufficient, hepatic glucose output during the fasting state will be excessive, thereby producing hyperglycemia
- Insufficient dinner coverage with insulin aspart, resulting in hyperglycemia that persists into the morning. This can be distinguished from insufficient basal insulin by assessing glucose control at bedtime
- Reactive hyperglycemia in response to a nocturnal hypoglycemic episode (Somogyi effect or rebound hyperglycemia)
- Excessive bedtime snacking
- The dawn phenomenon (see Case 53-3)

The presence of normoglycemia at bedtime, low BG concentrations at 3:00 AM, and symptoms of nocturnal hypoglycemia (nightmares, sweating, hunger, and morning headache) in A.H. are consistent with a rebound hyperglycemic reaction in the morning (ie, posthypoglycemic hyperglycemia, also referred to as the Somogyi effect).[104,129,130]

Theoretically, this effect occurs after any episode of severe hypoglycemia and is secondary to an excessive increase in glucose production by the liver that is activated by insulin counterregulatory hormones such as cortisol, glucagon, epinephrine, and growth hormone. The waning effects of the basal insulin dose can also be a cause of fasting hyperglycemia because insulin is needed to suppress hepatic glucose output during the fasting state; however, this is not likely in A.H.'s case. Asymptomatic nocturnal hypoglycemia can occur in patients taking more than necessary doses of insulin in the evening, and may potentially cause rebound hyperglycemia in the morning. By correcting the nocturnal hypoglycemia, normalization of A.H.'s fasting hyperglycemia also may be achieved. Thus, a decrease in the daily dose of insulin glargine is warranted. A.H. should continue to monitor her BG concentrations at 3:00 AM to determine whether her BG levels return to normal.

Caveat: If A.H. were using NPH bid to supply her basal insulin, one option would be to shift the evening injection of NPH from before dinner to bedtime. This preferred method effectively shifts the peak action of NPH to the early morning, when she is awake, and decreases the risk of nocturnal hypoglycemia.[131,132] This peak action also corresponds to the dawn phenomenon (see Case 53-3) and the breakfast meal.

Another option if a patient is using NPH and experiencing nocturnal hypoglycemia is to change from NPH to either insulin glargine or insulin detemir because these insulins are associated with less nocturnal hypoglycemia.[133] When switching from NPH insulin to insulin detemir, a one-to-one dose conversion may be used, although higher doses of detemir may be required. In one

crossover study of patients with type 1 diabetes, the average detemir basal dose was approximately double that of the NPH basal dose.[134] However, when switching from NPH insulin to insulin glargine, a one-to-one dose conversion is utilized only when a patient is using NPH insulin once daily. If a patient is taking NPH insulin twice daily, then the total daily insulin dose should be decreased by 20% when switching to insulin glargine. In this case of AH, the daily dose of NPH should be decreased by 20% to determine the insulin glargine dose, to err on the conservative side.[86,88] Alternatively, switching to an even longer-acting basal insulin such as glargine U-300 (brand name Toujeo®) or degludec (either U-100 or U-200) (brand name Tresiba®) would be an option to decrease a patient's overall risk of nocturnal hypoglycemia. Both U-300 insulin glargine and insulin degludec (both U-100 and U-200) have been shown to decrease the overall risk of hypoglycemia compared to use of NPH, detemir, or glargine U-100 insulin.[135] When switching a patient to insulin degludec from another basal insulin, patients should begin using insulin degludec at the same unit dose as their total daily long or intermediate-acting insulin.[109] When switching to insulin glargine U-300, patients currently using their basal insulin once daily should be converted at the same unit dose as their total daily long or intermediate-acting insulin dose. Patients currently using their intermediate or long-acting basal insulin twice daily should begin glargine U-300 at 80% of their total daily basal insulin dose.

Although A.H.'s prelunch BG values are above her goal, this may be attributable to the fasting BG being elevated and then continuing to be elevated midmorning, like a domino effect. It is important to first correct fasting hyperglycemia and generally correct one BG concentration at a time.

MIXING INSULINS

Case 53-2, Question 14: If A.H. were to use NPH as basal insulin, how should she be instructed to measure and withdraw this insulin mixture?

Although mixing two insulins in the same syringe has become less common with use of basal-bolus therapy (because insulin degludec, glargine, and detemir cannot be mixed) and the use of rapid-acting insulin pen devices, the procedure used to mix and withdraw NPH and mealtime insulin (regular or rapid-acting insulin) is basically the same as that described in Case 53-2, Question 8. The major difference is that an adequate volume of air must be injected into the NPH vial before the regular or insulin aspart is measured and withdrawn. Also, the mealtime clear insulin is measured and withdrawn into the insulin syringe *first* to avoid contamination of the vial of regular, aspart, lispro, or glulisine insulin with NPH. For example, contamination with NPH ultimately alters the NPH to regular insulin ratio that is administered. When patients withdraw NPH insulin first, the vial of regular insulin eventually becomes cloudy. In contrast, contamination of the NPH insulin with regular insulin is insignificant because the protamine contained in NPH can bind the regular insulin (see Case 53-2, Question 15). The procedure A.H. should use to mix her insulins is described in the section on Premeal Hyperglycemia, using her morning dose as an example.

- After dispersing the NPH insulin suspension, inject 14 units of air into the NPH vial and withdraw the needle.
- Inject 7 units of air into the insulin aspart vial and withdraw the 7 units of insulin, as described in Case 53-2, Question 8.
- Insert the needle into the NPH vial and pull the plunger down to the 21-unit mark (14 units of NPH plus 7 units of insulin aspart).

STABILITY OF MIXED INSULINS

CASE 53-2, QUESTION 15: Will mixing NPH with a rapid-acting insulin or regular insulin blunt the rapid action of the mealtime insulins? How stable are other insulin mixtures?

Regular insulin and all of the rapid-acting insulin analogs (aspart, lispro, and glulisine) may be mixed with NPH. In general, it is recommended to mix the insulins just before administration. See

Table 53-19 for details on compatibility and stability of insulin mixtures. However, with the increased use of longer-acting basal insulins and the use of insulin pen devices, mixing of insulins in the same syringe has become a less common practice.

Table 53-19
Compatibility of Insulin Mixtures

Mixture	Proportion	Comments
Regular + NPH	Any proportion	The pharmacodynamic profiles of regular and NPH insulin are unchanged when premixed and stored in vials or syringes for up to 3 months.
Regular + normal saline	Any proportion	Use within 2–3 hours of preparation.
Regular + insulin diluting solution	Any proportion	Stable indefinitely
Rapid-acting insulin + NPH	Any proportion	The absorption rate and peak action of the rapid-acting insulins are blunted; total bioavailability is unaltered. Rapid-acting insulin and NPH should be mixed just before use (within 15 minutes).
Insulin glargine and detemir	Do not mix with other insulins	Pharmacodynamics could be modified.

NPH, neutral protamine Hagedorn.

Case 53-2, Question 16: After reducing the dose of insulin glargine to 14 units each evening, A.H.'s FPG is now 110 to 125 mg/dL. However, her noon BG concentrations remain in the 120- to 150-mg/dL range. Are there any other changes that you would recommend making at this time?

PREMEAL HYPERGLYCEMIA

When evaluating midmorning hyperglycemia, it is important to remember that the FPG concentration can contribute up to 50% of this plasma glucose excursion. Therefore, a key to the control of midmorning hyperglycemia may be to normalize the fasting glucose concentration. However, for A.H., the reduction in the insulin glargine has now corrected the reactive fasting hyperglycemia.

Hyperglycemia before a meal can be a result of several factors. The following are possible explanations for A.H.'s midmorning hyperglycemia:

- An insufficient dose of insulin aspart before breakfast: For A.H., this means that her insulin-to-carbohydrate ratio needs to be adjusted.
- Excessive carbohydrate ingestion at breakfast or inaccurate (under) counting of the carbohydrates ingested: Patients having difficulty accurately counting their carbohydrates should meet with a dietitian or diabetes educator for education; this is often necessary periodically throughout their lives as a refresher, just like many other skills require.
- Poor synchrony between meal intake and insulin action: This could be caused by the administration of rapid-acting insulin too long before or after the meal (eg, ≥30 minutes). If regular insulin is used, this could be caused by administering regular insulin just before or after meals.
- An insufficient dose of evenin*g* insulin glargine to suppress hepatic glucose production (glycogenolysis and gluconeogenesis) during the fasting state or the dawn phenomenon (see Case 53-3): In A.H.'s case, however, her fasting blood glucose (FBG) values are on target, so this is not likely.

The following interventions may be considered:

- Adjust her insulin-to-carbohydrate ratio to increase her insulin aspart dose at breakfast: The ratio should be changed to 1 unit of aspart for every 10 or 12 g (which are typical ratios used) of carbohydrate for the breakfast meal. This assumes a patient is technically able to use a different "ratio" at different mealtimes.

- Alter the carbohydrate content of the meals: This may include decreasing the amount of carbohydrate in the breakfast meal, changing the type of carbohydrate ingested, or adding fiber to that meal to minimize glucose excursions.
- Adjust the high-sugar correction factor if the glucose excursions appear to be caused by reduced insulin sensitivity in the morning: For example, the high-sugar correction can be adjusted to give 1 unit of aspart for every 50 mg/dL above 130 mg/dL.

PREPRANDIAL HYPOGLYCEMIA

Case 53-2, Question 17: A.H. is now taking insulin glargine 12 units each night and using an insulin-to-carbohydrate ratio of 1:15 (1 unit of insulin aspart for every 15 g of carbohydrate) at lunch and dinner and 1:12 at breakfast. She is continuing with the same high-sugar premeal correction of 1 unit of insulin aspart for every 70 mg/dL more than her premeal BG target of 120 mg/dL. Two weeks later, she brings in her BG records.

Time	Glucose Concentration (mg/dL)
7:00 AM	110–120
Noon	90–115
5:00 PM	60–110
11:00 PM	80–110
3:00 AM	110–120

A.H. feels that she is now “back to normal.” She has no signs or symptoms of hyperglycemia, and her weight has remained stable. Occasionally, she becomes hypoglycemic before dinner, but this most often occurs when her dinner is delayed because of a hectic work schedule. Evaluate A.H.’s BG trends. What could be the cause of her predinner hypoglycemia, and how could she be managed?

A.H.’s BG concentrations indicate that her basic insulin regimen is generally adequate to achieve the overall goal of preprandial BG concentrations of <80 to 130 mg/dL.

The hypoglycemia that A.H. is experiencing before dinner could be caused by insufficient carbohydrate intake at lunch (inaccurate carbohydrate counting), increased activity during the day, or an excessive dose of insulin aspart (insulin-to-carbohydrate ratio is too high). Thus, the problem could be resolved by augmenting A.H.'s lunch meal, adjusting the lunch insulin-to-carbohydrate ratio to 1 unit of insulin aspart for every 18 (or 20) g of carbohydrate, or adding a midafternoon snack.

CASE 53-3

QUESTION 1: R.D., a 37-year-old male, has had type 1 diabetes since age 14. During the past 2 years, he has been very well controlled on the following insulin regimen: insulin glargine 20 units each morning with insulin lispro 3 to 4 units depending on carbohydrate intake before meals. On this regimen, his BG concentrations for the past 2 weeks have been as follows:

Time	Glucose Concentration (mg/dL)
7:00 AM	140–170
Noon	100–120
5:00 PM	100–130
11:00 PM	115–140
3:00 AM	100–120

What are the likely causes of R.D.'s fasting hyperglycemia?

DAWN PHENOMENON

As discussed in Case 53-2, Question 13, fasting hyperglycemia may be the result of insufficient doses of insulin in the evening and, possibly, reactive hyperglycemia. In R.D.'s case, the dawn phenomenon also must be considered.[89] The *dawn phenomenon* is a rise in the BG concentration that occurs between 4:00 and 8:00 AM after a physiologic nadir in the BG concentration that occurs between midnight and 3:00 AM. This 30- to 40-mg/dL increase in the morning BG concentration cannot be attributed to increases in

counterregulatory hormones secondary to an antecedent hypoglycemic event, but it may be secondary to rising growth hormone levels. This phenomenon is inconsistently observed in individuals with type 1 and type 2 diabetes as well as nondiabetic individuals; furthermore, it is inconsistently present from one day to the next.[136]

R.D.'s normal 3:00 AM BG concentration indicates that posthypoglycemic hyperglycemia is an unlikely cause of his fasting hyperglycemia. Thus, the modest increase in his BG concentration between 3:00 and 8:00 AM may be attributed to the waning effects of insulin or the dawn phenomenon. In both cases, an increase in R.D.'s daily dose of insulin glargine would be indicated. Another option would be to switch R.D. to an insulin pump. He has demonstrated a desire and the ability for intensive management with multiple daily injections, frequent SMBG, record-keeping skills, the ability to make appropriate insulin dose adjustments, and accurate carbohydrate counting. The advantage to using a pump is the ability to program an increase in the basal infusion rate in the early morning hours (eg, beginning around 2:00–3:00 AM and continuing until 7:00–9:00 AM).

Type 1 Diabetes in Children

DIAGNOSIS AND CLINICAL PRESENTATION

CASE 53-4

QUESTION 1: J.C., a 7-year-old, 66.14-pound (30-kg; 95th percentile), 50-inch (127-cm) tall (90th percentile) girl, was brought to the emergency department by her parents because of nausea, vomiting, and a persistent stomach pain secondary to the flu. For the past week, J.C. had flulike symptoms, resulting in a 6-pound (2.72-kg) weight loss. Initial laboratory values revealed a BG of 600 mg/dL, serum pH of 6.8 with bicarbonate level of 13 mEq/L, plasma ketone level of 5.2 mmol/L, and positive ketonuria. J.C. was diagnosed with DKA secondary to new-onset type 1 diabetes. In retrospect and on further questioning, J.C.'s parents realized that she probably had symptoms as early as 4 weeks before her hospitalization. While on a driving vacation, she drank large quantities of

juice and had to stop hourly to urinate. She began experiencing enuresis, which her parents attributed to her increased fluid intake.

What signs and symptoms are consistent with the diagnosis of type 1 diabetes in a child?

The diagnosis of type 1 diabetes in children is generally straightforward. Presenting symptoms include a several-week history of polyuria, polydipsia, polyphagia, and weight loss, with hyperglycemia, glucosuria, ketonemia, and ketonuria. J.C.'s presentation is typical for a child newly diagnosed with diabetes who is brought in for medical attention because of severe symptoms related to the flu. An acute viral illness can trigger autoimmune destruction of the pancreas and abdominal pain, which may masquerade as gastroenteritis. Abdominal pain is a common presenting symptom of DKA.[19] J.C.'s weight loss probably represents fluid and caloric loss secondary to uncontrolled diabetes as well as decreased caloric intake from the flu. The symptoms of polyuria are less obvious in an infant and are frequently missed until metabolic derangement has occurred. Unlike J.C., infants frequently present with severe dehydration and metabolic acidosis despite a negative history of diarrhea or significant vomiting.

GOALS OF THERAPY

Case 53-4, Question 2: What are the goals of therapy for J.C.? Do the results of the DCCT apply to children such as J.C.? Are there age-specific goals?

Current ADA guidelines recommend an A_{1c} goal of <7.5% for all pediatric groups and adolescents (<19 years old) such as J.C. with DM. Individualization of goals, however, is still encouraged.[19,137–139]

Additional targets should also be kept in mind, including (a) to achieve normal growth and development, (b) to facilitate positive psychosocial adjustment to diabetes, and (c) to prevent acute and chronic complications. Attainment of these goals requires a tremendous amount of support and education for the parents, and can best be provided by a multidisciplinary team of professionals,

including a pediatric endocrinologist, nurse educator, pharmacist, dietitian, and mental health professional.[140]

Growth serves as an important clinical indication of overall general health and well-being in children with diabetes. Height and weight should be measured at each visit and plotted on standard growth grids. If, at the time of diagnosis, a child has fallen behind in height or weight, prompt and appropriate treatment should quickly return the child to the appropriate percentile and pattern of growth. An overweight child should be encouraged to achieve a more appropriate percentile of weight gradually, over the course of several months.[141]

Although recommendations for glycemic control are based on data from studies mostly in adult patients with diabetes, achieving the same near normalization of BG levels in children and adolescents is recommended. However, special consideration must be given to the unique risks and consequences of hypoglycemia in young children. A cohort of adolescents included in the DCCT was analyzed separately.[142] Similar to the adults in the DCCT, adolescents had sustained benefits from intensive management with little further progression to proliferative retinopathy 4 years after the DCCT was terminated.[41] Thus, J.C.'s pediatrician must strive for the best glucose control that she, her family circumstances, and currently available treatment regimens will permit.

The risk of hypoglycemia is of great concern in children younger than 6 years of age because they can have a form of hypoglycemic unawareness that results partly from their reduced capacity to communicate symptoms of hypoglycemia, but may be contributed to by less-developed counterregulatory mechanisms.[137] In addition, food intake and physical activity are unpredictable in this age group. These factors must be taken into consideration when determining an A_{1c} goal in this patient population where the long-term benefits of achieving a lower A_{1c} need to be weighed against the risk of hypoglycemia.[41,137,143] Per the ADA recommendations, the ultimate goal is to achieve the best A_{1c} possible without experiencing symptoms of hypoglycemia. The management of diabetes in children

ages 6 to 12 years, such as J.C., is particularly challenging because many children require insulin with lunch or at other times when they are away from home. Administration of insulin at school demands flexibility and close communication between the parents, the health care team, and school personnel (Table 53-4).[41,137,143] The greatest amount of evidence-based data exists for adolescents with diabetes (13–19 years). As mentioned, teenagers included in the DCCT achieved a mean A_{1c} level of 8.06% in an era before the availability of rapid-acting or basal insulins. As stated previously, an A_{1c} goal of <7.5% is recommended in this age group.[137]

INSULIN THERAPY

Case 53-4, Question 3: How should J.C. be started on insulin? Is the use of an insulin pump appropriate in children such as J.C.?

Generally, rapid-acting and basal insulin analogs are used in children to reduce the risk of hypoglycemia. Insulin requirements are generally based on body weight, age, and pubertal status. Newly diagnosed children with type 1 diabetes usually require an initial TDD of ~0.5 to 1.0 unit/kg.[76,77] The small insulin requirements of infants and toddlers may be delivered by using diluted insulin (eg, 10 units/mL, U-10; or 50 units/mL, U-50)[144] to measure doses in <1-unit increments. Diluents are available for insulin aspart and lispro. Insulin syringes and pens that deliver insulin in 0.5-unit increments are also very useful in pediatric patients. Most children are treated with basal-bolus regimens. These regimens have demonstrated lower FBG levels with less nocturnal hypoglycemia versus regimens using NPH in children and adolescents.[137,145]

Basal-bolus insulin regimens combined with carbohydrate counting are attractive regimens for middle and high school students. Because children often have erratic eating habits, rapid-acting insulins are advantageous over regular insulin because they can be injected directly before or immediately after a meal, accounting for the portion of the meal a child actually consumed. J.C. should be

started on approximately a TDD of 15 units (ie, 0.5 units/kg/day), such as 3 units of rapid-acting insulin before meals and 7 units of insulin glargine at bedtime.[137] In some patients, insulin glargine may not last a full 24 hours; in this case, the dose of insulin glargine should be divided and given twice daily, and then each adjusted based on the BG patterns.[146] Alternatively, insulin glargine U-300 glargine may be beneficial in this situation and is indicated for use in children ages 6 years and older.[135] Insulin degludec would last 24 hours; however, it is not an option for J.C. because it is not FDA approved for use in children at this time.[147,148]

When J.C. and her caregivers become skilled with carbohydrate counting, insulin kinetics, dosing insulin based on her carbohydrate intake, and diabetes management, the use of an insulin pump may be considered. The insulin pump therapy in the pediatric population is increasing rapidly because it provides increased flexibility with meal timing and has been shown to improve glycemic control and quality of life.[147] Young children (not just adolescents) are now recommended for consideration of insulin pump therapy.[149] Family and adult support both at home and school is critical for successful pump use until the child is able to manage his/her diabetes independently.

INJECTION SITES

Case 53-4, Question 4: Where should J.C. administer her insulin? Are the recommended sites of injection different for children? Does the age of the child play a factor?

For infants with abundant SC tissue, injection sites are usually plentiful. For some toddlers who have lost their “baby fat,” locating an appropriate site for injection can be difficult. Injecting insulin into the abdomen of children with minimal SC abdominal fat or in very young children may not be advisable. Rotation of injection sites among arms, thighs, and the upper outer quadrant of the buttock or hip area, as well as the abdominal area in older children, may be

beneficial. To achieve consistent absorption, insulin injections can be patterned, for example, using the arms for the morning injection and the thighs for the evening injection. Children and teens should be cautioned to not consistently inject their insulin into a single area, which may be more convenient for them.[150] Fatty deposits and scar tissue can develop secondary to insulin action at the local tissue level. Insulin absorption from these hypertrophied areas is generally poor and unpredictable, resulting in variability in glycemic control. Insulin pen devices are very helpful for use in children because they are easy to use, have the option for an even smaller needle size, and are less intimidating (see Case 53-2, Question 7).[137]

BLOOD GLUCOSE MONITORING

Case 53-4, Question 5: How often should J.C. monitor her BG?

The eventual goal for children with diabetes is self-management, with insulin dosing decisions based on interpretation of BG results. Self-management skills and basal-bolus insulin regimens rely on frequent SMBG. For children with type 1 diabetes, four or more BG tests per day are generally necessary. Many home BG meters allow for alternative site testing, which may also decrease the discomfort of finger sticks. Enthusiasm for frequent BG testing tends to wane with duration of diabetes. However, families who are instructed on managing diabetes on the basis of test results are better motivated to persevere with SMBG. CGM may also be considered as a more convenient method to assess glucose control particularly to detect nocturnal hypoglycemia. If using a conventional home BG monitor, J.C. should test her BG before each meal and at bedtime, at a minimum. Additional tests should be performed whenever J.C. experiences hypoglycemia, ketonuria, or when she becomes acutely ill.

HONEYMOON PERIOD

Case 53-4, Question 6: During the next 2 months, J.C.'s insulin requirements decreased to a TDD of 10 units (~0.3 unit/kg). Has her diabetes gone into remission?

Approximately 20% to 30% of individuals with type 1 diabetes go into a remission phase (honeymoon period) within days to weeks of their diagnosis.[137,151] During this phase, which can last for weeks to months, insulin requirements can fall well below the usual initial dose of 0.5 to 1.0 units/kg/day, and C-peptide can be detected, indicating a return of pancreatic function. A child may require minimal to no basal insulin replacement, and mealtime replacement requirements may need to be reduced. As illustrated by J.C., this presents clinically as markedly decreased insulin requirements to maintain normoglycemia. J.C. should continue to perform SMBG and closely monitor for rising BG concentrations, as β-cell destruction continues during the honeymoon phase, and she will eventually return to higher insulin requirements.

Case 53-4, Question 7: J.C.'s parents contacted the clinic to report that J.C. is having nightmares and is awakening in the middle of the night reporting symptoms of a headache and stomach pain. However, these symptoms resolve by noon the following day. Her current insulin regimen is insulin aspart 2 units before meals and 3 units of insulin glargine twice daily (at breakfast and bedtime). Could J.C. be experiencing nocturnal hypoglycemia? How do the symptoms of hypoglycemia differ in a child compared with an adult? How can the risk of hypoglycemia be minimized for J.C.?

HYPOGLYCEMIA

J.C.'s parents are appropriately worried. Hypoglycemia is a serious and often life-threatening complication of diabetes management in children, and the risk of hypoglycemia increases with attempts to maintain meticulous control of BG levels.[152] It was previously thought that pediatric patients may be at risk for cognitive impairment following severe episodes of hypoglycemia; however, current literature does not support this finding. Common causes of hypoglycemia include changes in carbohydrate intake, late or

skipped meals or snacks, exercise or unusual activity, and administration of excessive insulin. Young children may not be able to identify or express symptoms of hypoglycemia, caretakers must observe the child closely and identify symptoms or behaviors associated with a falling BG. Symptoms of hypoglycemia may include crankiness, sudden crying, restless sleep, or nightmares as seen in J.C.

- Hypoglycemia is more frequent in children with lower A_{1c} values, a prior history of severe hypoglycemia, larger insulin doses, and younger children.[153] Nocturnal hypoglycemia is reported in 14% to 47% of children with type 1 diabetes and is thought to be related to impaired counterregulatory response to hypoglycemia during sleep.[137] Bedtime BG levels are poor predictors of nocturnal hypoglycemia. J.C.'s parents should be instructed to test her BG at 2:00 AM closely for the next few nights, and then continue to check at least twice weekly. In children, insulin glargine can exhibit a small peak effect during the initial 3 to 5 hours after administration, increasing the risk for nocturnal hypoglycemia.[143,144,154] If this is the case, the insulin glargine dose should be moved to dinnertime or in the morning. If this does not correct the nocturnal hypoglycemia, then the dose should be reduced. Use of insulin glargine is associated with less nocturnal hypoglycemia (and asymptomatic nocturnal hypoglycemia) compared with NPH insulin in children and adolescents.[155] Insulin glargine U-300 may also be a consideration for J.C. Because U-300 insulin glargine has a longer duration of action, it may be beneficial in this situation. One study comparing the use of insulin glargine U-100 to U-300 evaluated the overall risk of hypoglycemia in children ages 6 and older. The results displayed a similar percentage of severe hypoglycemia in both groups; however, the overall number of events was smaller in the insulin glargine U-300 group. This may indicate a clinical benefit of using U-300 insulin glargine versus U-100 glargine in this patient population.[155] A bedtime snack may also be needed. Treatment of hypoglycemia is addressed in Case 53-8, Question 3.

SICK DAY MANAGEMENT

CASE 53-5

QUESTION 1: G.M., a 32-year-old female with type 1 diabetes, has been well controlled on a basal-bolus regimen (four injections daily) for the past 6 months. However, 2 days ago, she began to exhibit signs and symptoms consistent with the flu. This has made her nauseated, and now she has begun to vomit; consequently, her food intake has been minimal.

Because R.D. is not eating at this time, should she discontinue her insulin?

Insulin requirements always increase in the presence of an infection or acute illness, even if food intake is diminished. Patients with type 1 diabetes, such as G.M., commonly decrease or eliminate insulin doses under these circumstances, and it is in just this setting that ketoacidosis may occur.

Therefore, G.M. should be instructed to maintain her usual dose of insulin and test her BG and urine ketones every 3 to 4 hours. If BG concentrations are above the usual range, extra doses of her rapid-acting insulin should be administered according to a prescribed algorithm based on her body's sensitivity to insulin (eg, 1 unit for each 50 mg/dL above her BG target). People with type 1 diabetes should be instructed to test for ketones if their BG concentration is 300 mg/dL or higher. G.M. should call her physician if her BG concentration remains >240 mg/dL after three corrective insulin doses; if she has moderate-to-large amounts of ketones in her urine or blood (if using a meter that can measure these); if she has been vomiting or having diarrhea for >6 hours; or if she begins to experience signs and symptoms related to ketoacidosis (polyuria, polydipsia, dehydration, ketonuria, and a fruity breath [see Case 53-10]). G.M. also should attempt to maintain her fluid, mineral, and carbohydrate intake with easily digested food and fluids (**Table 53-20**).[156]

Table 53-20
Sick Day Management

1. Continue taking your basic dose of insulin *even* if you are not eating well or have nausea or vomiting.
2. Test your blood glucose more frequently: every 3–4 hours.
3. If indicated, give yourself extra doses (high-sugar correction) of lispro, aspart, glulisine, or regular insulin: for example, 1–2 units for every 30–50 mg/dL over an agreed-on target glucose concentration (eg, 150 mg/dL). Correction doses must be individualized based on the patient's sensitivity to insulin (Table 53-9).
4. Begin testing your ketones (urine or blood) if you have type 1 diabetes. If you have type 2 diabetes, begin testing especially when glucose readings exceed 300 mg/dL.
5. Try to drink plenty of fluids (½ cup/hour for adults) and maintain your caloric intake (50 g carbohydrate every 4 hours). Foods such as gelatin, noncarbonated soft drinks, crackers, soup, and soda may be used.
6. Call a physician if your blood glucose concentration remains >300 mg/dL, or your urine ketones remain high after two or three supplemental doses of insulin, or your blood glucose level remains >240 mg/dL for more than 24 hours.

INSULIN REQUIREMENTS IN RENAL FAILURE

CASE 53-6

QUESTION 1: M.B., a 32-year-old female, has had type 1 diabetes for 15 years. During the past 2 years, a gradual deterioration of her renal function—as reflected by increased proteinuria, serum creatinine (SCr), and blood urea nitrogen (BUN) values, and reduced glomerular filtration rate (GFR)—has been observed.

What are the anticipated effects of decreased renal function on M.B.'s insulin requirements?

The effects of renal failure on insulin requirements are complex, and under various circumstances, insulin requirements may increase or decrease. The kidney is the most important site of extrahepatic insulin metabolism and excretion. In nondiabetic individuals, the liver extracts ~60% of insulin secreted endogenously before it reaches the peripheral circulation.[83,157] Because exogenous insulin is delivered directly to the periphery, the kidneys play a more important

role in its elimination. Insulin is filtered by the glomerulus and reabsorbed in the proximal tubules, where it is destroyed enzymatically. The kidney also clears insulin from the peritubular circulation.[158] At that site, insulin can enhance the reabsorption of sodium, which may account for the edema occasionally observed after the initiation of insulin therapy in some individuals.

Diminished renal function can be accompanied by decreased clearance of endogenous and exogenous insulin, resulting in increased plasma concentrations of insulin. Therefore, M.B.'s insulin requirements may diminish as her renal disease progresses. Patients with moderate degrees of renal failure (GFR >22.5 mL/minute) remove 39% of insulin from arterial plasma, similar to normal subjects. In contrast, patients with severe renal insufficiency (GFR <6 mL/minute) have a marked reduction in insulin removal from arterial plasma (9%).[8] Decreased insulin clearance in conjunction with nausea and decreased food intake associated with uremia can lead to hypoglycemia in such individuals. In some patients with diabetes, particularly those with residual endogenous insulin secretion (eg, type 2 diabetes), glucose tolerance may normalize as renal function diminishes, eliminating the need for insulin. In contrast, severe uremia is associated with glucose intolerance. This seems to be related to tissue resistance to insulin secondary to an unknown factor that can be removed by dialysis.

As M.B.'s renal function worsens, a reduction in her insulin requirements should be anticipated.

MANAGEMENT OF THE HOSPITALIZED PATIENT

CASE 53-7

QUESTION 1: A.G., a 55-year-old, 132.28-pound (60-kg) female with a 35-year history of type 1 diabetes, was admitted to the critical care unit for an abdominal hysterectomy. Before admission, she was well controlled on 24 units of insulin glargine at bedtime and premeal doses of insulin aspart.

How should A.G.'s diabetes be managed while in the critical care unit?

In 2017, nearly 23 million inpatient hospital days were attributed to diabetes management.[8] Approximately 30% of the nearly $237 billion dollars spent annually on diabetes direct medical costs is related to inpatient care; nearly half is spent on inpatient care.[159] A clear, linear relationship exists between hyperglycemia and adverse clinical outcomes in the hospitalized patient.[159–161] However, this relationship exists regardless of a baseline diagnosis of diabetes at the time of admission, and iatrogenic hyperglycemia in the hospital does not have the same relationship morbidity that spontaneous hyperglycemia does.[162–165] These observations have raised important questions about the relationship between hyperglycemia and morbidity in the hospitalized patient.

Complex responses to acute illness including excess secretion of catecholamines and cortisol result in peripheral insulin resistance and so-called stress hyperglycemia. This makes it difficult to discern whether glycemia is a marker or a mediator of adverse outcomes in the acutely ill patient. Accordingly, historic practice had been to only aim for BG concentrations that prevent glucosuria (<200 mg/dL) and the subsequent risk of dehydration in the hospitalized patient. However, beginning in 2001, a series of randomized trials tested glycemic control in critically ill patients. Significant changes have subsequently been made to practice recommendations for both the critically and the noncritically ill hospitalized patient.

Although several trials beginning in the 1990s tested intensive insulin regimens in patients with acute MI, they were small, placebo-controlled studies and reached different conclusions that proved difficult to rectify.[166] In 2001, the first of the van den Berghe trials tested two different levels of glycemic control in a relatively large number of patients in surgical intensive care unit (ICU) with hyperglycemia with or without known diabetes.[166] A liberal glucose control strategy (reduction only if BG rose above 215 mg/dL) was compared with normalization of BG (80–110 mg/dL). Overall, normalization of BG significantly reduced ICU mortality from 8.0% to 4.5%.[167] However, the same researchers were unable to replicate their findings in a subsequent, similarly designed study in patients in the medical ICU with substantially higher baseline mortality rates.[168]

Although a substudy showed that an ICU stay of ≥3 days was predictive of benefit from tight control, a subsequent and much larger trial not only failed to confirm that finding but also found increased mortality from a blood sugar of 80 to 110 mg/dL compared with 140 to 180 mg/dL (27.5%, 829 of 3010 vs 24.9%, 751 of 3012).[166] The incidence of severe hypoglycemia (<40 mg/dL) in the different study groups assigned to tight control was between 7% and 18% and did not explain the different findings between studies. However, several important differences between these trials, which helped to inform current guidelines, should be noted.

The 2001 van den Berghe trial used parenteral nutrition in all patients and allowed for higher glucose values (insulin started if blood sugar exceeded 215 mg/dL) to occur in the conventional glycemia arm.[167] It is therefore possible that the aggressive insulin therapy in the tight control group helped blunt the excessive glucotoxicity that may have been occurring from the parenteral nutrition. In the second van den Berghe trial as in the Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) study, parenteral nutrition was rarely used, and initiation of insulin therapy in the conventional arms began at blood sugar values >180 mg/dL.[166–168] In addition, in NICE-SUGAR, a more aggressive target of <180 mg/dL was used rather than 180 to 200 mg/dL as in the two van den Berghe studies.[169,170] **Table 53-21** summarizes these three trials assessing the level of glucose control in critically ill patients.

Table 53-21

Summary Data of Three Major Trials of Intensive Versus Conventional Glycemic Control With Insulin in Critically Ill Patients

Trial	*N*	Glucose Target (mg/dL)		Glucose Achieved (mg/dL)		Primary Outcome	End Point	OR (95% CI)
		Intensive	Conventional	Intensive	Conventional			
Van den Berghe et al[166]	1548	80–110	180–200	103	153	ICU mortality	4.6% vs 8%	0.58 (0.38–0.78)
Van den Berghe et al[167]	1200	80–110	180–200	111	153	Hospital mortality	37.3% vs 40.0%	0.94 (0.84–1.06)
NICE-SUGAR[168]	6104	81–108	<180	115	145	90-day mortality	27.5% vs 24.9%	1.14 (1.02–1.28)

CI, confidence interval; OR, odds ratio.

Overall, numerous individual studies as well as meta-analyses have reached different conclusions regarding whether tight control of BG is superior to conventional control in the hospitalized, acutely ill patient.[171–173]

Although existing randomized trials of glycemic control have been performed in critical care settings, the ADA guideline included non-ICU settings. To make recommendations for patients in the non-ICU setting, ADA relied on case series and retrospective analyses, which will ultimately need to be subjected to randomized, prospective trials.[171–174] In the meantime, recommendations for both critically ill and noncritically ill hospitalized patients are the same: Initiate insulin therapy to treat persistent hyperglycemia (glucose levels ≥180 mg/dL) with a goal range of 140 to 180 mg/dL. A tighter goal of 110 to 140 mg/dL, however, may be beneficial in specific subgroups of patients, such as critically ill postsurgical patients or those patients undergoing cardiac surgery, if these levels are able to be achieved without significant hypoglycemia.[175] Admitted patients with severe comorbidities may benefit from even less stringent glucose control by maintaining BG levels between 180 and 250 mg/dL.[175]

For perioperative insulin needs, A.G. should receive her usual basal insulin dose (insulin glargine 24 units) on the night before surgery. If the basal insulin is normally administered in the morning, the usual dose can still be given for patients with type 1 diabetes; for those with type 2 diabetes, 78% to 80% of the basal insulin is administered the morning of surgery.[176]

Correction doses of rapid-acting insulin can be administered the morning of surgery if the BG is >180 mg/dL.[175] If a current A_{1c} is not available, it can be measured to assess the patient's glycemic control before admission.[176] Most insulin infusion protocols include the use of IV regular insulin and maintenance IV fluids, either 5% dextrose in water (D5W) or D5W with 0.45% normal saline (0.45% NaCl). For a patient requiring fluid restriction, 10% dextrose in water (D10W) may be used.[41] The adjustment algorithms are used by nursing to change the rate of infusion (in units/hour) depending on

the BG level. Most often, the insulin infusion is prepared in a solution of 1 unit/1 mL of normal saline (eg, 100 units of regular insulin in 100 mL of 0.9% NaCl). A dedicated IV line is used for the insulin infusion to avoid iatrogenic hypoglycemia. The insulin infusion is connected to the maintenance IV containing dextrose (can be Y-connected). Because insulin binds to plastic, the insulin solution should be flushed through the IV tubing before the line is connected to the patient. An IV dextrose infusion is maintained while a patient is on an insulin infusion. Most patients need 5 to 10 g of glucose per hour (or D5W or D5W/0.45% NaCl at 100–200 mL/hour). Additional maintenance fluids (and electrolytes) can be administered via a different port or line. Some protocols include an initial bolus dose of insulin. The initial insulin infusion rate is primarily based on current BG level and BMI; other factors such as body weight, current daily insulin requirements, and renal function should be taken into consideration. An initial rate of 1 unit/hour is common (can range from 0.5 units/hour to ≥2 units/hour). The choice of initial infusion rate is not critical but should be based on patient history. A rate of 0.5 units/hour is appropriate for a patient who has never previously received insulin, whereas 2 units/hour would be appropriate for a patient with known insulin-dependent diabetes. Adjustments in the insulin infusion rate are determined by BG levels every 60 minutes until the BG is stable and close to the target. Then, the frequency of BG testing may be reduced to every 2 to 3 hours. Algorithms should consider both the current and previous BG level, the rate of change of the BG level, and the current infusion rate.[177]

Insulin infusion should be started at least 2 to 3 hours before the surgery to titrate to the desired level of glucose control.

Thus, A.G.'s usual SC insulin regimen should be discontinued, and she should be initiated on an insulin infusion that is adjusted according to an algorithm. Throughout the perioperative period, she should receive a minimum of 100 g of glucose daily to prevent starvation ketosis.

Assessment of interfering substances with point-of-care BG testing is particularly important for hospitalized patients. Some immunoglobulins and dialysates contain nonglucose sugars

(including maltose, xylose, and galactose), which can interfere with glucose measurements with glucose dehydrogenase pyrroloquinoline quinone test strips (will falsely elevate the reading, Table 53-16). BG concentrations should only be performed by the laboratory in these patients.[41]

Adverse Effects of Insulin

HYPOGLYCEMIA

CASE 53-8

Question 1: G.O., a 42-year-old, slightly overweight (71 inches [180.34 cm], 200 pounds [90.72 kg], BMI 27.9 kg/m^2) male, has had a history of type 1 DM for 17 years. G.O.'s medical care was sporadic until 1 year ago when he referred himself to a diabetes clinic because he was beginning to experience pain and numbness in his feet. At that time, he was poorly controlled on a single daily dose of a premixed NPH and regular insulin mixture (Humulin® 70/30), 45 units. He had not been testing his BG concentrations, and his A_{1c} was 13%.

On physical examination, G.O. was found to have an elevated BP (160/94 mm Hg), background retinopathy, and decreased pedal pulses bilaterally. He had decreased sensation to vibration and monofilament testing in both feet. G.O. also reports of impotence and "shooting pains" in both legs. A spot collection for microalbuminuria was 450 mg of albumin/g creatinine (normal, <30 mg/g creatinine).[41]

G.O. was transitioned to a basal-bolus insulin regimen. His physician gave him a premeal BG target of 80 to 130 mg/dL.[178] For the past several months, he has been treated with the following regimen: 14 to 18 units of insulin glulisine before breakfast; 14 to 18 units of insulin glulisine before lunch; 16 to 18 units of insulin glulisine before dinner; and 40 units of insulin glargine at bedtime. If his BG level is high after lunch, he takes additional glulisine (~2 hours after eating). If his BG is high at bedtime (eg, >150 mg/dL), he takes additional insulin glulisine (7–10 units) because his physician told him that his BG level needed to be lowered significantly. BG concentrations have been as follows:

Time	Glucose Concentration (mg/dL)
7:00 AM	60–320
Noon	140–280
5:00 PM	40–300

In the past year, G.O.'s A_{1c} has decreased to 7.1%. Currently, he has approximately five hypoglycemic episodes per week, primarily in the late afternoon and early morning hours. These are characterized by intense hunger, sweating, palpitations, and (according to his wife) a short temper. He has found that he can avoid nocturnal hypoglycemia (night sweats, nightmares, and headaches) by eating a large bedtime snack. During the past 3 months, he has gained 15 pounds (6.80 kg).

Are G.O.'s signs and symptoms consistent with mild, moderate, or severe hypoglycemia? What are the causes?

G.O.'s case illustrates one of the major hazards of aggressive BG targets and intensive insulin therapy: hypoglycemia. Hypoglycemia is a fact of life for patients with type 1 diabetes, virtually all of whom experience a hypoglycemic episode at one time or another. Nocturnal hypoglycemia is of particular concern. A syndrome called *dead-in-bed* has been described for patients with type 1 diabetes, who experience repeated hypoglycemia and have an underlying CV pathology, and die in their sleep.[179]

Hypoglycemia is a BG concentration <70 mg/dL, and its occurrence is potentially fatal if not promptly recognized and treated. However, the exact level at which patients experience symptoms is difficult to define and will vary from patient to patient. Clinical hypoglycemia is associated with typical autonomic (neurogenic) and neuroglycopenic symptoms relieved by the administration of a quickly absorbed carbohydrate.

Pathophysiology

Normal brain function depends on glucose, the exclusive fuel for cerebral metabolism. Because the brain is unable to synthesize or store glucose, it must be provided with a constant exogenous quantity via the brain's blood supply. As BG concentrations fall, a series of physiologic responses occur to restore glucose levels. These responses create symptoms warning a patient to take corrective action by consuming carbohydrates. If these counterregulatory responses fail to alert the patient and BG concentrations fall below a critical level, cognitive function becomes impaired, and confusion and coma may ensue.

In people without diabetes, the peripheral responses to hypoglycemia are so efficient that clinically important hypoglycemia probably never occurs. As glucose levels fall between 50 and 60 mg/dL, a series of neuroendocrine events occur, raising the plasma glucose concentration back toward normal by increasing hepatic glucose output. The major hormone responsible for producing acute recovery from insulin-induced hypoglycemia is glucagon; however, epinephrine alone also can produce near-normal recovery. Rising levels of adrenergic and cholinergic hormones generate warning symptoms of hypoglycemia. When hypoglycemia is prolonged, growth hormone and cortisone play a greater role in producing recovery.

Patients with type 1 diabetes who maintain insulin depots throughout the day are predisposed to severe hypoglycemic reactions because deficiencies in the normal feedback system occur with time. Glucagon secretion becomes deficient within the first 2 to 5 years of diagnosis, and by 10 years or longer, epinephrine secretion may become impaired. The latter defect leads to asymptomatic hypoglycemia or hypoglycemic unawareness (see Case 53-9).

Certain circumstances predispose patients with type 1 diabetes to severe hypoglycemia. These include (a) a defective counterregulatory hormonal response to hypoglycemia (see Case 53-9), which may be further diminished with frequent hypoglycemia, (b) medications such as β-blockers that diminish early warning signs of impending hypoglycemia, (c) intensive insulin therapy that can alter secretion of counterregulatory hormones, (d) skipped meals or inadequate carbohydrate intake relative to the insulin dose, (e) physical activity, and (f) excessive alcohol intake (Table 53-12).

Symptoms

The signs and symptoms associated with hypoglycemia vary in intensity according to the presence of cognitive deficits and the patient's ability to self-treat the reaction. They vary substantially from

one patient to another. Symptoms are conventionally divided into two categories: neurogenic (or autonomic) and neuroglycopenic.[63,179]

Autonomic symptoms include sweating, intense hunger, palpitations, tremor, tingling, and anxiety. Epinephrine is thought to mediate many of the neurogenic responses to hypoglycemia.

Neuroglycopenic symptoms resulting from neuronal fuel deprivation (glucose) include difficulty concentrating, lethargy, confusion, agitation, weakness, and, possibly, slurred speech, dizziness, and fainting. Profound behavioral changes, seizures, and coma are more severe manifestations of neuroglycopenia. Prolonged, severe neuroglycopenia may ultimately result in death if gone untreated. The ADA categorizes hypoglycemia based on levels of severity, which are listed along with symptoms as follows:

- Level 1 hypoglycemia: Defined by a glucose level <70 mg/dL but >54 mg/dL. Symptoms include tremor, palpitations, sweating, and intense hunger. Diminished cerebral function is not present, and patients are capable of self-treating.
- Level 2 hypoglycemia: Defined by a glucose level <54 mg/dL. Neuroglycopenic and autonomic symptoms may occur, including headache, mood changes, irritability, decreased attention, and drowsiness. Patients may require assistance in treating themselves because of the presence of impaired judgment or weakness. Symptoms are more severe, usually last longer, and often require a second dose of a simple carbohydrate. If patients do not experience symptoms in this level, then they likely have hypoglycemia unawareness.
- Level 3 hypoglycemia: Symptoms of severe hypoglycemia include an altered physical function and mental status. Patients may potentially become unresponsive, unconscious, or convulse. These reactions require assistance from another individual for appropriate treatment. Approximately 10% of patients treated with insulin experience at least one severe, disabling episode of hypoglycemia per year that requires emergency treatment.[33]

G.O. is experiencing level 2 hypoglycemia, which he is able to self-treat. This is likely caused by G.O. receiving too much insulin resulting in “stacking” (giving rapid- or short-acting insulin injections too close together, so that the doses “stack” on top of the other) with his rapid-acting insulin.

INSULIN STACKING

CASE 53-8, QUESTION 2: Evaluate G.O.’s overall control. What signs and symptoms in G.O. are consistent with insulin stacking? How should he be managed?

The following is a list of signs and symptoms indicating that G.O. is receiving too much rapid-acting insulin:

- A total daily insulin dose of more than 1 unit/kg: This dose is unusually high for a patient with type 1 diabetes, who should not be resistant to the action of insulin.
- Weight gain in the past several months: This is secondary to the anabolic effects of insulin and G.O.’s increased carbohydrate intake to match his high insulin doses for treatment of hypoglycemia.
- Frequent hypoglycemic reactions
- High glycemic variability (ie, BG concentrations that fluctuate wildly between hypoglycemia and hyperglycemia): In G.O.’s case, high BG concentrations may represent reactive hyperglycemia or overtreatment of hypoglycemic episodes. His low BG level may represent excessive rapid-acting insulin at bedtime and insulin stacking of his rapid-acting insulin after lunch. At lunchtime, he is administering a high-sugar correction dose of insulin glulisine too soon; his mealtime glulisine is still likely at a peak action and working to lower his prandial BG. By administering additional glulisine soon after the meal, the two insulin doses are adding up, or stacking, causing hypoglycemia.

- Near-normal A_{1c} levels: Such levels indicate mean BG concentrations that must be within the normal range even though the patient has recorded numerous high BG concentrations. Patients treated with intensive insulin therapy in the DCCT experienced hypoglycemic episodes three times more often than did patients treated with standard insulin therapy.[180] A_{1c} levels were ~7.2%.

G.O. should be managed by discontinuing his high-sugar corrections at bedtime and after lunch. He should check his BG premeal, 1 to 2 hours after meals, and at bedtime to obtain a better picture of his glucose patterns and insulin requirements. He should avoid the large bedtime snack because one should not have to add food just to avoid hypoglycemia (ie, the insulin regimen should be adjusted). He should also begin testing his BG at 2:00 or 3:00 AM to assess whether he is still experiencing nocturnal hypoglycemia after stopping the bedtime insulin glulisine. It will be important that he records the actual dose he administers before each meal and brings the record to the clinic so that his insulin doses can be fine-tuned. Next, if he is capable, an algorithm for adjusting his preprandial insulin glulisine doses should be provided to minimize hypoglycemic and hyperglycemic reactions (see Case 53-2, Question 12); eventually, he can transition to counting carbohydrates (see Case 53-2, Questions 11 and 12).

TREATMENT OF HYPOGLYCEMIA

CASE 53-8, QUESTION 3: How should G.O.'s hypoglycemic episodes be managed?

As G.O. illustrates, many patients with diabetes are frightened of hypoglycemia and have a tendency to over-treat their reactions with, for example, large quantities of juice or regular soda. This should be discouraged because overcorrection together with glucose

generated by counterregulatory hormones ultimately results in hyperglycemia.

The key to successful management of hypoglycemia is recognition and prevention. Because early warning symptoms of hypoglycemia vary from person to person, it is important that G.O. learns to recognize and pay attention to his earliest warning symptoms and treat early. Patients generally can recall prodromal symptoms after recovery from a severe hypoglycemic reaction if they have not developed hypoglycemic unawareness (see Case 53-9). As a caveat, occasionally patients “feel” hypoglycemic after their BG concentrations have been normalized from very high levels with intensive insulin therapy, owing to the amount of BG change. Encourage patients to test their BG level any time they “feel unusual” to verify a low BG concentration before treatment. G.O. should treat his symptoms only if he is truly hypoglycemic.

A second component of prevention is determining its cause and taking preventive or corrective action. This entails assessment of his diet (did he skip or delay a meal or change its content?), exercise pattern, time of insulin administration, insulin dose, and accuracy of carbohydrate counting, and dose administered. If hypoglycemic reactions consistently occur at a certain time of day, he should determine whether this corresponds with a mealtime dose of his rapid-acting insulin and reduce that insulin dose by 1 to 2 units. If his FPG is running low, his insulin glargine dose can be reduced.

If a reaction occurs, G.O. should be instructed to treat it as follows (Table 53-12).

Management of level 1 and level 2 hypoglycemia

Most hypoglycemic reactions are managed readily with the equivalent of 10 to 20 g of glucose (see Table 53-12 for examples of carbohydrate sources containing 15 g of glucose). If the blood concentration remains low after 15 minutes, the patient should ingest another 10 to 20 g of carbohydrate. This quick-acting source of glucose should be followed by a small complex carbohydrate or protein snack (eg, milk or peanut butter sandwich) to provide a

continual source of glucose if a meal is not scheduled within the next 1 to 2 hours. An easy rule of thumb that can be used by patients is "15-15-15": 15 g of glucose followed by a second 15 g if the patient is still symptomatic after 15 minutes.

Glucose tablets are available and have the added benefit of being premeasured to prevent overtreatment of hypoglycemia. Glucose gels, liquid, or small tubes of cake frosting are useful for children or patients who become uncooperative and combative when hypoglycemic.

Management of level 3 hypoglycemia

As previously stated, patients experiencing level 3 hypoglycemia will have an altered mental and/or physical functioning and will require the assistance of another person to treat their hypoglycemia. In this case, treatment with oral glucose is not an appropriate option owing to the risk of choking, and, instead, treatment of hypoglycemia in this case will require the administration of glucagon. There are multiple, commercially available glucagon-containing products, which deliver glucagon via SC, IM, IV (under medical supervision), or nasal routes.

Originally, glucagon was only available in an emergency kit, which included a powder that required reconstitution before use where parents, spouses, or other close contacts should be taught how to mix, draw up, and administer glucagon during emergency situations.

The dose of glucagon recommended to treat severe hypoglycemia for a pediatric patient <55.12 pounds (25 kg) or of unknown weight younger than 6 years old is 0.5 mg (0.5 mL).

Pediatric patients weighing ≥55.12 pounds (25 kg) or children older than 6 years of unknown weight should receive 1 mg (1 mL), which is the same dose for adult patients. The dose should be administered either IM or SC into the upper arm, thigh, or buttocks.[181]

Glucagon is now also available in prefilled syringes, autoinjecting devices, and nasal spray for more convenient administration. Glucagon prefilled syringes and autoinjecting devices (brand name GVOKE®) are indicated for use in patients age older than 2 years

and do not require reconstitution. These products easily deliver either 0.5 or 1 mg of glucagon to patients experiencing severe hypoglycemia. The recommended dose for adults and patients 12 years and older is 1 mg, whereas the dosing for patients 2 to 12 years old is weight based (children <99.20 pounds [45 kg] should receive 0.5 mg, and children >99.20 pounds [45 kg] should receive 1 mg). The dose should be administered SC into the lower abdomen, outer thigh, or outer upper arm.[182]

Glucagon powder (brand name Baqsimi®) is available in a single-use device that administers 3 mg of glucagon powder nasally and is recommended for use in patients ages 4 years and older to treat severe hypoglycemia. The recommended dose for all patients is 3 mg delivered as one actuation into one nostril. Patients do not need to inhale the powder; it is absorbed following actuation of the device.[63]

Patients who are administered glucagon should be positioned so that their face is turned toward the floor to prevent aspiration in the event of vomiting. As soon as the patient awakens (10–25 minutes), he/she should be fed. Because glucagon is recommended to treat severe hypoglycemia in patients who cannot treat their symptoms independently, family members, friends, and coworkers should be educated on the proper use of the prescribed glucagon device. This should include where the device is stored so that it can be easily obtained and administered during an emergency.[41]

Intravenous Glucose

If glucagon is unavailable, the patient should be taken to the hospital's emergency department, where he/she can be treated with IV glucose (~10–25 g administered as 20–50 mL of 50% dextrose for 1–3 minutes) in preference to glucagon. After the bolus injection of glucose, IV glucose (5–10 g/hour) should be continued until the patient has gained consciousness and is able to eat.

HYPOGLYCEMIC UNAWARENESS

CASE 53-9

QUESTION 1: M.M., a 35-year-old, 165.35-pound (75-kg), unemployed male, has had type 1 diabetes since the age of 3. As a consequence of diabetes, he has developed proliferative retinopathy and progressive diabetic nephropathy (current SCr, 2.2 mg/dL). M.M. has an erratic lifestyle. Because he does not work, he often stays out late at night and sleeps late into the morning. His insulin is injected whenever he awakens, and his meals are irregularly spaced. Each time he comes to the clinic, he brings with him a complete log of glucose concentrations that range from 80 to 140 mg/dL. He has two to three severe hypoglycemic reactions a month that require trips to the emergency department for treatment with IV glucose. On several occasions, his BG concentration has been 30 mg/dL, and he states he may feel weak, but otherwise feels "not too bad." M.M.'s last A_{1c} was 10%. He says that he adheres to the following insulin regimen: 18 units NPH/11 units regular insulin before breakfast, 10 units regular insulin before lunch and dinner, and 14 units NPH at bedtime.

At this visit, M.M. comes with his girlfriend. He has a large gash on his nose that occurred 3 days ago when he lost consciousness at ~1:30 PM while pushing his stalled car. He was unable to eat lunch at the usual hour because he had problems with his car.

Assess M.M.'s hypoglycemic reactions and BG control.

Should his current insulin regimen be continued? How should he be managed?

M.M. illustrates a patient with type 1 diabetes who has defective glucose counterregulation and, as a result, is unable to counteract a hypoglycemic reaction effectively. He also is an example of a patient who should not have aggressive BG targets because he does not feel the symptoms of low blood sugar and has already developed end-stage organ damage (proliferative retinopathy and nephropathy). Neither is likely to be reversed with improved glycemic control. In fact, proliferative retinopathy may actually worsen with intensive insulin therapy initially.[33] In the DCCT study, severe hypoglycemic reactions were three times more common among patients treated with intensive insulin therapy, and nocturnal hypoglycemia accounted for 41% of the total hypoglycemic episodes.[179] In patients with defective counterregulation, the risk of severe hypoglycemia may be 25 times higher than that in patients with adequate counterregulatory mechanisms treated with intensive

insulin therapy.[183] M.M. is at great risk for death secondary to hypoglycemia.

M.M.'s lifestyle is erratic, he eats irregularly, and his reported BG concentrations (80–140 mg/dL) do not correspond to his elevated A_{1c} value. This may indicate that M.M.'s technique is incorrect or that he simply fills in the log with fictitious numbers before he comes to the clinic. Irregular entries in different colored inks and bloodstains usually indicate authentic records.

As noted, the primary hormones that are secreted in response to a low BG concentration are glucagon and epinephrine. In patients who have had type 1 diabetes for >2 to 5 years, a deficiency in glucagon secretion is a relatively consistent finding, and these patients must rely on epinephrine to reverse low BG concentrations.[179] Unfortunately, ~40% of patients with long-standing type 1 diabetes (8–15 years) have defective epinephrine secretion as well, and this may be related to the development of autonomic neuropathy. Patients whose diabetes is tightly controlled also have reduced counterregulatory hormone responses to hypoglycemia. As illustrated by M.M., patients with defective epinephrine secretory responses also lose the warning signs and symptoms of hypoglycemia. These patients are said to have hypoglycemia unawareness because they have no awareness of BG concentrations <50 mg/dL. In these individuals, loss of consciousness, seizures, or irrational behavior may be the first objective sign of exceedingly low BG concentrations. The glycemic threshold for symptoms also is lowered in patients on intensive insulin therapy whose glucose concentrations have been lowered to normal or near-normal levels.[184] Consequently, their hypoglycemic reactions may go unnoticed and untreated until they lose consciousness. M.M. should be managed as follows:

- Because his waking, sleeping, and eating patterns are highly irregular, M.M. should be treated with an insulin regimen that addresses his lifestyle. For example, he could be switched to a basal-bolus insulin regimen, in which he can give himself a rapid-acting insulin just before he actually intends to eat. A dose of

insulin degludec could be given before his first meal to supply a basal level of insulin between meals. Because M.M. has an inconsistent sleep pattern, he may be administering his basal insulin dose at varying times. This would not be a concern if MM was using degludec because of its extremely long half-life. In addition, when switching to insulin degludec, M.M. should be provided this insulin in a pen formulation if cost is not a concern, so as to avoid any dosing errors from drawing insulin into a syringe based on M.M.'s current symptoms of visual impairment.

- Because M.M. has no warning symptoms of hypoglycemia, the importance of regular SMBG should be emphasized. When BG testing was reviewed with M.M., it was discovered that his eyesight was so poor that he was unable to distinguish between the right and wrong sides of the glucose test strip. Furthermore, because he had lost his depth of field, he was unable to apply the drop of blood into the test strip. To address this situation, M.M.'s girlfriend was taught how to perform BG testing. Also, a glucose monitor that requires a very small blood sample and beeps with an adequate blood sample would be beneficial for him. Alternatively, a CGM may be an excellent option for MM to more easily obtain glucose values versus using a traditional finger stick home BG monitor.
- M.M.'s girlfriend also was taught how to recognize and treat symptoms of hypoglycemia and how to administer glucagon. Often, patients ignore early warning symptoms and progress to a point that they lose the judgment needed to treat the condition. If M.M. has not yet become combative, a quick-acting carbohydrate source should be offered. If he has lost consciousness, glucagon should be administered.

All of these maneuvers diminished the frequency of M.M.'s severe hypoglycemic reactions. On the whole, his BG concentrations were maintained <180 mg/dL, and he remained relatively free of hyperglycemic symptoms. M.M.'s A_{1c} using a basal-bolus insulin regimen was 8.0%.

DIABETIC KETOACIDOSIS

CASE 53-10

QUESTION 1: J.L., a 40-year-old, 132.27-pound (60-kg) female with an 8-year history of type 1 diabetes, is moderately well controlled on 24 units of insulin glargine plus premeal doses of insulin lispro. Her family brings her to the emergency department, where she reports abdominal tenderness, nausea, and vomiting. According to her family, J.L. was well until 2 days ago when she awoke with nausea, vomiting, diarrhea, and chills. Because she has been unable to eat, she has omitted her usual morning dose of insulin for the past 2 days. Her gastrointestinal (GI) symptoms progressed, and she was brought to the emergency department when she became lethargic.

Physical examination reveals an ill-appearing female who is lethargic but responsive. Her temperature is 98.60 °F (37 °C). Skin turgor is poor, mucous membranes are dry, and her eyeballs are shrunken and soft. J.L.'s lungs are clear, but respirations are deep, and her breath has a fruity odor. Cardiac examination is within normal limits.

In the supine position, J.L.'s pulse rate is 115 beats/minute, and her BP is 105/60 mm Hg. In the upright position, her pulse increased to 140 beats/minute, and her BP dropped to 85/40 mm Hg. There is mild, diffuse tenderness over her abdomen.

Laboratory results on admission disclosed the following:

BG, 450 mg/dL
Sodium (Na), 150 mEq/L
Potassium (K), 5.4 mEq/L
Chloride (Cl), 106 mEq/L
HCO_3, 10 mEq/L
SCr, 2.0 mg/dL
Hemoglobin, 15.7 g/dL
Hematocrit, 49%

White blood cell count, 15,000/μL with 3% bands (normal, 3%–5%), 70% polymorphonuclear neutrophils (normal, 54%–62%), and 27% lymphocytes (normal, 25%–33%)

Serum ketones, moderate at 1:10 dilution (normal, negative)
The urinalysis showed the following:
Glucose, 2+ (normal, 0)
Moderate ketones (normal, 0)
pH, 5.5 (normal, 4.6–8)
Specific gravity, 1.029 (normal, 1.020–1.025)
No white blood cells, RBCs, bacteria, or casts

Arterial blood gas results were as follows:
pH, 7.05 (normal, 7.36–7.44)
Pco_2, 20 mm Hg (normal, 35–45)
Po_2, 120 mm Hg (normal, 90–100)

What supports the diagnosis of DKA in J.L.?

The fact that J.L. has type 1 diabetes puts her at risk for developing ketoacidosis. About 80% of DKA cases occur in patients older than age 18 years with about one-third of those occurring in patients older than age 45 years.[185] In DKA, an absolute or relative insulin deficiency promotes lipolysis and metabolism of free fatty acids to β-hydroxybutyrate, acetoacetic acid, and acetone in the liver. Excess glucagon enhances gluconeogenesis and impairs peripheral ketone utilization. Physiologic stress contributes to the development of DKA by stimulating the release of insulin counterregulatory hormones including glucagon, catecholamines, glucocorticoids, and growth hormone. Common stress factors include infection, pregnancy, pancreatitis, trauma, hyperthyroidism, and acute MI.

J.L. presented with symptoms of nausea, vomiting, diarrhea, and chills; and these are suggestive of an acute viral gastroenteritis. Patients such as J.L. commonly discontinue their insulin in this setting, which can rapidly precipitate the development of DKA (see Case 53-5). **Table 53-22** lists patient education points with regard to DKA.

Table 53-22
Diabetic Ketoacidosis: Patient Education

Definition: DKA occurs when the body has insufficient insulin.

Questions to Ask

1. Has insulin use been discontinued or a dose skipped for any reason?
2. If an insulin pump is being used, is the tubing clogged or twisted? Has the catheter become dislodged?
3. Has the insulin being used lost its activity? Is the bottle of rapid-acting/regular or basal insulin cloudy? Does the bottle of NPH look frosty?

4. Have insulin requirements increased owing to illness or other forms of stress (infection, pregnancy, pancreatitis, trauma, hyperthyroidism, or MI)?
What to Look for
1. Signs and symptoms of hyperglycemia: thirst, excessive urination, fatigue, blurred vision, consistently elevated blood glucose concentrations (>300 mg/dL) 2. Signs of acidosis: fruity breath odor, deep and difficult breathing 3. Signs of dehydration: dry mouth, warm, dry skin, fatigue 4. Others: stomach pain, nausea, vomiting, loss of appetite
What to Do
1. Review “sick day management” (Table 53-20). 2. Test blood glucose ≥four times daily. 3. Test urine for ketones when blood glucose concentration is >300 mg/dL. 4. Drink plenty of fluids (water, clear soups). 5. Continue taking insulin dose. 6. Contact physician immediately.

DKA, diabetic ketoacidosis; MI, myocardial infarction; NPH, neutral protamine Hagedorn.

As illustrated by J.L., patients with DKA present with moderate- to-high serum glucose concentrations secondary to decreased peripheral utilization and increased hepatic production (**Table 53-23**). This increases serum osmolality, which initially shifts fluid from the intracellular to the extracellular space. When serum glucose concentrations exceed the renal threshold for reabsorption of about 200 mg/dL, glucose “spills” over into the urine and causes an osmotic diuresis that depletes the total body water and electrolytes. J.L. also has lost fluid and electrolytes from vomiting and diarrhea. Eventually, as losses exceed input, the patient becomes dehydrated (dry mucous membranes; dry skin; soft, shrunken eyeballs; increased hematocrit), and intravascular volume becomes depleted (orthostatic BP and pulse changes).

Table 53-23

Common Laboratory Abnormalities in Diabetic Ketoacidosis

Glucose	250 mg/dL

Glucose	250 mg/dL
Serum osmolarity	Variable, can be >320 mOsm/kg in presence of coma
Sodium	Low, normal, or high[a]
Potassium	Normal or high
Ketones	Present in urine and blood
pH	Mild: 7.25–7.30
	Moderate: 7.00–7.24
	Severe: <7.00
Bicarbonate	Mild: 15–18 mEq/L
	Moderate: 10 to <15 mEq/L
	Severe: <10 mEq/L
WBC count	15,000–40,000 cells/mL even without evidence of infection

WBC, white blood cell.

[a]Total body sodium is always low.

The finding of hyperkalemia in J.L. is also common in DKA because insulin contributes to the intracellular shift of potassium.[186] The relative deficiency of insulin in DKA results in an extracellular shift of potassium that is worsened by the acidosis that often develops.[185] A finding of hypokalemia in DKA (<3.3 mg/dL) is uncommon and is a marker of more severe disease. In the patient with hypokalemia, the combination of the extracellular shift of potassium and polyuria has led to excessive depletion of total body potassium. Care must be used in these patients to replace potassium via IV before beginning insulin therapy, which will cause further hypokalemia as potassium shifts back into cells.[185,187]

Evidence of excessive ketone production in J.L. includes ketonuria, ketonemia, and the characteristic fruity odor of acetone on the breath. Elevated levels of these organic acids increase the anion gap and decrease the pH and carbonate levels. The respiratory rate is increased to compensate for the metabolic acidosis, leading to hypercapnia.[184]

Treatment

Case 53-10, Question 2: How should J.L. be treated?

Treatment of patients with DKA is aimed at expansion of intravascular and extravascular volume, replacement of electrolyte losses, and cessation of ketone production (**Table 53-24**).

Table 53-24
Management of Diabetic Ketoacidosis

Fluid Administration
Start IV fluids using normal saline (0.9% NaCl) unless patient has cardiac compromise.
Rate is 15–20 mL/kg body weight or 1–1.5 L during first hour.
Then, if corrected sodium is normal or elevated, use 0.45% NaCl at a rate of 4–14 mL/kg/hour (250–500 mL/hour). Use 0.9% NaCl if corrected sodium is low.
Once serum glucose reaches 200 mg/dL, change to 5% dextrose with 0.45% NaCl at 150–250 mL/hour.
Insulin
Continuous IV infusion of regular insulin is preferred. Use IM route only if infusion is not available.
Bolus dose: 0.1 units/kg IV
Maintenance dose: 0.1 units/kg/h our IV
If blood glucose level has not decreased by 50–75 mg/dL after 1 hour, double infusion rate.
Once blood glucose reaches 200 mg/dL, reduce infusion rate to 0.05–0.1 units/kg/hour and change fluid to 5% dextrose with 0.45% NaCl (do not stop insulin infusion).
When SC insulin can be initiated, administer dose 1–2 hours before discontinuing IV infusion.
For uncomplicated DKA, SC rapid-acting insulin can be considered. A bolus dose of 0.2 units/kg followed by 0.1 units/kg every hour *or* an initial dose of 0.3 units/kg followed by 0.2 units/kg every 2 hours until the blood glucose reaches <250 mg/dL; then the SC insulin dose is decreased by half (to either 0.05 or 0.1 units/kg every 1–2 hours).

Potassium
Establish adequate renal function (urine output ~50 mL/hour). If K is <3.3 mEq/L, hold insulin and give 20–40 mEq/hour until K >3.3 mEq/L. If K is >5.5 mEq/L, do not give K and check serum K every 2 hours. If K is >3.3 but <5.3 mEq/L, give 20–30 mEq in each liter of IV fluid to maintain K between 4 and 5 mEq/L.
Phosphate
Initiate if level <1 mg/dL, or in patients with cardiac dysfunction, anemia, or respiratory depression. Use potassium phosphate salt, 20–30 mEq added to replacement fluid. Rarely needed
Bicarbonate
Replacement is controversial and may be dangerous.
For adults with pH <6.9, 100 mmol of sodium bicarbonate may be added to 400 mL of sterile water with 20 mEq of KCl; infuse for 2 hours (200 mL/hour). For adults with pH of 6. 9–7.0, 50 mmol of sodium bicarbonate diluted in 200 mL of sterile water with 10 mEq of KCl; infuse for 1 hour (200 mL/hour). No bicarbonate is necessary if pH >7.0.

DKA, diabetic ketoacidosis; IM, intramuscular; IV, intravenous; SC, subcutaneous.

Source: Kitabchi AE, Umpierrez GE, Miles JM, Fisher JN. Hyperglycemic crises in adult patients with diabetes. *Diabetes Care*. 2009;32(7):1335–1343. doi:10.2337/dc09-9032

FLUIDS

Rapid correction of fluid loss is most crucial. The usual fluid deficit is difficult to estimate in the absence of overt hypernatremia but approximates 5% to 10% of body weight in most patients depending on the severity of the DKA. In the absence of cardiac compromise, hypernatremia, or significant renal dysfunction, isotonic saline (0.9% NaCl) should be used.[185]

J.L. has evidence of significant dehydration and intravascular volume depletion. Based on body weight, if the patient has the typical 5% to 10% weight loss, it will indicate that ~3 to 6 L of fluid will be needed to fully replete (10% of 132.27 pounds [60 kg]—13.23-pound [6-kg] loss and 1 L—2.20 pounds [1 kg]). It is recommended that fluids be replaced at the rate of 15 to 20 mL/kg/hour during the first hour (~1–1.5 L in the average adult). The subsequent choice for fluid replacement depends on the patient's state of hydration, serum electrolyte levels, and urinary output. If the

corrected sodium is normal or elevated, 0.45% NaCl infused at a rate of 4 to 14 mL/kg/hour is appropriate. If the corrected serum sodium is low, 0.9% NaCl is preferred.[185] When serum glucose concentrations approach 200 mg/dL, solutions should be changed to D5W/0.45% NaCl. Glucose is added to allow the continuation of insulin therapy without causing hypoglycemia (see Case 53-10, Question 5).[185]

SODIUM

Total body sodium usually is depleted by 7 to 10 mEq/kg of body weight in patients with DKA. In assessing serum sodium in these patients, it is important to remember that falsely low values (ie, pseudohyponatremia) may be the result of hyperglycemia and hypertriglyceridemia. A corrected sodium value can be estimated by adding 1.6 mEq/L to the observed sodium value for every 100 mg/dL glucose in excess of 100 mg/dL. Sodium is replaced adequately with normal saline, which has a sodium concentration of 154 mEq/L.[185,187]

POTASSIUM

Potassium balance is altered markedly in patients with DKA because of combined urinary and GI losses. Invariably, total body potassium is at least partly depleted; however, the serum potassium concentration may be high, normal, or low, depending on the degree of acidosis and volume contraction and severity of insulin deficiency. Usual potassium deficits in this situation average 3 to 5 mEq/kg of body weight, although they may be as high as 10 mEq/kg.[185]

Thus, J.L. needs ~200 to 350 mEq of potassium to replenish her body stores, assuming her normal weight is 154.32 pounds (70 kg). To prevent hypokalemia, potassium replacement should be started after her serum potassium concentrations decrease to <5.3 mEq/L (assuming an adequate urine output of 50 mL/hour). The addition of 20 to 30 mEq/L is usually sufficient to maintain the serum potassium at >4 mEq/L. In cases when serum potassium is low at presentation (<3.3 mEq/L), potassium replacement should be initiated with fluid therapy, and insulin therapy delayed until the potassium level is >3.3

mEq/L to avoid severe hypokalemia and the risk of cardiac arrhythmias and diaphragmatic weakness. In these cases, initial IV solutions should contain 20 to 30 mEq/L of potassium chloride.

PHOSPHATE

Phosphate is lost as the result of increased tissue catabolism, impaired cellular uptake, and enhanced renal excretion. As with other electrolytes, serum levels initially may seem normal, even though body stores are depleted. However, replacement can result in hypocalcemia, and the use of phosphate in DKA has resulted in no clinical benefit to patients.[185] Severe hypophosphatemia (<1.0 mg/dL) can cause cardiac and skeletal muscle weakness as well as respiratory depression. To avoid this, phosphate can be carefully replaced in patients with cardiac dysfunction or respiratory depression when phosphate concentrations are <1.0 mg/dL. Potassium phosphate can be added to the replacement fluids in amounts of 20 to 30 mEq/L.

INSULIN

Case 53-10, Question 3: What is an appropriate insulin dose and route of administration for J.L.?

Insulin therapy is the key to DKA management because it is what stops the production of ketones. Because insulin allows glucose metabolism to resume, the counterregulatory signals for ketone production are turned off. Unless the episode of DKA is mild (pH 7.25–7.30) and uncomplicated, regular insulin by continuous infusion is the treatment of choice. Once hypokalemia (K^+ <3.3 mEq/L) is excluded or treated, an IV bolus of regular insulin at 0.1 units/kg followed by a continuous infusion at a dose of 0.1 units/kg/hour should be administered. This should decrease the plasma glucose by at least 10% in the first hour. If there is not at least a 10% reduction in the first hour, then a second bolus of 0.15 units/kg should be administered. Once the plasma glucose reaches 200

mg/dL, the insulin infusion can be decreased to 0.05 units/kg/hour. Alternatively, insulin can be switched to SC at a dose of 0.1 units/kg every 2 hours. Regardless of the route of insulin therapy, serum glucose should be maintained at <200 mg/dL.[185] At this point, the fluid should be changed to D5W with 0.45% NaCl. Thereafter, the rate of insulin administration and the rate of infusion of D5W with 0.45% NaCl are adjusted to maintain the glucose value at around 200 mg/dL until the ketosis is resolved.[185] Resolution of ketosis is marked by a serum bicarbonate level of at least 15 mEq/L, a venous pH >7.3, and a calculated anion gap of ≤12 mEq/L. Once any two of those three findings are present, the patient can be converted to a longer-acting SC regimen.

For mild DKA (serum bicarbonate ≥15 mEq/L, anion gap <15), SC rapid-acting insulin has been used with no differences in patient outcomes. The advantage is that patients can be treated in a non-ICU setting, thus reducing hospital costs. The dosing for rapid-acting insulin is included in Table 53-24.

SODIUM BICARBONATE

Case 53-10, Question 4: J.L. was treated with fluids, electrolytes, and insulin, as discussed in previous questions. Laboratory and clinical data 4 hours after therapy are as follows:

pH, 7.1
BG, 400 mg/dL
K, 3.8 mEq/L
SCr, 3.1 mg/dL
Serum ketones, strongly positive at a 1:40 dilution

Her BP was 120/70 mm Hg with no orthostatic changes. Urine output for the past 3 hours has been 500 mL. Because serum ketones have increased, should J.L. receive more insulin? Should she receive bicarbonate therapy?

The assumption that ketosis is worse in J.L. is incorrect. In DKA, low levels of insulin and elevated glucagon levels promote the metabolism of free fatty acids in the liver to acetoacetate and β-hydroxybutyrate. The standard nitroprusside reaction test for ketones

measures only acetoacetate, even though β-hydroxybutyrate is the more important ketone. The conversion of acetoacetic acid to β-hydroxybutyrate is coupled closely with the reduced nicotinamide adenine dinucleotide hydrogen:nicotinamide adenine dinucleotide (NADH:NAD) ratio. If this ratio is high (as in the presence of alcohol), so much β-hydroxybutyrate may be formed that acetoacetate is virtually undetectable; thus, the absence of ketones in the serum does not rule out ketoacidosis.

Conversely, treatment with insulin begins to suppress lipolysis and fatty acid oxidation; NAD is regenerated, shifting the reaction back in favor of acetoacetate.[184] Thus, even though there seem to be higher concentrations of ketones in the serum, J.L.'s declining BG concentration, improved bicarbonate concentrations, and improved acid–base and CV responses indicate that she is responding appropriately. Therefore, no change in the insulin dose is indicated. It is important to emphasize that the glucose concentrations normalize before ketones (4–6 hours vs 6–12 hours) because the latter are metabolized more slowly. For this reason, it is important to continue insulin to maintain suppression of lipolysis until plasma and urine ketones have cleared.

The use of bicarbonate in patients with DKA has been controversial.[185] Most investigators discourage its routine use, reserving it for patients with severe acidemia (pH <6.9) or those in clinical shock. Coma is correlated most closely with BG concentrations (>700 mg/dL) and hyperosmolality (calculated osmolality >340 mOsm/kg).[188] In a small randomized, prospective study, bicarbonate did not affect recovery in patients with severe DKA (arterial pH, 6.9–7.14).[189] Thus, even though J.L.'s acidosis seemed severe on admission (pH, 7.05; bicarbonate, 10 mEq/L; Kussmaul respirations [deep, frequent respirations resulting in blowing off of CO_2]), bicarbonate was not administered. It is apparent that with fluid and insulin therapy alone, her acidosis is beginning to improve.

Case 53-10, Question 5: What is the expected course of DKA in J.L.?

After 3 L of fluid and a constant insulin infusion of 6 units/hour for 3 hours, J.L.'s glucose concentration had dropped to 400 mg/dL and she had no orthostatic BP changes, reflecting recovery from her volume-depleted status. Potassium (40 mEq/L) was added to her fluids, which were administered at a reduced rate of 300 mL/hour.

Three hours later, the glucose concentration had dropped to 350 mg/dL, and her pH had increased to 7.21 with an anion gap of 24 mEq/L. The serum potassium remained low-normal at 3.4 mEq/L, and serum sodium increased to 151 mEq/L. In view of these changes, the IV infusion fluid was changed to half-normal saline with 5% dextrose to which 40 mEq/L of potassium was added. The rate was slowed to 250 mL/hour, and the insulin infusion was continued at 6 units/hour.

Four hours later (10 hours after admission), the BG was 205 mg/dL, and the serum potassium was 3.5 mEq/dL. The IV fluids were changed to 5% dextrose with 40 mEq/L of potassium chloride, administered at a rate of 250 mL/hour, and the regular insulin infusion was decreased from 6 to 3 units/hour. J.L. continued to improve during the next 12 hours, and she began taking full oral liquids by the second hospital day. At that time, her IV infusion rate was decreased to 200 mL/hour, but her insulin infusion was continued.

Approximately 24 hours after admission, J.L.'s BG concentration was 175 mg/dL, potassium was 4.6 mEq/L, sodium was 144 mEq/L, and the anion gap had closed down to 16 mEq/L. There were no ketones in the plasma. The urine contained 1% glucose and moderate amounts of ketones. IV fluids were discontinued, and a rapid-acting insulin was administered SC 1 hour before the insulin infusion was discontinued. J.L. continued to receive rapid-acting insulin SC every 4 hours according to a sliding scale (see Case 53-2, Question 12). Thirty-six hours after admission, J.L. was given her usual dose of insulin glargine and insulin lispro and was sent home for follow-up in the clinic.

TREATMENT OF TYPE 2 DIABETES: ANTIDIABETIC AGENTS

Type 2 diabetes must be managed in the context of metabolic syndrome. At the time of diagnosis, many people with type 2 diabetes already have evidence of macrovascular and microvascular disease. Every effort to lower glucose concentrations toward normal values and to control BP and lipids is important to delay the onset or slow the progression of these complications, improve the overall quality of the patient's life, and save the health care system millions of dollars in hospitalization costs to treat these complications. MNT, physical activity, and SMBG are cornerstones in the treatment of people with type 2 diabetes. Unfortunately, these measures alone are usually not successful in achieving control for the majority of patients, and drug therapy is eventually required. Because these patients also often require a number of medications to treat related conditions (eg, hypertension, dyslipidemia, CVD, and depression) and may also be medicating themselves with over-the-counter drugs, herbal products, and nutritional supplements, the aim of therapy for type 2 diabetes should be the simplest and safest regimen that provides the best glycemic control possible.

Tables 53-25 and **53-26** summarize the comparative pharmacology, pharmacokinetics, and dosing of the noninsulin antidiabetic drugs. The clinical use of these agents in specific situations is illustrated in cases presented later in this chapter.

Table 53-25
Comparative Pharmacology of Antidiabetic Agents

Agent/Generic Name (Brand Name)/Mechanism	FDA Indications	A_{1c} Efficacy*	Adverse Effects	Comments
Insulin replaces 01 augmems endogenous insulin	Monotherapy: combined with any oral agent	▪ A_{1}, b iTPGb iPPGb ▪ TG	Hypoglycemia. weight gain, lipodystrophy. local skin	Ofreis flexible dosing to match lifestyle and glucose concentrations Rapid onset Safe In pregnancy. renal failure. and liver dysfunction Diug of choice when patients do not respond to other antidiabetic agents.
Insulin-Augmenting Agents				
Nonsu[illegible]nylurea secretagogues (glinides) Repaglmlde (Prandin) Nateglinide (Scarltx) Stimulates Insulin secretion	Monotherapy; combined with metformin or TZD	Monotherapy; IA$_{1c}$ −1% (repaglinide) ▪ A_{1}, −0 5% (nateglinide) Combination additional 1% ▪ A_{1c}	Hypoglycemia. weight gain	Take only with meats If a meal is skipped. skip a dose Flexible dosing with lifestyle Safe in renal and liver failure. Rapid onset Useful to lower PPG
Sulfonylureas Various. see Table 53-26 Stimulates Insulin secretion May decrease hepatic glucose output and enhance peripheral glucose utliizatlon	Monotherapy. combined with metformin: combined with insulin (glimepiride)	Monotherapy ▪ A_{1}, −1% Combination additional 1% ▪ in A_{1c}	Hypoglycemia. especially long-acting agents; waght gain (5−10 pounds 12.26−4.54 kgl); rash, hepatotoxfcity. alcohol intoierance. and hyponatremla are rare	Very effeaive agents. Some can be dosed once daily Rapid onset of effect (I week)

Incretin-Based Therapies				
Glucagon-like peptide-1 receptor agonlsts/incretin mimetic Exenallde (Byetta*) Extended-release exenatide (Bydureon®) lixisenatide (Adlyxin*) Liragiutide (Victoza®) Dulaglutide (trulicity*) Semagiutlde (Ozempic*) Semaglutide oral (Rybelsus™) Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety	Monotherapy combined wlth metformin, SFU, oi TZD, combined with metformin + SFU, combined with metformin + TZD Can be used In combination with basal insulin	Monotherapy 1A1, 08%–0.9% Combination additlonal 1% ▪ in A1c	GI nausea, vomiting, diarrhea, hypoglycemia (with SFUs), weight loss; reports of acute pancreatitis, URTIs	Weight loss Exenatide: take in the 60 minutes before morning and evenlng meals or before two main meals of the day (∧6 hours apart). Liragiutide, extended-release exenatide, lixisenatide, dulaglutide, semaglutide: Do not use if there is personal or famlly hlstory of medullary thyroid carcinoma (MTC) or In patients with multiple endocrlne neoplasia syndrome type 2 Do not use in patients with gastroparesis or severe GI disease Administered by SC Injectlon; pen device In use does not need to be refrigerated Rare cases of pancreatitis
DPP-4 inhibitors Sitagliptin (Januvia*) Saxagliptin (Onglyza*) Llnagiipiin (Trad|enta*) Alogliptin (Neslna®) Stimulates insulin secretion and reduces postprandial glucagon levels	Monotherapy; combined with metformin, SFU, or TZD, Insulin (sitagliptin, linagllptin, and saxagliptin)	Monotherapy ▪ A1c 0.5%–0.8% Combination / A1c 0.5%–0.9%	Headache, nasopharyngltis, hypoglycemia (with SFU), rash (rare)	Dosed once daily. Taken with or without food. No weight gain or nausea Need to adjust sitagliptin, saxagliptin, and alogliptin dose in renal dysfunction Reduce dose of SFU when combined. Rare reports of pancreatitis. Saxagliptin and alogliptin may Increase the risk of exacerbating HF
Amylin Receptor Agonists				
Amylin mimetic Pramiintide (Symlin*)	Type 1 Adjunct to mealtime insulin	TI Á A1c 0 33%	GI nausea, decreased appetite, headache; hypoglycemia; weight loss (mild)	Take oniy fmmedlately before meals, admimstered by SC Injection Do not use in patients with gastroparesis Reduce dose of mealtime insulin by 50% to avoid hypoglycemia when starting therapy.
Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety	Type 2 Adjunct to mealtime Insu lin; ± SFU and metformin	T2 iAlC O AO%		
Insulin Sensitizers				
Biguanides Metformin (Glucophage*) / Hepatic glucose output. T peripheral glucose uptake	Monotherapy; combined with SFU or TZD. or with insulin	Monotherapy: ·A A1c ~1% Combination: additional 1% Á in At.	GI nausea, cramping, diarrhea; lactic acldosis (rare)	Titrate dose slowly to mimmize GI effects. No hypoglycemia or weight gain. weight loss possible Mild teduction in cholesterol Do not use In patients with renal or severe hepatic dysfunction
Thiazolidinediones Rosiglitazone (Avandia*) Pioglitazone (Actos*) Enhances insulin action In periphery, increases glucose utllization by musete and fat tlssue; decreases hepatic glucose output	Monotherapy, combined with SFU, TZD, or insulin; combined with SFU + TZD	Monotherapy iAh −1% Combination: addlitional 1% Á In A1c	Mild anemia: fluid retention and edema. weight gain, macular edema, fractures (In females)	Can cause or exacerbate HF; do not use In patients with symptomatic HF or class III or IV HF Rosiglitazone may Increase risk of MI Increased risk of distal fractures In older females. Pioglitazone may In crease risk of bladder cancer when used for >1 year Slight reduction In TG with pioglitazone; slight Increase In LDL-C with rosiglitazone. LFTs must be measured at baseline and periodlcally thereafter Slow onset (2–A weeks)

Glucose Reabsorption Inhibltors				
Sodium–glucose cotrans-porCer type 2 inhibitors Canagllflozin (Invokana®) Dapagliflozin (Farxiga®) Empagllflozin (Jardiance®) Ertugliflozin (Steglatro®) Selectively and reversibly bind to SGLT-2 preventing reab-sorption of glucose leading to the excretlon of glucose in the urine	May be used as sec-ond- or third-llne agent or First line in patients who cannot tolerate metformin	↓Au 0.7%–1.0% iFPG ↓PPG May cause weight loss	Genital mycotic infections Urinary tract infections iGFR in patients wlth renal failure	Low risk of hypoglycemla. Dose ad-justments may be necessary in pa-tlents with renal impalrment. SGLT-2 inhibitors not recommended In patients with eGFR <30
Delayers of Carbohydrate Absorption				
u-Glucosidase inhibitors Acarbose (Precose*) Miglitol (Glyset*) Slow absorption of complex carbohydrates	Monotherapy; com-bined with SFUs, metformin, or insulin	Monotherapy ↓ A_{1c} −0.5% Combination: addi-tlonal −0.5% ↓ A_{1c}	Gl: flatulence, diarrhea. Elevations in LFTs seen In doses >50 mg tid of acarbose	Useful for PPG control (↓PPG 25–50 mg/dl) LFTs should be monitored every 3 months during the first year of therapy and periodically thereafter. Because miglitol is not metabo-lized, monitoring of LFTs is not required. Titrate dose slowly to mlnimlze Gl effects. No hypogly-cemia or weight gain. If used in combination with hypoglycemic agents, advise patients to treat hypoglycemla with glucose tablets because absorption is not inhiblted as with sucrose Avoid use in patients with Gl disor-ders (IBD, Crohn disease, intestinal obstruction).
Bile acid sequestrant Colesevelam (Welchol®)	Combined with met-formin, SFU, or insulin	↓ A_{1c} 0.3%–0.4%	Constlpation, dyspep-sia, and nausea; ↑ TG	Added benefit of ↓ LDL-C (by 12%–16%). Adminlster certain drugs A hours before Take with a meal and liquid.
Enhancers ot Dopanrinergic Tone				
Bromocriptine (Cycloset')	Monotherapy: com-bined with SFU or metformin in patients with type 2 diabetes	Monotherapy ↓ A_{1c} 0.1%: Combo: ↓ A_{1c} 0.5%	Hypotension, dizzlness, syncope, nausea, somnolence, head-ache, exacerbation of psychotic disorders	Very limited role as a therapeutic agent

Theoretically, unlimited glucose lowering with insulin therapy.

A_{1c}, glycated hemoglobin; DPP-4, dipeptidyl peptidase-4; FDA, U.S. Food and Drug Administration; FPG, fasting plasma glucose; GI, gastrointestinal; HF, heart failure; IBD, irritable bowel disease; LDL-C, low-density lipoprotein cholesterol; LFTs, liver function tests; MI, myocardial infarction; PPG, postprandial glucose; SC, subcutaneously; SFU, sulfonylureas; SGLT2, sodium–glucose transporter 2; TG, triglycerides; tid, three times a day; T1, type 1 diabetes; T2, type 2 diabetes; TZD, thiazolidinediones.

[a]Comparative effectiveness data provided for sulfonylureas (SFUs), glinides, thiazolidinediones (TZDs), and α-glucosidase inhibitors.[325]

Table 53-26
Antidiabetic Pharmacokinetic Data

Drug (Brand Name), Available Tablet Strengths (mg)	Typical Dosing Regimen (mg)	Usual Minimum and Maximum TDD/How Divided	Mean Half-Life	Approximate Duration of Activity	Bioavailability, Metabolism, and Excretion	Comments
α-Glucosidase Inhibitors						
Acarbose (Precose®) 25, 50, 100 mg	25–100 mg with first bite of each meal Begin with 25 mg; ↑ by 25 mg/meal every 4–8 weeks	Minimum: 25 mg tid Maximum dose is 50 mg tid if ≤60 kg; 100 mg tid if >60 kg	2 hours	Affects absorption of complex carbohydrates in a single meal	F = 0.5%–1.7%; extensively metabolized by GI amylases to inactive products; 50% excreted unchanged in the feces	Titrate doses slowly to avoid GI effects.
Miglitol (Glyset®) 25, 50, 100 mg	25–100 mg with first bite of each meal Begin with 25 mg; ↑ by 25 mg/meal every 4–8 weeks	Minimum: 25 mg tid Maximum: 100 mg tid	2 hours	Affects absorption of complex carbohydrates in a single meal	Dose of 25 mg is completely absorbed; dose of 100 mg 50%–70% absorbed; elimination by renal excretion as unchanged drug	
Biguanides						
Metformin (-Glucophage®) 500, 850, 1000 mg; 500 mg/mL liquid	Begin with 500 mg daily or bid; ↑ by 500 mg daily every 1–2 weeks	0.5–2.5 g bid or tid	Plasma, 6.2 hours Whole blood, 17.6 hours	6–12 hours	F = 50%–60%; excreted unchanged in urine	Take with food. Avoid in patients with renal dysfunction or those who could be predisposed to lactic acidosis (eg, alcoholism, severe HF, severe respiratory disorders, liver failure).
Metformin extended-release (Glucophage® XR) 500, 750, 1000 mg	500–1000 mg daily with evening meal; ↑ by 500 mg every 1–2 weeks	1500–2000 mg daily	As for metformin, but active drug is released slowly.	24 hours	As for metformin	As for metformin
Nonsulfonylurea Insulin Secretagogues (Glinides)						
Repaglinide (Prandin®) 0.5, 1, 2 mg	If A_{1c} is <8% or if this is first drug, begin with 0.5 mg with each meal. For others, begin with 1–2 mg/meal.	0.5–4 mg with each meal (16 mg/day) tid or qid	1 hour	C_{max} is at 1 hour; duration is ~2–3 hours	F = 56%; 92% metabolized to inactive products by the liver; 8% excreted as metabolites unchanged in the urine	Take only with meals. Skip dose if meal is skipped. Maximum dose per meal is 4 mg.
Nateglinide (Starlix®) 60, 120 mg	120 mg tid 1–30 minutes before meals; 60 mg tid for patients with near-normal A_{1c} at initiation	60 or 120 mg tid	1.5 hours	Onset, 20 minutes; peak, 1 hour; duration, 2–4 hours	F = 73%; metabolized to inactive products (predominantly) that are excreted in the urine (83%) and feces (10%)	Skip dose if meal is skipped.

First-Generation Sulfonylureas						
Acetohexamide (Dyrnelor*) 250. 500 mg	250 or 500 mg daily: T by 250 mg daily every 1–2 weeks	0 25–1 5 gdaily or bid	5 hours (active metabolite)	12–18 hours	Activiry of metabollte greater ttian thai of parent drug. Metabolite excreted. In part, by kidney	Caution in elderly and patients with renal disease, Significant uricosuric effects
Chlorpropamide (Diabinese*) 100. 250 mg	100 or 250 mg daily. T by 100 or 250 mg every 1–2 weeks	0 1-0.5 g daily	a35 hours	24-72 hours	Inacrive and weakly active metabolites, 20% excreted unchanged; varles wldely	Caution jn elderly and patients With renal impalrment. Highest frequency of side effects relative to other sulfonylureas
Tolazamide (Tolinase*) 100.250. 500 mg	100–250 mg daily. T by 100 or 250 mg every 1–2 weeks	0.2–1 g daily or bid	7 hours (4–25)	12–24 hours	Some metabolites wlth moderate actlvity excreted via kidney	Active metabolites may accumulate in renal failure.
Tolbutamide (Orlnase*) 250. 500 mg	250 mg bid before meals. tby 250 mg daily every 1–2 weeks	0.5–3 g bid or tid	7 hours	6–12 hours	Metabolized to compounds with negllgible activity	No speclai precautlons. Shortest-acting sulfonylurea
Second-Generation Sulfonylureas						
Glimeprride (Amaryl®) 1.2. 4 mg	1–2 mg daily Initially, usual malntenance dose is 1–4 mg.	1–8 mg daily	9 hours	24 hours	*F* = 100% completely metabolized by liver. Principal metabolite is sllghtly active (30% of parent compound) Excreted by the urine (60%) and feces (40%)	Probably safe m patients with renal failure, but low initial doses recommended for older patients and those with renal Insuffiiciency Incidenceof hypoglycemia may be lower than with other long-acting sulfonylureas.
Gllplzide (Glucotrol*) 5. 10 mg	2 5 mg daily In the elderly, 5 mg daily in others. t by 2.5 or 5 mg every 1–2 weeks	2 5–40 mg daily or bid[a]	2–4 hours	12–24 hours	Metabolized to Inactive compounds	No speclai precautions. Daily dose >15 mg should be divided. Dose 30 minutes before meals.
Glipizide extended-release (Glucotrol* XL) 5 mg	5 mg daily: t by 5 mg every 1–2 weeks	5–20 mg daily	4–13 hours	24 hours	Same as glipizide	Use with caution In patients with preexisting Gl narrowing owlng to possible obstruction.
Glyburide (Diabeta*. Micronase®) 1.25. 2.5, 5 mg	1.25 mg daily in the elderly. 2.5 mg daily in others. T by 1,25 or 2.5 mg every 1–2 weeks	1 25-20 mg daily or bid	4-13 hours	12–24 hours	Metabolized to inactlve or weakly inacrive compounds; 50% excreted in urine and 50% in feces	Caution In elderly patients with renal failure and others predisposed to hypoglycemia. Daily doses >10 mg should be divided.

Micronized glybutide (Glynase* PresTab*) 1 5. 3 mg	1.5 mg daily: t by 1.5 mgevery 1–2 weeks	10-12 mg daily	4 hours	24 hours	Metabolized to Inactlve or weakly Inactive compounds: 50% excreted in urine and 50% In feces.	Daily doses >6 mg should be divided T Bioavailability relative to original Iormulalion Resulted in reduced dose
Thiazolidinediones						
Rosiglitazone (Avandia*) 2. 4. 8 mg	A mg daily: T tp 8 mg daily (or A mg bid)	4–8 mg daily in single or divided doses	3–4 hours	Onset and duration poorly correlated with half-life because of mechanism of action. Onset at 3 weeks; max at ≥4 weeks Offset likely to be similai	F = 99%, extensively metabolized in liver Into inactive metabolites; excreted two-thirds in urine and one-third in feces	Food has no effect on absorption. Bid dosing may have greater A_1, lowering effect No dose adlustments required In renai failure Avoid In patients with liver disease and heart failure.
Pioglitazone (Actos*) 15, 30, 45 mg	15–30 mg daily. T to 45 mg daily. If used with insulin. ▮ Insulin dose by 10%–25% once FPG <120 mg/dL	15–45 mg daily	3–7 hours (16–24 hours for all metabolites)	Same as previous	Extensively metabolized in liver; 15%–30% excreted In urine. remainder eliminated in the feces	Food delays absorption. but is not cllnically significant No dose adjuscments required in renai disease Avoid in patients with liver disease and heart failure.
Olucagon-Like Peptide-1 Receptor Agonists/Incretin Mimetics						
Exenatide (Byetta*)	5 pg SC bid: T to 10 ug SC bid after 1 month	5–10 pg bid	2 4 hours	C_{max} is at 2.1 hours. duration 10 hours	Glomerular filtration	Take In the 60 minutes before morning and evening meal. Nausea usuaily subsides with time
Exenatide ER (Bydureon*)	2 mg SC once weekly	2 mg once weekly	10 weeks	Initial CnvW is at 2 weeks. second peak is at 6–7 weeks	Glomerular filtration	Take daily without regard to meals. Nausea usuaily subsides with time.
Uragiutide (Victoza*)	0.6 mg daily for 1 week, T to 1.2 mg daily	0.6-18 mg daily	13 hours	24 hours: Q,.,, Is 8–12 hours after dosing	Metabolized as other large proteins	take daily without regard to meals. Nausea usuaily subsides with time
Uxisenatide	10 pg daily for 2 weeks: t to 20 mg once daily on day 15	10–20 pg daily	-3 hours	C^ is 1–3 5 hours after dosing	Eltminated through glomerular filtration and proteoiytlc degradation	Take once daily 1 hour before the first meal of the day.
Dutagiutide (Trulicity*)	0.75 mg SC once weekly. can t to 1.5 mg once weekly	0 75–1.5 mg weekly	Approximately 5 days	C_{max} is at 48 hours.	Degraded Into amino acids by protein catabolism	Take daily without regard to meals. Nausea usuaily subsides with time.

Semaglutide (Ozempic*)	0.25 mg weekly for I week; t to 0.5 mg daily, can T to 1.0 mg	0.25–1.0 mg weekly	–7 days	Cn>> – t–3 days	F = 87% Metabollsm following proteolytic cleavage of peptide back bone and p-oxidation of fatty aod side Chain –3% excreted unchanged in urine	Admmister weekly wlthout regard to meals.
Semaglutide (Rybelsus*)	3 mg daily r0r 30 days; T to 7 mg daily, can T to IA mg	3–1A mg daily	Approximately 7 days	–1 hour	F = O.A%-1% Metabollsm following proteolytic cleavage of peptide backbone and (i-oxidatlon of fatty acid side Chain –3% excreted unchanged in urine	Take 30 minutes before any food, beverage, or oral medication wlth plain water only (no mote than A oz)
DPP-A Inhibitors						
Sitagliptm (Januvia*)	100 mg daily CrCl ≥ 30 to <50 ml/minute: 50 mg daily CrCl <30 miy minute: 25 mg daily	100 mg daily	12.A hours	2A hours	F = 87%; 79% excreted unchanged in urine.	Requires dose ad (ustment in nenal insufficiency
Saxagliptin (Onglyza*)	5 mg daily CrCl <<50 ml/ minute: 2 5 mg daily	2.5–5 mg daily	2 5 hours (3.1 hours for active metabolite)	2A hours	Metabolized by CYP 3AA/5. Excreted by renal and hepatic pathways	Active metabolite is half as potent Reduce dose to 2.5 mg with strong CYP 3AA/5 Inhibitors.
Ilnagiiptin (Tradjenta*)	5 mg daily	5 mg daily	12 houts	2A hours	F = 30%; 9031 ex-creted unchanged (80% enterohepatic system, 5% urine) Small fraction metabolized to inactive metabolite.	No dose adjustment needed in liver or renal disease.
Alogliptin (Nesina*I	25 mg daily CrCl 30–59 ml/ minute: 12.5 mg daily CrCl <30 ml/ minute 6.25 mg daily	25 mg daily	21 hours	2A hours	F = 100%, 76% excreted unchanged and 13% eliminated in feces. Small fraclIon metabolized to inactive metabolite	Requires dose adjustment in renal insufficiency.
Amylin Mimetics						
Pramlintide (Symiin*)	Type 1 DM 15 pg SC before major meals, t by 15-Ig Increments after minimum of 3 days	Type I 15–60 (ig before major meals	A8 minutes	Cm>> is 20 minutes	F = 30%–A0%: metabolized by kidneys	Reduce mealtime insulin dose by 50% Titrate dose if no signlficant nausea.

	Type 2 DM: 60 pg SC belore maior meals. T to 120 pg after 3–7 days	Type 2: 60 or 120 pg before maior meals				
Sodium–Glucose Transporter 2 Inhibitors						
Canagliflozin (Invokana*)	100 mg by mouth before first meal	May increase to 300 mg daily	10.6 hours		*F* = ~65% *Metabolism*: Primarily UGT1A9 and UGT2B4. ~7% *Metabolism* through CYP3A4	
Dapagliflozin (Farxiga*)	5 mg by mouth daily before first meal	May increase to 10 mg daily	12.9 hours		f = 78% *Metabolism*: Primarlly (UGT) isoenzyme IA9	
EmpagliflozIn (Jardiance®)	10 mg by mouth daily before first meal	May increase to 25 mg daily	12.A hours		*Metabolism*: Primarily through glucuronldatlon by UGT2B7, UGT1A3, UGT1A8, UGT1A9	
Ertugliflozin (SteglatrcT)	5 mg by mouth every morning with or without food	May increase to 15 mg	16.6 hours		*Metabolism*: O-glucuronldation by UGTIA9, UGT 2B7	
Bile Acid Sequestrants						
Colesevelam (Welchol*)	6 tabletsonce daily or 3 tablets bld (625-mg tablets)	3.75 g	N/A	N/A	Drug is not absorbed systemically and not metabolized.	Take with food and llquid. Do not use if history of bowel obstruetion, TG >500 mg/dL, or history of pancreatitis from TTG
Enhancers of Dopaminergic Tone						
Bromocriptine (Cycloset®), 0.8 mg	I.6–4.8 mg once daily In the morning; Begin with 0.8 mg daily and increase by 1 tablet each week until max tolerated dose	1 6-4.8 mg daily	6 hours		*F* = 65%–95% Metabolized extensively by CYP3A4; 93% undergoes first-pass metabolism Excreted primarily in bile; 2%–6% in urlne	Take with food to reduce GI side effects. Food increases AUC. Highly protein bound

A_{1c}, glycated hemoglobin; bid, two times a day; C_{max}, maximal concentration; CrCl, creatinine clearance; CYP, cytochrome P-450; DM, diabetes mellitus; DPP-4, dipeptidyl peptidase-4; F, bioavailability; FPG, fasting plasma glucose; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; HF, heart failure; N/A, not available; qid, four times a day; SC, subcutaneously; TG, triglycerides; tid, three times a day.

Biguanides

Metformin belongs to the biguanide class of oral antidiabetic agents. It has been available in the United States since 1995 and became

generically available in 2002; Currently, both the immediate-release and the extended-release (ER) formulations are available generically.[26,189] Metformin is recommended by both the AACE and ADA guidelines as the first-line agent for patients with prediabetes or type 2 diabetes.

MECHANISM OF ACTION

The biguanides are described more accurately as antihyperglycemic agents. Although they lower BG concentrations in people with type 2 diabetes, they do not cause hypoglycemia in nondiabetic individuals or individuals with diabetes when used as monotherapy. Partly because of this lack of hypoglycemia, metformin is recommended by the ADA to reduce the risk of developing diabetes in patients at high risk (IGT and IFG) because of its strong evidence base and long-term safety. Metformin is considered first-line therapy for diabetes because it has been considered safe, cost-effective, and it was the first agent with outcome data showing a reduction in all-cause mortality and vascular complications independent of glycemic control.[189] Metformin primarily lowers FPG concentrations by decreasing hepatic gluconeogenesis, increasing insulin-stimulated glucose uptake by skeletal muscle and adipose tissue by increasing insulin sensitivity, and also decreasing intestinal absorption of glucose.[190]

Metformin modestly lowers total cholesterol and triglycerides and may maintain or improve HDL-C levels.[190] The observed effects on lipid metabolism as well as others on clotting factors, platelet function, and vascular function may impart some of metformin's favorable effects on CVD and outcomes (see Case 53-11, Question 3). A key advantage with metformin is that weight loss rather than weight gain is more likely to occur with its use (mean weight loss of 1.10–8.38 pounds [0.5–3.8 kg] can occur in adults receiving metformin immediate-release tablets as monotherapy and negligible weight loss occurs with ER tablets).[190]

PHARMACOKINETICS

Approximately 50% to 60% of metformin is absorbed from the small intestine, and peak plasma concentrations are achieved at ~2.5 hours.[190] Approximately 10% of an oral dose is excreted in the feces, and about 90% of a dose is excreted through an active tubular process in the kidneys. The rate and extent of absorption are both decreased by food. Metformin has a plasma half-life of 6.2 hours in patients with normal renal function and a whole-blood half-life of 17.6 hours.[190] It is not bound to plasma proteins.

ADVERSE EFFECTS

Gastrointestinal effects

Transient side effects include diarrhea and other GI disturbances such as nausea, abdominal discomfort, metallic taste, flatulence, and anorexia.[191] Relative to placebo, diarrhea is the most common GI complaint with immediate-release tablets (53.2% metformin vs 11.7% placebo-treated patients) which decreases to ~9.6% in patients taking ER tablets. Symptoms can be further minimized by taking metformin with food and slowly titrating the dose. To enhance adherence to therapy, patients should be informed of the possibility of GI side effects that will likely subside with continued use and instructed to discuss any suspected side effects with their provider before discontinuing therapy (see Case 53-11, Question 4). Patients should not crush or chew metformin tablets and should be counseled regarding the appearance of a ghost tablet that may be noticeable in the stool when taking the ER tablets. Metformin is also available as a liquid formulation for patients who have difficulty swallowing large tablets.[192]

Lactic acidosis

Much of the perceived risk of lactic acidosis secondary to metformin use is based on historic data for phenformin, a biguanide that was withdrawn from the market in 1977.[193] The risk of lactic acidosis secondary to metformin is 10 to 20 times lower than that with phenformin. Unlike phenformin, metformin is not metabolized, does not inhibit peripheral glucose oxidation, and does not enhance

peripheral lactate production.[193,194] However, it may decrease the conversion of lactate to glucose (decreased gluconeogenesis) and increase lactate production in the gut and liver.[186] Metformin has rarely been associated with lactic acidosis. The few patients in whom this event has been reported had renal, liver, or cardiorespiratory contraindications to the use of biguanides. A Cochrane review including 347 studies compared the risk of lactic acidosis among patients taking metformin, placebo, or other nonbiguanide therapies. The review found no difference between groups in either lactate levels or in the development of lactic acidosis.[190] Despite the rarity of lactic acidosis with metformin therapy, patients should be warned to bring the following symptoms of lactic acidosis to the attention of their physician: weakness; malaise; myalgias; abdominal distress; and heavy, labored breathing.

CONTRAINDICATIONS AND PRECAUTIONS

Patients with renal impairment, liver disease, or other states predisposing them to hypoxia, acute or chronic metabolic acidosis, DKA, or a history of lactic acidosis should be excluded from therapy.[195] Metformin can accumulate in patients whose renal function is impaired, thereby increasing their risk for lactic acidosis. For this reason, metformin carries a black box warning. The FDA changed the metformin label restrictions from contraindicated at SCr level >1.5 mg/dL in males and >1.4 mg/dL in females to contraindicated at an estimated glomerular filtration rate (eGFR) <30 mL/minute/1.73 m^2, and not recommended to initiate metformin at eGFR <45 mL/minute/1.73 m^2 (see Dosage and Clinical Use; see Case 53-16, Question 2, for a detailed discussion).[190] Because even a temporary reduction in renal function could cause lactic acidosis in patients taking metformin, the manufacturer recommends withholding it after some radiologic procedures (see the section on Drug Interactions). Other predisposing factors for lactic acidosis include the following: excessive alcohol ingestion, dehydration, surgery, decompensated congestive HF, hepatic failure, shock, or sepsis. Because aging is associated with reduced renal function,

metformin should be titrated to the minimal effective dose, and renal function should be monitored regularly. An eGFR or creatinine clearance (CrCl) should be measured in patients older than age 80 years to ensure adequate renal function before metformin use because these patients are more susceptible to experiencing lactic acidosis.[196]

DRUG INTERACTIONS

- Alcohol potentiates the effect of metformin on lactate metabolism. Patients should be warned against excessive alcohol intake while taking metformin. Metformin should be avoided in patients who are alcoholics.
- Vitamin B_{12} absorption may be decreased in patients taking metformin. Each 1 g/day increment dose of metformin significantly increases the odds of vitamin B_{12} deficiency, as well as taking metformin therapy for more than 3 years.
- Dofetilide should not be administered in patients taking metformin because of the competition for common renal tubular transport systems, which may result in an increase in the plasma concentrations of either drug.
- Topiramate should be avoided in patients on metformin because topiramate may increase the risk of developing metabolic acidosis via inhibition of carbonic anhydrase.
- Parenteral contrast studies (eg, pyelography or angiography) that use iodinated materials may pose—although minimal—a risk for acute kidney injury and lactic acidosis when combined with metformin. It is recommended that metformin be stopped at the time of or before administration of iodinated IV contrast only in patients with an eGFR <60 mL/minute/1.73 m^2, or in patients with a history of liver disease, alcoholism, or HF. After 48 hours, eGFR should be reevaluated, and metformin should be restarted if renal function is stable.[189]

EFFICACY

As monotherapy, metformin can be expected to reduce the A_{1c} by 1.3% to 2.0% and the FPG by 50 to 70 mg/dL[197] Research suggests that certain genetic variations may impact patient response to metformin therapy. Patients exhibiting reduced function polymorphisms of organic cation transporter (OCT) 1, which is involved in the hepatic uptake of metformin, may be less responsive to metformin therapy.[26,41]

DOSAGE AND CLINICAL USE

Metformin is the first line of therapy for type 2 diabetes.[64] The ADA recommends its initiation as monotherapy in combination with lifestyle interventions (eg, MNT, physical activity, weight loss education, and lifestyle education) on diagnosis. To minimize GI side effects, metformin should be initiated at 500 mg twice a day or 850 mg once a day, to be taken with food, followed by weekly increases in 500-mg increments or 850-mg increases every 2 weeks (see Case 53-11, Question 4). Metformin is dosed bid to three times daily (tid; 500–1000 mg/dose; maximal dose 2550 mg/day or 850 mg PO tid), unless an ER preparation is prescribed. Using the ER formulation as initial therapy may decrease GI side effects. It should still be initiated at 500 mg daily and titrated similarly. It can, however, be dosed once a day, usually with the evening meal. Clinicians should obtain an SCr/eGFR (using the Modification of Diet in Renal Disease equation) and hepatic function tests at baseline and then annually. The AACE recommends that metformin dose reduction should be considered in patients with an eGFR <45 mL/minute/1.73 m^2, and the TDD should not exceed 1000 mg/day. Renal function should be closely monitored in these patients every 3 months. Metformin should be discontinued in patients with an eGFR <30 mL/minute/1.73 m^2 or in patients with additional risk factors such as hypotension, hypoxia, sepsis, or an increased risk of acute kidney injury (eg, use of radiocontrast dye in patients with an eGFR <60 mL/minute/1.73 m^2.[26] Metformin should not be used in patients older than age 80 years unless a CrCl/eGFR demonstrates normal renal function.[198,199] Patients are good candidates for treatment if the CrCl is >60 mL/minute (or eGFR >60

mL/minute/1.73 m^2). For patients unable to achieve goals of therapy with metformin alone within 3 months of initiating therapy, addition of insulin or another agent should be considered (also see Case 53-13).

Nonsulfonylurea Insulin Secretagogues (Glinides)

Repaglinide (Prandin®) and nateglinide (Starlix®) are nonsulfonylurea insulin secretagogues (ie, they stimulate insulin secretion). They belong to a class of agents referred to as meglitinides and are often called *glinides*. Repaglinide was approved by the FDA in December 1997, and nateglinide was approved in December 2000 (Table 53-25).

MECHANISM OF ACTION
