the spread of the tumor. Consideration with a surgeon of whether the biopsy approach is a potential prelude to a curative surgery may inform the approach taken. *Core-needle biopsy* usually obtains considerably less tissue but can provide information to plan a treatment. *Fine-needle aspiration* generally yields a suspension of cells from a mass. If positive for cancer, it may allow inception of systemic treatment, or it can provide a basis for planning a more extensive surgical procedure. A "negative" fine-needle aspiration cannot be taken as definitive evidence that a tumor is absent. In some instances, features of diagnostic imaging are sufficient to make a reliable diagnosis without obtaining tissue, usually with presence of a tumor-associated circulating diagnostic marker, e.g., α fetoprotein in hepatocellular carcinoma or prostate-specific antigen (PSA) in prostate cancer with apparent typical metastatic disease.

CANCER STAGING

Defining the extent of disease determines whether localized treatments, "combined-modality" approaches, or systemic treatments should initially be considered. Radiographic and other imaging tests can be helpful in defining the *clinical stage*; *pathologic staging* documents the histologic presence of tumor in tissue biopsies. Lymph node sampling in breast cancer, melanoma, lung, head and neck, colon, and other intra-abdominal cancers may provide crucial information.

Staging systems define a "T" component related to the size of the tumor or its invasion into local structures, an "N" component related to the number and nature of lymph node groups with tumor involvement, and an "M" component, based on the presence of local or distant metastatic sites. The various TNM components are then aggregated to stages, usually stage I to III or IV, depending on the anatomic site. The numerical stages reflect similar long-term survival outcomes of the respective TNM grouping stage after treatment tailored to the stage. In general, stage I tumors are T1 (reflecting small size), N0 or N1 (reflecting no or minimal node spread), and M0 (no metastases). Such early-stage tumors are usually amenable to curative approaches with local treatments. On the other hand, stage IV tumors have metastasized to distant sites or locally invaded viscera in a nonresectable way. They are treated with palliative intent, except for those diseases with exceptional sensitivity to systemic treatments such as chemotherapy or immunotherapy. Also, the TNM staging system is not useful in diseases such as leukemia, where bone marrow infiltration is never localized, or central nervous system (CNS) tumors, where tumor histology and the extent of feasible resection are more important in driving prognosis.

CANCER TREATMENT

The goal of cancer treatment is first to eradicate the cancer. If this is not possible, the goal shifts to palliation: amelioration of symptoms and preservation of quality of life while striving to extend life. When cure of cancer is possible, cancer treatments may be undertaken despite the certainty of severe toxicities, but these may produce toxicity with no benefit. Conversely, when the clinical goal is palliation, careful attention to minimizing the toxicity of treatments becomes a significant goal.

The two main types of cancer treatment are *local* and *systemic*. Local treatments include surgery, radiation therapy (including photodynamic therapy), and ablative approaches, including radiofrequency and thermal or cryosurgical approaches. Systemic treatments include chemotherapy (including hormonal therapy and molecular targeted therapy) and biologic therapy (including immunotherapy). The modalities are often used in combination. *Oncology*, the study of tumors including treatment approaches, is a multidisciplinary effort with surgical, radiation, and internal medicine–related areas of oncologic expertise.

Normal organs and cancers share the property of having a population of cells actively progressing through the cell cycle, with their division providing a basis for organ or tumor growth, and a population of cells not in cycle; these include *stem cells*, whose properties are being elucidated. Cancer stem cells serve as a basis for tumor initiating or repopulating cells. Tumors follow a Gompertzian growth curve **(Fig. 78-1)**, with the growth fraction of a neoplasm high with small tumor burdens but declining until, at the usual time of diagnosis (tumor burden of $1–5 \times 10^9$) the growth fraction is only 1–4% for many

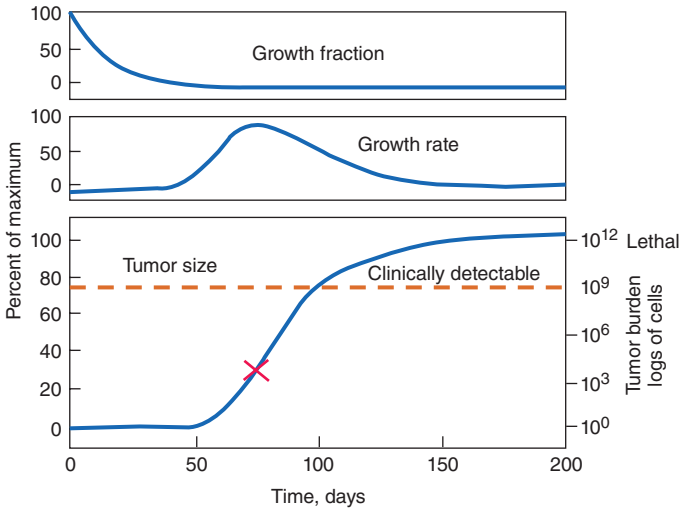

FIGURE 78-1 Gompertzian tumor growth. The growth fraction of a tumor declines exponentially over time (*top*), peaking before it is clinically detectable (*middle*). Tumor size increases slowly, goes through an exponential phase, and slows again as the tumor has limitation of nutrients or host regulatory influences occur. The maximum growth rate occurs at 1/e, the point at which the tumor is about 37% of its maximum size (*marked with an X*). Tumor becomes detectable at a burden of about 10^9 (1 cm^3) cells and kills the patient at a tumor cell burden of about 10^{12} (1 kg).

solid tumors. Thus the most rapid growth rate occurs before the tumor is detectable. An alternative explanation for such growth properties may also emerge from the ability of tumors at metastatic sites to recruit circulating tumor cells from the primary tumor or other metastases. Key features of tumor growth are the ability to stimulate new supporting stroma through angiogenesis and ingrowth of fibroblasts and immune cells **(Chap. 77)**.

LOCALIZED CANCER TREATMENTS

SURGERY

Surgery is the most effective means of treating cancer. At least 40% of cancer patients are cured by surgery. Unfortunately, many patients with solid tumors have disease not practically removable. "Palliative" surgeries, however, may afford local control of tumor, preserve organ function, and achieve debulking that permits more effective subsequent therapy, while allowing more detailed staging. Cancer surgery aiming for cure is usually planned to excise the tumor completely with an adequate margin of normal tissue (the margin varies with the tumor and the anatomy). Such a resection is defined as an R0 resection. R1 and R2 resections, in contrast, are imprecisely defined pathologically as having microscopic or macroscopic, respectively, tumor at resection margins. Such outcomes may be the basis for reoperation to obtain optimal margins if feasible and of likely clinical utility. Extending the procedure to resect draining lymph nodes obtains prognostic information and may, in some anatomic locations, improve survival.

Laparoscopic approaches are being used for primary abdominal and pelvic tumors, although with certain tumors (e.g., uterine and cervix), controversy exists as to the desirability of laparoscopic tumor removal. Lymph node spread may be assessed using the sentinel node approach, in which the first draining lymph node is defined by injecting a dye or radioisotope into the tumor site at operation and then resecting the first node to turn blue or collect isotope. Sentinel node assessment appears to provide information without the risks (lymphedema, lymphangiosarcoma) associated with resection of all regional nodes. Advances in adjuvant chemotherapy (given systemically after removal of all local disease without evidence of metastatic disease) and radiation therapy following surgery have permitted a decrease in the extent of primary surgery. Thus, "lumpectomy" with radiation therapy is as effective as modified radical mastectomy for breast cancer, and limb-sparing surgery followed or preceded by adjuvant radiation therapy and chemotherapy has replaced amputation for most childhood

rhabdomyosarcomas and osteosarcomas. More limited surgery spares organ function, as in larynx and bladder cancer. In some settings (e.g., bulky testicular cancer or stage III breast cancer), surgery is not the first treatment modality used. After diagnostic biopsy, chemotherapy and/or radiation therapy is delivered, followed by a surgical procedure to remove residual masses; this is called *neoadjuvant therapy*. Coordination among the surgical oncologist, radiation oncologist, and medical oncologist is crucial.

Surgery may be curative in a subset of patients with metastatic disease. Patients with limited lung metastases from osteosarcoma may be cured by resection of the lung lesions. In patients with colon cancer who have fewer than five liver metastases restricted to one lobe and no extrahepatic metastases, hepatic lobectomy may produce long-term disease-free survival in 25% of selected patients. In the setting of hormonally responsive tumors, oophorectomy may eliminate estrogen production, and orchiectomy may reduce androgen production, hormones that drive many breast and all prostate cancers, respectively. In selecting a surgeon or center for primary cancer treatment, consideration must be given to the volume of cancer surgeries undertaken by the site. Studies in a variety of cancers have shown that increased annual procedure volume appears to correlate with outcome. Surgery is used in a number of ways for palliative or supportive care of the cancer patient. These include insertion and care of central venous catheters, control of pleural and pericardial effusions and ascites, caval interruption for recurrent pulmonary emboli, stabilization of cancer-weakened weight-bearing bones, and control of hemorrhage, among others. Surgical bypass of gastrointestinal, urinary tract, or biliary tree obstruction or spinal cord decompression can alleviate symptoms and may prolong survival. Splenectomy may relieve symptoms and reverse hypersplenism. Intrathecal or intrahepatic therapy relies on surgical placement of appropriate infusion portals. Surgery may correct other treatment-related toxicities such as adhesions or strictures. Plastic and reconstructive surgery can correct the effects of disfiguring primary treatment. Surgery is also a tool valuable in the prevention of cancers in high-risk populations. Prophylactic mastectomy, colectomy, oophorectomy, and thyroidectomy are mainstays of cancer prevention in inherited cancer susceptibility syndromes.

RADIATION

Radiation Biology and Medicine Therapeutic radiation is generally ionizing, causing breaks in DNA and generation of free radicals from cell water that damage cancer cell membranes, proteins, and organelles.

$$\text{Ionizing radiation} + H_2O \rightarrow H_2O^+ + e^-$$
$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH^\bullet$$
$$OH^\bullet \rightarrow \text{cell damage}$$

Radiation damage is augmented by oxygen; hypoxic cells are more resistant. X-ray and gamma-ray photons are the forms of ionizing radiation most commonly used to treat cancer. Particulate ionizing radiation using protons has also become available.

Radiation dose is quantitated based on the amount of energy absorbed by the tumor, not on radiation generated by the machine. The International System (SI) unit for radiation dose is the Gray (Gy): 1 Gy refers to 1 J/kg of tissue; 1 Gy equals 100 centigrays (cGy) of absorbed dose. A historically used unit appearing in the oncology literature, the *rad* (*r*adiation *a*bsorbed *d*ose), is defined as 100 ergs of energy absorbed per gram of tissue and is equivalent to 1 cGy. Radiation dose is measured by placing detectors at the body surface or in radiated phantoms that resemble human form and substance. The features that make a particular cell more or less sensitive to radiation involve DNA repair proteins that, in their physiologic role, protect against environmentally related DNA damage.

Localized Radiation Therapy Radiation effect is influenced by three determinants: total absorbed dose, number of fractions, and time of treatment. A typical course of radiation therapy should be described as 4500 cGy delivered to a particular target (e.g., mediastinum) over 5 weeks in 180-cGy fractions. Most curative radiation treatment programs are delivered once a day, 5 days a week, in 150- to 200-cGy fractions. Nondividing cells are more resistant than dividing cells; delivering radiation in repeated fractions is done to expose a larger number of tumor cells that have entered the division cycle. The energy of the radiation determines its ability to penetrate tissue. Low-energy x-rays (150–400 kV) scatter when they strike the body, resulting in more damage to adjacent normal tissues and less radiation delivered to the tumor. Megavoltage radiation (>1 MeV) has very low lateral scatter; this produces a skin-sparing effect, more homogeneous distribution of the radiation energy, and greater deposit of the energy in the tumor, or *target volume*. The *transit volume* includes the tissues through which the beam passes to the target volume. Computational approaches and delivery of many beams to converge on a target volume are the basis for "gamma knife" and related approaches to deliver high doses to tumor, sparing normal tissue.

Therapeutic radiation is delivered in three ways: (1) *teletherapy*, with focused beams of radiation generated at a distance and aimed at the tumor within the patient; (2) *brachytherapy*, with encapsulated sources of radiation implanted directly into or adjacent to tumor tissues; and (3) *systemic therapy*, with radionuclides administered, for example, intravenously but perhaps targeted by some means to a tumor site. For example, systemically administered isotopes of iodide have an important role in the treatment of thyroid neoplasms, owing to the selective upregulation of the iodide transporter in the tumor cell compartment. Likewise, isotopes of samarium and radium have been found useful in the palliation of bony metastases of prostate cancer owing to their selective deposition at the tumor-bone matrix interface.

Teletherapy with x-ray or gamma-ray photons is the most commonly used form of radiation therapy and also delivers particulate forms of radiation such as proton beams. The difference between photons and protons relates to volume with greatest delivery of energy: protons have a narrow range of energy deposition. Electron beams are a particulate form of radiation that, in contrast to photons and protons, have a very low tissue penetrance and are used to treat cutaneous tumors. Certain drugs used in cancer treatment may also act as radiation sensitizers. For example, compounds that incorporate into DNA (e.g., halogenated pyrimidines, cisplatin) augment radiation effects at local sites and are important adjuncts to radiation of certain tumors (e.g., squamous head and neck, uterine cervix, and rectal cancers).

Toxicity of Radiation Therapy Although radiation therapy is most often administered to a local region, systemic effects, including fatigue, anorexia, nausea, and vomiting, may develop that are related in part to the volume of tissue irradiated, dose fractionation, radiation fields, and individual susceptibility. Radiation-injured tissues release cytokines that act systemically to produce these effects. Bone is among the most radio-resistant organs, with radiation effects being manifested mainly in children through premature fusion of the epiphyseal growth plate. By contrast, the male testis, female ovary, and bone marrow are the most sensitive organs. Any bone marrow in a radiation field will be eradicated by therapeutic irradiation. Organs with less need for cell renewal, such as heart, skeletal muscle, and nerves, are more resistant to immediate radiation effects. In radiation-resistant organs, the vascular endothelium is the most sensitive component. Acute toxicities include mucositis, skin erythema (ulceration in severe cases), and bone marrow toxicity. Often these can be alleviated by periodic interruption of treatment.

Chronic toxicities are more serious. Radiation of the head and neck region produces thyroid failure; cataracts and retinal damage can lead to blindness; salivary glands stop making saliva, which leads to dental caries and poor dentition. Mediastinal irradiation increases myocardial vascular disease. Other late vascular effects include chronic constrictive pericarditis, lung fibrosis, viscus stricture, spinal cord transection, and radiation cystitis or enteritis.

A serious late toxicity is the development of hematologic tumors or second solid tumors in or adjacent to the radiation fields. Such tumors can develop in any organ or tissue and occur at a rate of ~1% per year beginning in the second decade after treatment.

OTHER LOCALIZED CANCER TREATMENTS

Endoscopy allows placement of stents to unblock viscera, palliating, for example, gastrointestinal or biliary obstructions. Radiofrequency ablation (RFA) refers to microwave nonionizing radiation to induce thermal injury within a volume of tissue. RFA can be useful in the control of metastatic lesions, particularly in liver, that may threaten biliary drainage. Cryosurgery uses extreme cold to sterilize lesions in certain sites, such as prostate and kidney, at a very early stage, eliminating the need for modalities with more side effects such as surgery.

Some chemicals (porphyrins, phthalocyanines) are preferentially taken up by cancer cells. When intense light, delivered by a laser, is shone on cells containing these compounds, free radicals are generated and the cells die. Such phototherapy is used to treat skin cancer; ovarian cancer; and cancers of the lung, colon, rectum, and esophagus. Palliation of recurrent locally advanced disease can sometimes be dramatic and last many months.

Infusion of chemotherapeutic or biologic agents or radiation-bearing delivery devices such as isotope-coated glass spheres into local sites through catheters have been used to treat disease limited to that site; in selected cases, prolonged control of truly localized disease has been possible.

SYSTEMIC CANCER TREATMENTS

The concept that systemically administered chemicals might have a useful effect on cancers was historically derived from three sets of observations. Paul Ehrlich in the nineteenth century observed that different dyes reacted with different cell and tissue components. He hypothesized the existence of "magic bullets" that might bind to tumors, owing to the affinity of the agent for the tumor. Observation of the toxic effects of certain mustard gas derivatives on the bone marrow during World War I suggested that smaller doses of these agents might be used to treat tumors of marrow-derived cells. Finally, the fact that tumors from hormone-responsive tissues, e.g., breast tumors, could shrink after oophorectomy led to the idea that endogenous or exogenous substances might modulate tumor growth by altering its regulatory biology. Chemicals achieving each of these goals are currently used as cancer chemotherapy agents.

Anecdotal reports of tumor regression following intratumoral injection of bacterial extracts raised the possibility of immune system–mediated tumor regression. Serotherapy of infectious disease in the preantibiotic era encouraged analogous efforts to develop vaccine- and antibody-based treatments for cancer. Administration of autologous immune cells obtained by pheresis procedures from a patient or purified from a patient's removed tumor, activated by cytokines ex vivo, achieved durable disease control in a small fraction of patients with certain tumors, particularly renal cell cancers or melanoma. These observations provided the rationale for more modern efforts to treat tumors using cell-mediated immunity.

Systemic cancer treatments are of three broad types. *Cytotoxic chemotherapy agents* are "small molecules" (generally with molecular mass <1500 Da) that cause major regression of experimental tumors growing in animals. These agents mainly target DNA structure or segregation of chromosomes in mitosis. *Cancer molecular target therapies* refer to small molecules designed and developed to interact with a defined macromolecule important in maintaining the malignant state. As described in **Chap. 77**, successful tumors have activated biochemical pathways that lead to uncontrolled proliferation through the action of hormone receptor proteins, oncogene products, loss of cell cycle inhibitors, or loss of cell death regulation, and have acquired the capacity to replicate chromosomes indefinitely, invade, metastasize, and evade the immune system. *Cancer biologic therapies* are most frequently macromolecules, cells, or cell extracts that have a particular target (e.g., anti–growth factor receptor, cytokine, or immunomodulatory antibodies) or may have the capacity to induce a host immune response to kill tumor cells. Most recent additions to cancer biologic therapies include genetically modified cells that directly attack tumor cells and tumor-infecting viruses that can kill tumor cells but also elicit host antitumor immune responses.

SYSTEMIC CANCER THERAPY OVERVIEW

General Principles The *therapeutic index* of any drug is the degree of separation between toxic and therapeutic doses. Really useful drugs have large therapeutic indices, and this usually occurs when the drug target is expressed in the disease-causing compartment as opposed to the normal compartment. Cytotoxic chemotherapeutic agents have the unfortunate property that their main targets, DNA and microtubules, are present in both normal and tumor tissues. Therefore, they have relatively narrow therapeutic indices. Targeted agents can also cause effects on their target in normal tissues, or "off-target" effects on unrelated targets in organs experiencing damage. Biologic therapies may elicit misdirected immune responses on normal organ function. A key activity in oncology drug development is striving to administer a dose that can convey benefit with a minimal or tolerable side effect profile.

Figure 78-2 illustrates steps in cancer drug development. Following demonstration of antitumor activity in animal models, potentially useful anticancer agents are further evaluated to define an optimal schedule of administration and suitable drug formulation. Safety testing in two animal species on an analogous schedule of administration defines the starting dose for a phase 1 trial in humans, usually but not always in patients with cancer who have exhausted "standard" (already approved) treatments. The initial dose is usually one-sixth to one-tenth of the dose just causing easily reversible toxicity in the more sensitive animal species. If the agent is not intrinsically toxic, doses of drug achieving fractions of the useful plasma concentrations from model systems are studied. Escalating doses of drug are then given during the human phase 1 trial until reversible toxicity is observed or the desired drug concentration is achieved. Dose-limiting toxicity (DLT) defines a dose that conveys greater toxicity than would be acceptable in routine practice, allowing definition of a lower maximum-tolerated dose (MTD). The occurrence of toxicity is, if possible, correlated with plasma drug concentrations. The MTD or a dose just lower than the MTD is usually the dose suitable for phase 2 trials, where a fixed dose and schedule is administered to a relatively homogeneous set of patients with a particular tumor type. If no toxicity has emerged in phase 1 trials, administration of the optimal biologic dose to achieve effective drug concentrations is undertaken. A partial response historically was defined as a decrease of at least 50% in a tumor's bidimensional area obtained by imaging; more recent response criteria (e.g., Response Evaluation Criteria in Solid Tumors [RECIST]) may use a 30% decrease in aggregate unidimensional areas of target lesions. Response criteria for immunologically directed agents may allow a substantial transient increase in tumor volume as long as a patient's clinical status is stable, as these agents may evoke inflammatory responses in tumors with subsequent shrinkage or stabilization of lesions. A complete response connotes disappearance of all tumor; progression of disease signifies an increase in size of existing lesions by >25% from baseline or best response or development of new lesions; stable disease fits into none of the above categories.

In a phase 3 trial, evidence of improved overall survival or improvement in the time to progression of disease on the part of the new drug is sought in comparison to an appropriate control population. Data from the entire process are the basis for application to a regulatory agency to approve the new agent for commercial marketing.

Cancer drug clinical trials conventionally use a toxicity grading scale where grade 1 toxicities do not require treatment, grade 2 toxicities may require symptomatic treatment but are not life-threatening, grade 3 toxicities are potentially life-threatening if untreated, grade 4 toxicities are actually life-threatening, and grade 5 toxicities result in the patient's death. Active efforts to quantitate effects of anticancer agents on quality of life also frequently occur in early development of oncology drugs.

Development of targeted agents may proceed differently. While phase 1–3 trials are still conducted, focus on a particular tumor type even in phase 1 may be enabled by molecular analysis to define target expression in a patient's tumor necessary for or relevant to the drug's action. Ideally, pharmacodynamic studies would also assess whether the drug's target has been affected. The failure of a targeted therapy can

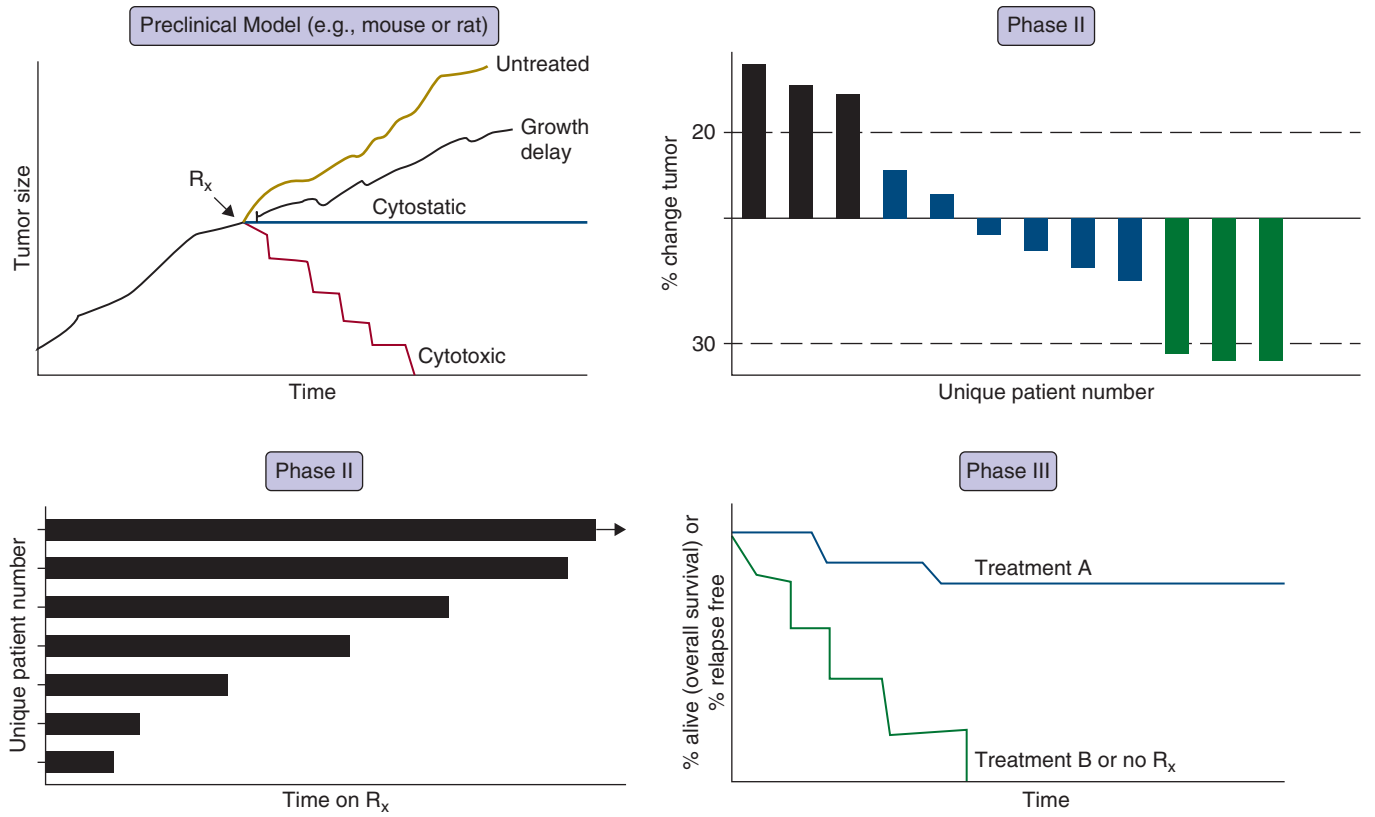

FIGURE 78-2 Steps in cancer drug discovery and development. Preclinical activity (*top left*) in animal models of cancers may be used as evidence to support the entry of the drug candidate into phase 1 trials in humans to define a correct dose and observe any clinical antitumor effect. The drug may then be advanced to phase 2 trials directed against specific cancer types, with rigorous quantitation of antitumor effects. *Waterfall plots* are a standard representation of how patients' tumor sizes change in relation to treatment, with predefined cutoffs defining progression of disease (20% increase in size) or partial response (30% decrease in size) serving as benchmarks of potential valuable effect (*top right*). *Swimmer plots* (*bottom left*) allow the delineation of patients with especially long (or short) times on treatment even without response, another basis in the former case for potential perceived clinical benefit of the treatment. *Kaplan-Meier plots* (*bottom right*) of survival indices in phase 3 comparative trials may allow definition of superiority, inferiority, or no difference of treatment effect compared to standard or no treatment.

be either because the drug missed the target or it hit the target but the target was not central to the tumor's growth and survival. Within the past decade, agents have been approved for clinical use not in relation to an originating organ site of disease but across all organ types possessing certain molecular or biologic features.

Useful cancer drug treatment strategies using conventional chemotherapy agents, targeted agents, hormonal treatments, or biologicals all have one of two valuable outcomes. They can induce cancer cell death, resulting in tumor shrinkage with corresponding clinical benefit evidenced by improvement in patient survival, or increase in time until the disease progresses. Another potential outcome is induction of cancer cell *differentiation* or *dormancy* with loss of tumor cell replicative potential and reacquisition of phenotypic properties resembling normal cells. Interaction of a chemotherapeutic drug with its target induces a "cascade" of further signaling steps. These signals ultimately lead to cell death by triggering proteases, nucleases, and endogenous regulators of the cell death pathway **(Fig. 78-3)** or differentiation by alteration of cancer genome function.

Targeted agents differ from chemotherapy agents in that they do not indiscriminately cause macromolecular lesions but regulate the action of specific driver molecules regulating processes considered "hallmarks" of cancer, including unregulated proliferation, physiologic cell death, gene expression, angiogenesis, and escape from immune mechanisms retarding tumor development.

Strategies in Systemic Cancer Management The past 35 years have witnessed a marked evolution in the systemic treatment of cancer not amenable to cure by locally applied treatments. Nonspecific cytotoxic agents of limited efficacy for most patients but highly active and curative in a minority disease types have been joined by targeted and biologic therapies. **Table 78-3, A** lists those tumors considered curable by conventionally available chemotherapeutic agents even when disseminated or metastatic. If a tumor is truly localized to a single site, consideration of surgery or primary radiation therapy should be given as well. Chemotherapy may be used as part of multimodality approaches to offer primary treatment to a clinically localized tumor **(Table 78-3, B)**, interdigitated with radiation and surgery. Chemotherapy can be administered as an *adjuvant*, i.e., in addition to surgery or radiation **(Table 78-3, C)**, even after all clinically apparent disease has been removed. This use of chemotherapy has curative potential in, for example, lung, breast, and colorectal neoplasms, as it eliminates micrometastatic clinically unapparent tumor. *Neoadjuvant* chemotherapy refers to administration of chemotherapy before any surgery or radiation to a local tumor in an effort to enhance the effect of subsequent local treatment.

Chemotherapy is routinely used in doses that produce reversible acute side effects, primarily consisting of transient myelosuppression with or without gastrointestinal toxicity (usually nausea). "High-dose" chemotherapy regimens can produce markedly increased therapeutic effect, although at the cost of potentially life-threatening complications that require intensive support, usually in the form of hematopoietic stem cell support from the patient (*autologous*) or from donors matched for histocompatibility loci (*allogeneic*), or pharmacologic "rescue" strategies to block the effect of the high-dose chemotherapy on normal tissues. High-dose regimens have curative potential in defined clinical settings **(Table 78-3, D)**.

If cure is not possible, chemotherapy may be undertaken with the goal of palliating the tumor's effect on the host **(Table 78-3, E)**. In this usage, value is perceived by the demonstration of improved symptom relief, progression-free survival, or overall survival. The best data to support these different therapeutic approaches result from clinical research protocols. In the case of a new drug, these trials might be the

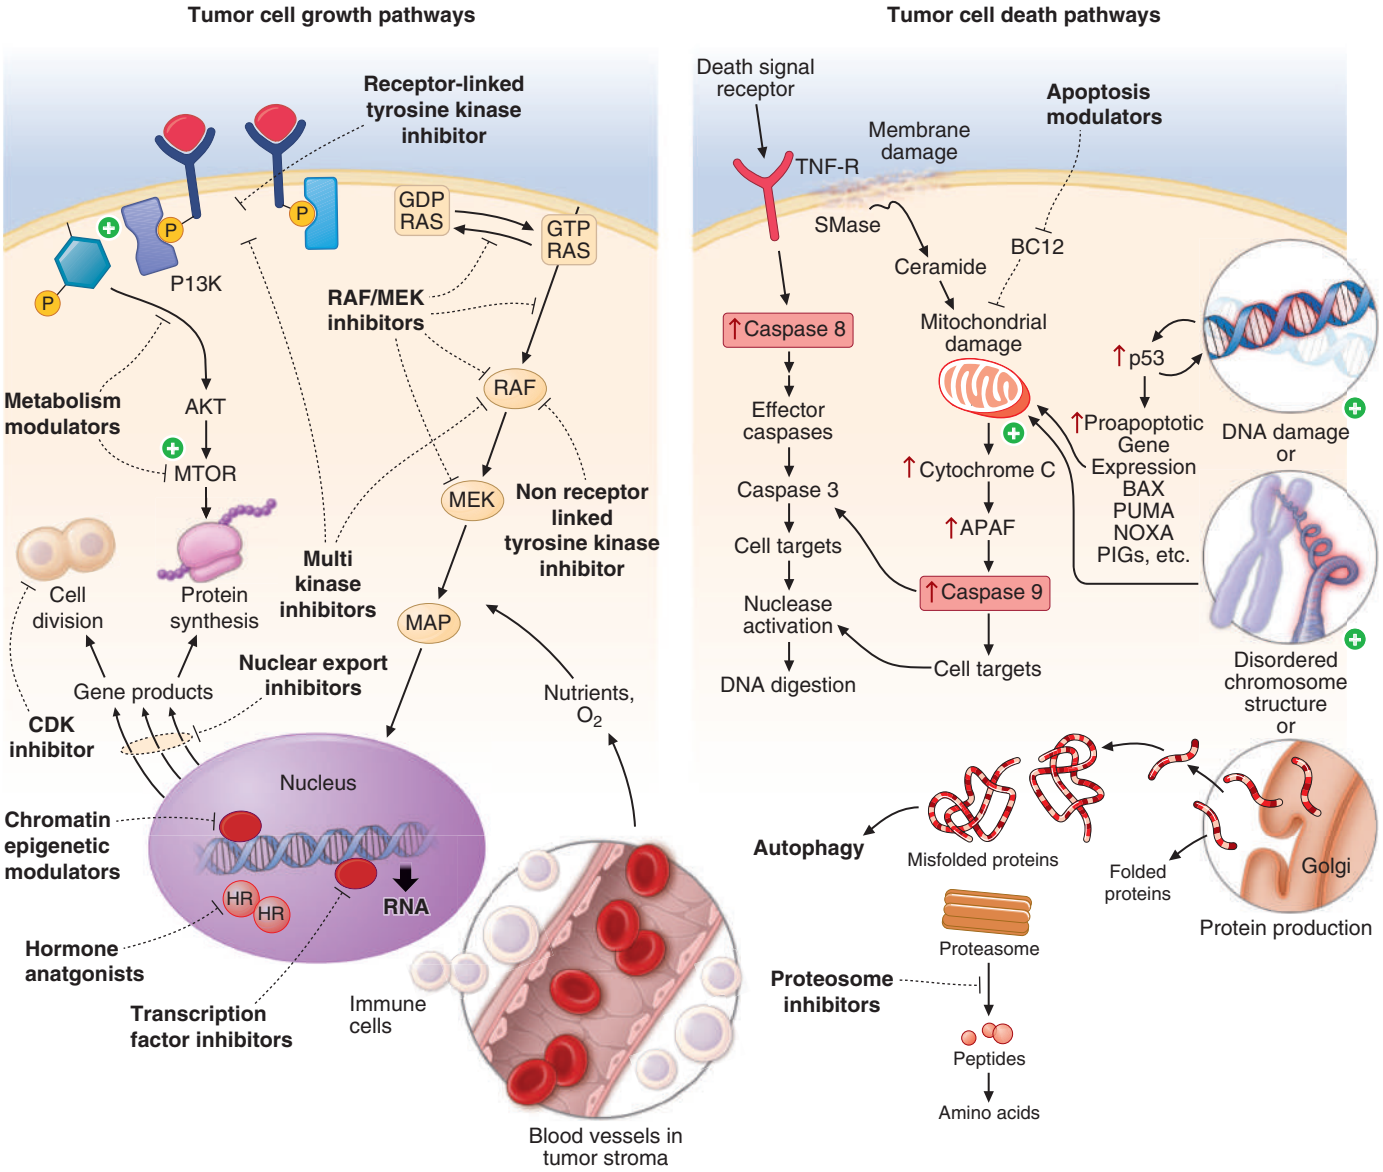

FIGURE 78-3 Tumor growth and death pathways affected by targeted and cytotoxic agents. After a growth factor binds to its receptor (*left side of figure*), in the most commonly activated cell proliferation pathway, increased tyrosine kinase activity occurs, either by autophosphorylation of receptor-linked kinases or through recruitment of non-receptor-linked tyrosine kinases, which may also be active constitutively, without requiring a growth factor. This leads to docking of "adaptor" proteins to the phosphorylated tyrosines. One important pathway activated occurs after exchange of GDP for GTP in the RAS family of proto-oncogene products. GTP-RAS activates the RAF kinase, leading to a phosphorylation cascade of MEK and MAP kinases. Mutated KRAS inhibitors have been defined, as well as RAF isoform and MEK inhibitors. The RAF/MEK/MAP kinase pathway ultimately alters gene function to activate cell cycle progression through cyclin-dependent kinases (CDKs). Another route to gene activation utilizes hormone receptors (HRs) interacting with tissue-specific growth regulators such as steroid hormones to alter gene function leading to cell cycle activation. Transcription factors acting at the level of RNA polymerase function at ensembles of gene promoters have proved difficult to target directly, but direct and indirect modulators of transcription factor activity have been defined. Receptor and non-receptor linked tyrosine phosphorylation can lead to activation of phosphatidylinositol-3-kinase (PI3K) to produce the phosphorylated lipid phosphatidylinositol-3-phosphate, which activates the AKT kinase to act downstream on the mammalian target of rapamycin kinase (mTOR), directly increasing translation of key mRNAs for gene products regulating cell growth and stimulating cell metabolism by, for example, increasing glucose transporter function. Cytotoxic agents cause cell death (*right side of figure*) through apoptosis and/or induction of autophagy. Apoptosis is also stimulated by interruption of growth factor (GF) cytokine death signals (e.g., tumor necrosis factor receptor [TNF-R]), which activate "upstream" cysteine aspartyl proteases (caspases) to directly digest cytoplasmic and nuclear proteins, resulting in activation of "downstream" caspases; these activate nucleases to cause DNA fragmentation, a hallmark of apoptosis. Chemotherapy agents that create lesions in DNA or alter mitotic spindle function activate gene function to alter mitochondrial integrity. The antiapoptotic protein BCL2 attenuates mitochondrial toxicity, whereas proapoptotic gene products such as BAX, PUMA, etc., antagonize the action of BCL2. Damaged mitochondria release cytochrome C and apoptosis-activating factor (APAF), which activate caspase 9 to cause DNA fragmentation. In addition, membrane damage with activation of sphingomyelinases results in the production of ceramides that can cause direct damage to mitochondria. Protein translation is followed by a folding process in the Golgi apparatus. Misfolded proteins are processed through the proteasome for protease digestion and recycling of amino acids. Disruption of this process can contribute to autophagy, where the cell starves for critical nutrients, or itself induce apoptosis through a distinct pathway activated by misfolded protein accumulation. Antiangiogenic agents and immune therapies work in the tumor stroma (*lower left*) on supporting elements including blood vessels and host inflammatory cells.

basis for U.S. Food and Drug Administration (FDA) approval for commercial use of the agent.

Patients treated with palliative intent should be aware of their diagnosis and the limitations of the proposed treatments, have access to supportive care, and have suitable "performance status," according to assessment algorithms such as the one developed by Karnofsky (see Table 73-4) or by the Eastern Cooperative Oncology Group (ECOG) (see Table 73-5). ECOG performance status (PS) 0 patients are without symptoms; PS1 patients are ambulatory but restricted in strenuous physical activity; PS2 patients are ambulatory and active 50% or more of the time but unable to work; PS3 patients are capable of limited self-care but are active <50% of the time; and PS4 patients are totally

TABLE 78-3 Clinical Impact on Cancers with Cytotoxic Chemotherapy

A. Advanced Cancers with Possible Cure

Acute lymphoid and acute myeloid leukemia (pediatric/adult)
Hodgkin's disease (pediatric/adult)
Lymphomas—certain types (pediatric/adult)
Germ cell neoplasms
- Embryonal carcinoma
- Teratocarcinoma
- Seminoma or dysgerminoma
- Choriocarcinoma

Gestational trophoblastic neoplasia
Pediatric neoplasms
- Wilms' tumor
- Embryonal rhabdomyosarcoma
- Ewing's sarcoma
- Peripheral neuroepithelioma
- Neuroblastoma

Small-cell lung carcinoma
Ovarian carcinoma

B. Advanced Cancers Possibly Cured by Chemotherapy, Radiation, ± Surgery

Squamous carcinoma (head and neck)
Squamous carcinoma (anus)
Bladder carcinoma
Breast carcinoma
Carcinoma of the uterine cervix
Esophageal carcinoma
Non-small-cell lung carcinoma (stage III)
Small-cell lung carcinoma

C. Cancers Possibly Cured with Chemotherapy as Adjuvant to Surgery

Breast carcinoma
Colorectal carcinoma[a]
Osteogenic sarcoma
Soft tissue sarcoma

D. Cancers Possibly Cured with High-Dose Chemotherapy with Stem Cell Support

Relapsed leukemias, lymphoid and myeloid
Relapsed lymphomas, Hodgkin's and non-Hodgkin's
Chronic myeloid leukemia
Multiple myeloma

E. Cancers Responsive with Useful Palliation, But Not Cured, by Chemotherapy

Bladder carcinoma
Chronic myeloid leukemia
Hairy cell leukemia
Chronic lymphocytic leukemia
Lymphoma—certain types
Multiple myeloma
Gastric carcinoma
Cervix carcinoma
Endometrial carcinoma
Soft tissue sarcoma
Head and neck cancer
Adrenocortical carcinoma
Islet cell neoplasms
Breast carcinoma
Colorectal carcinoma
Glioma
Lung cancer
- Small-cell
- Non-small-cell

F. Tumors Poorly Responsive in Advanced Stages to Chemotherapy

Pancreatic carcinoma
Biliary tract neoplasms
Thyroid carcinoma
Carcinoma of the vulva
Prostate carcinoma
Melanoma
Hepatocellular carcinoma
Salivary gland cancer

[a]Rectum also receives radiation therapy.

confined to bed or chair and incapable of self-care. Only PS0, PS1, and PS2 patients are generally considered suitable for palliative (noncurative) treatment. If there is curative potential, even poor-PS patients may be treated (especially if their symptoms are directly related to a cancer that may respond to treatment), but their prognosis is usually inferior to that of good-PS patients treated with similar regimens. Assessment of physiologic reserve through use of the geriatric assessment tool can be helpful, but no measure of comorbidities or physiologic reserve is considered standard.

The turn of the millennium marked the arrival of new strategies for cancer treatment. Prominent among these are *cancer biologic therapy*, which harnesses the use of immune system–derived reagents or strategies, and *cancer targeted therapies*, which are directed at specific molecular targets differentially expressed in malignant as opposed to normal tissues.

CANCER BIOLOGIC THERAPY

Figure 78-4 presents the landscape of cancer biologic therapy agents and actions. The goal of biologic therapy is to manipulate the host-tumor interaction in favor of the host, potentially at an optimum biologic dose that might be different than MTD. As a class, biologic therapies may be distinguished from cytotoxic and molecularly targeted agents in that biologic therapies require activity (e.g., antigen expression or internalization) on the part of the tumor cell or on the part of the host (e.g., T-cell engagement or cytokine elaboration) to allow therapeutic effect.

Antibody-Mediated Therapeutic Approaches Figure 78-4 illustrates current antibody-based strategies in cancer treatment. The ability to grow very large quantities of high-affinity monoclonal antibodies directed at specific tumor antigens produced by animals allows the grafting of animal-derived antigen-combining sequences into human immunoglobulin genes (chimerized or humanized products) or derived de novo from mice bearing human immunoglobulin gene loci. Four general strategies have emerged using antibodies. *Anti-tumor cell antibodies* target tumor cells directly to inhibit intracellular functions or attract immune or stromal cells. *Bispecific tumor engaging (BiTe) antibodies* directly bind to a tumor cell and to a host immune cell. *Immunoregulatory antibodies* target antigens expressed on host immune cells to boost the host's immune response to the tumor. Finally, *antibody conjugates* link the antibody to drugs, toxins, or radioisotopes to target these "warheads" for delivery to the tumor. *Stroma-directed antibodies* are currently available against tumor-supporting vasculature.

ANTI-TUMOR CELL ANTIBODIES (FIG. 78-4) Humanized antibodies against the CD20 molecule expressed on B-cell lymphomas (rituximab and ofatumumab) are exemplary of antibodies that affect both signaling events driving lymphomagenesis as well as activating immune responses against B-cell neoplasms. They are used as single agents and in combination with chemotherapy and radiation in the treatment of B-cell neoplasms. Obinutuzumab is an antibody with altered glycosylation that enhances its ability to activate killer cells; it is also directed against CD20 and is of value in chronic lymphocytic leukemia.

Unintended side effects of any antibody include infusion-related hypersensitivity reactions, which can be managed with glucocorticoid and/or antihistamine prophylaxis, and prolonged infusion strategies.

Anti-B-cell-directed antibodies can have the unintended effect of exacerbating immunosuppression with the emergence of increased opportunistic infections. Reactivation of latent infections may also occur; an assessment of a patient's hepatitis B and C status is conventionally done before treatment. Concomitant use of antivirals directed against hepatitis may be indicated. Patients with HIV and lymphoma need antivirals optimized to minimize interaction with anti-lymphoma treatments; consultation with infectious disease specialists is warranted. Anti-tumor cell antibodies also include approaches to activate complement and are exemplified by alemtuzumab directed against CD52; it is active in chronic lymphoid leukemia and T-cell malignancies. Tumor lysis syndrome prophylaxis may be warranted.

Epidermal growth factor receptor (EGFR)-directed antibodies (e.g., cetuximab and panitumumab) have activity in colorectal cancer refractory to chemotherapy, particularly when used to augment the activity of an additional chemotherapy program, and in the primary treatment of head and neck cancers treated with radiation therapy. Direct effects on the tumor may mediate an antiproliferative effect as well as stimulate the participation of host mechanisms involving immune cell or complement-mediated response to tumor cell–bound antibody. Anti-EGFR antibodies can cause an acneiform rash requiring topical antibiotic and glucocorticoid cream treatment; photosensitivity also occurs.

The HER2/neu receptor overexpressed on epithelial cancers, especially breast and certain gastrointestinal cancers, was initially targeted by trastuzumab, with activity in potentiating the action of chemotherapy in breast cancer as well as evidence of single-agent activity. Trastuzumab appears to interrupt intracellular signals derived from HER2/neu and to stimulate anti-tumor cell immune mechanisms. The anti-HER2 antibody pertuzumab, specifically targeting the domain of HER2/neu responsible for dimerization with other HER2 family members, is more specifically directed against HER2 signaling function and augments the action of trastuzumab. Both trastuzumab and pertuzumab can damage cardiac function, particularly in patients with prior exposure to anthracyclines, and left ventricular function should be checked before treatment and monitored during treatment.

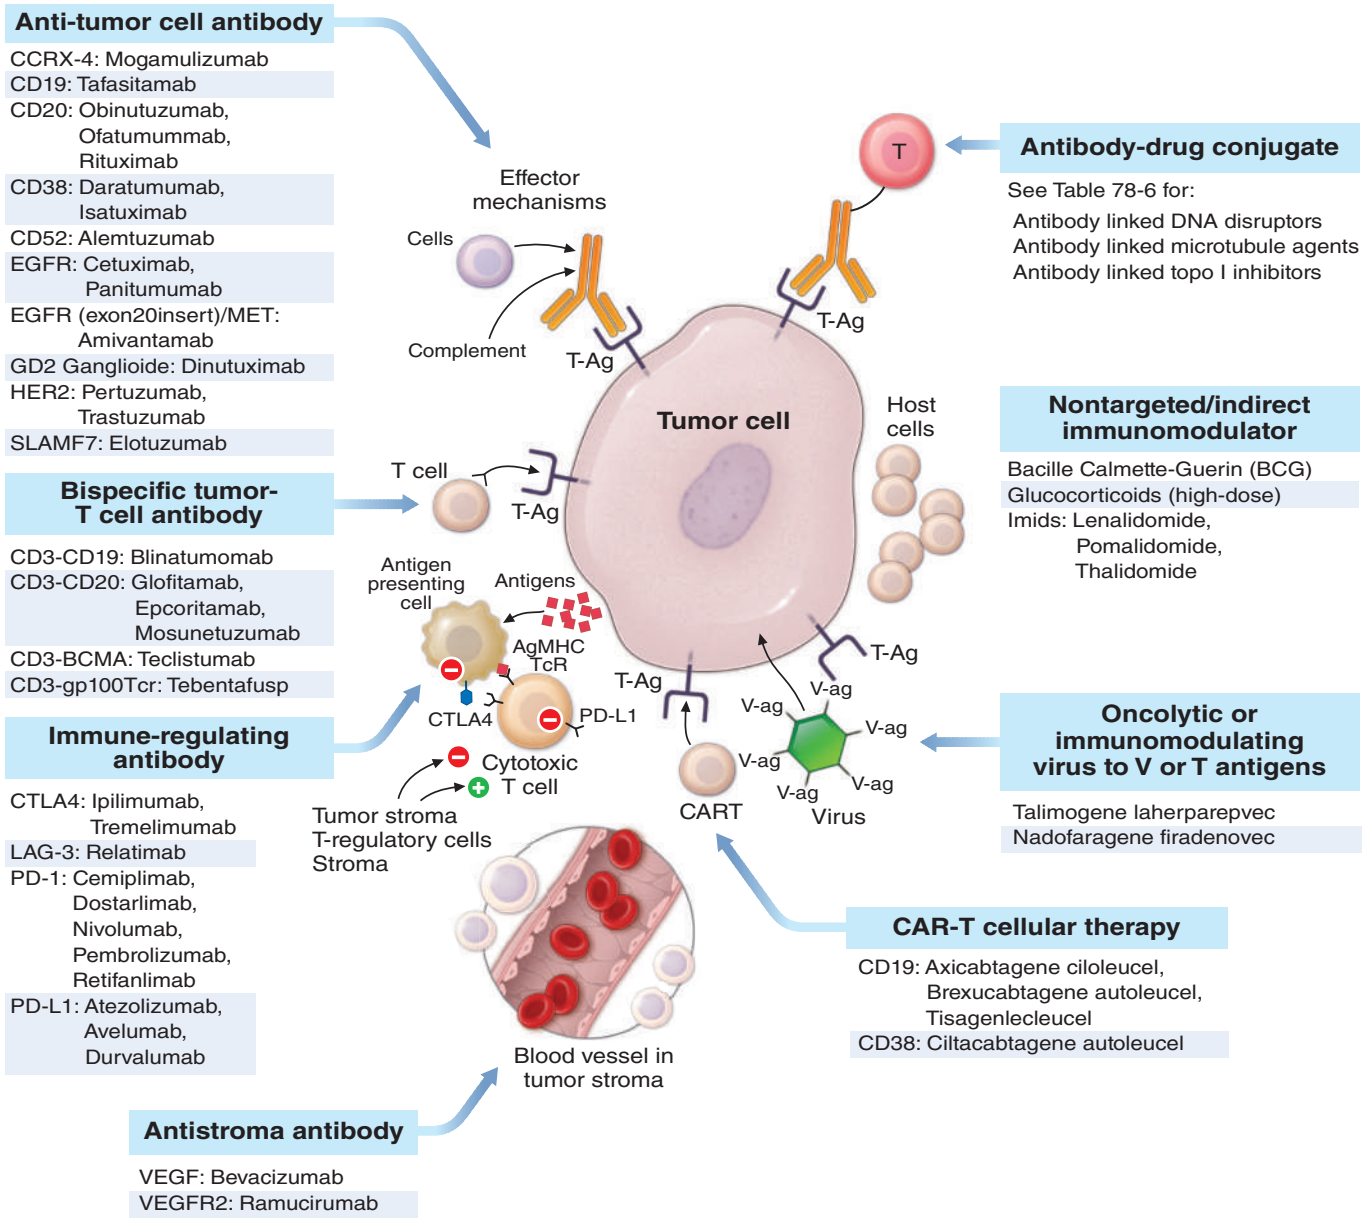

FIGURE 78-4 Immunologic treatments for cancer. Anti–tumor cell antibodies targeting the indicated antigens (T-Ag) expressed on tumor cells or antibody-derived constructs (*upper left*) can either directly interfere with tumor cell function by, e.g., inhibiting growth-promoting pathways, or recruit host immune effector cells actively (especially through bispecific tumor-engaging [BiTe] strategies; *middle left*), Fc receptors, or cytotoxic mechanisms such as complement. Endogenous T cells can be activated by *immunomodulatory cell targeting antibodies* (*lower left*). Specifically, tumor cell–derived antigens are taken up by antigen-presenting cells (APCs), also in the stroma. Antigens are processed by the APCs to peptides presented by the major histocompatibility complex (MHC) to T-cell antigen receptors (TcRs), thus providing a positive (+) activation signal for the cytotoxic tumor cells to kill tumor cells bearing that antigen. Negative (–) signals inhibiting cytotoxic T-cell action include the CTLA4 receptor (on T cells), interacting with the B7 family of negative regulatory signals from APCs, and the PD receptor (on T cells), interacting with the PD ligand-1 (PD-L1) (–) signal coming from tumor cells expressing the PD-L1. Strategies that inhibit CTLA4 and PD-1 function are a means of stimulating cytotoxic T-cell activity to kill tumor cells. Lymphocyte activating gene 3 (LAG3) has recently been shown to promote PD axis immunosuppression, and inhibition of that target has shown clinical value. *Tumor stroma-directed antibodies* cause anti–vascular endothelial cell growth factor (VEGF)–mediated antiangiogenic and tumor interstitial pressure-modulating strategies. Proceeding *clockwise* in the figure from the upper right, *antibody-drug conjugates* have recently been designed to deliver cytotoxic drugs, indicated by "T" (*upper right*). Relatively *nonspecific immunomodulators* include vaccines instilled directly into the tumor stroma, agents such as the "imids" that alter tumor and stromal cell cytokine production, and cytokines such as interferon or interleukin 2 (IL-2), which can affect tumor-infiltrating lymphocyte function or have direct antitumor effects. *Vaccines* targeting tumor cell antigens or live attenuated *oncolytic viruses* injected into tumors can cause tumor cell lysis with induction of a prominent host antitumor immune response to virus antigens and target antigens (T-Ags) (*middle right*). In the *right lower* portion of the figure, strategies to deliver activated immune cells include harvest of autologous T cells that are then infected with a lentivirus or other construct that targets antigens (T-Ags) expressed on tumor cells (*chimeric antigen receptor [CAR] T cells*), with the targeted antigen indicated.

The BiTe antibody blinatumomab was constructed to have an anti-CD19 antigen-combining site directed at a cancer cell as one valency with an anti-CD3 binding site as the other. This antibody can bring T cells (with their anti-CD3 activity) close to neoplastic B cells bearing the CD19 determinant. Blinatumomab is active in B-cell neoplasms such as acute lymphocytic leukemia. Unique toxicities include cytokine release syndrome (fever, hypotension, tachycardia) and neurologic deterioration manifest initially by deterioration in handwriting accuracy, which can proceed to more florid cortical dysfunction, suggesting a need for dose pausing and/or glucocorticoid use.

STROMA-DIRECTED ANTIBODIES (FIG. 78-4) The anti–vascular endothelial growth factor (VEGF) antibody bevacizumab shows evidence of value in renal cancers, where activation of VEGF signaling occurs as part of disabled hypoxia-induced signaling in the tumor cells. When combined with chemotherapeutic agents, it may increase responses in colorectal and nonsquamous lung cancers. The mechanism for this effect may relate to improved delivery and tumor uptake of the cytotoxic, or even immunoregulatory, antibodies used to treat hepatocellular cancer, owing to decreased tumor interstitial pressure. VEGF was originally isolated as a "tumor permeability factor" causing leakiness

of tumor blood vessels. When used in gliomas, it may, by decreasing vascular permeability, allow replacement of steroids to decrease intracranial pressure. Bevacizumab has a number of side effects including hypertension, thrombosis, proteinuria, hemorrhage, and gastrointestinal perforations with or without prior surgeries; these adverse events also occur with small-molecule drugs modulating VEGF receptor (VEGFR) function.

IMMUNOREGULATORY ANTIBODIES (FIG. 78-4) Purely immunoregulatory antibodies stimulate immune responses to mediate tumor-directed cytotoxicity. An understanding of the tumor-host interface has revealed that cytotoxic tumor-directed T cells are frequently inhibited by ligands upregulated in the tumor cells. The programmed death ligand 1 (PD-L1; also known as B7-homolog 1) was initially recognized as inducing T-cell death through a receptor present on T cells, termed the programmed death (PD) receptor, which physiologically regulates the intensity of the immune response to any antigen. The PD family of ligands and receptors also regulates macrophage function, present in tumor stroma. These actions raised the hypothesis that antibodies directed against the PD signaling axis (both anti-PD-L1 and anti-PD) might be useful in cancer treatment by allowing reactivation of the immune response against tumors.

Ipilimumab, an antibody directed against the anti-CTLA4 (cytotoxic T lymphocyte antigen 4), which is expressed on T cells (not tumor cells), responds to signals from antigen-presenting cells (Fig. 78-4) and also downregulates the intensity of the T-cell proliferative response to antigens derived from tumor cells. Indeed, manipulation of the CTLA4 axis was the first demonstration that purely immunoregulatory antibody strategies directed at T-cell physiology could be safe and effective in the treatment of cancer. Ipilimumab, alone or in combination with PD-1-directed antibodies, is approved for treatment of metastatic melanoma and lung cancers.

Nivolumab, directed against the PD-1 receptor, and atezolizumab (anti-PD-L1) are exemplary of anti-PD-1-directed immunoregulatory antibodies, with clinical benefits in many cancers **(Table 78-4)**. Pembrolizumab is approved for first-line treatment of metastatic non-small-cell lung cancer tumors that express the PD-L1 ligand. This development was a milestone in cancer therapeutics, replacing chemotherapy in this patient subset. Lymphocyte activation gene 3 (*LAG3*) binds to major histocompatibility complex (MHC) on antigen-presenting cells to augment the effect of the PD-1 and CTLA4 pathways. Relatlimab is a first-in-class inhibitor of LAG3 action and augments the effect of nivolumab in melanoma.

Importantly, the clinical observation that tumors most amenable to treatment with immunoregulatory antibodies were in sites (lung, skin, genitourinary) exposed to environmental carcinogens or occurred in patients with known mutations in DNA repair pathways stimulated specific research as to whether the "mutational burden" of tumors could predict value from anti-PD strategies. Results to date in general support this hypothesis and led to the first regulatory approvals for immunomodulating antibodies in a "tissue agnostic" fashion. Specifically, detection of deficiencies in a tumor DNA mismatch repair system or with evidence of increased tumor mutation burden is a specific indication for use of certain immunoregulatory agents, irrespective of the disease site of origin. The increased efficacy in the setting of higher tumor mutational burden is thought to be due to the presence of more proteins in the tumor structurally altered by mutation that can be recognized as foreign by the immune system.

Prominent autoimmune hepatic, cardiac, endocrine, cutaneous, neurologic, and gastrointestinal adverse events can occur with the use of ipilimumab as well as the PD-1-directed antibodies. Emergency use of glucocorticoids may be required to attenuate severe toxicities. Although theoretically such glucocorticoid use can attenuate the antitumor effect, response rates do not appear to be compromised by their use to abrogate serious organ toxicity attributable to use of immunomodulatory antibodies. Importantly for the general internist, immunologic toxicities can occur late after exposure to the modulators of PD and CTLA4 action, even while the patient may have sustained control of tumor growth.

TABLE 78-4 Clinical Impact of Host T Lymphocyte–Modified Cells[a] or Host T Lymphocyte–Directed Immunoregulatory Antibodies[c]

A. Advanced Cancers with Positive Effect (at least 25% of treated patients have stable disease or progression-free survival of ≥27 weeks or better) or Frequent or Unexpected Prolonged Responders (efficacy may be limited to CD expression–dependent or PD-1 ligand–expressing subtypes)
Acute lymphoid leukemia[b]
Adrenocortical carcinoma[c]
Breast cancer, hormone receptor negative, HER2 negative (with chemotherapy)[c]
Colorectal cancer (microsatellite instability-high [MSI-H] or mismatch repair deficient, usually with fluoropyrimidine, oxaliplatin, or irinotecan)[c]
Cervix, squamous carcinoma[c]
Cutaneous, squamous carcinoma[c]
Diffuse large B-cell non-Hodgkin's lymphoma, not otherwise specified[a]
Diffuse large B-cell non-Hodgkin's lymphoma, primary mediastinal subtype[b]
Endometrial carcinoma (with lenvatinib, if microsatellite instability-stable [MSI-S] or mismatch repair wild-type)[c]
Esophageal squamous carcinoma[c]
Gastric/gastroesophageal adenocarcinoma[c]
Head and neck squamous carcinoma[c]
Hepatocellular cancer (after sorafenib)[c]
Hodgkin's disease[c]
Mantle cell lymphoma[a]
Melanoma[c]
Merkel cell carcinoma[c]
Mesothelioma[c]
MSI-H or mismatch repair–deficient solid tumors without satisfactory alternative[c]
Mycosis fungoides[c]
Multiple myeloma[a]
Non-small-cell lung carcinoma[c]
Paraganglioma/pheochromocytoma[c]
Renal cell carcinoma[c]
Sarcoma, alveolar soft part[c]
Small-cell lung carcinoma[c]
Solid tumors with high tumor mutational burden (TMB) (≥10 mutations/megabase) that have progressed following prior therapy without satisfactory alternative treatment[c]
Urothelial carcinoma[c] (including bladder, ureter)
B. Advanced Cancers with Insufficient Data to Support Host-Derived T Lymphocyte or Immunoregulatory Antibody Treatment[d]
Acute myeloid leukemia
Anus, squamous carcinoma
Breast cancer, hormone receptor positive
Breast cancer, hormone receptor negative, HER2 positive
Biliary tract cancers (if MSI-S or mismatch repair wild-type)
Chronic lymphocytic leukemia
Chronic myeloid leukemia
Gastrointestinal neuroendocrine/islet cell carcinoma
Glioma, all grades including glioblastoma
Germ cell neoplasms
Ovarian cancer
Osteogenic sarcoma
Pancreas adenocarcinoma
Pediatric tumors (Wilms', rhabdomyosarcoma, Ewing's, neuroblastoma, osteosarcoma)
Prostate adenocarcinoma
Salivary gland carcinoma
Soft tissue sarcoma (except alveolar soft part)
T-cell non-Hodgkin's lymphoma (except mycosis fungoides)
Vulva, squamous carcinoma

[a]Chimeric antigen receptor (CAR)-modified autologous T cells in relapsed or refractory cases. [b]Both CAR-modified autologous T cells or an immunoregulatory antibody. [c]T-cell-directed immunoregulatory antibody strategies including anti-PD-1 and/or anti-PD-L1 antibodies or bispecific tumor engaging (BiTe) antibodies against a particular tumor cell antigen. [d]Unless MSI-high, mismatch repair deficient, or TMB ≥10 mutations/megabase.

Nontargeted Immunomodulators (Fig. 78-4) Bacille Calmette-Guérin, a killed mycobacterial product, invokes a useful immune response when instilled locally into the bladder in the setting of preinvasive bladder cancers. The "imids" thalidomide, lenalidomide, and pomalidomide alter cytokine elaboration in the tumor microenvironment and have antiangiogenic actions. They are a cornerstone in the management of multiple myeloma. Thromboses (warranting consideration of prophylactic anticoagulation), gastrointestinal and neuropathic adverse events, and prominent teratogenicity can occur as a consequence of their use. "High-dose" glucocorticoids stimulate apoptosis in normal and neoplastic lymphoid cells and are a mainstay in the treatment of lymphoid leukemias, lymphomas, and plasma cell neoplasms.

Cytokines Only interferon α (IFN-α) and interleukin 2 (IL-2) are considered for current treatment indications. IFN is not curative for any tumor but can induce partial responses in follicular lymphoma, hairy cell leukemia, chronic myeloid leukemia, melanoma, and Kaposi's sarcoma. It produces fever, fatigue, a flulike syndrome, malaise, myelosuppression, and depression and can induce clinically significant autoimmune disease.

IL-2 exerts its antitumor effects indirectly through augmentation of immune function. Its biologic activity is to promote the growth and activity of T cells and natural killer (NK) cells. High doses of IL-2 can produce tumor regression in certain patients with metastatic melanoma and renal cell cancer. About 2–5% of patients may experience complete remissions that are durable. Patients may require blood pressure support and intensive care to manage the toxicity. However, once the agent is stopped, most of the toxicities reverse completely within 3–6 days. Use of "high-dose" IL-2 regimens has been superseded by immunoregulatory antibodies. Efforts to develop new IL-2-based strategies with less toxicity and improved efficacy are continuing.

T Cell–Mediated Therapies Three types of currently used cancer treatments take advantage of the ability of T cells to kill tumor cells.

1. *Transfer of allogeneic T cells.* This occurs in three major settings: in allogeneic bone marrow transplantation; as purified lymphocyte transfusions following bone marrow recovery after allogeneic bone marrow transplantation; and as pure lymphocyte transfusions following immunosuppressive (nonmyeloablative) therapy (also called reduced-intensity or minitransplants). In each of these settings, the effector cells are donor T cells that recognize the tumor as being foreign, probably through minor histocompatibility differences. The main risk of such therapy is the development of graft-versus-host disease because of the minimal difference between the cancer and the normal host cells. This approach has been useful in certain hematologic cancers refractory to chemotherapeutic strategies.
2. *Transfer of autologous T cells.* In this approach, the patient's own T cells are removed from the tumor-bearing host, manipulated in several ways in vitro, and given back to the patient. Tumor antigen–specific T cells can be developed after retroviral transduction of the desired T-cell antigen receptor and expanded to large numbers over many weeks ex vivo before administration. These chimeric antigen receptor (CAR) T cells (Fig. 78-4) have evidence of sustained value in patients with refractory hematopoietic neoplasms such as diffuse large B-cell lymphoma, multiple myeloma, and mantle cell lymphoma. Prominent adverse effects include *cytokine release syndrome* (fever, tachycardia, hypotension) and neurologic manifestations. Clinical investigations are seeking to develop solid-tumor antigen-directed CAR strategies, as well as to utilize different immune cell populations such as NK cells to cause useful antitumor activity in ways that may allow "off-the-shelf" products not requiring manipulation and purification of patients' autologous cells.
3. *Tumor vaccines aimed at boosting T-cell immunity.* Two types of vaccine approaches are currently approved. Purified autologous antigen-presenting cells can be pulsed with tumor, its membranes, or particular tumor antigens and delivered as a vaccine. Vaccine adjuvants such as granulocyte-macrophage colony-stimulating factor (GM-CSF) may be co-administered. One such vaccine, sipuleucel-T, is approved for use in patients with asymptomatic or minimally symptomatic metastatic hormone-independent prostate cancer. In this approach, the patient undergoes leukapheresis, wherein mononuclear cells (that include antigen-presenting cells) are removed from the patient's blood. The cells are pulsed in a laboratory with an antigenic fusion protein comprising a protein frequently expressed by prostate cancer cells, prostate acid phosphatase, fused to GM-CSF, and matured to increase their capacity to present the antigen to immune effector cells. The cells are then returned to the patient in a well-tolerated treatment. Although no objective tumor response was documented in clinical trials, median survival was increased by about 4 months.

   Another important vaccine strategy is directed at infectious agents whose action ultimately is tied to the development of human cancer. Hepatitis B vaccine in an epidemiologic sense prevents hepatocellular carcinoma, and a tetravalent human papillomavirus vaccine prevents infection by virus types currently accounting for 70% of cervical cancer. Unfortunately, these vaccines are ineffective at treating patients who have developed a virus-induced cancer.

Oncolytic or Immunomodulating Viruses (Fig. 78-4) Laboratory studies in animals have utilized viruses to destroy tumors because tumor cells lack endogenous host mechanisms, e.g., IFN elaboration or recognition strategies of viral nucleic acids, that limit virus spread. Viral infection of tumors also can stimulate a prominent host response to viral and tumor cell antigens, leading to immune effects against local tumor cells. Talimogene laherparepvec is a clinically approved attenuated herpes virus that acts to stimulate immune responses when instilled locally into melanoma deposits. Systemic effects are minimal in this application. This general strategy is being considered particularly in tumors not amenable to useful effects of currently approved immunoregulatory antibodies or in conjunction with immunoregulatory antibodies. Nadofaragene firadenovec is an adenovirus construct instilled into the bladder; it is nonreplicating but can infect urothelial cells to deliver a gene resulting in consistently produced IFN-α2b, which has a local antitumor effect. It is useful in the treatment of superficial bladder cancers. It is not established whether infection of tumor cells, normal urothelial cells, or both contribute to the antitumor effect.

CANCER CYTOTOXIC THERAPY

Table 78-5 lists commonly used cytotoxic cancer chemotherapy agents and pertinent clinical aspects of their use, with particular reference to adverse effects that might be encountered by the generalist in the care of patients. The drugs were initially discovered through screening of chemicals and natural product extracts for evidence of antitumor activity in animals or were designed with knowledge of biochemical pathways affecting nucleic acid synthesis. They may be usefully grouped into two general categories: those affecting DNA and those affecting microtubules.

As illustrated in Fig. 78-3, disruption of DNA or microtubule integrity is a major trigger of cellular apoptosis pathways. An additional factor in drug effect stems from recent observations that tumor cells have increased tolerance of specific types of DNA damage owing to defects in DNA repair pathways. This state is thought to facilitate the survival of the neoplastic clone as it experiences DNA mutations during the course of carcinogenesis. DNA-directed cytotoxic agents can create lesions in DNA that are poorly tolerated by cells with neoplasm-promoting DNA repair pathway mutations. This results in a "synthetic lethal" interaction of the drug with cells bearing the DNA repair pathway mutation. Examples of a potential "synthetic lethal effect" will be pointed out in relation to clinical applications below.

DNA-Interactive Agents DNA replication occurs during the synthesis or S-phase of the cell cycle, with chromosome segregation of the replicated DNA in the M, or mitosis, phase. The G_1 and G_2 "gap phases" precede S and M, respectively. Chemotherapeutic agents have been divided into "phase-nonspecific" agents, which can act in any phase of the cell cycle, and "phase-specific" agents, which require the cell to be at a particular cell cycle phase to cause greatest effect.

TABLE 78-5 Commonly Used Cytotoxic Chemotherapy Agents

DRUG	ADVERSE EVENTS	NOTES
Direct DNA-Interacting Agents[a]		
Alkylator or platinating drug		
Bendamustine	Vehicle allergy, My, Der, ↑LFTs	TLS, Ves, IR, DA-R, DA-H
Carboplatin	My, N, V, R	Dose according to CrCl: to AUC of 5–7 mg/mL per min [AUC = dose/(CrCl + 25)]
Chlorambucil	Common alkylator	
Cisplatin	N, V, Neu, My, R, Ototoxic, ↓K^+, ↓Mg^{2+}, ↓Ca^{2+}	Osmotic diuresis, N, V prophylaxis, DA-R
Cyclophosphamide	Common alkylator, cystitis, cardiac (high dose)	Liver required to activate, DA-R, DA-H, hydration ± mesna protects bladder
Dacarbazine (DTIC)	Common alkylator, Ves	DA-R
Ifosfamide	My, common alkylator, bladder, CNS	DA-R, must use concomitant mesna
Lomustine (CCNU)	Common alkylator but My, has delayed nadir, ↑LFTs	Plm ± fibrosis: PFTs prior to treatment and repeat frequently; cease if fibrosis occurs
Lurbinectedin	My, ↑LFTs, N, V	CYP3A4
Melphalan	Common alkylator but My, has delayed nadir	DA-R
Oxaliplatin	N, V, My, Neu	Reversible laryngopharyngeal spasm risk
Procarbazine	Common alkylator, CNS	Disulfiram-like effect with alcohol, MAOI, like HBP after tyramine-rich foods
Temozolomide	Common alkylator but My, has delayed nadir	*Pneumocystis* prophylaxis
Antitumor antibiotics and topoisomerase poisons		
Bleomycin	Plm (↑FIO_2 worsen), Der, Raynaud's, IR*	Monitor DLCO before/during treatment, DA-R
Dactinomycin	My, N, V, mucositis, Ves, alopecia	Radiation recall
Doxorubicin, daunorubicin, epirubicin, idarubicin	TOPOII; My, mucositis, alopecia, ↓LVEF acute/chronic, Ves	Co-administration with heparin aggregate, secondary leukemia, DA-H, radiation recall
Doxorubicin, liposomal	TOPOII; My, ↓LVEF, IR*, PPED	DA-H, radiation recall
Etoposide	TOPOII; My, alopecia, IR with rapid IV, N, V, mucositis	DA-H, DA-R
Irinotecan	TOPOI; My, D: "early onset" with cramping, flushing, vomiting: treat with atropine; "late onset" after several doses: use loperamide 4 mg with first stool then 2 mg q2h until 12 h without stool up to 16 mg/24 h; My dependent on UGT1A1 phenotype, R, ILD	Prodrug requires metabolism to active drug SN-38, which is cleared by UGT1A1 with degree of My dependent on patient UGT1A1 genotype, DA-H
Irinotecan, liposomal	TOPOI; My, D (administer loperamide for D of any severity), IR*, ILD	Consider guide dosing by UGT1A1 genotype testing, CYP3A4; NO recommended dose for T Bili >ULN
Mitoxantrone	TOPOII; Ves, blue urine, nails, and sclerae	Interacts with heparin; DA-H, alopecia, N, V, radiation recall
Topotecan	TOPOI; My, mucositis, N, V, alopecia	DA-R, rare ILD
Indirectly DNA-Interacting Agents		
Pyrimidine analogues		
Capecitabine	My, D, PPED, cardiac adverse events, R, Der	Oral prodrug of 5-FU
Cytarabine (cytosine arabinoside [ara-C])	My, mucositis, CNS (high dose), conjunctivitis (high dose; use steroid eyedrops until 72 h after last dose), noncardiogenic pulmonary edema	Metabolized in tissues by deamination but renal excretion prominent at doses >500 mg; therefore, DA-R in "high-dose" regimens
5-Fluorouracil (5-FU)	My, D, mucositis, CNS, Der, cardiac adverse events, PPED	Toxicity *enhanced* by leucovorin by increasing "ternary complex" with thymidylate synthase; metabolism in tissue; dihydropyrimidine dehydrogenase deficiency increases toxicity; enhances warfarin effect
Gemcitabine	My, N, V, ↑LFT, fever/"flu syndrome"	Rare ARDS; rare HUS, rare PRES, radiosensitization with long infusion
Trifluridine/tipiracil	My, mucositis, N, V, unusual PPED	Trifluridine directly inhibits thymidylate synthase and is incorporated into DNA; tipiracil inhibits thymidine phosphorylase, which degrades trifluridine
Purine analogues		
Fludarabine phosphate	My, mucositis, CNS, Der	Converted to F-ara ATP in cells by deoxycytidine kinase; DA-R
6-Mercaptopurine (6-MP), 6-thioguanine (6-TG)	Mv, N, ↑LFT	6-MP metabolized by xanthine oxidase, decrease dose with allopurinol; 6-MP and 6-TG increased toxicity with thiopurine methyltransferase deficiency
Antifolates		
Methotrexate	My, ↑LFT with fibrosis with chronic use, Plm, R, mucositis	Toxicity *lessened* by leucovorin, bypassing block of dihydrofolate reductase, excreted in urine; DA-R or hold; NSAIDs increase renal toxicity; sequestered in third space fluids
Pemetrexed	My	Supplement folate/B_{12}, omit for CrCl <45 mL/min
Miscellaneous Antimetabolite-Like Agents		
Asparaginase	Thrombosis by decrease of antithrombin IIII, but ↓fibrinogen can cause hemorrhage; ↑glucose; ↓albumin, hypersensitivity; CNS; pancreatitis; ↑LFTs	Decrease protein synthesis; indirect inhibition of DNA synthesis by decreased histone synthesis; blocks methotrexate action
Hydroxyurea	My, N, mucositis, rare ↓CrCl	DA-R, augments antimetabolite effect

(*Continued*)

TABLE 78-5 Commonly Used Cytotoxic Chemotherapy Agents (Continued)

DRUG	ADVERSE EVENTS	NOTES
Antimitotic agents		
Docetaxel	IR*, VLS, My, ↑LFTs, Der, Neu, stomatitis, alopecia, N, V, D	Premedicate with steroids, H_1 and H_2 blockers; DA-H; monitor for second primary malignancies; alcohol in vehicle
Eribulin	My, Neu, ↑QT	DA-H, DA-R
Ixabepilone	My, Neu, IR*, N, V, D, alopecia	Premedicate with steroids, H_1 and H_2 blockers; CYP3A4, DA-H
Nab-paclitaxel	My, Neu, Ves	DA-H, CYP3A4, CYP2C8
Paclitaxel	IR*, My, alopecia, N, V, D, mucositis, Neu, Ves	Premedicate with steroids, H_1 and H_2 blockers; DA-H, CYP3A4, CYP2C8, alcohol in vehicle
Vinblastine	My, Ves, Neu, HBP, Raynaud's, Ves, ↑LFTs, ileus/constipation (use prophylactic stool softeners)	DA-H, unusual; Plm, CYP3A4
Vincristine	Ves, Neu, SIADH, ileus/constipation (use prophylactic stool softeners)	DA-H, CYP3A4; less My than with vinblastine; unusual Plm
Vinorelbine	My, Ves, allergic bronchospasm (immediate), dyspnea/cough (subacute)	DA-H; less neurotoxic than other vincas

Note: Data abstracted in part from publicly available U.S. Food and Drug Administration label. All agents in this class have the potential for prominent embryofetal toxicity; use without contraception by female patients of childbearing potential is not recommended. Effective contraception for female partners who are of childbearing potential of patients undergoing treatment should also be considered; use during lactation is also not recommended; all DNA interacting agents have theoretical risk of late secondary neoplasms, particularly where noted. Indications and events of prominent general medical importance include the following: ARDS, acute respiratory distress syndrome; AUC, area under concentration-time curve; Common alkylator toxicities: N, V, My, alopecia, mucositis, ↓fertility, cumulative lung toxicity; CNS, central nervous system (can include altered sensorium, cortical and cerebellar signs, dysarthria, altered seizure threshold); Cor, corneal keratopathy, consider pretreatment ophthalmologic exam with prophylactic lubricating eyedrops ± ocular steroids; CrCl, creatinine clearance; CYP___, interaction with drugs metabolized by the indicated cytochrome(s) P450; DA-H, dose adjust for hepatic dysfunction; DA-R, dose adjust for renal dysfunction; Der, dermatologic toxicity; HBP, high blood pressure; HUS, hemolytic-uremic syndrome; ILD, interstitial lung disease; IR, infusion reaction; IR*, infusion reaction prophylaxis specifically recommended; LFT, liver function tests; ↓LVEF, left ventricular ejection fraction, monitor echocardiogram; My, anemia, decrease in white blood cells, platelets, with risk of neutropenic fever, hemorrhage, therefore dose reduce or hold dose for decreased neutrophil or platelet counts unless marrow infiltrated by drug-responsive tumor; N, nausea; Neu, peripheral neuropathy; Plm, pulmonary; PPED, palmar-plantar erythrodysesthesia (i.e., hand-foot syndrome); PRES, posterior reversible leukoencephalopathy syndrome; PT, prothrombin time; PTT, partial thromboplastin time; ↑QT, pre- and intratreatment electrocardiogram monitoring, normalize K^+, Mg^{2+}, ionized Ca^{2+}; R, renal injury possible; SIADH, syndrome of inappropriate antidiuretic hormone; TLS, risk of tumor lysis syndrome if brisk response; TOPO___, agent targets the indicated topoisomerase; UGT___, metabolism by UDP-glucuronosyltransferase of the indicated genotype; Ves, extravasation injury possible; V, vomiting; VLS, vascular leak syndrome; VOD, veno-occlusive liver disease.

Alkylating agents (Table 78-5) as a class are cell cycle phase–nonspecific agents. They break down, either spontaneously or after normal organ or tumor cell metabolism, to reactive intermediates that covalently modify bases in DNA. This leads to cross-linkage of DNA strands or the appearance of breaks in DNA as a result of repair efforts. Damaged DNA cannot complete normal cell division; in addition, it activates apoptosis. Alkylating agents share common toxicities: myelosuppression, alopecia, gonadal dysfunction, mucositis, and pulmonary fibrosis. They also share the capacity to cause "second" neoplasms, particularly leukemia, years after use, particularly when used in low doses for protracted periods.

Cyclophosphamide is inactive unless metabolized by the liver to 4-hydroxy-cyclophosphamide, which decomposes into an alkylating species, as well as to chloroacetaldehyde and acrolein. The latter causes chemical cystitis; therefore, excellent hydration must be maintained while using cyclophosphamide. If severe, the cystitis may be attenuated or prevented altogether (if expected from the dose of cyclophosphamide to be used) by mesna (2-*m*ercapto*e*thanesulfo*na*te). Liver disease impairs cyclophosphamide activation. Sporadic interstitial pneumonitis leading to pulmonary fibrosis can accompany the use of cyclophosphamide, and high doses used in conditioning regimens for bone marrow transplant can cause cardiac dysfunction. Ifosfamide is a cyclophosphamide analogue also activated in the liver, but more slowly, and it requires co-administration of mesna to prevent bladder injury. CNS effects, including somnolence, confusion, and psychosis, can follow ifosfamide use; the incidence appears related to low body surface area or decreased creatinine clearance.

Several alkylating agents are less commonly used. Bendamustine has activity in chronic lymphocytic leukemia and certain lymphomas. It is used in transplant preparation regimens. Melphalan shows variable oral bioavailability and undergoes extensive binding to albumin and α_1-acidic glycoprotein. Mucositis appears more prominently; however, it has prominent activity in multiple myeloma. Nitrosoureas break down to carbamylating species that not only cause a distinct pattern of DNA base pair–directed reactivity but also can covalently modify proteins. Lomustine is used to treat brain tumors but causes delayed myelotoxicity and can cause lung injury. Procarbazine is metabolized in the liver and possibly in tumor cells to yield a variety of free radical and alkylating species. In addition to myelosuppression, it causes hypnotic and other CNS effects, including vivid nightmares. It can cause a disulfiram-like syndrome on ingestion of ethanol. Both procarbazine and lomustine are used in the treatment of brain tumors. Dacarbazine (DTIC) is activated in the liver to yield the highly reactive methyl diazonium cation. It causes only modest myelosuppression 21–25 days after a dose but causes prominent nausea on day 1. It is an important component of treatment regimens for Hodgkin's lymphoma and sarcomas. Temozolomide is structurally related to DTIC but is activated by nonenzymatic hydrolysis in tumors and is bioavailable orally. Brain tumors with alkylguanine alkyl transferase deficiency are selectively susceptible to temozolomide, which alkylates the O^6 position of guanine.

Cisplatin was discovered fortuitously by observing that bacteria present in electrolysis solutions with platinum electrodes could not divide. Only the *cis* diamine configuration is active as an antitumor agent. In tumor cells, a chloride is lost from each position. The resulting positively charged species is an efficient DNA interactor, forming Pt-based cross-links. Therefore "platinating agents" are considered with alkylating agents as forming related lesions in DNA. Cisplatin is administered with abundant hydration, including forced diuresis with mannitol to prevent kidney damage; even with the use of hydration, gradual decrease in kidney function is common, along with noteworthy anemia. Hypomagnesemia frequently attends cisplatin use and can lead to hypocalcemia and tetany. Other common toxicities include neurotoxicity with stocking-and-glove sensorimotor neuropathy. Hearing loss occurs in 50% of patients treated with conventional doses. Cisplatin is intensely emetogenic, requiring prophylactic antiemetics. Myelosuppression is less evident than with other alkylating agents. Chronic vascular toxicity (Raynaud's phenomenon, coronary artery disease) is a more unusual toxicity. Carboplatin displays less nephro-, oto-, and neurotoxicity. However, myelosuppression is more frequent, and because the drug is exclusively cleared through the kidney, adjustment of dose for creatinine clearance must be accomplished through use of various dosing nomograms. Oxaliplatin is a platinum analogue with noteworthy activity in colon cancers refractory to other treatments. It is prominently neurotoxic.

Lurbinectedin binds to DNA through the "DNA minor groove" with covalent interaction with the N2 position of certain guanines. Transient altered liver function can occur, as well as cytopenias. Lurbinectedin has activity in small-cell lung cancer. The first example of this agent class, trabectedin, requires a prolonged infusion schedule but is active in certain sarcomas, in part due to its modulation of transcription factor function.

Antitumor Antibiotics and Topoisomerase Poisons Antitumor antibiotics are substances produced by bacteria that provide a chemical defense against hostile microorganisms. They bind to DNA directly and can frequently undergo electron transfer reactions to generate free radicals in close proximity to DNA, leading to DNA damage in the form of single-strand breaks or cross-links. Topoisomerase poisons include natural products or semisynthetic derivatives that modify enzymes that allow DNA to unwind during replication or transcription. These include topoisomerase I, which creates single-strand breaks that then rejoin following the passage of the other DNA strand through the break. Topoisomerase II creates double-strand breaks through which another segment of DNA duplex passes before rejoining. Owing to the role of topoisomerase I in the replication fork, topoisomerase I poisons cause lethality if the topoisomerase I–induced lesions occur in S-phase.

Doxorubicin intercalates into DNA, thereby altering DNA structure, replication, and topoisomerase II function. It can also undergo reduction of its quinone ring system, with reoxidation to form reactive oxygen radicals. It causes predictable myelosuppression, alopecia, nausea, and mucositis. In addition, it can cause acute cardiotoxicity in the form of atrial and ventricular dysrhythmias, but these are rarely of clinical significance. In contrast, cumulative doses >550 mg/m^2 are associated with a 10% incidence of chronic cardiomyopathy. The incidence of cardiomyopathy appears to be related to peak serum concentration, with low-dose, frequent treatment or continuous infusions better tolerated than intermittent higher-dose exposures. Cardiotoxicity has been related to iron-catalyzed oxidation and reduction of doxorubicin in the heart. Dexrazoxane is an intracellular chelating agent that can act as a cardio-protectant. Doxorubicin's cardiotoxicity is increased when given together with trastuzumab, the anti-HER2/neu antibody. Radiation recall or interaction with concomitantly administered radiation to cause local site complications is frequent. The drug is a powerful vesicant, with necrosis of tissue apparent 4–7 days after an extravasation; therefore, it should be administered into a rapidly flowing intravenous line. Dexrazoxane also can mitigate doxorubicin extravasation. Doxorubicin is metabolized by the liver, so doses must be reduced by 50–75% in the presence of liver dysfunction. Daunorubicin is closely related to doxorubicin and is preferable to doxorubicin owing to less mucositis and colonic damage with frequent high doses used in the curative treatment of leukemia. Idarubicin is also used in leukemia treatment and may have somewhat less cardiotoxicity. Encapsulation of daunorubicin into a liposomal formulation has attenuated cardiac toxicity with antitumor activity in Kaposi's sarcoma, other sarcomas, multiple myeloma, and ovarian cancer.

Mitoxantrone is a synthetic topoisomerase II–directed agent with a mechanism similar to the anthracyclines, with less but not absent cardiotoxicity, comparing the ratio of cardiotoxic to effective doses; it is still associated with a 10% incidence of cardiotoxicity at cumulative doses of >150 mg/m^2. Etoposide binds directly to topoisomerase II and DNA in a reversible ternary complex. It stabilizes the covalent intermediate in the enzyme's action where the enzyme is covalently linked to DNA. Prominent clinical effects include myelosuppression, nausea, and transient hypotension related to the speed of administration of the agent. Etoposide is a mild vesicant but is relatively free from other large-organ toxicities.

Camptothecins target topoisomerase I. Topotecan is a camptothecin derivative approved for use in gynecologic tumors and small-cell lung cancer. Toxicity is limited to myelosuppression and mucositis. Irinotecan is a camptothecin with evidence of activity in colorectal carcinoma. Irinotecan is a prodrug, metabolized in the liver to SN-38, its active metabolite. Levels of SN-38 are particularly high in the setting of Gilbert's disease, characterized by defective uridine diphosphate glucuronosyl transferase (UGT) 1A1 and indirect hyperbilirubinemia, a condition that affects ~10% of the white population in the United States. In addition, irinotecan's myelosuppression is clearly influenced by the patient's genotype for UGT1As. Irinotecan causes a delayed (48–72 h) secretory diarrhea related to the toxicity of SN-38. The diarrhea can be treated effectively with loperamide or octreotide; immediate diarrhea when it occurs is responsive to atropine.

Bleomycin remains an important component of curative regimens for Hodgkin's lymphoma and germ cell neoplasms. It forms complexes with Fe^{2+} while also bound to DNA. Oxidation of Fe^{2+} gives rise to superoxide and hydroxyl radicals, causing DNA damage. The drug causes little, if any, myelosuppression. Bleomycin is cleared rapidly, but augmented skin and pulmonary toxicity in the presence of renal failure necessitates dose reduction in renal failure. Bleomycin is not a vesicant and can be administered intravenously, intramuscularly, or subcutaneously. Common side effects include fever and chills, facial flush, and Raynaud's phenomenon. The most feared complication of bleomycin treatment is pulmonary fibrosis, which increases in incidence at >300 cumulative units administered and is minimally responsive to treatment (e.g., glucocorticoids). The earliest indicator of an adverse effect is usually a decline in the carbon monoxide diffusing capacity (DLCO) or coughing, although cessation of drug immediately upon documentation of a decrease in DLCO may not prevent further decline in pulmonary function. Bleomycin is inactivated by a bleomycin hydrolase, which is poorly expressed in skin and lung. Because bleomycin-dependent electron transport is dependent on O_2, bleomycin toxicity may become apparent after exposure to transient very high fraction of inspired oxygen (FIO_2) even late after treatment. Thus, during surgical procedures, patients with prior exposure to bleomycin should be maintained on the lowest FIO_2 consistent with maintaining adequate tissue oxygenation.

Dactinomycin interacts directly with DNA to inhibit RNA transcription. It is important in the curative treatment of pediatric neoplasms, some of which also occur in young adults. Prominent myelosuppression, mucositis, alopecia, radiation recall, and nausea require management.

Antimetabolites A broad definition of antimetabolites would include compounds that interfere with purine or pyrimidine synthesis. Some antimetabolites also cause DNA damage indirectly, through misincorporation into DNA. They tend to convey greatest toxicity to cells in S-phase, and the degree of toxicity increases with duration of exposure. Common toxic manifestations include stomatitis, diarrhea, and myelosuppression.

Methotrexate inhibits dihydrofolate reductase, which regenerates reduced folates from the oxidized folates produced when thymidine monophosphate is formed from deoxyuridine monophosphate. Without reduced folates, cells die a "thymine-less" death. *N*5-Tetrahydrofolate or *N*5-formyltetrahydrofolate (leucovorin) can bypass this block and rescue cells from methotrexate, which is retained in cells by polyglutamylation. Methotrexate is transported into cells by a membrane carrier, and high concentrations of drug can bypass this carrier and allow diffusion of drug directly into cells. These properties have suggested the design of "high-dose" methotrexate regimens with leucovorin rescue of normal marrow and mucosa as part of curative approaches to osteosarcoma in the adjuvant setting and hematopoietic neoplasms of children and adults. Methotrexate is cleared by the kidney via both glomerular filtration and tubular secretion, and toxicity is augmented by renal dysfunction and drugs such as salicylates, probenecid, and nonsteroidal anti-inflammatory agents that undergo tubular secretion. With normal renal function, 15 mg/m^2 leucovorin will rescue 10^{-8}–10^{-6} *M* methotrexate in 3–4 doses. However, with decreased creatinine clearance, doses of 50–100 mg/m^2 are continued until methotrexate levels are $<5 \times 10^{-8}$ *M*. In addition to bone marrow suppression and mucosal irritation, methotrexate can cause renal failure itself at high doses owing to crystallization in renal tubules; therefore, high-dose regimens require alkalinization of urine with increased flow by hydration. Methotrexate can be sequestered in third-space collections and diffuse back into the general circulation, causing

prolonged myelosuppression. Less frequent adverse effects include reversible increases in transaminases and hypersensitivity-like pulmonary syndrome. Chronic low-dose methotrexate can cause hepatic fibrosis. When administered to the intrathecal space, methotrexate can cause chemical arachnoiditis and CNS dysfunction.

Pemetrexed is a folate-directed antimetabolite that inhibits the activity of several enzymes, including thymidylate synthetase (TS), dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase. To avoid toxicity to normal tissues, pemetrexed is given with low-dose folate and vitamin B_{12} supplementation. Pemetrexed has notable activity against certain lung cancers and, in combination with cisplatin, also against mesotheliomas.

5-Fluorouracil (5-FU) represents an early example of "rational" drug design in that tumor cells incorporate radiolabeled uracil more efficiently into DNA than normal cells. 5-FU is metabolized in cells to 5′FdUMP, which inhibits TS. In addition, misincorporation can lead to single-strand breaks, and RNA can aberrantly incorporate FUMP. 5-FU is metabolized by dihydropyrimidine dehydrogenase, and deficiency of this enzyme can lead to excessive toxicity from 5-FU. Oral bioavailability varies unreliably, but prodrugs such as capecitabine have been developed that allow at least equivalent activity to parenteral 5-FU-based approaches. Intravenous administration of 5-FU leads to bone marrow suppression after short infusions but to stomatitis after prolonged infusions. Leucovorin augments the activity of 5-FU by promoting formation of the ternary covalent complex of 5-FU, the reduced folate, and TS. Less frequent toxicities include CNS dysfunction, with prominent cerebellar signs, and endothelial toxicity manifested by thrombosis, including pulmonary embolus and myocardial infarction. Trifluridine is a fluorinated pyrimidine that as the triphosphate is directly incorporated into DNA, evoking DNA damage, and as the monophosphate can inhibit TS. It is administered as a fixed-dose combination with tipiracil, an inhibitor of trifluridine degradation by thymidine phosphorylase.

Cytosine arabinoside (ara-C) is incorporated into DNA after formation of ara-CTP, resulting in S-phase–related toxicity. Continuous infusion schedules allow maximal efficiency, with uptake maximal at 5–7 μ*M*. Ara-C can be administered intrathecally. Adverse effects include nausea, diarrhea, stomatitis, chemical conjunctivitis, and cerebellar ataxia. Gemcitabine is a cytosine derivative that is similar to ara-C in that it is incorporated into DNA after anabolism to the triphosphate, rendering DNA susceptible to breakage and repair synthesis, which differs from that in ara-C in that gemcitabine-induced lesions are very inefficiently removed. In contrast to ara-C, gemcitabine appears to have useful activity in a variety of solid tumors, with limited nonmyelosuppressive toxicities.

6-Thioguanine and 6-mercaptopurine (6-MP) are used in the treatment of acute lymphoid leukemia. Although administered orally, they display variable bioavailability. 6-MP is metabolized by xanthine oxidase and therefore requires dose reduction when used with allopurinol. 6-MP is also metabolized by thiopurine methyltransferase; genetic deficiency of thiopurine methyltransferase results in excessive toxicity.

Fludarabine phosphate is a prodrug of F-adenine arabinoside (F-ara-A). F-ara-A is incorporated into DNA and can cause delayed cytotoxicity even in cells with low growth fraction, including chronic lymphocytic leukemia and follicular B-cell lymphoma. CNS and peripheral nerve dysfunction and T-cell depletion leading to opportunistic infections can occur in addition to myelosuppression.

Agents that indirectly affect purine and pyrimidine metabolism with anti-metabolite-like effects include hydroxyurea, which reversibly inhibits ribonucleotide reductase, resulting in S-phase block. It is orally bioavailable and useful for the acute management of myeloproliferative states. Asparaginase is a bacterial enzyme that causes breakdown of extracellular asparagine required for protein synthesis in certain leukemic cells. This effectively stops tumor cell DNA synthesis, as DNA synthesis requires concurrent protein synthesis. Because asparaginase is a foreign protein, hypersensitivity reactions are common, as are effects on organs such as pancreas and liver that normally support continuing protein synthesis of secreted products. This may result in decreased insulin secretion with hyperglycemia, with or without hyperamylasemia and clotting function abnormalities. Close monitoring of clotting functions should accompany use of asparaginase. Paradoxically, owing to depletion of rapidly turning over anticoagulant factors, thromboses particularly affecting the CNS may also be seen with asparaginase.

Mitotic Spindle Inhibitors Microtubules form the mitotic spindle, and in interphase cells, they are responsible for the cellular "scaffolding" along which various motile and secretory processes occur. Microtubules are composed of repeating heterodimers of α and β isoforms of the protein tubulin. Vincristine binds to the tubulin heterodimer with the result that microtubules are disaggregated. This results in the block of growing cells in M-phase, where a structurally disordered mitotic spindle apparatus is a powerful proapoptotic signal (Fig. 78-3). Vincristine is metabolized by the liver, and dose adjustment in the presence of hepatic dysfunction is required. It is a powerful vesicant, and infiltration can be treated by local heat and infiltration of hyaluronidase. At clinically used intravenous doses, neurotoxicity in the form of glove-and-stocking neuropathy is frequent. Acute neuropathic effects include jaw pain, paralytic ileus, urinary retention, and the syndrome of inappropriate antidiuretic hormone secretion. Myelosuppression is not seen at conventional doses. Vinblastine is similar to vincristine, except that it tends to be more myelotoxic, with more frequent thrombocytopenia and also mucositis and stomatitis. Vinorelbine is a vinca alkaloid that appears to have differences in resistance patterns in comparison to vincristine and vinblastine; it may be administered orally.

The taxanes include paclitaxel and docetaxel. These agents differ from the vinca alkaloids in that the taxanes stabilize microtubules against depolymerization. The "stabilized" microtubules function abnormally and are not able to undergo the normal dynamic changes of microtubule structure and function necessary for cell cycle completion. Taxanes are among the most broadly active antineoplastic agents for use in solid tumors, with evidence of activity in ovarian, breast, prostate, and non-small cell lung cancers, and Kaposi's sarcoma. They are administered intravenously, and their vehicles cause hypersensitivity reactions. Premedication with dexamethasone (8–16 mg orally or intravenously 12 and 6 h before treatment) and diphenhydramine (50 mg) and cimetidine (300 mg), both 30 min before treatment, decreases but does not eliminate the risk of hypersensitivity reactions to the paclitaxel vehicle. A protein-bound formulation of paclitaxel (called *nab-paclitaxel*) has at least equivalent antineoplastic activity and decreased risk of hypersensitivity reactions. Paclitaxel may also cause myelosuppression, neurotoxicity in the form of glove-and-stocking numbness, and paresthesia. Docetaxel causes comparable degrees of myelosuppression and neuropathy. Docetaxel uses a different vehicle that can cause fluid retention in addition to hypersensitivity reactions; dexamethasone premedication with or without antihistamines is also generally used. Cabazitaxel is a taxane with somewhat better activity in prostate cancers than earlier generations of taxanes, perhaps due to superior delivery to sites of disease.

Epothilones represent a class of microtubule-stabilizing agents optimized for activity in taxane-resistant tumors. Ixabepilone has clear evidence of activity in breast cancers resistant to taxanes and anthracyclines such as doxorubicin. Side effects include myelosuppression and peripheral sensory neuropathy. Eribulin is a microtubule-directed agent with activity in patients who have had progression of disease on taxanes. It alters dynamics of microtubule remodeling in cells.

ANTIBODY-DRUG CONJUGATES

In an effort to improve therapeutic index and enhance antitumor effect, antibody-drug conjugates (ADCs; Fig. 78-4) have recently entered clinical practice. In this approach, humanized monoclonal antibodies are covalently linked to cytotoxic agents by "linkers." When bound to target antigens on tumor cells, the nature of the linker determines whether the cytotoxic agent is released only after the ADC is internalized by degradation in a lysosomal compartment, or release of the cytotoxin might occur extracellularly by proteases or physical properties of the tumor microenvironment, in the latter case allowing "bystander" cell killing. Of importance is selection of antibodies with sufficient tumor

TABLE 78-6 Antibody-Drug Conjugates

TOXIC MECHANISM	TARGET ANTIGEN	DISEASE ACTIVITY	NOTES
DNA Structure			
Gemtuzumab ozogamicin	CD33	Acute myeloid leukemia, CD33+	IR*, My, ↑LFTs ± VOD
Inotuzumab ozogamicin	CD22	Pre-B acute lymphoid leukemia	IR*, My, ↑LFTs ± VOD, ↑QT
Loncastuximab tesirine-lpyl	CD19	Diffuse large B-cell lymphoma	VLS, My, Der
Microtubule Structure			
Ado-trastuzumab emtansine	HER2	Breast cancer, HER2+	IR, ↑LFTs, ↓LVEF, My, Plm, Neu
Belantamab mafadotin-blm	CD38	Myeloma	IR, My, Cor
Brentuximab vedotin	CD30	Hodgkin's disease; anaplastic large-cell lymphoma; mycosis fungoides, CD30+	Neu, IR, My, Plm, R, TLS, CYP3A4, ↑LFTs, DA-H, DA-R
Enfortumab vedotin	Nectin-4	Urothelial cancer	↑Glucose ± DKA, Neu, Cor, Ves, Der
Mirvetuximab soravtansine-gynx	Folate receptor α (FRα+)	Ovary, peritoneal, fallopian tube cancer, FRα+	Cor, Neu, My
Polatuzumab vedotin	CD79b	High-grade B-cell lymphoma	Neu, IR*, My, PML, TLS, ↑LFTs
Tisotumab vedotin-tftv	Tissue factor	Uterine cervix cancer	Neu, ↑PT, ↑PTT, Cor, bleeding, Plm
Topoisomerase I			
Fam-trastuzumab deruxtecan-nxki	HER2	HER2 1+/weak BC, HER2 activating mutation+ NSCLC, HER2+ gastric	N/V prophylaxis, ILD prompt evaluate cough, dyspnea, My, ↓LVEF
Sacituzumab govitecan-bziy	Trop2	Triple-negative BC, HR+/HER2– BC, urothelial cancer	IR*, N/V prophylaxis, diarrhea consider loperamide, My esp UGT1A1*28, consider G-CSF

Note: Data abstracted in part from publicly available U.S. Food and Drug Administration label. All agents in this class have the potential for prominent embryofetal toxicity; use without contraception by female patients of childbearing potential is not recommended. Effective contraception for female partners who are of childbearing potential of patients undergoing treatment should also be considered; use during lactation is also not recommended; all DNA interacting agents have theoretical risk of late secondary neoplasms, particularly where noted. Indications and events of prominent general medical importance include the following: BC, breast cancer; Cor, corneal keratopathy, consider pretreatment ophthalmologic exam with prophylactic lubricating eyedrops ± ocular steroids; CYP___, interaction with drugs metabolized by the indicated cytochrome(s) P450; DA-H, dose adjust for hepatic dysfunction; DA-R, dose adjust for renal dysfunction; Der, dermatologic toxicity; DKA, diabetic ketoacidosis; G-CSF, granulocyte colony-stimulating factor; HER2, human epidermal growth factor receptor 2; HR, hormone receptor; ILD, interstitial lung disease; IR, infusion reaction; IR*, infusion reaction prophylaxis specifically recommended; LFT, liver function tests; ↓LVEF, left ventricular ejection fraction, monitor echocardiogram; My, anemia, decrease in white blood cells, platelets, with risk of neutropenic fever, hemorrhage, therefore dose reduce or hold dose for decreased neutrophil or platelet counts unless marrow infiltrated by drug-responsive tumor; N, nausea; Neu, peripheral neuropathy; Plm, pulmonary; PML, progressive multifocal leukoencephalopathy risk; PT, prothrombin time; PTT, partial thromboplastin time; ↑QT, pre- and intratreatment electrocardiogram monitoring, normalize K^+, Mg^{2+}, ionized Ca^{2+}; R, renal injury possible; TLS, risk of tumor lysis syndrome if brisk response; UGT___, metabolism by UDP-glucuronosyltransferase of the indicated genotype; V, vomiting; Ves, extravasation injury possible; VLS, vascular leak syndrome; VOD, veno-occlusive liver disease.

cell selectivity to avoid damage to normal tissue. In addition, the linker strategy should have low spontaneous release of the cytotoxic agent prior to reaching the tumor environment. Table 78-6 lists currently approved ADCs and features of importance relevant to their use for the general internist.

Three major groups of ADCs are currently available, based on the nature of the cytotoxic payload. ADCs targeting DNA structure include those based on calicheamicin, a DNA-interacting antitumor antibiotic too toxic for clinical use but, when used as an ADC, can be useful in the treatment of CD33+ acute myeloid leukemia (gemtuzumab ozogamicin) and CD22+ acute lymphocytic leukemia (inotuzumab ozogamicin). Patients must be monitored for hypersensitivity reactions and for hepatotoxicity due to veno-occlusive disease of hepatic veins, resulting from release of the calicheamicin or its metabolites in the liver. Likewise, the minor groove binder and DNA alkylator pyrrolobenzodiazepine dimer is the basis for CD19-directed loncastuximab tesirine-lpyl, whose use in refractory diffuse large B-cell lymphoma can be complicated by vascular leak syndrome, cytopenias, and cutaneous reactions.

ADCs targeting microtubules (in all cases with the potential for cytopenias and neuropathic adverse events) are of two types. Maytansine derivatives include ado-trastuzumab emtansine, which is an ADC employing the HER2/neu-directed trastuzumab and a highly toxic microtubule-targeted emtansine, which by itself is too toxic for human use; the ADC shows valuable activity in patients with breast cancer who have developed resistance to trastuzumab alone (still watch for cardiac and pulmonary side effects). Mirvetuximab soravtansine-gynx targets folate receptor α in refractory ovarian cancers (monitor for corneal side effects). The second microtubule-directed class of ADCs is derived from the microtubule poison monomethylauristatin E as cytotoxic agent. Brentuximab vedotin is an anti-CD30 ADC with activity in neoplasms such as Hodgkin's lymphoma where the tumor cells frequently express CD30. Polatuzumab vedotin analogously targets CD79a in B-cell lymphomas. Enfortumab vedotin uses an antibody to NECTIN4 to target the vedotin "warhead" to urothelial neoplasms expressing that target. Belantamab mafodotin targets BCMA (B-cell maturation) expressed myeloma but using a distinct microtubule toxin derived from auristatin F. Belantamab mafodotin can cause ocular keratopathy, which requires prospective monitoring.

Topoisomerase I–directed ADCs, including fam-trastuzumab deruxtecan-nxki and sacituzumab govitecan-bziy, are ADCs that allow specific targeting of camptothecin and SN-38, respectively to HER2-positive neoplasms (monitoring for interstitial pneumonitis and cardiac dysfunction) and, in the latter case, triple-negative breast cancers, which abundantly express the antibody target Trop2, a cell surface glycoprotein first discovered in trophoblast cells (but diarrhea should be vigorously addressed with loperamide, similar to what might be encountered with irinotecan). Both agents can cause cytopenias, nausea, and vomiting.

CANCER MOLECULAR TARGETED THERAPY

Agents in this class share the characteristic that they are directed at specific cancer cell molecular targets important in the proliferation of tumors. While these agents can ultimately lead to tumor cell death, this occurs by altered regulation of a specific biochemical pathway affecting tumor cell susceptibility to apoptosis or growth arrest (Fig. 78-3). Since many approved agents of this type are directed at specific mutations present at diagnosis or that arise during the course of a patient's clinical course, their use must be guided by refined diagnostic strategies. Initial molecular testing of a diagnostic biopsy, with repeated biopsies as warranted, should be considered. Alternatively liquid biopsies to examine plasma DNA shed from tumors or present in circulating tumor cells have entered into routine clinical use to assist in making decisions about best strategies to consider.

Hormone Receptor–Directed Therapy Steroid hormone receptor–related molecules were arguably the first "molecular target"

classes of anticancer drugs. When bound to their ligands, these receptors can alter gene transcription in hormone-responsive tissues. While in some cases, such as breast cancer, demonstration of the target hormone receptor is necessary for their use, in other cases such prostate cancer (androgen receptor) and lymphoid neoplasms (glucocorticoid receptor), the relevant receptor is always present in the tumor.

Glucocorticoids are generally given in "pulsed" high doses in leukemias and lymphomas, where they induce cell death in tumor cells. Cushing's syndrome and inadvertent adrenal suppression on withdrawal from high-dose glucocorticoids can be significant complications, along with infections common in immunosuppressed patients, in particular *Pneumocystis* pneumonia, which classically appears a few days after completing a course of high-dose glucocorticoids.

Tamoxifen is a partial estrogen receptor (ER) antagonist; it antagonizes growth in wild-type (ER; also designated ESR1 to specify estrogen receptor α) breast tumors, mirroring its effect on breast tissue, but owing to agonistic activities in vascular and uterine tissue, side effects include increased risk of thromboembolic phenomena and a small increased incidence of endometrial carcinoma, which appears after chronic use (usually >5 years). Progestational agents—including medroxyprogesterone acetate, androgens including fluoxymesterone (Halotestin), and paradoxically, estrogens—have approximately the same degree of activity in primary hormonal treatment of breast cancers that have elevated expression of ER protein. Estrogen itself is not used often due to prominent cardiovascular and uterotropic activity.

Aromatase refers to a family of enzymes that catalyze the formation of estrogen in various tissues, including ovary, peripheral adipose tissue, and some tumor cells. Aromatase inhibitors are of two types: irreversible steroid analogues such as exemestane and the reversible inhibitors such as anastrozole and letrozole. Anastrozole is superior to tamoxifen in the adjuvant treatment of breast cancer in postmenopausal patients with ER-positive tumors. Letrozole treatment affords benefit following tamoxifen treatment. Adverse effects of aromatase inhibitors may include an increased risk of osteoporosis, fatigue, and altered serum lipids. ESR1 mutations of various types are detected at increased frequency after resistance to aromatase inhibitors occurs.

Fulvestrant is the prototype of a selective ER degrader. As a result of its binding, the ER is degraded and ER-dependent proliferation may diminish.

Metastatic prostate cancer is treated primarily by androgen deprivation. Orchiectomy causes responses in 80% of patients. If not accepted by the patient, testicular androgen suppression can also be induced by luteinizing hormone–releasing hormone (LHRH) agonists such as leuprolide and goserelin. These agents cause tonic stimulation of the LHRH receptor, with loss of normal pulsatile activation resulting in net decreased output of luteinizing hormone (LH) by the anterior pituitary. Therefore, as primary hormonal manipulation in prostate cancer, one can choose orchiectomy or an LHRH agonist, but not both. This pathway can also be blocked by relugolix, an oral gonadotropin-releasing hormone antagonist.

The addition of androgen receptor blockers, including flutamide or bicalutamide, is of uncertain additional benefit in extending overall response duration, although pretreatment with these agents before LHRH agonists is important to avoid a surge in testosterone after initial LH release. Enzalutamide also binds to the androgen receptor and antagonizes androgen action in a mechanistically distinct way. Somewhat analogous to inhibitors of aromatase, agents have been derived that inhibit testosterone and other androgen synthesis in the testis, adrenal gland, and prostate tissue. Abiraterone inhibits 17 α-hydroxylase/C17,20 lyase (CYP17A1) and has been shown to be active in prostate cancer patients experiencing disease progression despite androgen blockade.

Tumors that respond to a primary hormonal manipulation may frequently respond to second and third hormonal manipulations. Thus, breast tumors that had previously responded to tamoxifen have, on relapse, notable response rates to withdrawal of tamoxifen itself or to subsequent addition of an aromatase inhibitor or progestin. Likewise, initial treatment of prostate cancers with leuprolide plus flutamide may be followed after disease progression by response to withdrawal of flutamide. These responses may result from the removal of antagonists from mutant steroid hormone receptors that have come to depend on the presence of the antagonist as a growth-promoting influence.

Non-Receptor-Linked Tyrosine Kinase Antagonists Table 78-7 lists currently approved non–hormone receptor pathway-directed molecularly targeted chemotherapy agents, with features of their use of import to the generalist, particularly in recognizing potential drug-induced morbidities and interactions with other classes of drugs. The basis for discovery of drugs of this type was the prior knowledge of oncogene-directed pathways driving tumor growth (Fig. 78-3). In most cases, non-receptor tyrosine kinases ultimately activate signaling through the RAF/MEK/MAP kinase cascade, in common with the receptor-linked tyrosine kinases. Diagnostic demonstration of an active non-receptor tyrosine kinase may guide selection of an agent. A repeated preclinical and clinical observation in a variety of tumor types is that mutational activation of the tyrosine kinase target induces a state of "oncogene addiction" on the part of the tumor. This then is the basis for a "synthetic lethal" effect of the kinase inhibitor with respect to tumor viability.

In hematologic tumors, the prototypic agent of this type is imatinib, which targets the ATP binding site of the $p210^{bcr\text{-}abl}$ protein tyrosine kinase that is formed as the result of the chromosome 9;22 translocation producing the Philadelphia chromosome in chronic myeloid leukemia (CML). Subsequent studies have shown value of imatinib in gastrointestinal stromal tumor (GIST) and certain myeloproliferative disorders, driven by certain mutants of cKIT and platelet-derived growth factor receptor (PDGFR). Imatinib has lesser activity in the blast phase of CML, where the cells may have acquired additional mutations in $p210^{bcr\text{-}abl}$ itself or other genetic lesions. Imatinib's side effects are relatively limited in most patients and include hepatic dysfunction, diarrhea, and fluid retention. Rarely, patients receiving imatinib have decreased cardiac function, which may persist after discontinuation of the drug. The quality of response to imatinib enters into the decision about when to refer patients with CML for consideration of stem cell transplant approaches. Nilotinib is a tyrosine protein kinase inhibitor with activity against $p210^{bcr\text{-}abl}$ but with increased potency and perhaps better tolerance by certain patients. Dasatinib, another inhibitor of the $p210^{bcr\text{-}abl}$ oncoproteins, also has activity against certain mutant variants of $p210^{bcr\text{-}abl}$ that are refractory to imatinib and arise during therapy or are present de novo. Dasatinib also has inhibitory action against kinases belonging to the src tyrosine protein kinase family; this activity may contribute to its effects. The T315I mutant of $p210^{bcr\text{-}abl}$ is resistant to imatinib, nilotinib, bosutinib, and dasatinib; ponatinib has activity in patients with this T315Ip210$^{bcr\text{-}abl}$, but ponatinib has noteworthy associated thromboembolic toxicity. Use of this class of targeted agents is thus critically guided not only by the presence of the $p210^{bcr\text{-}abl}$ tyrosine kinase, but also by the presence of specific mutations in the ATP binding site. Asciminib is a first-in-class non-ATP site $p210^{bcr\text{-}abl}$ inhibitor that also has activity in BRC/ABL T315I mutant CML.

Janus kinases (JAK) 1 and 2 are mutated in certain myeloproliferative states; cytopenias and infrequent arrhythmias infrequently complicate the use of ruxolitinib, the prototypic JAK inhibitor. Bruton's tyrosine kinase (BTK) is an intrinsic component of B-cell antigen receptor signaling activated in many types of proliferating B cells and B-cell neoplasms. Irreversible inhibitors of BTK, including ibrutinib, acalabrutinib, and zanubrutinib, have noteworthy activity in certain lymphomas. Cytopenias and cardiac arrhythmias can occur, along with propensity to infection (indeed, the BTK was discovered as deficient in congenital hypogammaglobulinemia, presenting with repeated infections in childhood). Initial use of the BTK inhibitors requires consideration of prophylaxis against tumor lysis syndrome in case of a robust lympholytic effect of the agent. If and when resistance to irreversible BTK inhibitors develops (often associated with a C481S mutation), the noncovalent inhibitor pirtobrutinib may have activity.

Receptor-Linked Tyrosine Kinase Antagonists Mutated *EGFR* drives a significant fraction of non-small-cell lung cancers (NSCLCs). Erlotinib and gefitinib are the prototypic EGFR antagonists that, in early clinical trials, showed evidence of responses in a small

TABLE 78-7 Molecularly Targeted Agents

DRUG	TARGET/INDICATION	ADVERSE EVENTS	NOTES
Non-Receptor Tyrosine Kinase Antagonists			
Acalabrutinib	BTK/certain B-cell malignancies	My, atrial fibrillation/flutter, infection	CYP3A4; avoid PPIs and stagger doses with H2 blockers; irreversible BTK inhibitor
Asciminib	BCR/ABL/CML chronic phase after 2 TKIs or with BCR/ABL T315I	My, ↑lipase, ↑amylase, HBP, hypersensitivity, cardiac events	CYP3A4, CYP2C9, Pgp; not an ATP site inhibitor but inhibit by allosteric mechanism binding to myristoyl pocket in BCR/ABL
Bosutinib	BCR/ABL wild-type, some mutants/CML	My, ↑LFT, cardiac, R, fluid retention	CYP3A4, PPI (use short-acting antacids or H2 blocker staggered with dose)
Dasatinib	BCR/ABL/Ph+ CML, Ph+ ALL	My, pulmonary hypertension, fluid retention, ↓LVEF, ↑LFT, Der	CYP3A4, avoid PPIs and stagger doses with H2 blockers; caution with agents with ↑QT
Ibrutinib	As with acalabrutinib	My, stomatitis, HBP, arrhythmia, TLS	CY3A4, second primary malignancy
Imatinib	ABL, BCR/ABL wild-type, cKIT PDGFR/ CML, some ALL, certain GISTs, eosinophil, mast cell, myelodysplastic syndromes	My, edema, fluid retention, ↓LVEF, ↑LFT rare liver failure, GI perforation, Der, TLS, ↓CrCl	DA-H, DA-R, CYP3A4, CYP2D6; hemorrhage at tumor site in GIST, cardiogenic shock with high eosinophil levels; monitor TFTs with thyroid replacement
Nilotinib	BCR/ABL wild-type/CML	CHF, ↑LFT, ↑QT, fluid retention, ↑lipase, TLS	CYP3A4, CYP2C8, CYP2C9, CYP2D6, CYP2B6; no food 2 h before, 1 h after dose; monitor electrolytes, TFTs
Pirtobrutinib	As with acalabrutinib	My, arrhythmia, infection, hemorrhage	DA-R, CYP3A4; CYP2C8, 2C19, Pgp, BCRP substrates; reversible BTK inhibitor, second primary malignancy
Ponatinib	T315I mutant BCR/ABL CML	Clotting, ↑LFT, TLS, ↓LVEF, pancreatitis, Neu, arrhythmia	CYP3A4, PRES possible
Ruxolitinib	JAK1,2/myeloproliferative disorders	My, dizziness, headache	DA-R, DA-H, CYP3A4 or with fluconazole >200 mg doses except with GVHD
Zanubrutinib	As with acalabrutinib	My, hemorrhage, cardiac arrhythmias	CYP3A4
Receptor-Linked Tyrosine Kinase Antagonists			
Afatinib	Nonresistant ATP site mutated *EGFR*/ NSCLC	D, Der, Cor, ILD; ↑LFT	DA-R, DA-Pgp inhibitors, no food 2 h before, 1 h after dose
Alectinib	*ALK* rearranged/NSCLC	↑LFT, ILD, R, bradycardia, ↑CPK	Administer with food; can have muscle pain, tenderness, weakness
Avapritinib	*PDGFR* mutants/GIST, mastocytosis	N, edema, CNS, sleep, mood change, hallucinations	CYP3A4, monitor for intracranial hemorrhage
Capmatinib	*MET* + exon 14 skip/NSCLC	ILD, ↑LFT, photosensitivity, pancreatitis, hypersensitivity	
Ceritinib	*ALK* rearranged/NSCLC	GI, ↑LFT, ↑glucose, ↑QT, bradycardia, pancreatitis	CYP3A4, CYP2C9; if ILD, permanently discontinue
Crizotinib	*ALK* rearranged/NSCLC; inflammatory myofibroblastic tumor, anaplastic large-cell lymphoma	ILD, ↑LFT, ↑QT, bradycardia, ↓vision	CY3A4
Dacomitinib	*EGFR* exon 19 deletion or exon 21 L858R/ NSCLC	D, Der: hold and/or dose reduce; ILD (permanently discontinue)	CYP2D6; avoid PPIs, use local antacids or give 6 h before or 10 h after H2 blockers
Erdafitinib	FGFR2/3 altered/urothelial cancer after Pt regimen	Der, D, stomatitis, retina (ophthalmologic exam before/during)	CYP2C9, CYP3A4, also organic cation transporter 2 and Pgp substrates, give 6 h before/after Pgp substrates; ↑PO_4 due to effect on FGFR2/3/Klotho
Erlotinib	As with afatinib; also wild-type EGFR/ NSCLC 2nd line or pancreatic 1st line with gemcitabine	Der, D, R, ILD, ↑LFT, rare microangiopathic anemia	CYP3A4, give 1 h before/2 h after meals, avoid PPIs, stagger with H2 blockers; alter warfarin effect
Fruquintinib	Target VEGFR1,2,3/CRC	HBP, hemorrhage, arterial thromboses, infection, GI perforation, ↑LFT, proteinuria, ↓wound healing, allergic bronchospasm	CYP3A4; unusual, PPED, PRES
Futibatinib	*FGFR2* gene fusions/ cholangiocarcinoma	Retina (ophthalmologic exam before/during)	CYP3A4, Pgp substrates; ↑PO_4 due to effect on FGFR2/3/ Klotho, tissue and vascular calcification
Gefitinib	As with afatinib	Der, D, ILD, ocular keratitis, GI perforation	CYP3A4; avoid with PPIs; monitor warfarin effect
Gilteritinib	*FLT3* mutated/AML	↑LFT, ↑QT, myalgia/arthralgia, N, V, GI, Der, edema, dyspnea	Monitor for PRES, pancreatitis, ↑Cr, eye disorders
Infigratinib	*FGFR2* variants/cholangiocarcinoma	Retina (ophthalmologic exam before/during)	CYP3A4, avoid gastric acid reduction or stagger with H2 blockers or locally acting agents, ↑PO_4 due to effect on FGFR2/3/Klotho, soft tissue including myocardial mineralization
Lapatinib	HER2/HER2+ breast cancer	↓LVEF, ↑LFT, N, V, D, PPED	CYP3A4, CYP2C8, Pgp substrate; interaction, ILD, ↑QT
Larotrectinib	*NTRK* gene fusion without a resistance mutation/any solid tumor	CNS with potential cognitive impairment; ↑LFT	CYP3A4
Lorlatinib	*ALK* rearranged/NSCLC	Hyperlipidemia, AV block, CNS including seizures, mental status changes	CYP3A4 with severe ↑LFT with CYP3A interactors; monitor for ILD and discontinue if occur
Neratinib	As with lapatinib	N, V, D, abdominal pain, ↑LFT	CYP3A4, aggressive D prophylaxis with loperamide; avoid PPIs and stagger H2 blocker doses

(*Continued*)

TABLE 78-7 Molecularly Targeted Agents (Continued)

DRUG	TARGET/INDICATION	ADVERSE EVENTS	NOTES
Osimertinib	*EGFR* exon 19 altered or exon 21L858R or T790M mutations/NSCLC	ILD, ↑QT, ↓LVEF, Cor	CYP3A4
Pemigatinib	*FGFR2* fusion or other rearrangement/ cholangiocarcinoma *FGFR1* rearranged myeloid/lymphoid neoplasms	N, D, stomatitis, ↑PO_4 due to effect on FGFR2/3/Klotho	CYP3A4, retinal detachment: ophthalmologic exam with ocular tomography before and every 2–3 months during treatment
Pralsetinib	*RET* mutant or fusion/NSCLC, thyroid carcinomas	ILD, HBP, hemorrhage, ↑LFT, TLS, ↓wound healing	CYP3A4, Pgp
Quizartinib	*FLT3* mutated/AML	↑QT with risk of cardiac arrest	CYP3A4
Repotrectinib	Target *ROS1* rearranged/NSCLC	CNS, ILD, ↑LFT, myalgia, ↑CPK	CYP3A4, Pgp, OCs; also target TRKA,B,C
Selpercatinib	*RET* mutant or fusion/NSCLC, thyroid carcinomas	↑LFT, ↑QT, HBP, bleeding, ↓wound healing; hold 1 week prior and 2 weeks after surgery	Avoid with antacids, but take if not avoidable with food if PPI or stagger with other antacid, CYP3A, CYP2C8
Tepotinib	*MET* with exon 14 skipping mutations/ NSCLC	ILD, ↑LFT	CYP3A4, Pgp; DA-H
Tucatinib	As with lapatinib	↑LFT, D	CYP3A4, CYP2C8
KRAS-G12C/RAF/MEK Antagonists			
Adagrasib	*KRAS* G12C mutation/NSCLC	N, V, D, ↑LFT, ↑QT, ILD	CYP3A4, CYP2C9, CYP2D6, agents that ↑QT
Binimetinib	Targets MEK/*BRAF* V600E or V600K mutated melanoma combined with encorafenib	↓LVEF, venous thrombosis; ocular, ILD, ↑LFT, rhabdomyolysis	DA-H
Cobimetinib	Targets MEK/*BRAF* V600E or V600K melanoma combined with vemurafenib; alone in *BRAF* V600E or V600K histiocytic neoplasms	Hemorrhage, retinal ↓LVEF, Der, photosensitivity, rhabdomyolysis, ↑LFT	CYP3A4, new malignancies, cutaneous and noncutaneous
Dabrafenib	Targets *BRAF* in *BRAF* V600E or V600K mutated tumors (not CRC) with trametinib	Hemorrhage, uveitis ↓LVEF, Der, ↑glucose, hemolysis if G6PD deficient, pyrexia	CYP3A4, CYP2C8, CYP2C9, CYP2C19, CYP2B6, new malignancies, cutaneous and noncutaneous
Encorafenib	Targets *BRAF* in *BRAF* V600E or V600K mutated tumors combined with binimetinib (melanoma) or CRC with cetuximab	Hemorrhage, uveitis, ↑QT	CYP3A4, organic anion transporter 1B1, BCRP interactions, new malignancies, cutaneous and noncutaneous
Sotorasib	*KRAS* G12C mutation/NSCLC	↑LFT, ILD, N, V, D	Avoid with PPIs and H2 receptor antagonists; if necessary, administer 4 h before or 10 h after a local antacid, avoid CYP3A4, Pgp substrates
Trametinib	Targets MEK/*BRAF* V600E or V600K mutated tumors (not colorectal) combined with dabrafenib	Hemorrhage, venous thromboembolism, ↓LVEF, ILD, pyrexia, Der, ↑glucose	Colitis with GI perforation, ocular including retinal vein occlusion, new malignancies, cutaneous and noncutaneous
Vemurafenib	Targets BRAF in *BRAF* V600E or V600K mutated melanoma and Erdheim-Chester disease	Der including Stevens-Johnson, anaphylaxis and allergic hypersensitivity, ↑QT, ↑LFT, photosensitivity, radiation recall	Dupuytren's contracture and plantar fascial fibromatosis has occurred; usually combined with cobimetinib in melanoma; CYP3A4, CYP1A2, CYP2D6, new primary cutaneous and noncutaneous neoplasms
Multikinase Antagonists			
Axitinib	VEGFR, PDGFR, KIT/RCC	HBP, hemorrhage, thrombotic events; D, other GI including GI perforation, PPED, hypothyroidism, PRES, proteinuria, ↑LFT	DA-H, CYP3A4/5
Brigatinib	ALK, EGFR/NSCLC	ILD, bradycardia, HBP, visual disturbances, ↑glucose, ↑CPK	CYP3A4, decreased hormonal contraceptive effectiveness
Cabozantinib	VEGFR2, MET, AXL, RET/RCC, HCC, certain thyroid carcinoma	HBP, hemorrhage, thrombotic events, D, other GI including fistula, perforation, wound healing, PRES, PPED, proteinuria, ONJ	CYP3A4
Capivasertib	Target *PIK3CA/AKT1/PTEN*- axis; BC-HR(+) with mutation in pathway	Hypersensitivity reactions, Der, ↑glucose, pneumonitis, ILD, D	CYP3A4, CYP2C9, BCRP substrates
Entrectinib	*NRTK* gene fusion/any solid tumor; *ROS1* gene alteration/NSCLC	ILD, ↑LFT, photosensitivity, ↓LVEF, CNS effect, skeletal fractures; hyperuricemia, ↑QT,	CYP3A4, ophthalmologic exam if vision change
Fedratinib	JAK2, FLT3, RET/myeloproliferative diseases	My, N, V, D, ↑LFT pancreatitis, encephalopathy: check thiamine levels prior, replete if deficient	CYP3A4, CYP2C19
Lenvatinib	VEGFR1/2/3, FGFR1/2/3/4, PDGFRα, KIT, RET/thyroid, RC, HCC, endometrial cancer	HBP, ↓LVEF, bleeding, arterial/venous clots, RF, ONJ, proteinuria, ↑LFT, GI including D, fistula/perforation, ↓wound healing, ↑QT, ↓Ca^{2+}, PRES, ↓TFT	DA-H, DA-R
Midostaurin	FLT3 mutated/AML newly diagnosed, mast cell neoplasms	ILD; N, D	CYP3A4; many other protein kinase targets in addition to FLT3

(*Continued*)

TABLE 78-7 Molecularly Targeted Agents (Continued)

DRUG	TARGET/INDICATION	ADVERSE EVENTS	NOTES
Pazopanib	VEGFR 1/2/3, KIT, PDGFR, and FGFR/ RCC soft tissue sarcoma (not GIST or adipocytic)	D, HBP; arterial and venous thrombosis ± embolism, ↑QT, hemorrhage, ↑LFT potentially severe/fatal; GI perforation or fistula; proteinuria, ↓TFT, ↓LVEF, PRES, ILD, thrombotic microangiopathy	CYP3A4, CYP22D6, CYP2C8 interaction; use with simvastatin increases the risk of ALT elevations and should be undertaken with caution; avoid with PPIs or H2 blocker, stagger with other antacid doses
Regorafenib	VEGFR1/2/3, KIT, RET, PDGFR-α/β, FGFR1/2, TIE2, DDR2, Trk2A, Eph2A, RAF1, BRAF, BRAF V600E, SAPK2, PTK5, and ABL/CRC, GIST	↑LFT potentially severe/fatal; hemorrhage, thromboses, PPED, Der, HBP, ↓LVEF, ↑QT, GI perforation	CYP3A4, impaired TSH suppression in thyroid cancer
Sorafenib	VEGFR2, VEGFR3, PDGFRβ, Flt3, KIT, RAF1, BRAF/RCC, HCC, differentiated thyroid carcinoma	D, ↑LFT potentially severe/fatal; hemorrhage, PPED, Der, HBP, ↓LVEF, ↑QT, GI perforation	As with regorafenib
Sunitinib	VEGFRs; PDGFR, RET, KIT; other protein kinases/RCC, pancreatic neuroendocrine, GIST	HBP, ↑LFT potentially severe/fatal; hemorrhage, GI perforation, CHF, altered TFTs, ONJ, ↓wound healing, proteinuria, R	CYP3A4, rare ↑QT, rare TLS in RCC and GIST with high tumor burden
Vandetanib	VEGFR, RET, EGFR/medullary thyroid cancer	D, Der, HBP, ↑QT, thromboses, ↓LVEF, fistulas, ILD, ONJ, proteinuria, PRES	CYP3A4
Cyclin-Dependent Kinase (CDK) Inhibitors			
Abemaciclib	CDK4/6/HR+ BC	D, My, ↑LFT, venous thromboembolism, ILD	CYP3A4, avoid concomitant use of ketoconazole
Palbociclib	CDK4/6/HR+ BC	D, My, stomatitis, ILD, D	CYP3A4
Ribociclib	CDK4/6/HR+ BC	Der, ILD, ↑QT, ↑LFT, My	CYP3A4, agents known to ↑QT
Protein Homeostasis Modulators			
Bortezomib	Proteasome inhibitor/multiple myeloma, mantle cell lymphoma	Neu, N, V, D, C, ↓BP, My, ILD, ↑LFT worsening cardiac disease	Rare TLS, PRES
Carfilzomib	Proteasome inhibitor/multiple myeloma	↓LVEF, myocardial ischemia, R, TLS, pulmonary including ARDS, ILD, HBP, IR*, thrombosis, hemorrhage, PRES, thrombocytopenia, thrombotic microangiopathy, ↑LFT potentially severe	Administer after a hemodialysis procedure
Ixazomib	Proteasome inhibitor/multiple myeloma relapsed, not as maintenance	Thrombocytopenia, N, V, D, C, Neu, edema, Der, thrombotic microangiopathy, ↑LFT	DA-R, DA-H, CYP3A4
Nuclear Export Inhibitor			
Selinexor	Targets exportin 1/multiple myeloma, certain DLBCLs	My, N, V, D, anorexia, ↓Na^+, CNS, cataract development or progression	Advise against driving or dangerous equipment operation if CNS altered
Chromatin-Modifying Epigenetic Modulators			
DNA Hypomethylating Agents			
Azacytidine	Target DNA methyltransferase/ myelodysplastic syndromes, AML	My, ↑LFT, TL, CNS	Monitor if renal impairment, more N, V, D if SC administration
Decitabine	As with azacytidine	My	Combined with cedazuridine (a cytidine deaminase inhibitor) in an oral regimen
Histone Deacetylase Inhibitors			
Belinostat	Peripheral T-cell lymphoma, relapsed or refractory	My, ↑LFT, TLS, N, V	
Panobinostat	Multiple myeloma, relapsed or refractory	My, hemorrhage, ↑LFT, ↓Na^+, ↓K^+, ↓PO_4, ↑Cr	CYP3A4, CYP2D6, avoid agents that ↑QT
Romidepsin	CTCL after one systemic therapy	My, ↑QT	CYP3A4, alter warfarin effect, may ↓ effectiveness of oral contraceptives
Vorinostat	CTCL after two systemic therapies	My, N, V, D, venous thrombosis, ↑glucose	Monitor with mild or moderate liver disease
Histone Methyltransferase Inhibitors			
Tazemetostat	Target *EZH2* mutant or nonmutant/ epithelioid sarcoma, certain follicular lymphomas	N, V, C, abdominal pain	CYP3A4, increased risk of secondary malignancies (MDS, AML, lymphomas)
Transcription Factor Modulation			
Arsenic trioxide	Target PML-RARα and redox homeostasis/t(15;17) acute promyelocytic leukemia	↑QT, hypersensitivity	APL differentiation syndrome: with pulmonary dysfunction/infiltrate, pleural/pericardial effusion, fever, treat with dexamethasone ± hydroxyurea
Belzutifan	Target HIF2α/von Hippel-Lindau (VHL) disease–associated RCC, CNS hemangioblastomas, GI neuroendocrine tumors, non-VHL RCC after PD-1, VEGFR inhibitor	Anemia, hypoxia, N, ↑Cr, ↑glucose	CYP2C19, UGTB17
Glasdegib	Targets smoothened receptor in hedgehog pathway/AML	↑QT	CYP3A4, transmission to potentially pregnant partner through semen or to blood product recipient

(*Continued*)

TABLE 78-7 Molecularly Targeted Agents (Continued)

DRUG	TARGET/INDICATION	ADVERSE EVENTS	NOTES
Nirogacestat	Targets γ-secretase to inhibit Notch signaling/desmoid tumor	D (can be severe), ovarian dysfunction, ↑LFTs, PO_4 and K^+ abnormalities	CYP3A4; avoid PPIs and stagger doses with H2 blockers; nonmelanoma skin cancers; Der: monitor before and during treatment
Sonidegib	Targets smoothened receptor in hedgehog pathway/basal cell carcinoma locally advanced or metastatic	Musculoskeletal adverse events with ↑CPK, potential R, N, V, D	As with glasdegib
Tretinoin	Target PML-RARα/t(15;17) acute promyelocytic leukemia	Der including cheilitis, skin dryness; ↑ intracranial pressure; ↑lipids, ↑LFT, usually resolve	As with arsenic trioxide; also headache, visual changes may indicate ↑intracranial pressure; check for papilledema
Vismodegib	As with sonidegib	Musculoskeletal adverse events, N, V, D, C	Transmission to potentially pregnant partner through semen or to blood product recipient
Apoptosis Modulation			
Venetoclax	Targets BCL2/CLL, SLL; AML + azacytidine, decitabine, or low-dose cytarabine	My, D, TLS	CYP3A4, stagger with Pgp substrates, no live attenuated vaccines prior to, during, or after venetoclax treatment
Metabolism Modulation: mTOR Inhibitors/PI Kinase/IDH Inhibitors			
Alpelisib	*PIK3CA* mutated/HR+HER2– BC	Der, hypersensitivity, ↑glucose, ILD, D	CYP3A, CYP2C9, BCRP substrates
Copanlisib	PI3Kα,δ/FL	My, HBP, noninfectious pneumonitis, ↑glucose, Der	CYP3A4
Duvelisib	PI3Kδ,γ/CLL, SLL, FL	My, infection, D, colitis, Der, pneumonitis, ↑LFTs	CYP3A4
Enasidenib	IDH2 mutated/AML	N, V, D, ↑LFTs	AML differentiation syndrome with pulmonary dysfunction/infiltrate, pleural/pericardial effusion, fever treat with dexamethasone ± hydroxyurea
Everolimus	mTOR/RCC, tuberous sclerosis–associated neoplasms, HR+ BC, neuroendocrine, pancreatic, lung, GI NOT functional carcinoid	My, noninfectious pneumonitis, infections, hypersensitivity reactions, R, impaired wound healing, ↑glucose, ↑lipids, stomatitis	CYP3A4, Pgp substrates, angioedema with concomitant ACE inhibitors, consider alcohol-free mouthwash when starting treatment; risk of reduced efficacy of vaccination
Ivosidenib	IDH1 mutated/AML, cholangiocarcinoma, MDS	↑QT, Guillain-Barré syndrome	CYP3A4, QT-prolonging agents; AML differentiation syndrome requiring corticosteroid treatment
Idelalisib	PI3Kδ/non-first-line CLL, SLL, FL	Fatal or serious ↑LFTs, D, colitis with GI perforation, pneumonitis, infection, Der, hypersensitivity	CYP3A4, not with bendamustine or rituximab
Olutasidenib	IDH1/AML	↑LFTs	CYP3A4, differentiation syndrome requiring corticosteroid ± hydroxyurea treatment
Sirolimus protein bound particles	mTOR/perivascular epithelioid cell tumor (PEComa)	My, stomatitis, infection, ↓K^+, IR, ↑glucose, ILD, hemorrhage, male infertility	CYP3A4, avoid live vaccines
Temsirolimus	mTOR/RCC	Hypersensitivity, ↑LFTs, infection, ILD, stomatitis, thrombocytopenia, N, ↑glucose, ↑lipids, ↓wound healing, GI perforation, R ± proteinuria	DA-H, CYP3A4
Poly-ADP Ribose Polymerase (PARP) Inhibitors			
Niraparib	Ovarian, fallopian tube, or primary peritoneal cancer with good response to Pt	My, N, V, D, HBP, PRES	MDS
Olaparib	Ovarian: as with niraparib also with various *BRCA* or HRR mutations; BC mutant *BRCA,* HER2–; pancreatic mutant *BRCA* with good response to Pt; prostate with *BRCA* or HRR mutations	My, N, stomatitis, DVT ± PE, rare ILD	MDS, CY3A4
Rucaparib	As with niraparib; prostate *BRCA* mutated after hormone and after taxane	My, stomatitis, N, V, D, ↑LFTs	MDS
Talazoparib	BC *BRCA* mutated HER2–; prostate cancer, castrate-resistant HRR mutation(+), with enzalutamide	My, N, V, D, ↑LFTs	MDS
Miscellaneous			
^{177}Lu-dotatate	Target somatostatin receptor (SSR)/ gastroenterohepatic neuroendocrine tumors (SSR)+	My, R, ↑LFTs, IR,	Neuroendocrine hormonal crisis including flushing, diarrhea, hypotension, bronchoconstriction; secondary MDS, risks from radiation exposure
^{177}Lu-vipivotide tetraxetan	Target prostate-specific membrane antigen (PSMA)/refractory prostate cancer	My, R	Temporary or permanent infertility, risks from radiation exposure

(*Continued*)

TABLE 78-7 Molecularly Targeted Agents (Continued)

DRUG	TARGET/INDICATION	ADVERSE EVENTS	NOTES
Tagraxofusp-erzs	Targets CD123 (IL-3 receptor)/blastic plasmacytoid dendritic cell neoplasm	IR*, ↑LFTs, VLS	Delivers a fragment of diphtheria toxin
Ziv-aflibercept	Targets VEGF by solubilized VEGFR/CRC with chemotherapy after an oxaliplatin regimen	↓Wound healing with fistula, GI perforation, hemorrhage, HBP, DVT, arterial thromboembolism, proteinuria, PRES	Administer over 1 h, not as push or bolus

Note: Data abstracted in part from publicly available U.S. Food and Drug Administration label. All agents in this class have the potential for prominent embryofetal toxicity; use without contraception by female patients of childbearing potential is not recommended. Effective contraception for female partners who are of childbearing potential of patients undergoing treatment should also be considered; use during lactation is also not recommended. Gene products are in capital letters; genes are italicized in capitals. Indications and events of prominent general medical importance include the following: ACE, angiotensin-converting enzyme; ALK, anaplastic lymphoma kinase; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; ARDS, acute respiratory distress syndrome; AV, atrioventricular; BC, breast cancer; BCRP, breast cancer resistance protein; BP, blood pressure; *BRCA*, breast cancer gene; BTK, Bruton's tyrosine kinase; C, constipation; CHF, congestive heart failure; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CNS, can include altered sensorium, cortical and cerebellar signs, dysarthria, altered seizure threshold; Cor, corneal keratopathy, consider pretreatment ophthalmologic exam with prophylactic lubricating eyedrops ± ocular steroids; CRC, colorectal cancer; CrCl, creatinine clearance; CTCL, cutaneous T-cell lymphoma; CYP___, interaction with drugs metabolized by the indicated cytochrome(s) P450; D, diarrhea; DA-H, dose adjust for hepatic dysfunction; DA-R, dose adjust for renal dysfunction; Der, dermatologic toxicity; DLBCL, diffuse large B-cell lymphoma; DVT, deep vein thrombosis; EGFR, epidermal growth factor receptor; FGFR, fibroblast growth factor receptor; FL, follicular lymphoma; GIST, gastrointestinal stromal tumor; GVHD, graft-versus-host disease; H2, histamine receptor antagonist; HBP, high blood pressure; HCC, hepatocellular carcinoma; HER2, human epidermal growth factor receptor 2; HRR, homologous recombination repair; HR, hormone receptor; HUS, hemolytic-uremic syndrome; IDH, isocitrate dehydrogenase; ILD, interstitial lung disease; IR, infusion reaction; IR*, infusion reaction prophylaxis specifically recommended; LFT, liver function tests; LVEF, left ventricular ejection fraction monitor echocardiogram; MDS, myelodysplastic syndrome; MET, hepatocyte growth factor; My, anemia, decrease in white blood cells, platelets, with risk of neutropenic fever, hemorrhage, therefore dose reduce or hold dose for decreased neutrophil or platelet counts unless marrow infiltrated by drug-responsive tumor; N, nausea; Neu, peripheral neuropathy; NSCLC, non-small-cell lung cancer; OC, oral contraceptive; ONJ, osteonecrosis of the jaw; PDGFR, platelet-derived growth factor receptor; PE, pulmonary embolism; Pgp, P-glycoprotein drug resistance protein; Ph, Philadelphia chromosome; Plm, pulmonary; PML, progressive multifocal leukoencephalopathy risk; PPED, palmar-plantar erythrodysesthesia (i.e., hand-foot syndrome); PPI, proton pump inhibitor; PRES, posterior reversible leukoencephalopathy syndrome; Pt, platinating agent; PT, prothrombin time; PTT, partial thromboplastin time; ↑QT, increase of QT interval needs pre- and intratreatment electrocardiogram monitoring and normalizing K^+, Mg^{2+}, ionized Ca^{2+}; R, renal injury possible; RCC, renal cell carcinoma; ROS1, receptor tyrosine kinase 1; SLL, small lymphocytic lymphoma; TFT, thyroid function test; TKI, tyrosine kinase inhibitor; TLS, risk of tumor lysis syndrome if brisk response; TOPO___, agent targets the indicated topoisomerase; TSH, thyroid-stimulating hormone; UGT___, drug metabolism by UDP-glucuronosyltransferase of the indicated genotype; V, vomiting; VEGFR, vascular endothelial growth factor receptor; Ves, extravasation injury possible; VLS, vascular leak syndrome; VOD, veno-occlusive liver disease.

fraction of patients with NSCLC. Subsequent studies by clinical oncologists in an effort to understand the basis of these excellent responses found that the probability of response to the agents was markedly increased in patients with an activating *EGFR* mutation, and current practice now routinely profiles patients with NSCLC for the presence of sensitizing mutations of *EGFR*. Side effects were generally acceptable, consisting mostly of acneiform rash (treated with glucocorticoid creams and clindamycin gel) and diarrhea. Patients with activating mutations who initially responded to gefitinib or erlotinib but who then had progression of the disease then acquired additional mutations in the enzyme, analogous to the mutational variants responsible for imatinib resistance in CML. Subsequent generations of EGFR antagonists have activity against more uncommon mutants (osimertinib) or a biochemically irreversible mechanism (dacomitinib).

Mutated anaplastic lymphoma kinase (*ALK*) and activated *RET* oncogene likewise drive distinct fractions of NSCLCs. Alectinib, ceritinib, crizotinib, and lorlatinib target ALK, but have prominent adverse cardiac, metabolic, and, in the case of lorlatinib, pulmonary events. Selpercatinib targets RET in NSCLCs (and thyroid cancers) but also with the chance of cardiac and liver toxicity. Repotrectinib is active in *ROS1* mutant NSCLC.

HER2-driven breast cancers may be usefully treated with lapatinib; diarrhea and cardiac dysfunction can occur. Neratinib or tucatinib may also be useful in HER2-positive breast cancers after trastuzumab has ceased to be of value; diarrhea and liver toxicity also require monitoring and management.

Alteration of fibroblast growth factor (FGF) signaling can contribute to the growth of urothelial carcinomas and cholangiocarcinomas. Erdafitinib and pemigatinib, respectively, may be of utility with careful attention to ocular toxicity and hyperphosphatemia; the latter is an "on-target" toxicity of disrupting FGF receptor signaling in the kidney. Likewise, gilteritinib is active against the FMS-like tyrosine kinase-3 (FLT3) mutated in a fraction of poor-prognosis (treated by conventional chemotherapy) acute myeloid leukemias (AMLs). Cardiac, hepatic, gastrointestinal, and neurologic adverse events can occur, along with "differentiation" of the AML cells with cytokine elaboration and pulmonary side effects, requiring management with steroids and potentially hydroxyurea.

The neurotropic tyrosine kinase receptor (NRTK) undergoes translocation with fusion to a variety of different partner genes to produce a family of chimeric proteins in a small fraction of a variety of solid tumors. Larotrectinib and entrectinib may be quite useful in managing these tumors; indeed, these agents are exemplary of "histology agnostic" agents, where the utility of the drug is not tied to a particular histologic diagnosis, but to the possession of a specific *NRTK* gene alteration. Neurotoxicity, a long half-life of the agents, and hepatotoxic adverse events are of concern. Neuroregulin 1 (produced by the *NRG1* gene) undergoes gene fusions to produce activators of HER family heterodimer signaling, including HER3 and HER4; afatinib covalently binds to all HER family members and has activity in patients with *NRG1* gene fusions.

RAF/MEK Pathway Antagonists The *RAS* proto-oncogene family members (including *HRAS, KRAS,* and *NRAS*) act as "switches" to bind GTP in response to activation of receptor tyrosine kinases; RAS-GTP activates the *RAF* proto-oncogene–derived serine-threonine kinase. *RAS* mutations of various types result in persistent activation of RAS isoforms, resulting in hyperactivation of RAF and "downstream" kinases, including MEK and MAPK. Sotorasib is a first-in-class inhibitor of *KRAS* G12C signaling that in early clinical reports has evidence of effecting stable disease in patients with a variety of neoplasm histologies bearing that mutation, with fewer actual responses. Adagrasib also targets *KRAS-G12C* with a distinct pharmaceutical profile. Neither sotorasib nor adagrasib has activity against wild-type or other RAS mutants, but their discovery marked a milestone, encouraging continuing efforts to produce RAS-directed therapeutics.

The *BRAF* V600E mutation drives a substantial fraction of melanomas and certain NSCLCs and has been detected in certain thyroid tumors, colorectal tumors, hairy cell leukemias, and unusual gliomas. BRAF inhibitors such as dabrafenib, vemurafenib, and encorafenib have activity as single agents in many such tumors but are usually most active when co-administered as "doublets" with the MEK inhibitors trametinib, cobimetinib, and binimetinib, respectively, to promote "shutdown" of RAF/MEK signaling at more than pathway member. Cutaneous adverse events including generally indolent cutaneous second neoplasms, and thromboembolic, cardiac, and ocular toxicity can occur.

Multikinase Inhibitors Agents in this class also target specific macromolecules promoting the viability of tumor cells. They are "small-molecule" ATP site-directed antagonists that inhibit more than

one protein kinase and may have value in the treatment of several solid tumors. Drugs of this type with prominent activity against the VEGFR tyrosine kinase have activity in renal cell carcinoma. Sorafenib is a VEGFR antagonist also with activity against the RAF serine-threonine protein kinase, and regorafenib is a closely related drug with value in relapsed advanced colon cancer. Pazopanib also prominently targets VEGFR and has activity in renal carcinoma and soft tissue sarcomas. Sunitinib has anti-VEGFR, anti-PDGFR, and anti-KIT activity. It causes prominent responses and stabilization of disease in renal cell cancers and GISTs. Side effects for agents with anti-VEGFR activity, similar to those of the anti-VEGF antibody bevacizumab, prominently include hypertension, proteinuria, and, more rarely, bleeding and clotting disorders, perforation of scarred gastrointestinal lesions, and posterior leukoencephalopathy, probably reflecting CNS vascular damage. Also encountered are fatigue, diarrhea, and hand-foot syndrome, with erythema and desquamation of the distal extremities, in some cases requiring dose modification, particularly with sorafenib.

Other agents in this class include agents such as brigatinib (clinical activity in ALK-dependent NSCLC, but also with anti-EGFR action), entrectinib (clinical activity in NTRK fusion protein diseases, but also in *ROS*-mutated NSCLC), and fedratinib (clinical activity in myeloproliferative neoplasms, but with RET activity in addition to JAK2 and FLT3 antagonism). Agents with anti-RET activity are useful in certain differentiated thyroid cancers and RET-fusion NSCLC.

Cyclin-Dependent Kinase Inhibitors Cyclin-dependent kinases (CDKs) are activated as the result of oncogene pathway activity, and CDK4 and CDK6 phosphorylate the retinoblastoma (RB) tumor-suppressor gene to allow entry into S-phase. Palbociclib, abemaciclib, and ribociclib, selective inhibitors of CDK4 and CDK6, have noteworthy activity in advanced breast cancers also expressing the ER, usually in conjunction with continued efforts to suppress ER signaling, and frequently in conjunction with mammalian target of rapamycin (mTOR) inhibitors. Further clinical investigations in other RB intact tumors may broaden their role.

Protein Homeostasis Modulators The proteasome is a macromolecular complex that degrades misfolded proteins tagged for removal by ubiquitin ligases. Proteasome inhibitors were originally designed as potential anti-inflammatory agents owing to proteasome activity to produce inflammatory cytokines but had unexpected antiproliferative activity in a variety of cell types. Proteasome inhibitors have clinical utility in myeloma and lymphoma, where unbalanced synthesis of immunoglobulin components can accumulate after proteasome inhibitor treatment and induce apoptosis or starve cells for amino acids, inducing autophagy. Boronic acid proteasome inhibitors, including bortezomib and ixazomib, cause thrombocytopenia, gastrointestinal dysfunction, and neuropathy. Carfilzomib is a distinct chemotype with attenuated neuropathy but increased incidence of infusion reactions and cytokine release, with attendant risk of cardiopulmonary adverse events.

Exportin 1 is a nuclear membrane transport protein that is responsible for normal exit and entry of a variety of nuclear proteins. Selinexor is an inhibitor of exportin action, resulting in abnormal nuclear accumulation of, for example, tumor-suppressor gene products or needed export of other products, such as oncogene products. Useful clinical activity has been seen in myeloma and diffuse large B-cell lymphomas including those arising from previously treated indolent lymphomas. Cytopenias, gastrointestinal distress, and hyponatremia are features of its clinical use.

Chromatin-Modifying Agents Gene function is altered not only by mutation of DNA structure but also by "epigenetic" mechanisms that alter the capacity of DNA to be transcribed or interact with regulatory proteins in the nucleus including transcription factors. Initial epigenetic approaches to modulate gene expression extended from the observation that 5′azacytidine and decitabine are misincorporated into DNA and then scavenge DNA methyl transferase to disable DNA methylation of cytosine near gene promoter regions and thus alter their transcription. This "hypomethylation" causes differentiation of AML cells with notably less host toxicity than higher concentrations of these agents or indeed cytosine arabinoside, which does not have prominent hypomethylation activity.

Histone deacetylase inhibitors alter the histone protein "packing" density of chromatin and induce global changes in expression of cell cycle regulatory proteins. Vorinostat, belinostat, and romidepsin are useful in cutaneous and peripheral T-cell lymphomas; panobinostat has activity in multiple myeloma. The agents are generally well tolerated but with the potential for cytopenias. The histone methyltransferase inhibitor tazemetostat is a first-in-class inhibitor of histone methyltransferase with unique activity in epithelioid sarcoma owing to its modulation of transcriptional mechanisms unique to that tumor and, recently, in certain follicular lymphomas.

Transcription Factor Modulation Distinct from hormone receptor agonists and antagonists, which as previously described modulate transcription factor activity by affecting the binding of endogenously produced ligands, such as androgens and estrogens, tretinoin (all-*trans*-retinoic acid) binds to the fusion protein PML-RARα produced as a result of the t(15,17) chromosomal translocation that underlies the pathogenesis of most cases of acute promyelocytic leukemia (APL). PML-RARα functions as transcriptional co-repressor of normal granulocyte maturation; inhibiting the repressor leads to clinical value in the curative treatment of APL. Adverse events include typical symptoms of hypervitaminosis A, including skin dryness, cheilitis, increased intracranial pressure, and the development of a "leukemia differentiation syndrome" marked by fever and lung and other organ infiltration by newly differentiated leukocytes, which usually responds to glucocorticoids and hydroxyurea but can be life-threatening. Significantly, the coagulopathy of APL is attenuated. Arsenic trioxide nonspecifically affects PML-RARα and other targets by a redox mechanism, contributing to APL treatment with tretinoin regimens, but with a narrow therapeutic index particularly related to increase of the QT interval, which must be monitored during treatment, while also being carefully attentive to K^+, Mg^{2+}, ionized Ca^{2+}, and other drugs that can alter QT.

Belzutifan is a novel agent that antagonizes directly the action of hypoxia-inducible factor 2 (HIF2) α, activated in von Hippel-Lindau (VHL) disease–related neoplasms and many sporadic clear cell renal carcinomas through loss of the VHL ubiquitin ligase tumor-suppressor gene. It is safe, but anemia and hypoxemia may occur.

The sonic hedgehog factor pathway is regulated by the WNT ligands acting on smoothened receptors, named in reference to *Drosophila* mutants in which the pathway was originally revealed. In humans, the pathway acts during embryonic and fetal life and in certain neoplasms, and mediates effects on transcription through Gli proteins. Hedgehog pathway inhibitors sonidegib and vismodegib are useful in nonsurgically treatable cutaneous basal cell carcinomas, and glasdegib is active in certain AMLs where the pathway is active (see Table 78-7). The notch pathway was likewise first noted in *Drosophila* and acts in metazoans to signal cell position and motion. Notch receptors respond to their ligands by undergoing endocytosis and processing by a γ-secretase, followed by translocation to the nucleus, and function as specific gene transcription factors. The notch pathway has long been known to be active in hematopoietic tumors, but observation has shown confirmed activity in desmoid tumors, inflammatory mesenchymal tumors with poor evidence of control by conventional cytotoxic agents, by nirogacestat, the first γ-secretase inhibitor to enter clinical practice.

Cancer Cell Metabolism Modulators Oncogenic transformation causes a "rewiring" of cellular metabolism away from oxidative phosphorylation to glycolysis (historically defined as the "Warburg effect" of aerobic glycolysis in animal and human tumors) with attendant tolerance of hypoxia and production of metabolites important for sustaining cell proliferation. Recent clinical studies have defined clinical value from inhibitors of the cell lipid membrane localized phosphoinositide-3 (PI3) kinase, mTOR, and extra-mitochondrial isocitrate dehydrogenase isoforms 1 and 2.

mTOR is a kinase whose inhibition was originally discovered as the basis for activity by the immunosuppressant rapamycin, isolated from a soil bacterium (originally obtained from Rapa Nui), which had

evidence of antitumor activity in animals as well as decreased T-cell proliferation. Sirolimus as a protein-bound formulation is used for certain soft tissue tumors. Temsirolimus and everolimus are mTOR inhibitors with activity in renal cancers. They produce stomatitis and fatigue; some hyperlipidemia (10%) and myelosuppression (10%); and rare lung toxicity and immunosuppression in regimens used clinically. Everolimus is also useful in patients with hormone receptor–positive breast cancers displaying resistance to hormonal inhibition and in certain neuroendocrine and brain tumors, the latter arising in patients with sporadic or inherited mutations in the pathway activating mTOR. PI3 kinase is activated by numerous oncogenic tyrosine kinases to ultimately cause a cascade of metabolic alterations including increased glucose uptake and activation of mTOR isoforms, which selectively increase translation efficiency of key regulators of cell cycle progression and protein synthetic capacity.

Isoform-specific PI3 kinase inhibitors are of increasing importance in breast cancers with mutated *PI3Kα* (alpelisib; hyperglycemia and cutaneous eruptions can occur) or owing to selective use of PI3Kδ by lymphoid tissues in lymphomas (idelalisib, copanlisib, and duvelisib).

Isocitrate dehydrogenase (IDH) inhibitors (ivosidenib specific for IDH1 and enasidenib specific for IDH2) have activity in tumors with IDH mutants (AML, cholangiocarcinomas) that generate the "oncometabolite" 2-hydroxyglutarate, which alters DNA and histone methyltransferase activity. The drugs thus function indirectly as epigenetic chromatin modulating agents through effects on cellular metabolism. Vorasidenib, an IDH1/2 inhibitor with very favorable distribution across the blood-brain barrier, is in very advanced stages of development for certain brain tumors with IDH mutations.

DNA Repair Pathway Modulators DNA repair systems act physiologically to lessen the impact of environmental genomic damaging agents and influence the susceptibility to certain chemotherapy agents. DNA repair enzyme mutations underlie inherited cancer susceptibility syndromes such as mutated *BRCA* tumor-suppressor gene–associated breast and ovarian cancers, among others.

Laboratory investigations revealed that poly-ADP ribose polymerase (PARP) acts as a synthetic lethal gene with mutations in the homologous recombination repair pathway, including the *BRCA* gene. PARP responds to detection of DNA lesions by creating chains of poly-ADP, which serve as scaffolds for the localization of DNA repair proteins still active even with mutated *BRCA* isoforms. However, without PARP activity, the scaffolds cannot form, and the DNA damage becomes lethal. This observation immediately suggested the potential utility of PARP inhibitors (e.g., olaparib) as treatments potentially useful for *BRCA*-induced tumors. Recently, PARP inhibitor utility has been extended to tumors that do not harbor *BRCA* mutations but have given evidence of responding to platinum drugs, as a way of extending the useful effect of the chemotherapy treatment. This finding underscores the likelihood that sensitivity to DNA-directed cytotoxic drugs on the part of a tumor is at least in part related to the drugs' ability to take advantage of a sensitizing effect of a tumor's endogenous DNA repair capacity.

Miscellaneous Targeted Therapies High-affinity binding to receptors on tumor cells can target toxic agents besides drugs to tumor cells, exemplified by the IL-3–diphtheria toxin fusion protein tagraxofusp-erzs, targeting the IL-3 receptor (CD123) and useful in blastic plasmacytoid dendritic cell neoplasms (Table 78-7). Capillary leak syndrome induced due to adventitious "off-target" delivery of the toxin component requires careful monitoring of fluid balance to avoid pulmonary dysfunction in particular. The somatostatin receptor conjugated to a chelate of 177-lutetium can deliver targeted radiation to gastroenterohepatic endocrine neoplasms expressing that receptor. Acutely, release of vasoactive and locally acting hormonal components from dying tumor cells and myelosuppression can occur. Renal damage and the risk of second hematopoietic tumors can complicate continuing use of the agent. Likewise, 177-lutetium can be delivered via conjugation to a ligand of prostate-specific membrane antigen (PSMA) in the treatment of hormone-resistant prostate cancer. Ziv-aflibercept is not an antibody, but a solubilized VEGF receptor VEGF binding domain, and therefore may have a distinct mechanism of action from bevacizumab but with similar side effects.

RESISTANCE TO CANCER TREATMENTS

Resistance mechanisms to the conventional cytotoxic agents were initially characterized in the late twentieth century as defects in drug uptake, metabolism, or export by tumor cells. The *multidrug resistance* (*MDR*) gene, encoding P-glycoprotein (Pgp), is prototypic of transport proteins that efficiently excrete many drugs from tumor cells; no clinically useful modulator of this process has yet emerged. Drug-metabolizing enzymes such as cytidine deaminase are upregulated in resistant tumor cells, and this is the basis for so-called "high-dose cytarabine" regimens in the treatment of leukemia. Another resistance mechanism defined during this era involved increased expression of a drug's target, exemplified by amplification of the dihydrofolate reductase gene, in patients who had lost responsiveness to methotrexate, or mutation of topoisomerase II in tumors that relapsed after topoisomerase II modulator treatment.

A second class of resistance mechanisms involves loss of the cellular apoptotic mechanism activated after the engagement of a drug's target by the drug. This occurs in a way that is heavily influenced by the biology of the particular tumor type. For example, decreased alkylguanine alkyltransferase expression defines a subset of glioblastoma patients with the prospect of enhanced benefit from treatment with temozolomide but has no value in predicting benefit from temozolomide in epithelial neoplasms. Likewise, ovarian cancers resistant to platinating agents have decreased expression of the proapoptotic gene *BAX*.

A related class of resistance mechanisms emerged from sequencing of the targets of agents directed at oncogenic kinases, revealing mutated targets, as described previously (e.g., $p210^{bcr\text{-}abl}$T315I). This reflects the phenomenon of tumor heterogeneity with distinct populations of subclones that arise in a tumor during the process of carcinogenesis. These subclones share to variable degrees mutations that may promote the growth of some subclones but that are absent or are no longer relevant to the growth of other subclones. This general mechanism of resistance is emerging as a basis for limited value of clinical responses to sotorasib, where sequencing of tumor DNA after clinical resistance has documented "treatment-emergent" mutations in *KRAS* itself as well as alterations in other proto-oncogenes and their targets. Really useful targeted therapies address a "driver mutation" present in all subclones.

Finally, other mechanisms of resistance to targeted agents include the upregulation of alternate means of activating the pathway targeted by the agent. Thus, melanomas initially responsive to *BRAF* V600E antagonists such as vemurafenib may reactivate RAF signaling by employing variant isoforms that can bypass the drug. Likewise, inhibition of HER2/neu signaling in breast cancer cells can lead to the emergence of variants with distinct ways of activating downstream effectors such as PI3 kinase.

Mechanisms of resistance to immune checkpoint inhibitors such as nivolumab and ipilimumab have not been well defined, but initial characterization of tumors resistant to these agents demonstrates alterations in antigen presentation pathways, concordant with the basis for checkpoint inhibitor action.

SUPPORTIVE CARE DURING CANCER TREATMENT

MYELOSUPPRESSION

Most cytotoxic chemotherapeutic agents affect bone marrow function. Polymorphonuclear leukocytes (PMNs; $t_{1/2}$ = 6–8 h), platelets ($t_{1/2}$ = 5–7 days), and red blood cells (RBCs; $t_{1/2}$ = 120 days) have most, less, and least susceptibility, respectively, to usually administered cytotoxic agents. Maximal neutropenia occurs 6–14 days after conventional doses of anthracyclines, antifolates, and antimetabolites. Alkylating agents differ from each other in the timing of cytopenias. Nitrosoureas, DTIC, temozolomide, and procarbazine can display delayed marrow toxicity, first appearing 6 weeks after dosing.

Complications of myelosuppression relate to the missing cells' function. *Febrile neutropenia* refers to the clinical presentation of fever

TABLE 78-8 Indications for the Clinical Use of G-CSF or GM-CSF

Preventive Uses
With the first cycle of chemotherapy (so-called *primary CSF administration*)
Not needed on a routine basis
Use if the probability of febrile neutropenia is ≥20%
Use if patient has preexisting neutropenia or active infection
Age >65 years treated for lymphoma with curative intent or other tumors treated by similar regimens
Poor performance status
Extensive prior chemotherapy
Dose-dense regimens in a clinical trial or with strong evidence of benefit
With subsequent cycles if febrile neutropenia has previously occurred (so-called *secondary CSF administration*)
Not needed after short-duration neutropenia without fever
Use if patient had febrile neutropenia in previous cycle
Use if prolonged neutropenia (even without fever) delays therapy
Therapeutic Uses
Afebrile neutropenic patients
No evidence of benefit
Febrile neutropenic patients
No evidence of benefit
May feel compelled to use in the face of clinical deterioration from sepsis, pneumonia, or fungal infection, but benefit unclear
In bone marrow or peripheral blood stem cell transplantation
Use to mobilize stem cells from marrow
Use to hasten myeloid recovery
In acute myeloid leukemia
G-CSF of minor or no benefit
GM-CSF of no benefit and may be harmful
In myelodysplastic syndromes
Not routinely beneficial
Use intermittently in subset with neutropenia and recurrent infection
What Dose and Schedule Should Be Used?
G-CSF: 5 mg/kg per day subcutaneously
GM-CSF: 250 mg/m^2 per day subcutaneously
Pegfilgrastim: one dose of 6 mg 24 h after chemotherapy
When Should Therapy Begin and End?
When indicated, start 24–72 h after chemotherapy
Continue until absolute neutrophil count is 10,000/μL
Do not use concurrently with chemotherapy or radiation therapy

Abbreviations: CSF, colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

Source: From the American Society of Clinical Oncology: J Clin Oncol 24:3187, 2006.

and <1500 granulocytes/μL. Management of febrile neutropenia is considered in **Chap. 79**. Colony-stimulating factors (CSFs) are used to augment bone marrow production of PMNs. The American Society of Clinical Oncology has developed practice guidelines for the use of granulocyte CSF (G-CSF) and GM-CSF **(Table 78-8)**.

Dangerous degrees of thrombocytopenia do not frequently complicate the management of patients with solid tumors receiving cytotoxic chemotherapy (with the possible exception of certain carboplatin-containing regimens), but they are frequent in patients with hematologic neoplasms. Severe bleeding related to thrombocytopenia occurs with increased frequency at platelet counts <20,000/μL in patients with acute leukemia and <10,000/μL in patients with solid tumors and is prevalent at counts <5000/μL.

The precise "trigger" point at which to transfuse patients has been defined as a platelet count of 10,000/μL or less in patients without medical comorbidities that may increase the risk of bleeding. This issue is important not only because of the costs of frequent transfusion but also because unnecessary platelet transfusions expose the patient to the risks of allosensitization and loss of value from subsequent transfusion, as well as the infectious and hypersensitivity risks inherent in any transfusion. Careful review of medication lists to prevent exposure to nonsteroidal anti-inflammatory agents and maintenance of clotting factor levels adequate to support near-normal prothrombin and partial thromboplastin time tests are important in minimizing the risk of bleeding in the thrombocytopenic patient.

Anemia associated with chemotherapy can be managed by transfusion of packed RBCs. Transfusion is not undertaken until the hemoglobin falls to <80 g/L (8 g/dL), compromise of end-organ function occurs, or an underlying condition (e.g., coronary artery disease) calls for maintenance of hemoglobin >90 g/L (9 g/dL). Randomized trials in certain tumors have raised the possibility that erythropoietin (EPO) use may promote tumor cell survival.

NAUSEA AND VOMITING

The most common side effect of chemotherapy administration is nausea, with or without vomiting. Nausea may be acute (within 24 h of chemotherapy), delayed (>24 h), or anticipatory of the receipt of chemotherapy. Highly emetogenic drugs (risk of emesis >90%) include DTIC, cyclophosphamide at >1500 mg/m^2, and cisplatin; moderately emetogenic drugs (30–90% risk) include carboplatin, cytosine arabinoside (>1 g/m^2), ifosfamide, conventional-dose cyclophosphamide, and anthracyclines; low-risk (10–30%) agents include 5-FU, taxanes, etoposide, and bortezomib, with minimal risk (<10%) afforded by treatment with antibodies, bleomycin, busulfan, fludarabine, and vinca alkaloids.

Serotonin antagonists (5-HT$_3$) and neurokinin 1 (NK1) receptor antagonists are useful in "high-risk" chemotherapy regimens. The combination acts at both peripheral gastrointestinal and CNS sites that control nausea and vomiting. For example, the 5-HT$_3$ blocker dolasetron, 100 mg intravenously or orally; dexamethasone, 12 mg; and the NK1 antagonist aprepitant, 125 mg orally, are combined on the day of administration of severely emetogenic regimens, with repetition of dexamethasone (8 mg) and aprepitant (80 mg) on days 2 and 3 for delayed nausea. Alternate 5-HT$_3$ antagonists include ondansetron, given as 0.15 mg/kg intravenously for three doses just before and at 4 and 8 h after chemotherapy; palonosetron at 0.25 mg over 30 s, 30 min before chemotherapy; and granisetron, given as a single dose of 0.01 mg/kg just before chemotherapy. Emesis from moderately emetic chemotherapy regimens may be prevented with a 5-HT$_3$ antagonist and dexamethasone alone for patients not receiving doxorubicin and cyclophosphamide combinations; the latter combination requires the 5-HT$_3$/dexamethasone/aprepitant on day 1, but aprepitant alone on days 2 and 3. Emesis from low-emetic-risk regimens may be prevented with 8 mg of dexamethasone alone or with non-5-HT$_3$, non-NK1 antagonist approaches including the following.

Antidopaminergic phenothiazines act directly at the chemoreceptor trigger zone (CTZ) in the brainstem medulla and include prochlorperazine (Compazine), 10 mg intramuscularly or intravenously, 10–25 mg orally, or 25 mg per rectum every 4–6 h for up to four doses; and thiethylperazine, 10 mg by potentially all of the above routes every 6 h. Haloperidol is a butyrophenone dopamine antagonist given at 1 mg intramuscularly or orally every 8 h. Metoclopramide acts on peripheral dopamine receptors to augment gastric emptying and is used in high doses for highly emetogenic regimens (1–2 mg/kg intravenously 30 min before chemotherapy and every 2 h for up to three additional doses as needed); intravenous doses of 10–20 mg every 4–6 h as needed or 50 mg orally 4 h before and 8 and 12 h after chemotherapy are used for moderately emetogenic regimens. 5-9-Tetrahydrocannabinol (Marinol) is a rather weak antiemetic compared to other available agents, but it may be useful for persisting nausea and is used orally at 10 mg every 3–4 h as needed. Olanzapine, an "atypical antipsychotic" acting at multiple neurotransmitter receptors, may be of value, most clearly in cases refractory to the measures described above. Some practice guidelines have endorsed its earlier use in adults receiving highly emetogenic chemotherapy regimens in combination with an NK1 antagonist plus a 5-HT$_3$ antagonist plus dexamethasone.

DIARRHEA

Similar to the vomiting syndromes, chemotherapy-induced diarrhea may be immediate or can occur in a delayed fashion up to 48–72 h after the drugs. Careful attention to maintained hydration and electrolyte repletion, intravenously if necessary, along with antimotility treatments such as "high-dose" loperamide (4 mg at the first occurrence of diarrhea, with 2 mg repeated every 2 h until 12 h without loose stools, not to exceed a total daily dose of 16 mg), are appropriate. Octreotide (100–150 μg), a somatostatin analogue, or intralumenally acting opiate-based preparations may be considered for patients not responding to loperamide.

MUCOSITIS

Irritation and inflammation of the mucous membranes (mucositis) particularly afflicting the oral and anal mucosa, but potentially involving the entire gastrointestinal tract, may accompany cytotoxic chemotherapy. Topical therapies, including anesthetics and barrier-creating preparations, may provide symptomatic relief in mild cases.

ALOPECIA

Chemotherapeutic agents vary widely in causing alopecia, with anthracyclines, alkylating agents, and topoisomerase inhibitors reliably causing near-total alopecia when given at therapeutic doses. Antimetabolites are more variably associated with alopecia. Psychological support and the use of cosmetic resources are to be encouraged. "Chemo caps" that reduce scalp temperature to decrease the degree of alopecia are controversial during treatment with curative intent of neoplasms, such as leukemia or lymphoma, or in adjuvant breast cancer therapy. The richly vascularized scalp can certainly harbor micrometastatic or disseminated disease.

GONADAL DYSFUNCTION AND PREGNANCY

All cancer treatments described in this chapter should be regarded as potentially injurious to the developing fetus and to newborns via lactation. However, there are gradations to the degree of reproductive harm. All agents tend to have increased risk of adverse outcomes when administered during the first trimester, and strategies to delay chemotherapy, if possible, until after this milestone should be considered if the pregnancy is to continue to term. Patients in their second or third trimester can be treated with most regimens for the common neoplasms afflicting women in their childbearing years, with the exception of antimetabolites, particularly antifolates, which have notable teratogenic or fetotoxic effects throughout pregnancy. The need for anticancer chemotherapy per se is infrequently a clear basis to recommend termination of a concurrent pregnancy, although each treatment strategy in this circumstance must be tailored to the individual needs of the patient.

Cessation of ovulation and azoospermia reliably result from regimens that contain alkylating agents and topoisomerase poison. The duration of these effects varies with age and sex. Sperm banking before treatment may be considered. Females experience amenorrhea with anovulation after alkylating agent therapy; egg preservation may be considered but may delay inception of urgent treatment. Recovery of normal menses is frequent if treatment is completed before age 30, but patients are unlikely to recover menses after age 35. Even those who regain menses usually experience premature menopause. Because the magnitude and extent of decreased fertility can be difficult to predict, patients should be counseled to maintain effective contraception, preferably by barrier means, during and after therapy. Resumption of efforts to conceive should be considered in the context of the patient's likely prognosis. Hormone replacement therapy should be undertaken in women who do not have a hormonally responsive tumor. For patients who have had a hormone-sensitive tumor primarily treated by a local modality, conventional practice would counsel against hormone replacement, but this issue is under investigation.

PALLIATIVE AND SUPPORTIVE CARE

An important perspective the primary care provider may bring to patients and their families facing incurable cancer is that, given the limited value of chemotherapeutic approaches at some point in the natural history of most metastatic cancers, *palliative care* or *hospice-based* approaches, with meticulous and ongoing attention to symptom relief and with family, psychological, and spiritual support, should receive prominent attention as a valuable therapeutic plan **(Chaps. 13 and 73)**. Optimizing the quality of life rather than attempting to extend it becomes a valued intervention. Patients facing the impending progression of disease in a life-threatening way frequently choose to undertake toxic treatments of little to no potential value, and support provided by the primary caregiver in accessing palliative and hospice-based options in contrast to receiving toxic and ineffective regimens can be critical in providing a basis for patients to make sensible choices.

Late effects of cancer and its treatment are reviewed in **Chap. 100**.

79 Infections in Patients with Cancer

Brahm H. Segal, Juan C. Gea-Banacloche

GENERAL CONCEPTS

Infection is an important complication of cancer and cancer therapy and drives excess hospitalization and mortality. Prevention, diagnosis, and treatment of infection increases survival and improves quality of life. In this regard, the infectious diseases consultant works collaboratively with multiple stakeholders to prevent infection and to effectively diagnose and treat infections when they occur. Cornerstones of infection prevention are compliance with standard infection control guidelines, limiting exposure to pathogens, vaccination of patients and caregivers, and targeted use of antimicrobial prophylaxis. Although there have been substantial improvements in diagnostic modalities for infection including molecular and antigen-based diagnostics, the infectious diseases physician is frequently confronted with patients with suspected infection (e.g., neutropenic fever, lung lesions observed by imaging) without a definitive diagnosis. In addition, infectious and noninfectious disorders may have overlapping manifestations, such as

pneumonia versus drug-related pneumonitis and fever from infection versus cancer-associated fever. Given the broad differential diagnosis, aggressive diagnostic evaluation including biopsies may be required. Sometimes, empirical therapy must be administered based on the most likely or dangerous infections; these situations are common in patients with hematologic malignancies in whom an invasive tissue diagnosis may be unsafe due to thrombocytopenia.

We provide recommendations for therapy of both documented and suspected infections. Specific treatment plans should consider several factors, such as evidence of clearance of infection, whether a persistent nidus exists (e.g., abscess or infectious phlebitis), the specific pathogen, and the immune status of the patient. A general principle of therapy is that longer courses are required in patients with persistent and severe immunocompromise (e.g., prolonged neutropenia in patients with acute leukemia or myelodysplastic syndrome). An individualized approach to the diagnosis and management of infections that is tailored to overall goals of care is recommended. For example, in the setting of uncontrolled malignancy (e.g., recurrent cholangitis from obstructive pancreatic or biliary cancers or secondary infections of tumor from bowel fistulization), source control by surgery or catheter drainage may not be feasible, and antibiotics may be used palliatively for patient comfort and to avoid unnecessary hospitalizations rather than to cure an infection.

We will address the risk factors for infections and the preventive measures that may be adopted based on those risk factors. Most specific infections have dedicated chapters, and readers are advised to access those for in-depth discussions. We will focus here on infections associated with (or caused by) the treatment of cancer. Chemotherapy-induced neutropenia is the most important etiology, and the management of neutropenic fever will be discussed in detail. We will also discuss infections associated with new treatment modalities, including biologics, immunotherapy, and cellular therapies. Infections related to hematopoietic stem cell transplant (HCT) are discussed in **Chap. 148**.

RISK FACTORS FOR INFECTION IN PATIENTS WITH CANCER

When evaluating patients with cancer and suspected infection, it is important to consider the major factors—both intrinsic and treatment-associated—that predispose to infection. This knowledge, in turn, guides the differential diagnosis, diagnostic evaluation, and initial therapy.

RISK FACTORS INTRINSIC TO THE CANCER

These are the direct consequence of the cancer. In the case of solid tumors, the most obvious risk factor for infection relates to obstruction. As examples, lung tumors that obstruct the airway predispose to postobstructive pneumonia, obstructive pancreatic and biliary tumors predispose to cholangitis, and tumors that result in obstructive uropathy predispose to urinary tract infections. Tumors of the head and neck increase the risk of local infection and aspiration pneumonia. Gastrointestinal tumors can present with obstruction and local abscess production by enteric flora and bloodstream infection (e.g., bloodstream infection by *Streptococcus gallolyticus* or *Clostridium septicum* in colon cancer). Direct invasion through the colonic mucosa is associated with local abscess formation and sepsis by enteric flora.

Some hematologic malignancies are associated with specific immune deficits. Acute leukemia and myelodysplastic syndrome can manifest with pancytopenia at diagnosis. Patients may have a high burden of circulating leukemic cells and lack normal circulating neutrophils. Some patients with myelodysplastic syndrome or acute myelogenous leukemia (AML) have mutations that are associated marrow failure and immunodeficiency. For example *GATA2* deficiency is associated with major viral, bacterial, and fungal infections as well as hematological malignancies and solid tumors. Multiple myeloma and chronic lymphocytic leukemia are associated with impaired immunoglobulin production that can manifest with recurrent sinopulmonary infections and poor antibody responses to both prior infections and vaccination. Case series suggest that patients with hairy cell leukemia are at increased risk of nontuberculous mycobacterial infections. T cell–associated leukemias and lymphomas can be associated with human T lymphotropic virus 1 (HTLV1) and have T cell impairment and opportunistic infections by *Pneumocystis jirovecii*, *Cryptococcus neoformans*, tuberculosis, or disseminated strongyloidiasis.

RISK FACTORS ASSOCIATED WITH CANCER THERAPY

There has been a dramatic expansion in cancer therapeutics, most of which influence host defense against infections **(Table 79-1)**. Broadly speaking, cancer therapy can compromise either or both the physical barriers and immune responses that protect from infection. Examples of physical barrier disruption include central venous catheters, surgical wounds that can be a portal of entry for skin microbes, and disruption of the lymphatic drainage after mastectomy and lymphadenectomy for breast cancer.

The mucosal lining of the gastrointestinal tract, respiratory tract, and other luminal surfaces constitutes the first line of host defense, both as a physical barrier and by secretion of a variety of antimicrobial products, such as immunoglobulin A (IgA), lactoferrin, and antimicrobial peptides. Standard nonselective cytotoxic agents have the combined effect of both pancytopenia and mucosal disruption that predispose to infection. Radiation is sometimes administered concurrently with chemotherapy and, depending on the location of the radiation field, can cause significant mucosal injury. Antineoplastic agents that inhibit specific pathway(s) that drive tumor cell progression are considered targeted, but they also impair specific components of the immune system whose function relies on these same pathways. For example, the anti-tumor activity of Bruton tyrosine kinase inhibitors against B-cell malignancies is by inhibiting the B-cell receptor signaling cascade, but this property can have broad immune effects that increase the risk of viral and fungal infections.

Chemotherapy-Induced Neutropenia It has been recognized for more than 50 years that the duration and degree of neutropenia drive susceptibility to infections in patients with cancer. Cytotoxic regimens that result in prolonged neutropenia also deplete other immune cells (e.g., circulating monocytes and lymphocytes) and commonly cause mucosal injury. The risk of infection is proportional to the degree of neutropenia once the absolute neutrophil count (ANC) becomes <1000/μL. For example, standard induction chemotherapy with anthracycline plus cytarabine for AML causes prolonged neutropenia and severe mucositis. The combination of prolonged neutropenia and mucositis predisposes these patients to gastrointestinal tract infections that include ulcerations of the oral mucosa, neutropenic enterocolitis (typhlitis), and perirectal infections, as well as bloodstream infections by gastrointestinal flora such as viridians group streptococci, enterococci, and Enterobacterales. Reactivation of oral mucosal herpes simplex virus (HSV) is another common complication of leukemia therapy. Reflecting the fact that *Candida* species are endogenous gastrointestinal flora, these patients are also at risk for candidemia and chronic disseminated candidiasis. Patients with more prolonged neutropenia (e.g., ANC <500/μL for ≥2 weeks) are at risk for invasive aspergillosis and other molds. Refractory and relapsed acute leukemia further increase the risk of invasive fungal disease (Table 79-1).

Antimicrobial prophylaxis tailored to the underlying immune defects has been shown to be effective in several settings, and it should be used with knowledge of the proven benefits and the direct and indirect toxicities (prevention of fever differs from prevention of infection and prolongation of survival), as well as the limitations of the available evidence. As an example, prophylaxis with a fluoroquinolone like levofloxacin should be considered in adults with prolonged neutropenia (e.g., ANC <500/μL for ≥7 days). Multiple studies have shown decreased frequency of neutropenic fever and fewer documented infections, and meta-analyses suggest a survival benefit. In patients with AML receiving induction chemotherapy, prophylaxis with posaconazole was associated with less invasive fungal disease (IFD) and a survival benefit, so posaconazole is frequently recommended as prophylaxis in patients with profound, prolonged neutropenia. It is plausible that isavuconazole may be equally effective, but its efficacy in this setting has not been demonstrated.

TABLE 79-1 Immune Defects and Associated Infections in Cancer Patients

HOST DEFENSE DEFECT	PREDOMINANT PATHOGENS	PATIENTS WITH CANCER AT GREATEST RISK
Neutropenia (ANC <500/μL)	Gram-negative and gram-positive bacteria	Cytotoxic chemotherapy, underlying hematologic malignancy (e.g., myelodysplasia, acute leukemia)
Prolonged (≥10 days), profound neutropenia (ANC <100/μL)	Increased risk of bacterial infections Candidemia Invasive aspergillosis and other molds HSV reactivation Respiratory viral infections	Induction/reinduction therapy for acute leukemia; pancytopenia from underlying hematologic malignancy; myeloablative conditioning regimens for stem cell transplantation and lymphodepletion for adoptive cellular therapy
T cell immunodeficiency	Common bacterial infections Intracellular bacteria (e.g., *Listeria monocytogenes*, *Salmonella* species) *Nocardia* species Tuberculosis and NTM Respiratory viral infections Reactivation of herpes viruses (HSV, VZV); with severe impairment: CMV, EBV-associated lymphoproliferative disease; HHV-6-associated marrow suppression or encephalopathy, and HHV-8-associated malignancies) Mucosal candidiasis *Pneumocystis jirovecii* Dimorphic fungal infections (e.g., histoplasmosis, coccidioidomycosis) *Cryptococcus neoformans* Invasive aspergillosis and other molds Toxoplasmosis *Strongyloides* hyperinfection	Underlying hematologic malignancy including primary T cell malignancies AIDS-associated malignancies Corticosteroids, TNF-α blockade Janus kinase inhibitors Purine analogues Alemtuzumab GVHD Lymphodepletion for adoptive cellular therapy
B cell immunodeficiency	Encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*) Respiratory viral infections Reactivation of HSV and VZV Reactivation of HBV PML (reactivation of JC virus)	Lymphoid malignancies (e.g., chronic lymphocytic leukemia, multiple myeloma) B cell–depleting agents (e.g., rituximab, BTK inhibitors) Stem cell transplantation, particularly with chronic GVHD Bispecific antibodies and adoptive cellular therapy targeted against B cell antigens (e.g., CD19-directed CAR T cell regimens)
Splenectomy and functional asplenia	Encapsulated bacteria (can result in life-threating sepsis) Malaria, babesiosis	Functional asplenia in chronic GVHD
Mucosal injury	Localized infections by oral and GI flora (e.g., dental infections, neutropenic enterocolitis, perianal infection) Bacteremia (coliforms, oral streptococci, enterococci, anaerobes; can be polymicrobial)	Cytotoxic chemotherapy that results in both neutropenia and mucosal injury Radiation (e.g., for head and neck tumors or rectal cancer) predisposes to local tissue damage, impaired blood flow, and secondary bacterial infection
Systemic corticosteroids	Broad suppressive effect on innate and adaptive immunity related to dose and duration of treatment Increased risk of common bacterial and viral infections Prolonged high-dose corticosteroids (e.g., prednisone equivalent to ≥20 mg/day for ≥28 days) increases risk of multiple opportunistic pathogens associated with impaired T cell immunity (e.g., *Pneumocystis jirovecii*)	Corticosteroids are common components of antineoplastic regimens for hematologic cancers (e.g., for acute lymphoblastic leukemia, lymphomas, and multiple myeloma) and are administered concurrently with other immunosuppressive therapies Other common indications for corticosteroids are to reduce inflammation from central nervous system tumors and as therapy for immune-related toxicities

Abbreviations: AIDS, acquired immunodeficiency syndrome; ANC, absolute neutrophil count; BTK, Bruton tyrosine kinase; CAR, chimeric antigen receptor; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; HBV, hepatitis B virus; HHV, human herpes virus; HSV, herpes simplex virus; MDS, myelodysplastic syndrome; NTM, nontuberculous mycobacteria; PML, progressive multifocal leukoencephalopathy; TNF, tumor necrosis factor; VZV, varicella-zoster virus.

Corticosteroids Corticosteroids are part of several chemotherapy regimens used in hematologic malignancies, such as in acute lymphoid leukemias, lymphomas, and multiple myeloma. Patients with brain tumors, both primary and metastatic, are treated with corticosteroids to control edema. In addition, corticosteroids are a mainstay of therapy to control inflammatory complications of cancer therapy. For example, immune checkpoint inhibitors are associated with pneumonitis, colitis, and autoimmune endocrinopathies that are treated with corticosteroids, and additional agents such as tumor necrosis factor α blockade when corticosteroids alone are insufficient. Corticosteroids are also used as therapy for graft-versus-host disease (GVHD) following allogeneic stem cell transplantation and for cytokine release syndrome (CRS) following bispecific antibody therapy and adoptive cellular therapy.

High-dose corticosteroids have inhibitory effects on multiple components of innate and adaptive immunity. The risk of infections is related to their dose and duration, the underlying malignancy, and other immunosuppressive agents that are used concurrently. For example, induction therapy for acute lymphoblastic leukemia includes both cytotoxic agents that result in pancytopenia and corticosteroids that cumulatively increase infection risk. Corticosteroids can also decrease signs of infection such as fever and abdominal tenderness. The inhibitory effect of corticosteroids on T cell immunity increases the risk of infections by viruses (e.g., HSV, varicella-zoster virus [VZV]), mycobacteria, *Nocardia* species, and fungal infections, including mucosal candidiasis, dimorphic fungi, and *Pneumocystis jirovecii* pneumonia (PJP) (Table 79-1). Prophylaxis against *Pneumocystis jirovecii* with trimethoprim sulfamethoxazole (TMP-SMX) (or an alternative agent if

intolerant) is recommended in patients receiving the adult equivalent of prednisone ≥20 mg per day for at least 4 weeks.

Radiation Radiation causes direct tissue damage (including damage to the vasculature) and impairs wound healing. Infectious complications of radiation include local infection and fistulization. As an example, neoadjuvant radiation therapy for rectal tumors increases the risk of surgical site infections. Radiation to the head and neck increases the risk of infections related to the tumor and as a surgical complication. Osteoradionecrosis of the jaw predisposes to secondary infections of the soft tissue and bone that may require combined prolonged antibiotics and surgical removal of dead bone and reconstruction.

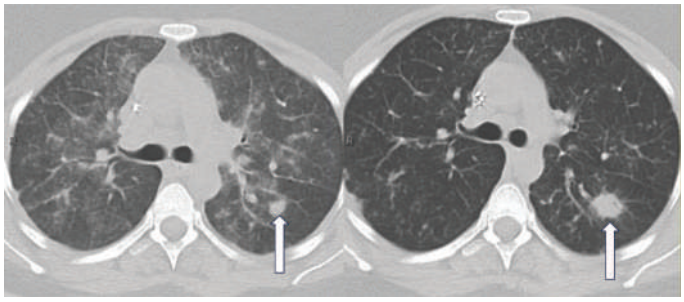
Splenectomy Splenectomy may be performed for diagnosis or treatment of cancer. The spleen has several key immune functions including removing of bacteria from blood, antigen presentation to T cells, and housing B cells that are activated and produce antibodies. Functional asplenia is present after splenic irradiation and with chronic GVHD. Asplenic patients are principally at risk for overwhelming sepsis by encapsulated bacteria like *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Patients should be vaccinated against these pathogens prior to planned splenectomy. Antibiotic prophylaxis (e.g., with penicillin) should be considered for the first 2 years after splenectomy, especially in patients with active malignancy or receiving immunosuppressive therapy. Asplenic patients with fever should be started promptly on antibiotics active against *S. pneumoniae* (e.g., ceftriaxone or levofloxacin or moxifloxacin). Vancomycin should be added in areas where high-level penicillin or cephalosporin resistance is common. Asplenic individuals also have increased risk of babesiosis, malaria, and infection with *Capnocytophaga canimorsus* (associated with animal bites or scratches) and *Salmonella* spp.

B Cell–Depleting Agents B cell–depleting agents are used as therapy for patients with B cell malignancies, such as B cell lymphomas and chronic lymphocytic leukemia. They are commonly used in combination with other antineoplastic agents. Antibody-based drugs such as rituximab result in prolonged B cell depletion, while Bruton tyrosine kinase (BTK) inhibitors (e.g., ibrutinib) interrupt a key enzyme and B cell activation but have shorter-acting effects. The effects of B cell depletion include increased risk of encapsulated bacteria and respiratory viral infections. Importantly, these patients are likely to have reduced immune responses to vaccination against bacteria and viruses, including influenza, SARS-CoV-2, and hepatitis B. The risk of severe COVID-19 is substantially increased in patients with hematologic malignancies compared with patients with solid tumors, and B cell–depleting agents are associated with increased COVID-19 severity and lack of serologic responses to SARS-CoV-2 infection and vaccination. All patients who will receive B cell–depleting agents should be screened for hepatitis B infection and receive therapy for hepatitis B (e.g., with entecavir or tenofovir alafenamide) for active or prior hepatitis B infection (see **Chaps. 350** and **352** on hepatitis viruses and **Chap. 208** on human immunodeficiency virus [HIV] infections). Rituximab and other B cell–depleting agents have been associated with progressive multifocal leukoencephalopathy (PML) and PJP, but the magnitude of the effect is difficult to ascertain. In addition, BTK inhibitors can have off-target effects on innate immune cells and increase the risk of other infections, including invasive aspergillosis, particularly when combined with other immunosuppressive agents, such as corticosteroids.

Bispecific Antibodies Bispecific antibodies are engineered to have dual specificity for a T cell antigen (e.g., CD3, a component of the T cell receptor complex) and a tumor antigen with the goal of stimulating T cell killing of tumor cells. When bispecific antibody constructs directed against B cell antigens (e.g., blinatumomab, a bispecific antibody against CD3 and the B cell antigen CD19) are used against B cell malignancies, the overall effect is a nonselective depletion of both tumor cells and normal B cells. Importantly, bispecific antibodies are commonly used in patients with refractory hematologic malignancies who already are at high risk for infection based on the underlying cancer and prior therapy. Bispecific antibody therapy can result in CRS, characterized by fever and inflammatory organ damage. Treatment of CRS involves high-dose corticosteroids and interleukin 6 (IL-6) blockade, which further increases the risk of infections.

Adoptive Cellular Therapy Adoptive cellular therapy (ACT) involves administration of genetically engineered cells targeted to tumor antigens. The most commonly used ACT is chimeric antigen receptor (CAR) T cells, in which autologous T cells are genetically engineered to express a receptor directed against a tumor antigen. Engagement of cells expressing this antigen results in the CAR T cell activation and tumor cell killing. In contrast to bispecific antibodies, current ACT involves lymphodepletion chemotherapy (usually with fludarabine and cyclophosphamide) to deplete immune cells and allow maximal expansion of the engineered T cells. A major goal of immunotherapy is to make ACT more effective for a broad range of solid tumors; however, the current use of ACT largely involves refractory B cell malignancies: lymphoblastic leukemia, lymphomas, and multiple myeloma. Lymphodepletion regimens result in pancytopenia, and both neutropenia and lymphopenia can be prolonged (months to years). In the case of standard CD19-directed CAR T cells, B cell depletion is by design; the persistence of CAR T cells is required for antitumor immunity, but it is nonselective, and the duration of global B cell depletion can be for years. ACT can also be complicated by CRS and an immune effector cell–associated neurotoxicity syndrome that can be life-threatening and requires treatment with intensive high-dose corticosteroids often combined with IL-6 blockade. Additional hematologic complications can occur after ACT, such as hemophagocytic lymphohistiocytosis (HLH), which extends pancytopenia and entails additional immunosuppressive therapy.

Recommendations regarding prophylaxis following ACT are based mainly on extrapolation and expert opinion. These include levofloxacin during neutropenia, TMP-SMX while on systemic corticosteroids or while CD4 count is <200/μL, acyclovir, and perhaps mold-active prophylaxis (e.g., posaconazole) during periods of prolonged neutropenia. Recipients of CAR T cells constitute a heterogeneous population due to the effect of multiple previous courses of therapy, sometimes including allogeneic HCT, and prophylaxis should be tailored to the degree of immunosuppression.



Cancer and HIV Infection HIV-associated malignancies include Epstein-Barr virus–associated non-Hodgkin and Hodgkin lymphomas, HHV-8-associated Kaposi sarcoma and primary effusion lymphoma, and human papilloma virus–associated cervical and anal cancer. HIV-positive patients have higher risks of chronic hepatitis B and hepatitis C infections that increase the risk of hepatocellular carcinoma. Patients with HIV infection can also have cancers that are not HIV-associated. A mainstay of cancer management in patients who are HIV-positive is that the antineoplastic regimen must be concurrent with antiretroviral therapy and appropriate prophylactic antimicrobials. The goals of antiretroviral therapy are a nondetectable HIV viral load and tolerability of the regimen, which includes monitoring and avoiding drug–drug interactions with antineoplastic chemotherapy. In general, it is recommended to test for HIV and hepatitis B and hepatitis C infection prior to starting antineoplastic therapy.

DIAGNOSIS AND MANAGEMENT OF INFECTIONS IN PATIENTS WITH NEUTROPENIA

Chemotherapy-induced neutropenia remains the major risk factor for infection in patients with cancer. However, patients with cancer frequently have multiple risk factors for infection, both from the underlying malignancy and its treatment. When evaluating patients with neutropenia and suspected infection, it is important to consider these other risk factors in the diagnostic evaluation and therapy **(Fig. 79-1)**.

NEUTROPENIC FEVER

A high proportion of cancer patients who become neutropenic after receiving chemotherapy develop fever. The standard definition of neutropenic fever (NF) is a single oral temperature ≥38.3°C or a temperature of ≥38.0°C sustained over 1 h, with an absolute neutrophil count

A B

FIGURE 79-1 Multiple pulmonary infections in a patient with acute myelogenous leukemia (AML). A patient with AML in remission after reinduction therapy with cytarabine, granulocyte colony-stimulating factor, and fludarabine (FLAG) presented with fever and neutropenia. A chest CT demonstrated diffuse pulmonary infiltrates (***A***). Bronchoalveolar lavage (BAL) was unrevealing except for positive PCR for *Pneumocystis jirovecii*, and trimethoprim-sulfamethoxazole was instituted. After 11 days of appropriate treatment (***B***), a repeat CT showed resolution of the infiltrates but a conspicuous, dense, well-circumscribed pulmonary nodule that had not been appreciated initially. Targeted BAL of the left lower lobe was positive for galactomannan, providing the diagnosis of probable invasive aspergillosis. The initial BAL had been of the right middle lobe only. Immunocompromised patients may have several infections simultaneously, and cancer patients often accumulate risk factors for infection during their treatment.

(ANC) of <500 cells/μL, or an ANC that is expected to decrease to <500 cells/μL over the next 48 h.

During neutropenia localizing signs and symptoms of infection may be subtle or altogether lacking, and infections may progress very quickly. These two basic features mandate early initiation of empirical antibacterial agents in neutropenic patients whenever infection is suspected. Although fever is the most common sign of infection, it is not the only one, and similar management should be used whenever infection is suspected in a neutropenic patient, such as in the presence of otherwise unexplained pain, tenderness, or erythema potentially secondary to infection.

NF is considered infectious in origin, but an infection is identified in only a minority of cases. An infection may be documented microbiologically (e.g., *Pseudomonas aeruginosa* bacteremia identified by positive blood cultures) or only clinically (e.g., abdominal pain and bloody diarrhea with negative blood cultures, presumed to represent neutropenic enterocolitis). Using standard diagnostic methods (i.e., routine cultures, serologic tests, and imaging studies) an infection is documented in approximately 40% of episodes of NF. However, newer diagnostic modalities using plasma cell–free DNA polymerase chain reaction (PCR) identify a potential bacterial etiology most of the time. Most bacteria identified by these studies are part of the normal flora of skin and bowel (as are the bacteria isolated by standard culture methods when these are positive), since these physical barriers are often disrupted by the cancer treatments that caused the neutropenia. Infections during neutropenia are typically caused by microorganisms carried by the patient as part of their microbiome.

MANAGEMENT OF NEUTROPENIC FEVER

First Neutropenic Fever There is a wealth of good-quality evidence to support standard-of-care guidelines for the management of the initial episode of NF. After a swift history and physical exam (focused on potential portals of entry like the vascular catheter exit site, mouth, and perianal area), blood cultures are obtained and empirical antibiotic therapy is initiated using a single agent (monotherapy) with broad-spectrum activity, including coverage of *P. aeruginosa*. Ideally, antibiotics should be given within 1 h of the onset of NF. The diagnostic utility of chest imaging in the absence of respiratory symptoms or signs has not been established.

Ceftazidime, cefepime, imipenem, meropenem, and piperacillin-tazobactam are the best-studied antibiotics used as monotherapy for NF. The specific choice will vary from institution to institution based on the local frequency of resistant bacteria. This "backbone regimen" may be complemented with a second agent against resistant gram-negative or gram-positive bacteria depending on clinical features, prior history of resistant pathogens, or local trends of antimicrobial resistance.

It should be emphasized that standard empirical monotherapy regimens for NF apply to clinically stable patients with NF of unclear etiology. Management of neutropenic patients with localized signs of infection (e.g., respiratory, intra-abdominal, intravascular catheter–associated) are discussed below. In patients who are clinically unstable, such as those with hypotension or signs of organ injury raising concern for sepsis (e.g., impaired mental status, pulmonary edema, acute renal injury), a broader-spectrum antimicrobial regimen is warranted. Although the specific regimen for presumed or documented septic shock varies based on the patient's prior history of resistant infection and local susceptibility patterns, an example of an initial regimen is vancomycin, meropenem, and possibly an aminoglycoside; in patients at risk for candidiasis, an echinocandin may be added.

The standard monotherapy regimens lack activity against specific gram-positive pathogens. Gram-positive coverage with a glycopeptide antibiotic (vancomycin in the United States) is not routinely part of the initial regimen. Instead, the addition of a glycopeptide is reserved for clinical situations in which a gram-positive pathogen resistant to the standard regimen (e.g., methicillin-resistant *Staphylococcus aureus* [MRSA]) is more likely. The Infectious Diseases Society of America (IDSA) guidelines recommend empirical gram-positive coverage with sepsis, clinically evident soft tissue infection, clinically suspected catheter exit site infection, pneumonia, severe mucositis (only if ceftazidime is used as empirical regimen, because mucositis is a risk factor for viridans group streptococci), and known carrier status of MRSA or penicillin-resistant pneumococcus. Meta-analysis has shown that the routine inclusion of vancomycin in the initial regimen is not associated with better outcomes but does result in more nephrotoxicity.

After starting antibiotics, fever usually resolves in 24–72 h. If an infection was diagnosed, antibiotics are continued for the appropriate amount of time for that specific infection. When a specific microbe is isolated (e.g., from blood cultures), experts disagree regarding the need for continuing the broad-spectrum coverage versus narrowing based on susceptibility results.

If no microorganism is isolated and no source is identified, the optimal strategy for antibiotic management of NF that resolves with antibiotics is debated. In the past, empirical antibiotics were continued until resolution of neutropenia. However, recent studies have suggested that de-escalation from empiric therapy to prophylaxis or discontinuation are safe if specific criteria are met, including clinical stability. The advantage of such de-escalation or early discontinuation strategies relates to reduced antibiotic exposure and lower risk of selection of resistant pathogens; these benefits must be balanced against the potential for inadequately treated infection. Large, randomized, multicenter trials are required to evaluate the benefits and safety of antibiotic de-escalation or discontinuation of empirical antibiotic therapy in patients with persistent neutropenia.

Persistent Fever If the fever continues while receiving empirical antibiotic therapy without a diagnosis, evidence supports and guidelines recommend continuing the same antibiotic without addition or modification in the absence of clinical changes or new microbiologic data. The antibacterial regimen should be modified only if new clinical features arise (e.g., hypotension) of if new microbiologic data become available (e.g., a positive culture), and not just because of persistent fever. Although there is agreement on this issue between different guidelines, persistent, stable fever is a common reason why the antibacterial regimen is modified in clinical practice. The longer the neutropenic fever persists during the administration of broad-spectrum antibiotics, the higher the likelihood of IFD. Depending on prior history, use of antifungal prophylaxis, and local practices, one may choose to initiate empirical antifungal treatment after 5 days of fever (this was standard of care for decades and is called *empirical antifungal therapy*) or to perform tests focused on diagnosing an occult fungal infection and initiate antifungals only if these additional tests support the

possibility of IFD. This more recent approach has been named *preemptive antifungal strategy* and seems to result in similar patient outcomes with less use of antifungals. The empirical antifungal of choice will vary depending on the antifungal prophylaxis used (if any). Caspofungin and liposomal amphotericin B are the best-studied empirical antifungal treatment of NF, but expert recommendations vary. A frequently used approach is to administer posaconazole as antifungal prophylaxis in high-risk patients with neutropenia (e.g., those receiving induction or reinduction regimens for acute myeloid leukemia) and to not modify the antifungal regimen based solely on persistent or recurrent neutropenic fever.

Recrudescent Fever and Fever at the Time of Neutrophil Recovery In addition to the initial episode of fever and persistent fever, there are two other NF scenarios that have been less well studied: recrudescent fever and fever at the time of neutrophil recovery. Recrudescent fever refers to the situation in which the initial episode of fever resolves without a diagnosis, neutropenia persists, the antibiotic regimen is continued unmodified, and fever reappears after the patient has been afebrile for 48–96 h. This is not uncommon during prolonged neutropenia during induction or reinduction therapy in acute leukemia. In this case (as opposed to the first episode of NF), an infection is identified most of the time (bacterial, fungal, or viral), and the recommended approach is to empirically modify the antimicrobial regimen that had successfully controlled the fever up to this point, aiming for coverage of resistant bacteria and fungi. Intensive diagnostic procedures, including CT imaging, should be undertaken. Where available, CT combined with positron emission tomography (CT-PET) may be considered.

Finally, fever at the time of neutrophil recovery may be infectious in origin: either a preexisting infection that was silent due to lack of neutrophils (sometimes this is considered analogous to the immune reconstitution inflammatory syndrome [IRIS] seen after initiation of antiretroviral therapy in AIDS) or, less likely, a superinfection. However, fever is frequently noninfectious at this time and is related to myeloid engraftment. In any case, the recommended response to fever that occurs simultaneously with resolution of neutropenia is not any specific empirical antimicrobial regimen, but to pursue a thorough diagnostic evaluation.

OUTPATIENT THERAPY FOR NEUTROPENIC FEVER

Outpatient therapy for neutropenic fever should be considered in patients at lower risk for infectious complications from neutropenia. These patients typically have solid rather than hematologic tumors with a short expected duration of neutropenia, usually 7 days or less. Criteria for candidates for outpatient empirical therapy include clinical stability, no localizing symptoms or signs of infection, ability to eat and drink without difficulty, absence of significant comorbidities such as chronic lung or cardiovascular disease, normal renal and liver function, and easy access to a hospital and a caregiver at home. Outpatient oral antibiotic therapy in adults typically involves a quinolone (e.g., levofloxacin or ciprofloxacin) plus amoxicillin-clavulanate; such regimens are appropriate only for patients who have not received a quinolone as prophylaxis.

DOCUMENTED INFECTIONS DURING NEUTROPENIA

BACTEREMIA

Bacteremia is the most common microbiologically documented infection in neutropenic patients with fever. NF is associated with bacteremia in only 10% of cases, but this subgroup of patients has much higher mortality than the general group of neutropenic patients with fever, particularly with gram-negative bacteremia. Most recent series show similar proportions of gram-positive (coagulase-negative *Staphylococcus*, *Streptococcus* species, *Enterococcus* species including vancomycin-resistant *Enterococcus* [VRE]) and gram-negative bacteria (Enterobacterales and *P. aeruginosa*).

Bacteremia in neutropenic patients may be secondary to another site of infection (e.g., pneumonia, neutropenic enterocolitis, cellulitis) or, most commonly, to mucosal barrier injury (MBI) caused by the antineoplastic treatment. The chemotherapy and/or radiation frequently damages the mucosa of the gastrointestinal tract, facilitating translocation of commensal bacteria during neutropenia. Clinically, one may question whether the bacteremia may be a central line–associated bloodstream infection (CLABSI). If the isolate is an intestinal bacterium, it is considered related to MBI in the absence of local signs of infection involving the venous catheter. If the isolate is part of the skin flora, like coagulase-negative *Staphylococcus*, it is more likely to be a CLABSI, but it may also represent a contaminant or colonization of the catheter. Colonization or contamination should be presumed when only one of several blood culture bottles is positive for normal skin flora, especially if the culture takes more than 24 h to turn positive. When a blood culture becomes positive for a gram-positive organism, it is important to repeat blood cultures, ideally from both central and peripheral sites, to determine whether the blood culture isolate is recovered from more than one bottle and at different time points. Skin flora growing from blood drawn from the catheter with negative peripheral blood cultures can reflect catheter colonization (i.e., not a true bloodstream infection) or CLABSI with low levels of bacteria in blood resulting in negative peripheral cultures. When both the peripheral and the central blood cultures are positive for the same organism, bacteremia is confirmed, and the differential time to positivity may allow establishing the diagnosis of catheter-related bacteremia if the central line culture grows at least 2 h earlier than the peripheral. However, the practice of always obtaining a peripheral blood culture may not be practical on an oncology ward, where patients may be febrile daily and are frequently thrombocytopenic.

More important than whether blood cultures are collected from the central catheter alone or from central and peripheral venous sources is ensuring that an adequate volume of blood (as determined by the specific blood culture platform) is collected. The optimal frequency of blood cultures in NF has not been established. Similarly, the use of surveillance blood cultures in neutropenic patients has not been adequately studied. The amplification by PCR of plasma cell–free DNA, with its superior yield compared with blood cultures, is still investigational, and its place in the routine management of NF remains to be defined.

If CLABSI is diagnosed, the preferred treatment is to remove the catheter. Again, this may not always be practical in the case of thrombocytopenic patients with limited access, and an attempt to salvage a permanent catheter (i.e., tunneled catheter or port) may be appropriate as long as the patient remains hemodynamically stable and the blood cultures become negative upon initiating appropriate antibiotics. Antibiotic lock therapy should be considered, if feasible. The likelihood of success when a catheter is colonized with *S. aureus*, mycobacteria, or *Candida* species is low, and these catheters should be removed as soon as possible. It is customary to provide some time without central access (e.g., a 48-h "line holiday") before replacing the central venous catheter, although the evidence supporting this practice is scant. Patients may require continuous central IV access, and in this case it is reasonable to use nonsurgically placed lines (e.g., a peripherally inserted central catheter) and to place a new surgically implanted port (e.g., mediport) only when there is clear evidence of blood culture clearance.

Endocarditis is rare during neutropenia, but it should be suspected with persistently positive blood cultures or with clinical findings like a new murmur or embolic phenomena. Routine echocardiogram in every case of bacteremia in neutropenic patients is not recommended, but patients with *S. aureus* bacteremia do require one.

RESPIRATORY INFECTIONS

Sinusitis Sinusitis may manifest by pressure, facial pain, rhinorrhea, and postnasal drip but occasionally has very mild symptoms that will be elicited only by targeted questioning during the physical exam. Symptomatic sinusitis in neutropenic patients may be caused by

pathogens relatively uncommon in immunocompetent people, including *S. aureus*, *P. aeruginosa*, and other gram-negative bacilli. Evaluation by CT and consultation by otolaryngology to examine the integrity of the mucosa and obtain samples for culture is recommended. Invasive fungal sinusitis may be caused by *Aspergillus* species, agents of mucormycosis, *Fusarium* species, and relatively less virulent dematiaceous molds like *Alternaria*, *Bipolaris*, or *Curvularia.* CT findings suggestive of fungal etiology include marked asymmetry, heterogeneous radiodensity of the contents of the sinuses, and, later in the disease, bony erosions. The endoscopic exam may show pale, devitalized mucosa and, sometimes, necrotic ulceration of a turbinate caused by the angioinvasive process. Invasive fungal sinusitis during neutropenia mandates surgical resection. Repeated visits to the operating room in conjunction with optimal antifungal therapy are necessary to save the patient's life. The empirical antifungal agent may vary depending on the preexisting antifungal prophylaxis, but, given the possibility of mucormycosis and fusariosis, many experts would recommend a lipid formulation of amphotericin B, often considered the antifungal of choice for mucormycosis, together with posaconazole, which is noninferior to voriconazole for *Aspergillus* species and has superior activity in vitro against dematiaceous molds.

Pneumonia Pulmonary infiltrates are a common diagnostic challenge in immunocompromised hosts. A systematic approach to the differential, which includes infections and noninfectious etiologies, is mandatory. Some important noninfectious conditions to be considered include heart failure, fluid overload, transfusion reactions like transfusion-associated circulatory overload (TACO) and transfusion-associated lung injury (TRALI), chemotherapy-associated pneumonitis, organizing pneumonia, and diffuse alveolar hemorrhage, as well as dissemination of the cancer itself. The radiologic appearance is useful to separate unilateral focal processes (suggestive of bacterial or mold infection) from multifocal or diffuse infections, which may be caused in addition by viruses, atypical bacteria, and PJP. Single or multiple dense, well-circumscribed nodules suggest IFD in high-risk patients (e.g., those with leukemia and allogeneic stem cell transplant recipients), but *Nocardia* species may have the same appearance and other bacteria like *P. aeruginosa* and *Stenotrophomonas maltophilia* may cause angioinvasive infection and result in similar radiology. Unfortunately, characteristic radiologic differences may not hold true in an individual case, and every attempt should be made to obtain a respiratory sample for microbiologic diagnosis.

Early bronchoscopy with bronchoalveolar lavage (BAL) in neutropenic patients with pneumonia is recommended. The yield of BAL is highest for diffuse and multifocal processes. In the case of pulmonary nodules accessible to percutaneous or endobronchial biopsy, the choice of diagnostic procedure will often depend on institutional expertise, clinical status, and comorbidities. The empirical antimicrobial regimen may vary slightly depending on the radiology and the individual risk factors but should always provide optimal antibacterial coverage by combining one of the antipseudomonal β-lactams together with vancomycin and an agent active against *Legionella*, like azithromycin, a fluoroquinolone, or doxycycline. If the patient has risk factors for *S. maltophilia* (high prevalence in the institution, previous exposure to carbapenems), the addition of TMP-SMX or levofloxacin should be considered.

The empirical addition of TMP-SMX for PJP depends on the clinical scenario and risk factors. If the only immune defect of the patient is neutropenia, the main concerns are bacteria and molds, the likelihood of PJP is low, and empirical anti-*Pneumocystis* coverage seems unnecessary. However, patients with hematologic malignancies often have received corticosteroids or other agents that decrease cellular immunity and put them at risk for PJP. In this case, empirical coverage until PJP has been ruled out is reasonable. The current gold standard for the diagnosis of PJP is PCR of respiratory secretions, which occasionally may detect patients who are merely colonized. Serum β-D-glucan is typically elevated in patients with PJP, and a positive result increases the likelihood of PJP in a patient with appropriate risk factors and radiologic findings. However, false-positive and -negative β-D-glucan results occur, and this test is not specific for PJP; therefore, a positive serum β-D-glucan does not always obviate the need for BAL.

Invasive fungal disease (IFD) is suggested by single or multiple dense, well-circumscribed nodules, particularly larger than 2 cm. The halo sign (ground glass opacity surrounding a dense nodule) or the reverse halo sign (ground glass opacity seen inside a nodule, sometimes said to be more common in mucormycosis) may be present, but these are not diagnostic. Peripheral wedge-shaped infiltrates also may be seen. In patients at high risk for IFD, initiation or escalation of antifungal therapy is commonly begun prior to establishing a diagnosis. Such decisions must consider the antifungal prophylaxis that the patient is receiving. If the patient is on fluconazole or no antifungal prophylaxis, a mold-active azole (e.g., voriconazole, posaconazole, isavuconazole) as empirical therapy is reasonable pending a diagnosis, since *Aspergillus* is by far the most likely mold infection. If on the other hand, a suspected fungal infection occurs while receiving a mold-active azole, many experts would recommend switching the regimen to liposomal amphotericin B, while aggressively pursuing a diagnosis.

Evaluation of suspected pneumonia involves sputum and blood cultures, nasopharyngeal swab for PCR for respiratory viruses, urine *Legionella* antigen, and in patients with neutropenia, evaluation for IFD (e.g., serum galactomannan, beta-glucan) should be included. If these studies are negative and the empirical antimicrobial regimen does not lead to improvement, early BAL or image-guided percutaneous lung biopsy should be considered. If non-invasive diagnostic studies identify a pathogen, it is important to consider the potential for concurrent or secondary infection by other pathogens. For example, respiratory viral infections can be complicated by secondary bacterial pneumonias, and cases of invasive pulmonary aspergillosis following COVID-19 have been documented. It is therefore important to consider a broad differential diagnosis and to repeat imaging and diagnostic evaluation in patients with worsening pneumonia even when an initial diagnosis has been made.

INTRA-ABDOMINAL INFECTIONS

Neutropenic Enterocolitis (Typhlitis) Sometimes bacteria invade the wall of the intestine and proliferate there, causing inflammation and even necrosis of segments of the bowel. The clinical syndrome includes fever, abdominal pain, and tenderness and diarrhea, which is occasionally bloody. The term *typhlitis* (inflammation of the cecum) is sometimes used, as the cecum is most commonly involved, but the terminal ileum, ascending colon, and other segments of the intestine also may be affected, so the more general term *neutropenic enterocolitis* is preferred. Blood cultures are frequently positive (with bowel flora), but not always. Plain films of the abdomen are not sensitive or specific, but a right lower quadrant soft tissue density, distended bowel loops, ileus, or "thumbprinting" suggesting mucosal edema may sometimes be seen. A CT scan of the abdomen and pelvis usually demonstrates a right lower quadrant inflammatory mass, with thickened bowel wall and stranding of the surrounding fat. Conservative management with broad-spectrum antibiotics, bowel rest, bowel decompression, and nutritional support is usually preferred. Surgery may be required if the patient deteriorates and intestinal perforation, peritonitis, and hemodynamic instability ensue. Carbapenems and piperacillin-tazobactam are appropriate given their broader spectrum. If ceftazidime or cefepime is used, additional agents against anaerobic bacteria (e.g., metronidazole) must be added. In selecting an empirical regimen, it is important to note prior infections with antibiotic-resistant infections, such as VRE, and extended-spectrum β-lactamase (ESBL) of carbapenem-resistant (CRE) gram-negative infections.

Similar to intra-abdominal infections, perirectal and perianal infections are caused by gastrointestinal flora in the context of neutropenia and mucosal injury. CT imaging is helpful to assess the extent of infection. These infections typically respond to broad-spectrum antibiotic therapy without the need for surgery, but follow-up imaging after neutrophil recovery may be necessary if symptoms or fever persist.

***Clostridioides difficile* (*C. difficile*)–Associated Disease** Cancer patients are at increased risk of *C. difficile*–associated disease (CDAD)

because of their frequent exposure to healthcare facilities, antibiotics, and chemotherapeutic drugs. Patients with a history of CDAD in the previous year are often treated prophylactically with oral vancomycin (125 mg daily) when empirical antibiotic therapy for neutropenic fever is begun. Every hospitalized neutropenic patient with diarrhea should be tested for *C. difficile*. It is unclear whether neutropenic patients with CDAD have worse outcomes, higher risk of complications, or increased frequency of neutropenic enterocolitis. First-line treatment is fidaxomicin, with oral vancomycin as an alternative. In case of ileus or overwhelming CDAD, combination of either oral fidaxomicin or vancomycin with IV metronidazole (which is secreted into the intestinal lumen) is recommended.

Cholecystitis Cholecystitis is a rare infection during neutropenia, and most cases have been seen during treatment of acute leukemia. The presentation is like that in nonneutropenic individuals, but bacteremia is more common. At least half of the reported cases have been acalculous cholecystitis. Conservative management, frequently including cholecystostomy, is used until resolution of neutropenia when cholecystectomy can be performed more safely.

CENTRAL NERVOUS SYSTEM INFECTIONS

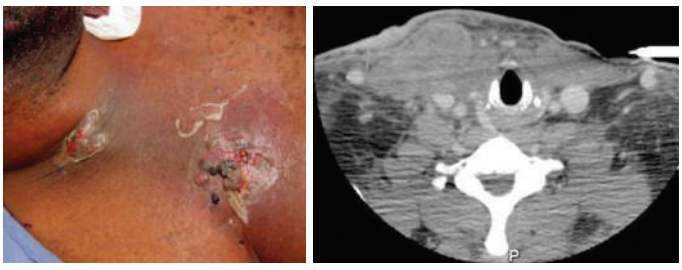
Bacterial central nervous system (CNS) infections are uncommon during neutropenia and usually secondary to an episode of bacteremia (which may or may not have been detected) or to extension from the paranasal sinuses. Meningitis caused by gram-negative bacilli, including *P. aeruginosa*, may occur in this setting. Two unexpected causes of CNS infections are worth mentioning. *Rothia mucilaginosa*, a gram-positive coccus that is part of the oral flora, may seed the meninges during a transient bacteremia that seemed to be controlled easily with appropriate antibiotic treatment. This is a rare infection, and most cases treated successfully have received meropenem and vancomycin. Similarly, *Bacillus cereus*, a gram-positive bacillus ubiquitous in the environment, has been reported as a cause of difficult-to-treat meningitis and brain abscess in neutropenic patients with acute leukemia. The combination of meropenem and vancomycin also has been used successfully. *Listeria monocytogenes* meningitis and bacteremia are most common in patients with impaired cellular immunity, including patients with cancer receiving immunosuppressive regimens. Besides meningitis, *L. monocytogenes* can also cause rhombencephalitis (inflammation of the brainstem and cerebellum) and brain abscess. The combination of ampicillin and gentamicin is recommended. In cases of penicillin allergy TMP-SMX may be used. *Listeria monocytogenes* is susceptible in vitro to meropenem and linezolid, but clinical experience is limited.

In patients with hematologic cancers and prolonged neutropenia, brain lesions should raise the concern for opportunistic pathogens, usually fungi. *Aspergillus* and *Candida* brain abscesses are usually hematogenous; mucormycosis more frequently follows extension from the sinuses. Empirical treatment should be administered including antibacterial (typically meropenem plus vancomycin) and antifungal agents until the etiology is established. As mentioned for pulmonary infections, the choice of antifungal may be conditioned by preexisting antifungal prophylaxis. Voriconazole is the preferred agent for CNS aspergillosis and liposomal amphotericin B for mucormycosis. Echinocandins do not achieve therapeutic levels in the brain or cerebrospinal fluid (CSF), and they should not be relied upon for the treatment of CNS infections.

Nocardia species and *Toxoplasma gondii* are important causes of brain abscess in immunocompromised patients. The major risk factor for these infections is suppressed T cell immunity. In patients with cancer, prolonged intensive corticosteroid therapy and use of purine analogues are examples of risk factors. TMP-SMX used as prophylaxis for PJP may also confer some protection against *Listeria*, *Nocardia*, and *Toxoplasma*.

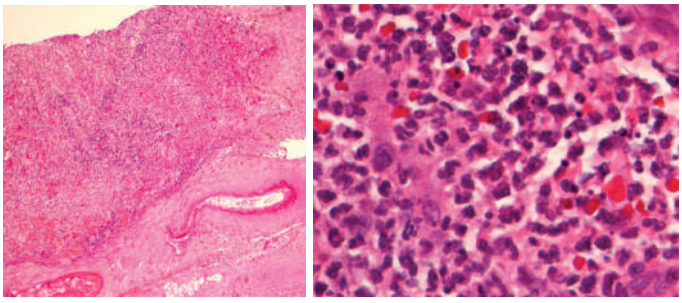
Patients with cancer are at increased risk of viral encephalitis. Herpes simplex virus (HSV) encephalitis is characterized by fever and decreased level of consciousness. Imaging shows unilateral involvement of the temporal lobe. Abnormalities in the CSF may be altered by radiation therapy or corticosteroids. The diagnosis is by PCR of the CSF, which may be falsely negative early in the course of the disease. Herpes zoster encephalitis is a rare but devastating complication in patients with defective T cell immunity. Human herpesvirus 6 (HHV-6) encephalitis is rare outside of allogeneic stem cell transplantation (allo-HCT) (see **Chap. 148**). Finding a high level of HHV-6 in blood in any other setting brings up the possibility of HHV-6 chromosomal integration, which is present in around 1% of the population.

In patients who have had neurosurgery, including those with neurosurgical devices (e.g., shunts or reservoirs), infections by gram-positive bacteria are most common, although gram-negative infections including coliforms and *P. aeruginosa* can occur. Risk factors include multiple neurosurgeries (e.g., for recurrent tumor), cranial irradiation, antiangiogenics (which disrupt blood supply), and use of immunosuppressives. Vancomycin plus an antipseudomonal cephalosporin (e.g., ceftazidime) is an appropriate initial regimen for postneurosurgical CNS infections, pending culture data. Surgical drainage and debridement of infected material and removal of hardware are usually required.



SKIN AND SOFT TISSUE INFECTIONS

As a rule, focal skin lesions in neutropenic, febrile patients should be biopsied, as the diagnostic possibilities are multiple, and some of the causes may be life-threatening and require immediate treatment. Cellulitis may be caused by streptococci or *S. aureus*, but also by gram-negative bacilli, and broad-spectrum coverage with an antipseudomonal β-lactam and vancomycin should be administered until an etiologic diagnosis is established. Multiple foci of erythematous tender plaques with underlying fasciitis and myositis are associated with bacteremia by *Clostridium septicum*, sometimes seen in patients with colorectal cancer. Ecthyma gangrenosum appears as a tender, erythematous papule that then becomes necrotic and ulcerated. It may be caused by local inoculation or by hematogenous seeding, typically of *P. aeruginosa* but sometimes other gram-negative bacteria or even molds like *Fusarium* species. Single or multiple lesions may be seen. Disseminated candidiasis with hematogenous cutaneous disease manifests with fever and other signs of systemic infection and multiple raised cutaneous papules. Hemorrhagic bullae are described in cellulitis caused by gram-negative bacteria (including *Vibrio vulnificus*, which may be suspected with a history of liver dysfunction and exposure to shellfish).



Many noninfectious processes can cause skin lesions, but the presence of fever is unusual except in Sweet syndrome, also known as acute neutrophilic dermatosis **(Fig. 79-2)**. This is characterized by fever and a variety of skin lesions including papules, nodules, plaques, and sometimes blisters. Skin lesions are often tender and may ulcerate. Sweet syndrome can have many causes, including underlying cancer, usually hematologic. Pathergy is characteristic, and lesions may appear at the insertion site of an intravascular catheter, mimicking infection (Fig. 79-2). Leukemia cutis may manifest as a variety of nontender papules, nodules, or plaques. Fever is unusual. Chemotherapeutic agents can cause a variety of skin reactions, including hyperpigmentation, hand-foot syndrome (erythema, edema, and blistering of palms and soles), and several rashes. Definitive diagnosis often requires biopsy of skin lesions with appropriate cultures and histopathology.

URINARY TRACT INFECTIONS

It is common to obtain urine cultures in patients with NF regardless of urinary symptoms, and sometimes bacteriuria is detected. The question of whether it is just asymptomatic bacteriuria (common and increasing with age in both men and women), unrelated to the fever, or reflects true urinary tract infection (UTI) necessitating specific treatment may not be immediately answerable. It is appropriate to treat bacteriuria in patients with NF, and standard empirical antibiotic regimens used for NF will cover most urinary pathogens. If UTI is believed to be the source of NF, CT imaging should be considered to

A B

C D

FIGURE 79-2 Sweet syndrome. A 47-year-old man admitted for acute myelogenous leukemia (AML) received a surgically implanted catheter and was started on idarubicin and cytosine arabinoside (Ara-C). He developed erythema and tenderness at the insertion site and the cuff site after 24 h, followed by fever. The catheter was removed and cultured (negative) and broad-spectrum antibiotics started, without effect. The catheter exit site worsened, with bullae formation (***A***). New skin nodules developed on his left thigh, both cheeks, and scalp. Tender induration of the sternocleidomastoid muscle was noticeable clinically and by CT (***B***). Skin biopsy showed a dense infiltrate of mature neutrophils consistent with Sweet syndrome (***C***, ***D***). The lesions and the fever resolved promptly with oral prednisone.

evaluate for complicated UTI with potential etiologies including genitourinary tract obstruction by tumor or kidney stones, pyelonephritis, and prostatitis.

PREVENTION OF INFECTIONS IN PATIENTS WITH CANCER

Prevention measures to avoid infections should be tailored to the immune status of the patient and consequent risk of infections. The most stringent measures apply to patients with hematologic malignancies with prolonged neutropenia, to stem cell transplant and adoptive cellular therapy recipients, and to other patients who may have prolonged neutropenia for other reasons (e.g., aplastic anemia) or are receiving intensive systemic corticosteroid therapy. At the other end of the spectrum are patients with solid tumors who are in remission and not receiving active chemotherapy or only receiving hormonal agents, such as antiestrogen therapy for breast cancer. These patients should adhere to guidelines to prevent infection that apply to the general population such as hand hygiene, food safety, and guideline-based vaccines. This section is focused on prevention measures for patients with cancer at high risk for infections including opportunistic infection.

ENVIRONMENTAL PRECAUTIONS

Inpatient leukemia and transplant wards are typically engineered with HEPA filters and appropriate air exchanges, and individual patient rooms are under positive pressure relative to the outside. The principal rationale for these precautions is to reduce mold spore exposure; these structural precautions were in part driven by outbreaks of aspergillosis. For similar reasons, houseplants are restricted from these wards. Construction, which can release mold spores, must be performed under stringent infection control precautions to minimize patient exposure. In addition to limiting mold exposure, these precautions may have additional benefits to limit airborne transmission of other infections.

The vast majority of chemotherapy regimens are administered to outpatients, including to patients with hematologic malignancies receiving intensive immunosuppressive regimens. The stringent environmental precautions used for inpatients are not feasible in the outpatient setting or in the home. Patients should not have construction done in their homes and should avoid exposure to construction sites during periods of significant immune compromise. Patients should also not be involved in gardening, mulching, or similar activities that result in spore exposure.

PROTECTION FROM FOOD-BORNE INFECTIONS

The old practice of implementing "low-microbial diets" for neutropenic patients did not show convincing benefit in well-designed studies and carries the disadvantages of limiting nutrition and affecting quality of life. Patients should be educated about food and water safety precautions issued by the Centers for Disease Control and Prevention (*www.cdc.gov/food-safety/foods/weakened-immune-systems.html*) and other authoritative bodies that are tailored to immunocompromised persons but are less restrictive than low-microbial diets. These guidelines stress hand hygiene, washing vegetables and fruits, not consuming raw or undercooked meat, poultry, or fish or unpasteurized dairy products, avoidance of waterborne infections, and awareness of food-borne outbreaks. Travel to regions where food and water safety is not reliable should be avoided.

Animals also are a potential source of infection, particularly via the fecal–oral route. Patients with cancer should avoid exposure to farm animals and wild animals (e.g., hunting and butchering). Acquiring a new pet while immunocompromised is not advisable. Existing pets can continue to live in the patient's house, but the patient should avoid direct exposure to animal waste, such as cleaning a cat litter box or bird cage. Patients should avoid dogs recently vaccinated for kennel cough, if possible. Contact with more exotic pets (e.g., reptiles) should be avoided because they can harbor more unusual pathogens (e.g., *Salmonella* species).

RESPIRATORY VIRAL INFECTIONS

Patients with cancer should avoid contact with persons with symptoms or signs of respiratory infection to the extent feasible. Risk of viral infection is increased in congregate settings that are indoors and involve large numbers of people in close proximity. Precautions to limit infection spread, such as choosing outdoor over indoor events and avoiding crowded settings, are advisable. For example, a dinner at a restaurant in which the table is limited to a few persons carries less risk of transmissible infections than a crowded buffet-style setting.

Patients with cancer should be aware of local patterns of viral infection. This point was amply demonstrated during the COVID-19 pandemic and applies to other viral infections, such as influenza and respiratory syncytial virus (RSV). If local viral outbreaks occur, patients with cancer should use additional precautions to limit exposure. In addition to avoiding crowds, masking may provide an additional layer of protection, especially in settings of high levels of community spread of respiratory viral infections.

SEXUAL INTIMACY

To avoid risk of sexually transmitted infections, it is recommended that sexual intercourse be in a monogamous relationship. During neutropenia, sexual intercourse and oral–genital or rectal stimulation may cause injury and predispose to infection. Once the ANC recovers, sexual activity usually can be resumed.

ANTIMICROBIAL PROPHYLAXIS

Antimicrobial prophylaxis should be tailored to infection risk. Most patients with solid tumors require no antimicrobial prophylaxis. In addition to side effects of antibiotics, increased risk of *C. difficile*, and selection of antibiotic-resistant flora, there is precedent for antibiotics diminishing the efficacy of immune checkpoint inhibitors by disruption of the microbiome.

As discussed above, prophylaxis with a quinolone should be considered in adults with prolonged neutropenia (e.g., ANC <500/μL for at least 7 days). Acyclovir prophylaxis to prevent HSV and VZV

reactivation is advised in the majority of patients with hematologic malignancies on active therapy. In patients with AML receiving induction or reinduction chemotherapy, prophylaxis with posaconazole should be included. Mold-active prophylaxis is also recommended in patients with significant GVHD. PJP prophylaxis is recommended for patients with severe T cell impairment (TMP-SMX is preferred). Examples include standard induction chemotherapy for acute lymphoblastic leukemia that involves systemic corticosteroids, prolonged corticosteroids (described above), use of purine analogues (e.g., cladribine-containing regimens), and GVHD. Pneumococcal prophylaxis (e.g., with penicillin) should be considered for persons with asplenia or chronic GVHD (described above).

VACCINATION

Patients with cancer should receive all recommended non-live vaccines based on their approved indications. Yearly recommendations regarding COVID-19 and influenza vaccines should be followed. Patients with solid tumors in general mount greater antibody titers than patients with hematologic malignancies, especially if they have received B cell–depleting agents (e.g., rituximab, BTK inhibitors). However, vaccination is still recommended for such patients with the rationale that they may derive some protective benefit even if suboptimal. We also stress vaccination of household members, caretakers, and other close contacts to prevent them from viral infection and transmission to the patient.

Live vaccines should not be given to immunocompromised persons. However, household members including children should receive age-appropriate vaccines, including live vaccines such as MMR and varicella. If the child develops a rash following MMR or varicella vaccination, contact with the cancer patient should be limited until the rash resolves.

80 Oncologic Emergencies

Rasim Gucalp, Janice P. Dutcher

Emergencies in patients with cancer may be classified into three groups: pressure or obstruction caused by a space-occupying lesion, metabolic or hormonal problems (paraneoplastic syndromes, **Chap. 98**), and treatment-related complications.

STRUCTURAL-OBSTRUCTIVE ONCOLOGIC EMERGENCIES

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is the clinical manifestation of superior vena cava (SVC) obstruction, with severe reduction in venous return from the head, neck, and upper extremities. Malignant tumors, such as lung cancer, lymphoma, and metastatic tumors, are responsible for the majority of SVCS cases. With the expanding use of intravascular devices (e.g., permanent central venous access catheters, pacemaker/defibrillator leads), the prevalence of benign causes of SVCS is now increasing, accounting for at least 40% of cases. Lung cancer, particularly of small-cell and squamous cell histologies, accounts for ~85% of all cases of malignant origin. In young adults, malignant lymphoma is a leading cause of SVCS. Hodgkin's lymphoma involves the mediastinum more commonly than other lymphomas but rarely causes SVCS. When SVCS is noted in a young man with a mediastinal mass, the differential diagnosis is lymphoma versus primary mediastinal germ cell tumor. Metastatic cancers to the mediastinal lymph nodes, such as testicular and breast carcinomas, account for a small proportion of cases. Other causes include benign tumors, aortic aneurysm, thyromegaly, thrombosis, and fibrosing mediastinitis from prior irradiation, histoplasmosis, or Behçet's syndrome. SVCS as the initial manifestation of Behçet's syndrome may be due to inflammation of the SVC associated with thrombosis.

Patients with SVCS usually present with neck and facial swelling (especially around the eyes), dyspnea, and cough. Other symptoms include hoarseness, tongue swelling, headaches, nasal congestion, epistaxis, hemoptysis, dysphagia, pain, dizziness, syncope, and lethargy. Bending forward or lying down may aggravate the symptoms. The characteristic physical findings are dilated neck veins; an increased number of collateral veins covering the anterior chest wall; cyanosis; and edema of the face, arms, and chest. Facial swelling and plethora are typically exacerbated when the patient is supine. More severe cases include proptosis, glossal and laryngeal edema, and obtundation. The clinical picture is milder if the obstruction is located above the azygos vein. Symptoms are usually progressive, but in some cases, they may improve as collateral circulation develops.

Signs and symptoms of cerebral and/or laryngeal edema, though rare, are associated with a poorer prognosis and require urgent evaluation. Seizures are more likely related to brain metastases than to cerebral edema from venous occlusion. Patients with small-cell lung cancer and SVCS have a higher incidence of brain metastases than those without SVCS.

Cardiorespiratory symptoms at rest, particularly with positional changes, suggest significant airway and vascular obstruction and limited physiologic reserve. Cardiac arrest or respiratory failure can occur, particularly in patients receiving sedatives or undergoing general anesthesia.

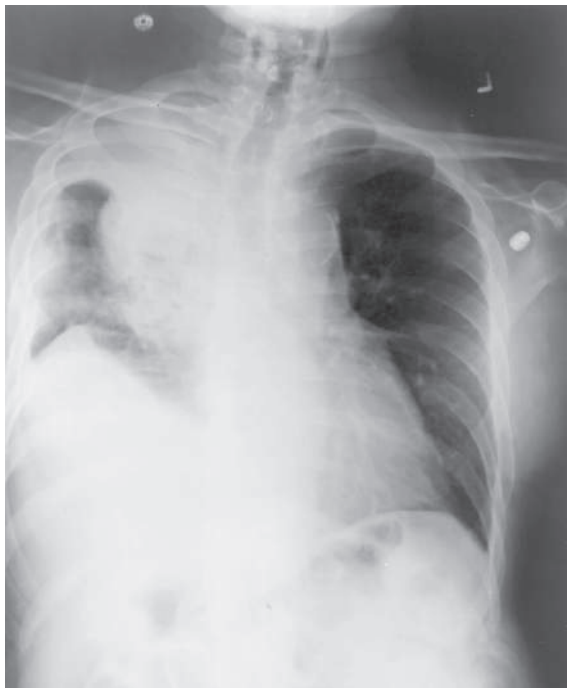
Rarely, esophageal varices may develop, particularly in the setting of SVC syndrome due to hemodialysis catheter. These are "downhill" varices based on the direction of blood flow from cephalad to caudad (in contrast to "uphill" varices associated with caudad to cephalad flow from portal hypertension). Variceal bleeding may be a late complication of chronic SVCS.

SVC obstruction may lead to bilateral breast edema with bilateral enlarged breasts. Unilateral breast dilation may be seen as a consequence of axillary or subclavian vein blockage.

The diagnosis of SVCS is a clinical one. The most significant chest radiographic finding is widening of the superior mediastinum, most commonly on the right side. Pleural effusion occurs in only 25% of patients, often on the right side. The majority of these effusions are exudative and occasionally chylous. However, a normal chest radiograph is still compatible with the diagnosis if other characteristic findings are present. Computed tomography (CT) provides the most reliable view of the mediastinal anatomy. The diagnosis of SVCS requires diminished or absent opacification of central venous structures with prominent collateral venous circulation. The focal hepatic hotspot on CT scan ("hot quadrate") sign suggests SVC obstruction, and it is caused by portosystemic venous shunting between the SVC and portal vein within liver. Magnetic resonance imaging (MRI) is increasingly being used to diagnose SVC obstruction with a 100% sensitivity and specificity, but dyspneic SVCS patients may have difficulty remaining supine for the entire imaging process. Invasive procedures, including bronchoscopy, percutaneous needle biopsy, mediastinoscopy, and even thoracotomy, can be performed by a skilled clinician without any major risk of bleeding. Endobronchial or esophageal ultrasound-guided needle aspiration may establish the diagnosis safely. For patients with a known cancer, a detailed workup usually is not necessary, and appropriate treatment may be started after obtaining a CT scan of the thorax. For those with no history of malignancy, a detailed evaluation is essential to rule out benign causes and determine a specific diagnosis to direct the appropriate therapy.

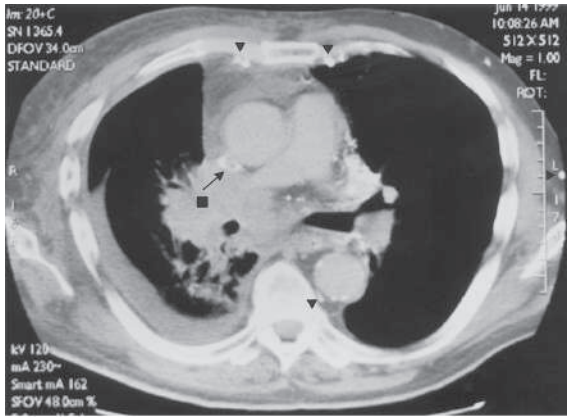
TREATMENT

Superior Vena Cava Syndrome



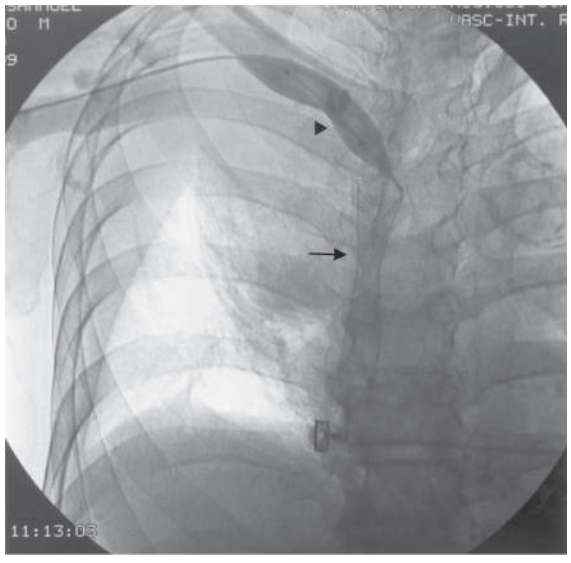
The one potentially life-threatening complication of a superior mediastinal mass is tracheal obstruction. Upper airway obstruction demands emergent therapy. Diuretics with a low-salt diet, head elevation, and oxygen may produce temporary symptomatic relief. Glucocorticoids have a limited role except in the setting of mediastinal lymphoma masses.

Radiation therapy is the primary treatment for SVCS caused by non-small-cell lung cancer and other metastatic solid tumors. Chemotherapy is effective when the underlying cancer is small-cell carcinoma of the lung, lymphoma, or germ cell tumor. SVCS recurs in 10–30% of patients; it may be palliated with the use of intravascular self-expanding stents **(Fig. 80-1)**. Endovascular therapy is more frequently used first, to provide rapid relief of clinical symptoms with reduced complications. Early stenting may be necessary in patients with severe symptoms, particularly cerebral or laryngeal edema or postural hypotension; however, the prompt increase in venous return after stenting may precipitate heart failure and pulmonary edema. Other complications of stent placement include hematoma at the insertion site, SVC perforation, stent migration in the right ventricle, stent fracture, and pulmonary embolism. Surgery may play role in treatment of SVCS secondary to nonmalignant mediastinal fibrosis.



Clinical improvement occurs in most patients, although this improvement may be due to the development of adequate collateral circulation. The mortality associated with SVCS does not relate to caval obstruction but rather to the underlying cause.

SVCS AND CENTRAL VENOUS CATHETERS IN ADULTS



The use of long-term central venous catheters has become common practice in patients with cancer. Major vessel thrombosis may occur. In these cases, catheter removal should be combined with anticoagulation to prevent embolization. SVCS in this setting, if detected early, can be treated by fibrinolytic therapy without sacrificing the catheter. When managing patients with transvenous lead-related SVC syndrome, anticoagulation, local and systemic thrombolytic therapy, and surgical intervention can be effective therapy in select patients. Endovascular stenting has also been shown to be safe and promising, with minimal procedural or clinical complications. The role of anticoagulation after SVC stent placement is controversial.

PERICARDIAL EFFUSION/TAMPONADE

Malignant pericardial disease is found at autopsy in 5–10% of patients with cancer, most frequently with lung cancer, breast cancer, leukemias, and lymphomas. Cardiac tamponade as the initial presentation of extrathoracic malignancy is rare. The origin is not malignancy in ~50% of cancer patients with symptomatic pericardial disease, but it can be related to irradiation; drug-induced pericarditis, including chemotherapeutic agents such as all-trans retinoic acid, arsenic trioxide, imatinib, and other abl kinase inhibitors; hypothyroidism; idiopathic pericarditis; infection; or autoimmune diseases. Pericardial disease has been associated with immune checkpoint inhibitors specifically in patients with advanced non-small-cell lung cancer. Two types of radiation pericarditis occur: an acute inflammatory, effusive pericarditis occurring within months of irradiation, which usually resolves spontaneously, and a chronic effusive pericarditis that may appear up to 20 years after radiation therapy and is accompanied by a thickened pericardium.

Most patients with pericardial metastasis are asymptomatic. However, the common symptoms are dyspnea, cough, chest pain, orthopnea, and weakness. Pleural effusion, sinus tachycardia, jugular venous distention, hepatomegaly, peripheral edema, and cyanosis are the most frequent physical findings. Relatively specific diagnostic findings, such as paradoxical pulse, diminished heart sounds, pulsus alternans (pulse waves alternating between those of greater and lesser amplitude with successive beats), and friction rub are less common than with nonmalignant pericardial disease. Chest radiographs and electrocardiogram (ECG) reveal abnormalities in 90% of patients, but half of these abnormalities are nonspecific. Echocardiography is the most helpful diagnostic test. Pericardial fluid may be serous, serosanguineous, or hemorrhagic, and cytologic examination of pericardial fluid is diagnostic in most patients. Measurements of tumor markers in the pericardial fluid are not helpful in the diagnosis of malignant pericardial fluid. Pericardioscopy with targeted pericardial and epicardial biopsy may differentiate neoplastic and benign pericardial disease. A combination of cytology, pericardial and epicardial biopsy, and guided pericardioscopy gives the best diagnostic yield. CT scan of chest may also reveal the presence of a concomitant thoracic neoplasm. Cancer patients with pericardial effusion containing malignant cells on cytology have a very poor survival.

TREATMENT

Pericardial Effusion/Tamponade

Pericardiocentesis with or without the introduction of sclerosing agents, the creation of a pericardial window, complete pericardial stripping, cardiac irradiation, and systemic chemotherapy are effective treatments. Acute pericardial tamponade with life-threatening hemodynamic instability requires immediate drainage of fluid. This can be quickly achieved by pericardiocentesis. The recurrence rate after percutaneous catheter drainage is ~20%. Sclerotherapy (pericardial instillation of bleomycin, mitomycin C, or tetracycline) may decrease recurrences. Alternatively, subxiphoid pericardiotomy can be performed in 45 min under local anesthesia. Thoracoscopic pericardial fenestration can be employed for benign causes; however, 60% of malignant pericardial effusions recur after this procedure. In a subset of patients, drainage of the pericardial effusion is paradoxically followed by worsening hemodynamic instability. This so-called "postoperative low cardiac output syndrome" occurs in up to 10% of patients undergoing surgical drainage and carries poor short-term survival.

INTESTINAL OBSTRUCTION

Intestinal obstruction and reobstruction are common problems in patients with advanced cancer, particularly colorectal or ovarian carcinoma. However, other cancers, such as lung or breast cancer and melanoma, can metastasize within the abdomen, leading to intestinal obstruction. Metastatic disease from colorectal, ovarian, pancreatic, gastric, and occasionally breast cancer can lead to peritoneal carcinomatosis, with infiltration of the omentum and peritoneal surface, thus limiting bowel motility. Typically, obstruction occurs at multiple sites in peritoneal carcinomatosis. Melanoma has a predilection to involve the small bowel; this involvement may be isolated, and resection may result in prolonged survival. Intestinal pseudoobstruction is caused by infiltration of the mesentery or bowel muscle by tumor, involvement of the celiac plexus, or paraneoplastic neuropathy in patients with small-cell lung cancer. Paraneoplastic neuropathy is associated with IgG antibodies reactive to neurons of the myenteric and submucosal plexuses of the jejunum and stomach. Ovarian cancer can lead to authentic luminal obstruction or to pseudoobstruction that results when circumferential invasion of a bowel segment arrests the forward progression of peristaltic contractions.

The onset of obstruction is usually insidious. Pain is the most common symptom and is usually colicky in nature. Pain can also be due to abdominal distention, tumor masses, or hepatomegaly. Vomiting can be intermittent or continuous. Patients with complete obstruction usually have constipation. Physical examination may reveal abdominal distention with tympany, ascites, visible peristalsis, high-pitched bowel sounds, and tumor masses. Erect plain abdominal films may reveal multiple air-fluid levels and dilation of the small or large bowel. Acute cecal dilation to >12–14 cm is considered a surgical emergency because of the high likelihood of rupture. CT scan is useful in defining the extent of disease and the exact nature of the obstruction and differentiating benign from malignant causes of obstruction in patients who have undergone surgery for malignancy. Malignant obstruction is suggested by a mass at the site of obstruction or prior surgery, adenopathy, or an abrupt transition zone and irregular bowel thickening at the obstruction site. Benign obstruction is more likely when CT shows mesenteric vascular changes, a large volume of ascites, or a smooth transition zone and smooth bowel thickening at the obstruction site. In challenging patients with obstructive symptoms, particularly low-grade small-bowel obstruction (SBO), CT enteroclysis often can help establish the diagnosis by providing distention of small-bowel loops. In this technique, water-soluble contrast is infused through a nasoenteric tube into the duodenum or proximal small bowel followed by CT images. The prognosis for the patient with cancer who develops intestinal obstruction is poor; median survival is 3–4 months. About 25–30% of patients are found to have intestinal obstruction due to causes other than cancer. Adhesions from previous operations are a common benign cause. Ileus induced by vinca alkaloids, narcotics, or other drugs is another reversible cause.

TREATMENT

Intestinal Obstruction

The management of intestinal obstruction in patients with advanced malignancy depends on the extent of the underlying malignancy, options for further antineoplastic therapy, estimated life expectancy, the functional status of the major organs, and the extent of the obstruction. The initial management should include surgical evaluation. Operation is not always successful and may lead to further complications with a substantial mortality rate (10–20%). Laparoscopy can diagnose and treat malignant bowel obstruction in some cases. Self-expanding metal stents placed in the gastric outlet, duodenum, proximal jejunum, colon, or rectum may palliate obstructive symptoms at those sites without major surgery. Patients known to have advanced intraabdominal malignancy should receive a prolonged course of conservative management, including nasogastric decompression. Percutaneous endoscopic or surgical gastrostomy tube placement is an option for palliation of nausea and vomiting, the so-called "venting gastrostomy." Treatment with antiemetics, antispasmodics, and analgesics may allow patients to remain outside the hospital. Octreotide may relieve obstructive symptoms through its inhibitory effect on gastrointestinal secretion. Glucocorticoids have anti-inflammatory effects and may help the resolution of bowel obstruction.

URINARY OBSTRUCTION

Urinary obstruction may occur in patients with prostatic or gynecologic malignancies, particularly cervical carcinoma; metastatic disease from other primary sites such as carcinomas of the breast, stomach, lung, colon, and pancreas; or lymphomas. Radiation therapy to pelvic tumors may cause fibrosis and subsequent ureteral obstruction. Bladder outlet obstruction is usually due to prostate and cervical cancers and may lead to bilateral hydronephrosis and renal failure.

Flank pain is the most common symptom. Persistent urinary tract infection, persistent proteinuria, or hematuria in patients with cancer should raise suspicion of ureteral obstruction. Total anuria and/or anuria alternating with polyuria may occur. A slow, continuous rise in the serum creatinine level necessitates immediate evaluation. Renal ultrasound is the safest and cheapest way to identify hydronephrosis. The function of an obstructed kidney can be evaluated by a nuclear scan. CT scan can reveal the point of obstruction and identify a retroperitoneal mass or adenopathy.

TREATMENT

Urinary Obstruction

Obstruction associated with flank pain, sepsis, or fistula formation is an indication for immediate palliative urinary diversion. Internal ureteral stents can be placed under local anesthesia. Percutaneous nephrostomy offers an alternative approach for drainage. The placement of a nephrostomy is associated with a significant rate of pyelonephritis. In the case of bladder outlet obstruction due to malignancy, a suprapubic cystostomy can be used for urinary drainage. An aggressive intervention with invasive approaches to improve the obstruction should be weighed against the likelihood of antitumor response, and the ability to reverse renal insufficiency should be evaluated.

MALIGNANT BILIARY OBSTRUCTION

This common clinical problem can be caused by a primary carcinoma arising in the pancreas, ampulla of Vater, bile duct, or liver or by metastatic disease to the periductal lymph nodes or liver parenchyma. The most common metastatic tumors causing biliary obstruction are gastric, colon, breast, and lung cancers. Jaundice, light-colored stools, dark urine, pruritus, and weight loss due to malabsorption are usual symptoms. Pain and secondary infection are uncommon in malignant biliary obstruction. Ultrasound, CT scan, magnetic resonance cholangiopancreatography (MRCP), or percutaneous transhepatic or endoscopic retrograde cholangiopancreatography (ERCP) will identify the site and nature of the biliary obstruction.

TREATMENT

Malignant Biliary Obstruction

Palliative intervention is indicated only in patients with disabling pruritus resistant to medical treatment, severe malabsorption, or infection. Stenting under radiographic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. The choice of therapy should be based on the site of obstruction (proximal vs distal), the type of tumor (sensitive to radiotherapy, chemotherapy, or neither), and the general condition of the patient. Stenting under radiographic or endoscopic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. Photodynamic therapy and radiofrequency ablation are promising endoscopic therapies for malignant biliary obstruction.

Endoscopic ultrasonography-guided biliary drainage is a safe and effective method of biliary drainage in patients with malignant biliary obstruction, particularly in patients whom standard ERCP failed.

SPINAL CORD COMPRESSION

Malignant spinal cord compression (MSCC) is defined as compression of the spinal cord and/or cauda equina by an extradural tumor mass. The minimum radiologic evidence for cord compression is indentation of the theca at the level of clinical features. Spinal cord compression (SCC) occurs in 5–10% of patients with cancer. Epidural tumor is the first manifestation of malignancy in ~10% of patients. The underlying cancer is usually identified during the initial evaluation; lung cancer is the most common cause of MSCC.

Metastatic tumor involves the vertebral column more often than any other part of the bony skeleton. Lung, breast, and prostate cancers are the most frequent offenders. Multiple myeloma also has a high incidence of spine involvement. Lymphomas, melanoma, renal cell cancer, and genitourinary cancers also cause cord compression. The thoracic spine is the most common site (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%). Involvement of multiple sites is most frequent in patients with breast and prostate carcinoma. Cord injury develops when metastases to the vertebral body or pedicle enlarge and compress the underlying dura. Another cause of cord compression is direct extension of a paravertebral lesion through the intervertebral foramen. These cases usually involve a lymphoma, myeloma, or pediatric neoplasm. Parenchymal spinal cord metastasis due to hematogenous spread is rare. Intramedullary metastases can be seen in lung cancer, breast cancer, renal cancer, melanoma, and lymphoma, and are frequently associated with brain metastases and leptomeningeal disease.

Expanding extradural tumors induce injury through several mechanisms. Expanding extradural tumors induce mechanical injury to axons and myelin. Compression compromises blood flow, leading to ischemia and/or infarction.

The most common initial symptom in patients with SCC is localized back pain and tenderness due to involvement of vertebrae by tumor. Pain is usually present for days or months before other neurologic findings appear. It is exacerbated by movement and by coughing or sneezing. It can be differentiated from the pain of disk disease by the fact that it worsens when the patient is supine. Radicular pain is less common than localized back pain and usually develops later. Radicular pain in the cervical or lumbosacral areas may be unilateral or bilateral. Radicular pain from the thoracic roots is often bilateral and is described by patients as a feeling of tight, band-like constriction around the thorax and abdomen. Typical cervical radicular pain radiates down the arm; in the lumbar region, the radiation is down the legs. *Lhermitte's sign*, a tingling or electric sensation down the back and upper and lower limbs upon flexing or extending the neck, may be an early sign of cord compression. Loss of bowel or bladder control may be the presenting symptom but usually occurs late in the course. Occasionally, patients present with ataxia of gait without motor and sensory involvement due to involvement of the spinocerebellar tract.

On physical examination, pain induced by straight leg raising, neck flexion, or vertebral percussion may help to determine the level of cord compression. Patients develop numbness and paresthesias in the extremities or trunk. Loss of sensibility to pinprick is as common as loss of sensibility to vibration or position. The upper limit of the zone of sensory loss is often one or two vertebrae below the site of compression. Motor findings include weakness, spasticity, and abnormal muscle stretching. An extensor plantar reflex reflects significant compression. Deep tendon reflexes may be brisk. Motor and sensory loss usually precedes sphincter disturbance. Patients with autonomic dysfunction may present with decreased anal tonus, decreased perineal sensibility, and a distended bladder. The absence of the anal wink reflex or the bulbocavernosus reflex confirms cord involvement. Autonomic dysfunction is an unfavorable prognostic factor. Patients with progressive neurologic symptoms should have frequent neurologic examinations and rapid therapeutic intervention. Other illnesses that may mimic cord compression include osteoporotic vertebral collapse, disk disease, pyogenic abscess or vertebral tuberculosis, radiation myelopathy, neoplastic leptomeningitis, benign tumors, epidural hematoma, and spinal lipomatosis.

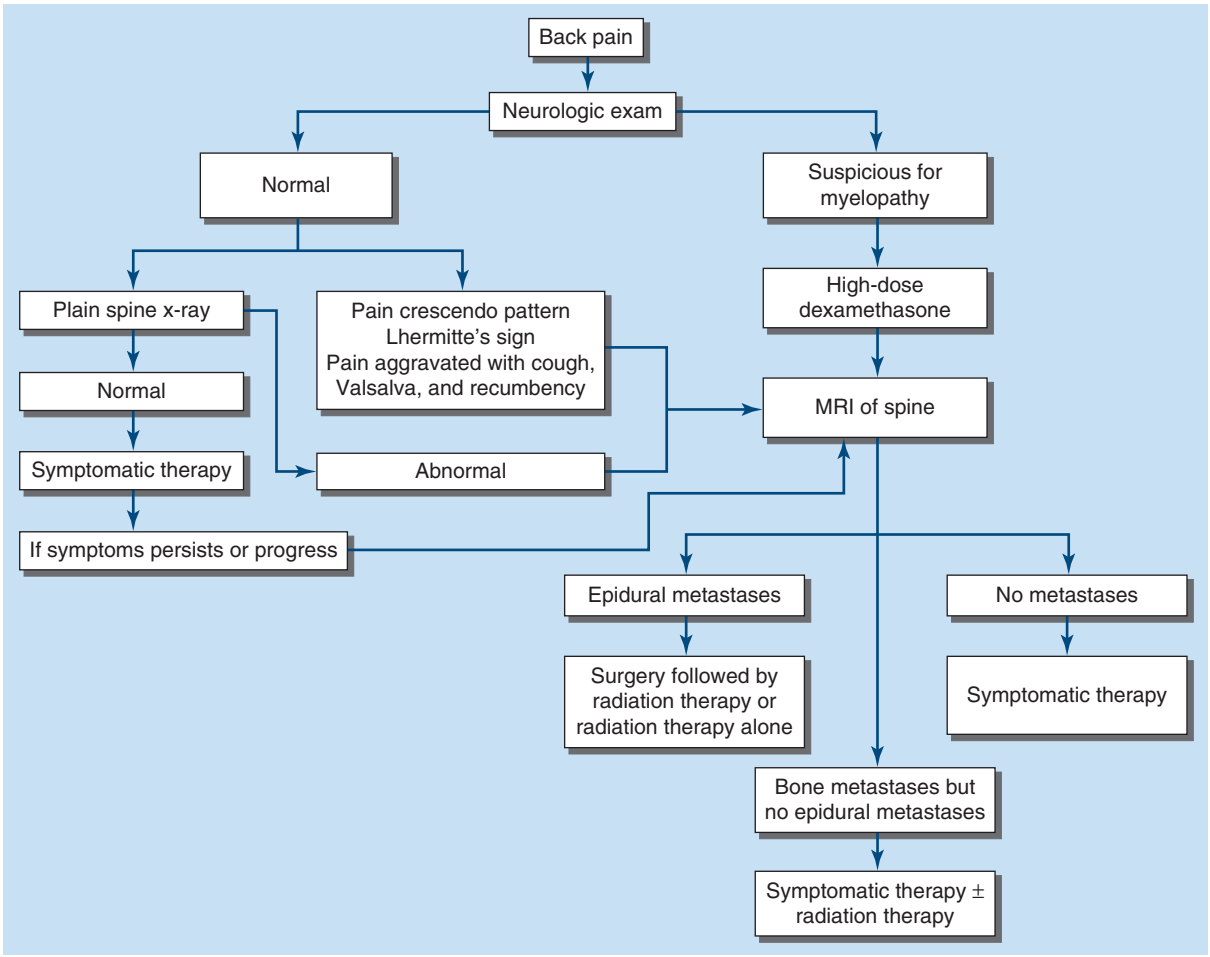

FIGURE 80-2 Management of cancer patients with back pain.

Cauda equina syndrome is characterized by low back pain; diminished sensation over the buttocks, posterior-superior thighs, and perineal area in a saddle distribution; rectal and bladder dysfunction; sexual impotence; absent bulbocavernous, patellar, and Achilles' reflexes; and variable amount of lower-extremity weakness. This reflects compression of nerve roots as they form the cauda equina after leaving the spinal cord. The majority of cauda equina tumors are primary tumors of glial or nerve sheath origin; metastases are very rare.

Patients with cancer who develop back pain should be evaluated for SCC as quickly as possible **(Fig. 80-2)**. Treatment is more often successful in patients who are ambulatory and still have sphincter control at the time treatment is initiated. Patients should have a neurologic examination and plain films of the spine. Those whose physical examination suggests cord compression should receive dexamethasone starting immediately and undergo MRI imaging.

Erosion of the pedicles (the "winking owl" sign) is the earliest radiologic finding of vertebral tumor in plain films; however, plain films are insensitive. Other radiographic changes include increased intrapedicular distance, vertebral destruction, lytic or sclerotic lesions, scalloped vertebral bodies, and vertebral body collapse. Vertebral collapse is not a reliable indicator of the presence of tumor; ~20% of cases of vertebral collapse, particularly those in older patients and postmenopausal women, are due not to cancer but to osteoporosis. Also, a normal appearance on plain films of the spine does not exclude the diagnosis of cancer. The role of bone scans in the detection of cord compression is not clear; this method is sensitive but less specific than spinal radiography.

The full-length image of the cord provided by MRI is the imaging procedure of choice. Multiple epidural metastases are noted in 25% of patients with cord compression, and their presence influences treatment plans. On T1-weighted images, good contrast is noted between the cord, cerebrospinal fluid (CSF), and extradural lesions. Owing to its sensitivity in demonstrating the replacement of bone marrow by tumor, MRI can show which parts of a vertebra are involved by tumor. MRI also visualizes intraspinal extradural masses compressing the cord. T2-weighted images are most useful for the demonstration of intramedullary pathology. Gadolinium-enhanced MRI can help to delineate intramedullary disease. MRI is as good as or better than myelography plus postmyelogram CT scan in detecting metastatic epidural disease with cord compression. Myelography should be reserved for patients who have poor MRIs or who cannot undergo MRI promptly. CT scan in conjunction with myelography enhances the detection of small areas of spinal destruction.

In patients with cord compression and an unknown primary tumor, a simple workup including chest radiography, mammography, measurement of prostate-specific antigen, and abdominal CT usually reveals the underlying malignancy.

TREATMENT

Spinal Cord Compression

The treatment of patients with SCC is aimed at relief of pain and restoration/preservation of neurologic function (Fig. 80-2). Management of MSCC requires a multidisciplinary approach.

Radiation therapy plus glucocorticoids is generally the initial treatment of choice for most patients with SCC. The management decision of SCC involves assessment of neurologic (N), oncologic (O), mechanical (M), and systemic factors (S). NOMS was

developed by Memorial Sloan Kettering Cancer Center (MSKCC) researchers to provide an algorithm for management of SCC. The neurologic assessment is based on the degree of epidural SCC, myelopathy, and/or functional radiculopathy. Oncologic assessment involves the radiosensitivity of the tumor type. In patients with radioresistant tumors, stereotactic body radiotherapy (SBRT) is the preferred approach if radiation is appropriate. Safe delivery of SBRT requires a 2- to 3-mm margin away from the spinal cord. Separation surgery followed by SBRT is necessary in patients with high-grade SCC due to radioresistant tumors. Separation surgery is the circumferential excision of epidural tumor to reconstitute the thecal sac and provide a 2-mm margin for safe delivery of an ablative radiation dose. In patients with mechanical instability or retropulsion of bone fragments into the spinal canal or cord, a surgical approach is the treatment of choice. Systemic factors that need to be considered are the extent of disease and medical comorbidities that determine the patient's ability to tolerate planned therapy. Chemotherapy may have a role in patients with chemosensitive tumors who have had prior radiotherapy to the same region and who are not candidates for surgery. Patients who previously received radiotherapy for MSCC with an in-field tumor progression can be treated with reirradiation with spine stereotactic radiosurgery (SRS) if they are not surgical candidates.

Patients with painful pathologic compression fractures without spinal instability may benefit from percutaneous vertebroplasty or kyphoplasty, the injection of acrylic cement into a collapsed vertebra to stabilize the fracture. Pain palliation is common, and local antitumor effects have been noted. Cement leakage may cause symptoms in ~10% of patients. Bisphosphonates and/or denosumab may be helpful in prevention of SCC in patients with bony involvement.

The histology of the tumor is an important determinant of both recovery and survival. Rapid onset and progression of signs and symptoms are poor prognostic features.

INCREASED INTRACRANIAL PRESSURE

About 25% of patients with cancer die with intracranial metastases. The cancers that most often metastasize to the brain are lung and breast cancers and melanoma. Brain metastases often occur in the presence of systemic disease, and they frequently cause major symptoms, disability, and early death. The initial presentation of brain metastases from a previously unknown primary cancer is common. Lung cancer is most commonly the primary malignancy. CT scans of the chest/abdomen and MRI of the brain as the initial diagnostic studies can identify a biopsy site in most patients.

The signs and symptoms of a metastatic brain tumor are similar to those of other intracranial expanding lesions: headache, nausea, vomiting, behavioral changes, seizures, and focal, progressive neurologic changes. Occasionally the onset is abrupt, resembling a stroke, with the sudden appearance of headache, nausea, vomiting, and neurologic deficits. This picture is usually due to hemorrhage into the metastasis. Melanoma, germ cell tumors, and renal cell cancers have a particularly high incidence of intracranial bleeding. The tumor mass and surrounding edema may cause obstruction of the circulation of CSF, with resulting hydrocephalus. Patients with increased intracranial pressure may have papilledema with visual disturbances and neck stiffness. As the mass enlarges, brain tissue may be displaced through the fixed cranial openings, producing various herniation syndromes.

MRI is superior to CT scan. Gadolinium-enhanced MRI is more sensitive than CT at revealing meningeal involvement and small lesions, particularly in the brainstem or cerebellum. The MRI of the brain shows brain metastases as multiple enhancing lesions of various sizes with surrounding areas of low-density edema.

Intracranial hypertension ("pseudotumor cerebri") secondary to tretinoin therapy for acute promyelocytic leukemia has been reported as another cause of intracranial pressure in the setting of a malignancy.

TREATMENT

Increased Intracranial Pressure

Dexamethasone is the best initial treatment for all symptomatic patients with brain metastases. The current success of immunotherapy approaches for primary and metastatic brain tumors may preclude or limit glucocorticoid use since it may decrease antitumor response. Bevacizumab should be considered in patients who are unable to wean completely off of steroids as well as those who have symptomatic brain edema and are on immunotherapy. Patients with a single brain metastasis and with controlled extracranial disease may be treated with surgical excision followed by SRS to the resection cavity. SRS is recommended in patients with a limited number of brain metastases (one to four) who have stable, systemic disease or reasonable systemic treatment options and in patients who have a small number of metastatic lesions in whom whole-brain radiation therapy has failed. The treatment of a larger number of intracranial metastases remains controversial. More patients now receive SRS because of cognitive dysfunction associated with whole-brain radiation. Some patients with increased intracranial pressure associated with hydrocephalus may benefit from shunt placement. If neurologic deterioration is not reversed with medical therapy, ventriculotomy to remove CSF or craniotomy to remove tumors or hematomas may be necessary.

Targeted agents and checkpoint inhibitors have significant activity in brain metastases from non-small-cell lung cancer, breast cancer, renal cancer, and melanoma.

NEOPLASTIC MENINGITIS

Tumor involving the leptomeninges is a complication of both primary central nervous system (CNS) tumors and tumors that metastasize to the CNS. The incidence is estimated at 3–8% of patients with cancer. Melanoma, breast and lung cancer, lymphoma (including AIDS-associated), and acute leukemia are the most common causes. The lobular or triple-negative subtypes of breast cancer, as well as tumors with expression of the mutant epidermal growth factor receptor (EGFR) or the anaplastic lymphoma kinase (ALK) rearrangement in non-small-cell lung cancer, are more likely to have CNS involvement including neoplastic meningitis and brain metastases. Synchronous intraparenchymal brain metastases are frequent in patients with neoplastic meningitis. Leptomeningeal seeding is frequent in patients undergoing resection of brain metastases or receiving stereotactic radiotherapy for brain metastases.

Patients typically present with multifocal neurologic signs and symptoms, including headache, gait abnormality, mental changes, nausea, vomiting, seizures, back or radicular pain, and limb weakness. Signs include cranial nerve palsies, extremity weakness, paresthesia, and decreased deep tendon reflexes.

Diagnosis is made by demonstrating malignant cells in the CSF; however, up to 40% of patients may have false-negative CSF cytology. An elevated CSF protein level is nearly always present. Patients with neurologic signs and symptoms consistent with neoplastic meningitis who have a negative CSF cytology should have the spinal tap repeated at least one more time for cytologic examination. MRI findings suggestive of neoplastic meningitis include leptomeningeal, subependymal, dural, or cranial nerve enhancement; superficial cerebral lesions; intradural nodules; and communicating hydrocephalus. Spinal cord imaging by MRI is a necessary component of the evaluation of nonleukemia neoplastic meningitis because ~20% of patients have cord abnormalities, including intradural enhancing nodules that are diagnostic for leptomeningeal involvement. Cauda equina lesions are common, but lesions may be seen anywhere in the spinal canal. Radiolabeled CSF flow studies are abnormal in up to 70% of patients with neoplastic meningitis; ventricular outlet obstruction, abnormal flow in the spinal canal, or impaired flow over the cerebral convexities may affect distribution of intrathecal chemotherapy, resulting in decreased efficacy or increased toxicity. Radiation therapy may correct CSF flow abnormalities before

use of intrathecal chemotherapy. Neoplastic meningitis can also lead to intracranial hypertension and hydrocephalus. Placement of a ventriculoperitoneal shunt may effectively palliate symptoms in these patients.

The development of neoplastic meningitis usually occurs in the setting of uncontrolled cancer outside the CNS; thus, prognosis is poor (median survival 10–12 weeks). However, treatment of the neoplastic meningitis may successfully alleviate symptoms and control the CNS spread.

TREATMENT

Neoplastic Meningitis

Chemotherapy provided by either intrathecal injection or systemic routes is used to control leptomeningeal disease throughout the entire neuroaxis. Intrathecal chemotherapy, usually methotrexate, cytarabine, or thiotepa, is delivered by lumbar puncture or by an intraventricular reservoir (Ommaya). Among solid tumors, breast cancer responds best to therapy. Focal radiotherapy may have a role in bulky disease and in symptomatic or obstructive lesions. Targeted therapy such as systemically administered EGFR tyrosine kinase inhibitors (TKIs) in non-small-cell lung cancer may lead to improvement in some patients with leptomeningeal spread. Patients with neoplastic meningitis from either acute leukemia or lymphoma may be cured of their CNS disease if the systemic disease can be eliminated.

SEIZURES

Seizures occurring in a patient with cancer can be caused by the tumor itself, by metabolic disturbances, by radiation injury, by cerebral infarctions, by chemotherapy-related encephalopathies, or by CNS infections. Metastatic disease to the CNS is the most common cause of seizures in patients with cancer. However, seizures occur more frequently in primary brain tumors than in metastatic brain lesions. Seizures are a presenting symptom of CNS metastasis in 6–29% of cases. Approximately 10% of patients with CNS metastasis eventually develop seizures. Tumors that affect the frontal, temporal, and parietal lobes are more commonly associated with seizures than are occipital lesions. Both early and late seizures are uncommon in patients with posterior fossa and sellar lesions. Seizures are common in patients with CNS metastases from melanoma and low-grade primary brain tumors. Very rarely, cytotoxic drugs such as etoposide, busulfan, ifosfamide, and chlorambucil cause seizures. Treatment with bispecific antibodies and chimeric antigen receptor (CAR) T cells may also cause CNS toxicity including seizures and encephalopathy. Another cause of seizures related to drug therapy is reversible posterior leukoencephalopathy syndrome (RPLS). Chemotherapy, targeted therapy, and immunotherapies have been associated with the development of RPLS. RPLS occurs in patients undergoing allogeneic bone marrow or solid-organ transplantation. RPLS is characterized by headache, altered consciousness, generalized seizures, visual disturbances, hypertension, and symmetric posterior cerebral white matter vasogenic edema on CT/MRI. Seizures may begin focally but are typically generalized.

TREATMENT

Seizures

Patients in whom seizures due to CNS metastases have been demonstrated should receive anticonvulsive treatment with levetiracetam, lacosamide, or lamotrigine. Prophylactic anticonvulsant therapy is not recommended. In postcraniotomy patients, prophylactic antiepileptic drugs should be withdrawn during the first 2 weeks after surgery. Most antiseizure medications including phenytoin induce cytochrome P450 (CYP450), which alters the metabolism of many antitumor agents, including irinotecan, taxanes, and etoposide, as well as molecular targeted agents, including imatinib, gefitinib, erlotinib, tipifarnib, sorafenib, sunitinib, temsirolimus, everolimus, and vemurafenib. Levetiracetam, lacosamide, and lamotrigine are anticonvulsant agents not metabolized by the hepatic CYP450 system and do not alter the metabolism of antitumor agents. Levetiracetam has become the preferred drug. Surgical resection and other antitumor treatments such as radiotherapy and chemotherapy may improve seizure control.

PULMONARY AND INTRACEREBRAL LEUKOSTASIS

Hyperleukocytosis and the leukostasis syndrome associated with it are potentially fatal complications of acute leukemia (particularly myeloid leukemia) that can occur when the peripheral blast cell count is >100,000/mL. The frequency of hyperleukocytosis is 5–13% in acute myeloid leukemia (AML) and 10–30% in acute lymphoid leukemia; however, leukostasis is rare in lymphoid leukemia. In AML, hyperleukocytosis is more commonly seen in myelomonocytic AML (Fab-M4 and M5), those with 11q13 abnormalities involving the *MLL* gene, and those with *FLT3* mutations. At such high blast cell counts, blood viscosity is increased, blood flow is slowed by aggregates of tumor cells, and the primitive myeloid leukemic cells are capable of invading through the endothelium and causing hemorrhage. Brain and lung are most commonly affected. Patients with brain leukostasis may experience stupor, headache, dizziness, tinnitus, visual disturbances, ataxia, confusion, coma, or sudden death. On examination, papilledema, retinal vein distension, retinal hemorrhages, and focal deficit may be present. Pulmonary leukostasis may present as respiratory distress and hypoxemia and progress to respiratory failure. Chest radiographs may be normal but usually show interstitial or alveolar infiltrates. Hyperleukocytosis rarely may cause acute leg ischemia, renal vein thrombosis, myocardial ischemia, bowel infraction, and priapism. Arterial blood gas results should be interpreted cautiously. Rapid consumption of plasma oxygen by the markedly increased number of white blood cells can cause spuriously low arterial oxygen tension. Pulse oximetry is the most accurate way of assessing oxygenation in patients with hyperleukocytosis. Hydroxyurea can rapidly reduce a high blast cell count while the diagnostic workup is in progress. After the diagnosis is established, the patient should start quickly with effective induction chemotherapy. Leukapheresis should be used in patients with symptoms of hyperleukocytosis. Patients with hyperleukocytosis are also at risk for disseminated intravascular coagulation and tumor lysis syndrome. The clinician should monitor the patient for these complications and take preventive and therapeutic actions during induction therapy. Intravascular volume depletion and unnecessary blood transfusions may increase blood viscosity and worsen the leukostasis syndrome. Leukostasis is very rarely a feature of the high white cell counts associated with chronic lymphoid or chronic myeloid leukemia.

When acute promyelocytic leukemia is treated with differentiating agents like tretinoin and arsenic trioxide, cerebral or pulmonary leukostasis may occur as tumor cells differentiate into mature neutrophils. This complication can be largely avoided by using cytotoxic chemotherapy together with the differentiating agents.

HEMOPTYSIS

Hemoptysis may be caused by nonmalignant conditions, but lung cancer accounts for a large proportion of cases. Up to 20% of patients with lung cancer have hemoptysis some time in their course. Endobronchial metastases from carcinoid tumors, breast cancer, colon cancer, kidney cancer, and melanoma may also cause hemoptysis. The volume of bleeding is often difficult to gauge. Massive hemoptysis is defined as >200–600 mL of blood produced in 24 h. However, any hemoptysis should be considered massive if it threatens life. When respiratory difficulty occurs, hemoptysis should be treated emergently. The first priorities are to maintain the airway, optimize oxygenation, and stabilize the hemodynamic status. If the bleeding side is known, the patient should be placed in a lateral decubitus position, with the bleeding side down to prevent aspiration into the unaffected lung and given supplemental oxygen. If large-volume bleeding continues or the airway is compromised, the patient should be intubated and undergo emergency bronchoscopy. If the site of bleeding is detected, either the patient undergoes a definitive surgical procedure or the lesion is treated with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, argon plasma

coagulation, or electrocautery. In stable patients, multidetector CT angiography delineates bronchial and nonbronchial systemic arteries and identifies the source of bleeding and underlying pathology with high sensitivity. Massive hemoptysis usually originates from the high-pressure bronchial circulation. Bronchial artery embolization is considered a first-line definitive procedure for managing hemoptysis. Bronchial artery embolization may control brisk bleeding in 75–90% of patients, permitting the definitive surgical procedure to be done more safely if it is appropriate.

Embolization without definitive surgery is associated with rebleeding in 20–50% of patients. Recurrent hemoptysis usually responds to a second embolization procedure. A postembolization syndrome characterized by pleuritic pain, fever, dysphagia, and leukocytosis may occur; it lasts 5–7 days and resolves with symptomatic treatment. Bronchial or esophageal wall necrosis, myocardial infarction, and spinal cord infarction are rare complications. Surgery, as a salvage strategy, is indicated after failure of embolization and is associated with better survival when performed in a nonurgent setting.

Pulmonary hemorrhage with or without hemoptysis in hematologic malignancies is often associated with fungal infections, particularly *Aspergillus* spp. After granulocytopenia resolves, the lung infiltrates in aspergillosis may cavitate and cause massive hemoptysis. Thrombocytopenia and coagulation defects should be corrected, if possible. Surgical evaluation is recommended in patients with aspergillosis-related cavitary lesions. Antibodies to vascular endothelial growth factor (VEGF) including bevacizumab and ramucirumab that inhibit angiogenesis, have been associated with life-threatening hemoptysis in patients with non-small-cell lung cancer, particularly of squamous cell histology. Non-small-cell lung cancer patients with cavitary lesions or previous hemoptysis (≥2.5 mL) within the past 3 months have higher risk for pulmonary hemorrhage.

AIRWAY OBSTRUCTION

Airway obstruction refers to a blockage at the level of the mainstem bronchi or above. It may result either from intraluminal tumor growth or from extrinsic compression of the airway. The most common cause of malignant upper airway obstruction is invasion from an adjacent primary tumor, most commonly lung cancer, followed by esophageal, thyroid, and mediastinal malignancies including lymphomas. Extrathoracic primary tumors such as renal, colon, or breast cancer can cause airway obstruction through endobronchial and/or mediastinal lymph node metastases. Patients may present with dyspnea, hemoptysis, stridor, wheezing, intractable cough, postobstructive pneumonia, or hoarseness. Chest radiographs usually demonstrate obstructing lesions. CT scans reveal the extent of tumor. Cool, humidified oxygen, glucocorticoids, and ventilation with a mixture of helium and oxygen (Heliox) may provide temporary relief. If the obstruction is proximal to the larynx, a tracheostomy may be lifesaving. For more distal obstructions, particularly intrinsic lesions incompletely obstructing the airway, bronchoscopy with mechanical debulking and dilation or ablational treatments including laser treatment, photodynamic therapy, argon plasma coagulation, electrocautery, or stenting can produce immediate relief in most patients (Fig. 80-3). However, radiation therapy (either external-beam irradiation or brachytherapy) given together with glucocorticoids may also open the airway. Symptomatic extrinsic compression may be palliated by stenting. Patients with primary airway tumors such as squamous cell carcinoma, carcinoid tumor, adenocystic carcinoma, or non-small-cell lung cancer, if resectable, should have surgery.

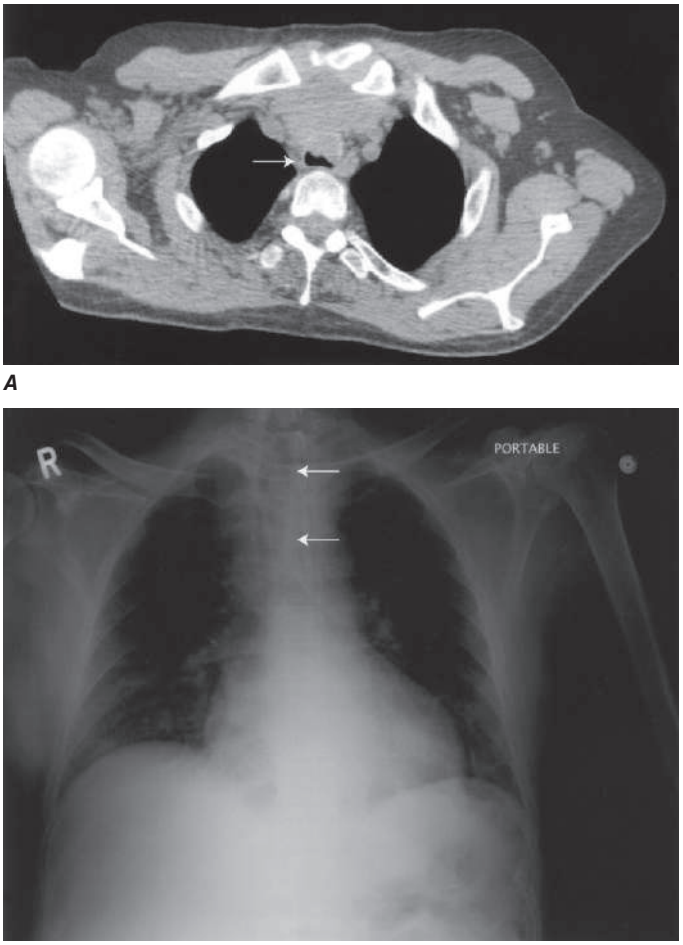

FIGURE 80-3 Airway obstruction. ***A.*** Computed tomography scan of a 62-year-old man with tracheal obstruction caused by renal carcinoma showing paratracheal mass with tracheal invasion/obstruction (*arrow*). ***B.*** Chest x-ray of same patient after stent (*arrows*) placement.

METABOLIC EMERGENCIES

HYPERCALCEMIA

Hypercalcemia is the most common paraneoplastic syndrome. Its pathogenesis and management are discussed fully in Chaps. 98 and 422.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

Hyponatremia is a common electrolyte abnormality in cancer patients, and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is the most common cause among patients with cancer. SIADH is discussed fully in Chaps. 98 and 393.

LACTIC ACIDOSIS

Lactic acidosis is a rare and potentially fatal metabolic complication of cancer. Lactic acidosis associated with sepsis and circulatory failure is a common preterminal event in many malignancies. Lactic acidosis in the absence of hypoxemia may occur in patients with leukemia, lymphoma, or solid tumors. In some cases, hypoglycemia also is present. Extensive involvement of the liver by tumor is often present. In most cases, decreased metabolism and increased production by the tumor both contribute to lactate accumulation. Tumor cell overexpression of certain glycolytic enzymes and mitochondrial dysfunction can contribute to its increased lactate production. HIV-infected patients have an increased risk of aggressive lymphoma; lactic acidosis that occurs in such patients may be related either to the rapid growth of the tumor or from toxicity of nucleoside reverse transcriptase inhibitors. Symptoms of lactic acidosis include tachypnea, tachycardia, change of mental status, and hepatomegaly. The serum level of lactic acid may reach 10–20 mmol/L (90–180 mg/dL). Treatment is aimed at the underlying disease. Sodium bicarbonate should be added if acidosis is very severe or if hydrogen ion production is very rapid and uncontrolled. Other treatment options include renal replacement therapy, such as hemodialysis, and thiamine replacement. The prognosis is poor regardless of the treatment offered.

HYPOGLYCEMIA

Persistent hypoglycemia is occasionally associated with tumors other than pancreatic islet cell tumors. Usually these tumors are large;

tumors of mesenchymal origin, hepatomas, or adrenocortical tumors may cause hypoglycemia. Mesenchymal tumors are usually located in the retroperitoneum or thorax. Obtundation, confusion, and behavioral aberrations occur in the postabsorptive period and may precede the diagnosis of the tumor. These tumors often secrete incompletely processed insulin-like growth factor II (IGF-II), a hormone capable of activating insulin receptors and causing hypoglycemia. Tumors secreting incompletely processed big IGF-II are characterized by an increased IGF-II to IGF-I ratio, suppressed insulin and C-peptide level, and inappropriately low growth hormone and β-hydroxybutyrate concentrations. Rarely, hypoglycemia is due to insulin secretion by a non–islet cell carcinoma. The development of hepatic dysfunction from liver metastases and increased glucose consumption by the tumor can contribute to hypoglycemia. If the tumor cannot be resected, hypoglycemia symptoms may be relieved by the administration of glucose, glucocorticoids, recombinant growth hormone, or glucagon.

Hypoglycemia can be artifactual; hyperleukocytosis from leukemia, myeloproliferative diseases, leukemoid reactions, or colony-stimulating factor treatment can increase glucose consumption in the test tube after blood is drawn, leading to pseudohypoglycemia.

ADRENAL INSUFFICIENCY

In patients with cancer, adrenal insufficiency may go unrecognized because the symptoms, such as nausea, vomiting, anorexia, and orthostatic hypotension, are nonspecific and may be mistakenly attributed to progressive cancer or to therapy. Primary adrenal insufficiency may develop owing to replacement of both glands by metastases (lung, breast, colon, or kidney cancer; lymphoma), to removal of both glands, or to hemorrhagic necrosis in association with sepsis or anticoagulation. Impaired adrenal steroid synthesis occurs in patients being treated for cancer with mitotane, ketoconazole, or aminoglutethimide or undergoing rapid reduction in glucocorticoid therapy. Megestrol acetate, used to manage cancer and HIV-related cachexia, may suppress plasma levels of cortisol and adrenocorticotropic hormone (ACTH). Patients taking megestrol may develop adrenal insufficiency, and even those whose adrenal dysfunction is not symptomatic may have inadequate adrenal reserve if they become seriously ill. Paradoxically, some patients may develop Cushing's syndrome and/or hyperglycemia because of the glucocorticoid-like activity of megestrol acetate. Ipilimumab, an anti-CTLA-4 antibody used for treatment of malignant melanoma and other cancers, may cause autoimmunity including autoimmune-like enterocolitis, hypophysitis (leading to secondary adrenal insufficiency), hepatitis, and, rarely, primary adrenal insufficiency. Autoimmune hypophysitis may present with headache, visual field defects, and pituitary hormone deficiencies manifesting as hypopituitarism, adrenal insufficiency (including adrenal crisis), or hypothyroidism. Ipilimumab-associated hypophysitis symptoms occur at an average of 6–12 weeks after initiation of therapy. An MRI usually shows homogenous enhancement of pituitary gland. Early glucocorticoid treatment and hormone replacement are the initial treatment. The role of high-dose glucocorticoids in the treatment of hypophysitis is not clear. High-dose glucocorticoids may not improve the frequency of pituitary function recovery. Autoimmune adrenalitis can also be observed with anti-CTLA-4 antibody. Pituitary dysfunction is usually permanent, requiring long-term hormone replacement therapy. Other checkpoint inhibitors, such as monoclonal antibodies targeting programmed cell death 1 (PD-1), an inhibitory receptor expressed by T cells or one of its ligands (PD-L1), may cause hypophysitis infrequently (~1%). Autoimmune adrenalitis is more frequent with use of PD-1/PD-L1 than with CTLA-4 inhibitors, but incidence is low. Cranial irradiation for childhood brain tumors may affect the hypothalamus-pituitary-adrenal axis, resulting in secondary adrenal insufficiency. Rarely, metastatic replacement causes primary adrenal insufficiency as the first manifestation of an occult malignancy. Metastasis to the pituitary or hypothalamus is found at autopsy in up to 5% of patients with cancer, but associated secondary adrenal insufficiency is rare.

Acute adrenal insufficiency is potentially lethal. Treatment of suspected adrenal crisis is initiated after the sampling of serum cortisol and ACTH levels (Chap. 398).

TREATMENT-RELATED EMERGENCIES

TUMOR LYSIS SYNDROME

Tumor lysis syndrome (TLS) is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia and is caused by the destruction of a large number of rapidly proliferating neoplastic cells. Acidosis may also develop. Acute renal failure occurs frequently.

TLS is most often associated with the treatment of Burkitt's lymphoma, acute lymphoblastic leukemia, AML, and other rapidly proliferating lymphomas, but it also may be seen with chronic leukemias and, rarely, with solid tumors. This syndrome is increased in frequency in lymphoid neoplasms treated with venetoclax, a bcl-2 antagonist. TLS has been observed with administration of glucocorticoids, hormonal agents such as letrozole and tamoxifen, and monoclonal antibodies such as rituximab, obinutuzumab, ofatumumab, and gemtuzumab. TLS usually occurs during or shortly (1–5 days) after chemotherapy. Rarely, spontaneous necrosis of malignancies causes TLS.

Hyperuricemia may be present at the time of chemotherapy. Effective treatment kills malignant cells and leads to increased serum uric acid levels from the turnover of nucleic acids. Owing to the acidic local environment, uric acid can precipitate in the tubules, medulla, and collecting ducts of the kidney, leading to renal failure. Lactic acidosis and dehydration may contribute to the precipitation of uric acid in the renal tubules. The finding of uric acid crystals in the urine is strong evidence for uric acid nephropathy. The ratio of urinary uric acid to urinary creatinine is >1 in patients with acute hyperuricemic nephropathy and <1 in patients with renal failure due to other causes. Other events may lead to renal failure in TLS. Calcium phosphate also precipitates in the interstitium and renal microvasculature, leading to nephrocalcinosis. Both types of crystals are toxic to the tubular epithelium, inducing local active inflammatory and pro-oxidative responses. Soluble uric acid may induce hemodynamic changes, with decreased renal blood flow due to vasoconstriction and impaired autoregulation (crystal-independent pathway).

Hyperphosphatemia, which can be caused by the release of intracellular phosphate pools by tumor lysis, produces a reciprocal depression in serum calcium, which causes severe neuromuscular irritability and tetany. Deposition of calcium phosphate in the kidney and hyperphosphatemia may cause renal failure. Potassium is the principal intracellular cation, and massive destruction of malignant cells may lead to hyperkalemia. Hyperkalemia in patients with renal failure may rapidly become life threatening by causing ventricular arrhythmias and sudden death.

The likelihood that TLS will occur in patients with Burkitt's lymphoma is related to the tumor burden and renal function. Hyperuricemia and high serum levels of lactate dehydrogenase (LDH >1500 U/L), both of which correlate with total tumor burden, also correlate with the risk of TLS. In patients at risk for TLS, pretreatment evaluations should include a complete blood count, serum chemistry evaluation, and urinalysis. High leukocyte and platelet counts may artificially elevate potassium levels ("pseudohyperkalemia") due to lysis of these cells after the blood is drawn. In these cases, plasma potassium instead of serum potassium should be followed. In pseudohyperkalemia, no electrocardiographic abnormalities are present. In patients with abnormal baseline renal function, the kidneys and retroperitoneal area should be evaluated by sonography and/or CT to rule out obstructive uropathy. Urine output should be watched closely.

TREATMENT

Tumor Lysis Syndrome

Recognition of risk and prevention are the most important steps in the management of this syndrome (Fig. 80-4). The standard preventive approach consists of allopurinol and aggressive hydration. Urinary alkalization with sodium bicarbonate is no longer recommended. It increases uric acid solubility, but a high pH decreases the solubility of xanthine, hypoxanthine, and calcium phosphate, potentially increasing the likelihood of intratubular crystallization. Intravenous allopurinol may be given in patients who cannot tolerate oral therapy. Febuxostat, a potent nonpurine selective xanthine

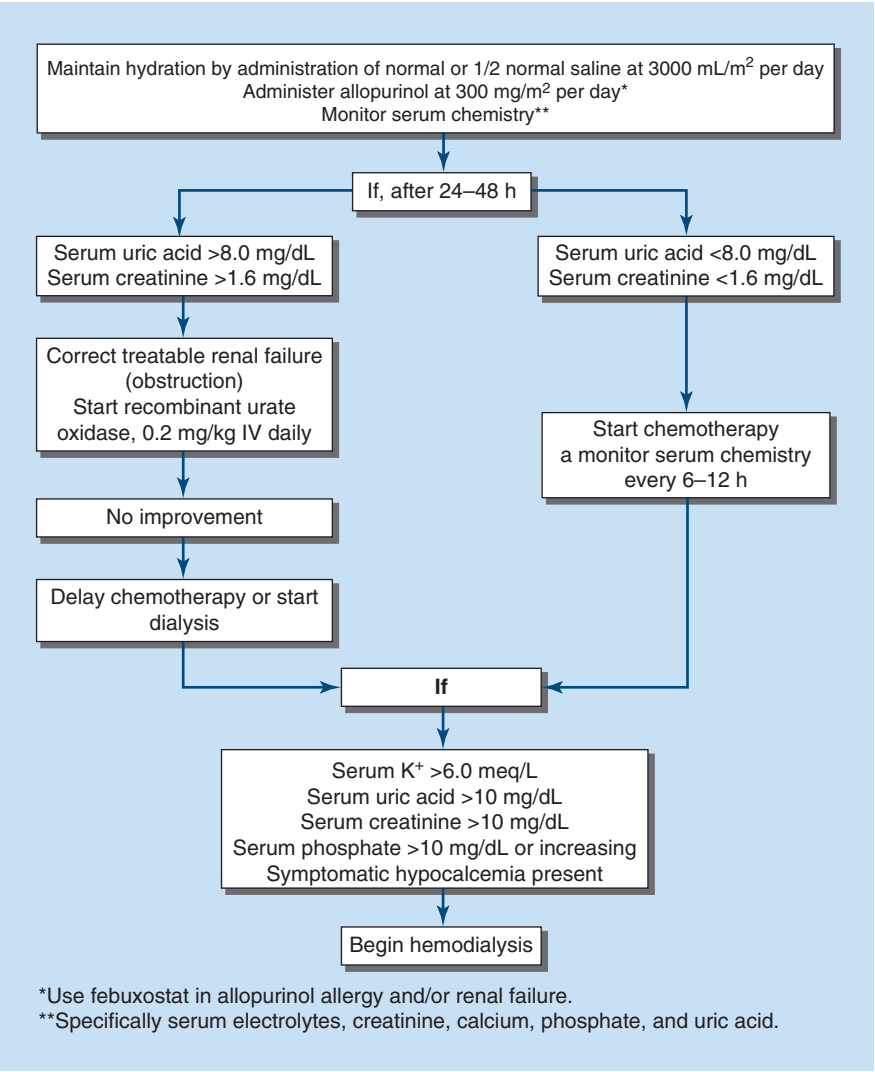

FIGURE 80-4 Management of patients at high risk for the tumor lysis syndrome.

oxidase inhibitor, is indicated for treatment of hyperuricemia. It results in fewer hypersensitivity reactions than allopurinol. Febuxostat does not require dosage adjustment in patients with mild to moderate renal impairment. Febuxostat achieved significantly superior serum uric acid control in comparison to allopurinol in patients with hematologic malignancies at intermediate to high TLS risk. In some cases, uric acid levels cannot be lowered sufficiently with the standard preventive approach. Rasburicase (recombinant urate oxidase) can be effective in these instances, particularly when renal failure is present. Urate oxidase is missing from primates and catalyzes the conversion of poorly soluble uric acid to readily soluble allantoin. Rasburicase acts rapidly, decreasing uric acid levels within hours; however, it may cause hypersensitivity reactions such as bronchospasm, hypoxemia, and hypotension. Rasburicase should also be administered to high-risk patients for TLS prophylaxis. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency who are unable to break down hydrogen peroxide, an end product of the urate oxidase reaction. Rasburicase is known to cause ex vivo enzymatic degradation of uric acid in test tube at room temperature. This leads to spuriously low uric acid levels during laboratory monitoring of the patient with TLS. Samples must be cooled immediately to deactivate the urate oxidase. Despite aggressive prophylaxis, TLS and/or oliguric or anuric renal failure may occur. Renal replacement therapy is often necessary and should be considered early in the course. Hemodialysis is preferred. Hemofiltration offers a gradual, continuous method of removing cellular by-products and fluid.

HUMAN ANTIBODY INFUSION REACTIONS

The initial infusion of human or humanized antibodies (e.g., rituximab, gemtuzumab, trastuzumab, alemtuzumab, panitumumab, brentuximab vedotin, blinatumomab) is associated with fever, chills, nausea, asthenia, and headache in up to half of treated patients. Bronchospasm and hypotension occur in 1% of patients. Severe manifestations including pulmonary infiltrates, acute respiratory distress syndrome (ARDS), and cardiogenic shock occur rarely. Laboratory manifestations include elevated hepatic aminotransferase levels, thrombocytopenia, and prolongation of prothrombin time. The pathogenesis is thought to be activation of immune effector processes (cells and complement) and release of inflammatory cytokines, such as tumor necrosis factor α, interferon γ, interleukin (IL) 6, and IL-10 (cytokine release syndrome [CRS]). Although its origins are not completely understood, CRS is believed to be due to activation of a variety of cell types including neutrophils, monocytes/macrophages, natural killer cells, and T and B lymphocytes. Hemophagocytic lymphohistiocytosis (HLH)/macrophage activation syndrome (MAS) can develop as part of CRS and usually is a manifestation of severe CRS.

Severe CRS may require intensive support for ARDS and resistant hypotension. Emerging clinical experience at several institutions has concluded that tocilizumab is an effective treatment for severe or life-threatening CRS. Tocilizumab prevents IL-6 binding to both cell-associated and soluble IL-6 receptors and therefore inhibits both classical and trans-IL-6 signaling. Other cytokine-directed therapies, such as siltuximab, a chimeric anti-IL-6 monoclonal antibody, and anakinra, an IL-1 receptor antagonist, have been used.

Adoptive transfer of CAR-engineered T cells is a promising therapy for cancers. The most common acute toxicity of CAR T cells is CRS. CAR T cell–associated CRS may be associated with cardiac dysfunction and neurotoxicity. In all cases, MAS could happen with CRS. The management includes supportive care and tocilizumab.

HEMOLYTIC-UREMIC SYNDROME

Malignancy can induce hemolytic-uremic syndrome (HUS) through a wide variety of mechanisms, including systemic microvascular metastases, extensive bone marrow invasion, or secondary necrosis. HUS syndromes have been reported with metastatic gastric and ovarian cancers, leukemias, and lymphomas. HUS and, less commonly, thrombotic thrombocytopenic purpura (TTP) **(Chap. 329)** may rarely occur after treatment with antineoplastic drugs, including mitomycin, gemcitabine, cisplatin, bleomycin, and proteasome inhibitors, and with VEGF inhibitors. Mitomycin and gemcitabine are the most common offenders. Unlike mitomycin, there is no clear-cut relationship between the cumulative dose of gemcitabine and risk of HUS. It occurs most often in patients with gastric, lung, colorectal, pancreatic, and breast carcinoma. In one series, 35% of patients were without evident cancer at the time this syndrome appeared. Secondary HUS/TTP has also been reported as a rare but sometimes fatal complication of bone marrow transplantation.

HUS usually has its onset 4–8 weeks after the last dose of chemotherapy, but it is not rare to detect it several months later. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Dyspnea, weakness, fatigue, oliguria, and purpura are also common initial symptoms and findings. Systemic hypertension and pulmonary edema frequently occur. Severe hypertension, pulmonary edema, and rapid worsening of hemolysis and renal function may occur after a blood or blood product transfusion. Cardiac findings include atrial arrhythmias, pericardial friction rub, and pericardial effusion. Raynaud's phenomenon is part of the syndrome in patients treated with bleomycin.

Laboratory findings include severe to moderate anemia associated with red blood cell fragmentation and numerous schistocytes on peripheral smear. Reticulocytosis, decreased plasma haptoglobin, and an LDH level document hemolysis. The serum bilirubin level is usually normal or slightly elevated. The Coombs test is negative. The white cell count is usually normal, and thrombocytopenia (<100,000/μL) is almost always present. Most patients have a normal coagulation profile, although some have mild elevations in thrombin time and in levels of fibrin degradation products. The serum creatinine level is elevated at presentation and shows a pattern of subacute worsening within weeks of the initial azotemia. The urinalysis reveals hematuria, proteinuria, and granular or hyaline casts, and circulating immune complexes may be present.

The basic pathologic lesion appears to be deposition of fibrin in the walls of capillaries and arterioles, and these deposits are similar to those seen in HUS due to other causes. These microvascular abnormalities involve mainly the kidneys and rarely occur in other organs. The pathogenesis of cancer treatment–related HUS is not completely understood, but probably the most important factor is endothelial damage. Primary forms of HUS/TTP are related to a decrease in processing of von Willebrand factor by a protease called ADAMTS13.

The case-fatality rate is high; most patients die within a few months. Optimal treatment for chemotherapy-induced HUS is debated. Immunocomplex removal through plasmapheresis, plasma exchange, immunoadsorption, or exchange transfusion, antiplatelet and anticoagulant therapies, and immunosuppression have all been employed with varying degrees of success.

The outcome with plasma exchange is generally poor, as in many other cases of secondary TTP. Rituximab is successfully used in patients with chemotherapy-induced HUS as well as in ADAMTS13-deficient TTP. Eculizumab, a complement inhibitor, is now considered first-line treatment of atypical HUS. Ravulizumab, a humanized monoclonal antibody that blocks terminal complement activation at C5 and is engineered from eculizumab, has an extended half-life and is approved by the U.S. Food and Drug Administration (FDA) for atypical HUS. Vaccination against *Neisseria meningitis* is mandatory before eculizumab and ravulizumab are administered.

NEUTROPENIA AND INFECTION

These remain the most common serious complications of cancer therapy. They are covered in detail in **Chap. 79**.

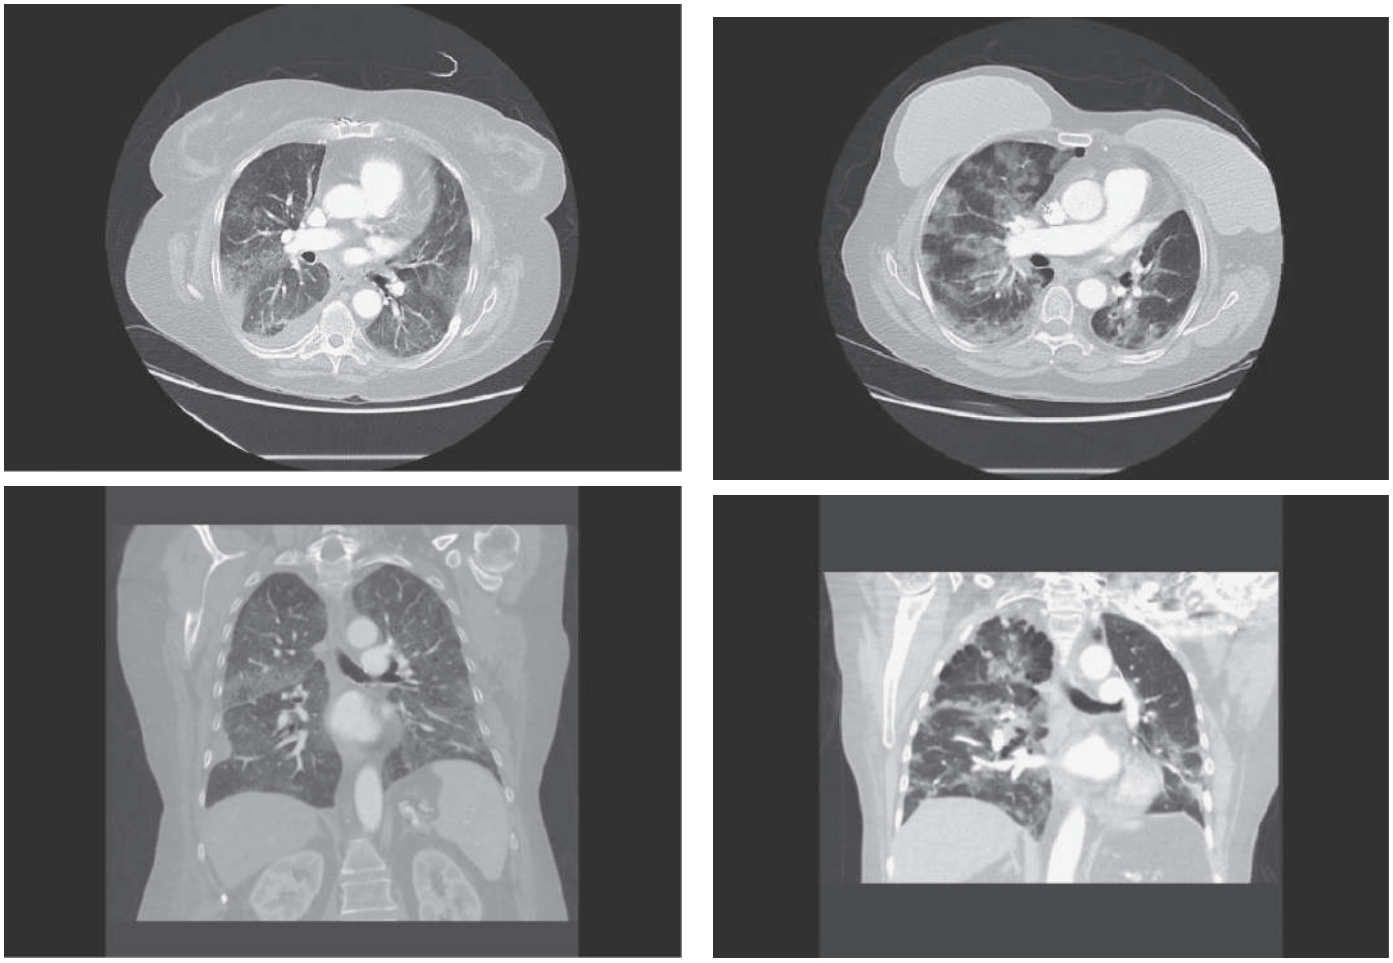
PULMONARY INFILTRATES

Patients with cancer may present with dyspnea associated with diffuse interstitial infiltrates on chest radiographs. Such infiltrates may be due to progression of the underlying malignancy, treatment-related toxicities, infection, and/or unrelated diseases. The cause may be multifactorial; however, most commonly, they occur as a consequence of treatment. Infiltration of the lung by malignancy has been described in patients with leukemia, lymphoma, and breast and other solid cancers. Pulmonary lymphatics may be involved diffusely by neoplasm (pulmonary lymphangitic carcinomatosis), resulting in a diffuse increase in interstitial markings on chest radiographs. The patient is often mildly dyspneic at the onset, but pulmonary failure develops over a period of weeks. In some patients, dyspnea precedes changes on the chest radiographs and is accompanied by a nonproductive cough. This syndrome is characteristic of solid tumors. In patients with leukemia, diffuse microscopic neoplastic peribronchial and peribronchiolar infiltration is frequent but may be asymptomatic. However, some patients present with diffuse interstitial infiltrates, an alveolar capillary block syndrome, and respiratory distress. Thickening of bronchovascular bundles and prominence of peripheral arteries are CT findings suggestive of leukemic infiltration. In these situations, glucocorticoids can provide symptomatic relief, but specific chemotherapy should always be started promptly.

Several cytotoxic agents, such as bleomycin, methotrexate, busulfan, nitrosoureas, gemcitabine, mitomycin, vinorelbine, docetaxel, paclitaxel, fludarabine, pentostatin, and ifosfamide, may cause pulmonary damage. The most frequent presentations are interstitial pneumonitis, alveolitis, and pulmonary fibrosis. Some cytotoxic agents, including methotrexate and procarbazine, may cause an acute hypersensitivity reaction. Cytosine arabinoside has been associated with noncardiogenic pulmonary edema. Administration of multiple cytotoxic drugs, as well as radiotherapy and preexisting lung disease, may potentiate the pulmonary toxicity. Supplemental oxygen may potentiate the effects of drugs and radiation injury. Patients should always be managed with the lowest F_{IO_2} that is sufficient to maintain hemoglobin saturation.

The onset of symptoms may be insidious, with symptoms including dyspnea, nonproductive cough, and tachycardia. Patients may have bibasilar crepitant rales, end-inspiratory crackles, fever, and cyanosis. The chest radiograph generally shows an interstitial and sometimes an intraalveolar pattern that is strongest at the lung bases and may be symmetric. A small effusion may occur. Hypoxemia with decreased carbon monoxide diffusing capacity is always present. Glucocorticoids may be helpful in patients in whom pulmonary toxicity is related to radiation therapy or to chemotherapy. Treatment is otherwise supportive.

Molecular targeted agents, imatinib, erlotinib, and gefitinib are potent inhibitors of tyrosine kinases. These drugs may cause interstitial lung disease (ILD). In the case of gefitinib, preexisting fibrosis, poor performance status, and prior thoracic irradiation are independent risk factors; this complication has a high fatality rate. In Japan, incidence of ILD associated with gefitinib was ~4.5% compared to 0.5% in the United States. Osimertinib may cause transient pulmonary opacities (TPOs). TPOs are characterized asymptomatic and localized ground-glass opacities (GGO) with or without nodular consolidation on CT. TPOs typically resolve during continued osimertinib therapy. Temsirolimus and everolimus, both esters of rapamycin (sirolimus), are agents that block the effects of mammalian target of rapamycin (mTOR), an enzyme that has an important role in regulating the synthesis of proteins that control cell division. These agents may cause GGO in the lung with or without diffuse interstitial disease and lung parenchymal consolidation. Patients may be asymptomatic with only radiologic findings or may be symptomatic. Symptoms include cough, dyspnea, and/or hypoxemia, and sometimes patients present



with systemic symptoms such as fever and fatigue. The incidence of everolimus-induced ILD also appears to be higher in Japanese patients. HER2-targeting ADC trastuzumab-deruxtecan carries a known risk of ILD with fatality. Treatment includes dose reduction or withdrawal and, in some cases, the addition of glucocorticoids.

The FDA-approved immune checkpoint inhibitors (ICIs) of the PD-1 and PD-L1 pathway, including nivolumab, pembrolizumab, durvalumab, avelumab, atezolizumab, and cemiplimab, enhance antitumor activity by blocking negative regulators of T-cell function. Immune-mediated pneumonitis is rare (10%) but may be a life-threatening complication of these drugs. Pneumonitis symptoms include cough, shortness of breath, dyspnea, and fever, and often involve only asymptomatic radiographic changes. Pneumonitis shows ground-glass patchy lesions and/or disseminated nodular infiltrates, predominantly in the lower lobes. Identifying the exact cause of a pneumonitis in a patient treated with ICIs could be challenging during the current COVID-19 outbreak **(Fig. 80-5*A*)**. Chest CT manifestations of COVID-19 include an imaging pattern of pure GGO, consolidation, nodules, fibrous stripes, and mixed patterns, with the distribution slightly predominant in the lower lobe and peripheral areas of the lung. Treatment of immune-mediated pneumonitis includes temporary or permanent withdrawal of drug and the addition of high-dose glucocorticoids **(Fig. 80-5*B*)**.

Radiation pneumonitis and/or fibrosis are relatively frequent side effects of thoracic radiation therapy. It may be acute or chronic. Radiation-induced lung toxicity is a function of the irradiated lung volume, dose per fraction, and radiation dose. The larger the irradiated lung field, the higher is the risk for radiation pneumonitis. The use of concurrent chemoradiation, particularly regimens including paclitaxel, increases pulmonary toxicity. Radiation pneumonitis usually develops 2–6 months after completion of radiotherapy. The clinical syndrome, which varies in severity, consists of dyspnea, cough with scanty sputum, low-grade fever, and an initial hazy infiltrate on chest radiographs. The infiltrate and tissue damage usually are confined to the radiation field. The CT scan may show GGOs, consolidation, fibrosis, atelectatic cicatrization, pleural volume loss, or pleural thickening. The patients subsequently may develop a patchy alveolar infiltrate and air bronchograms, which may progress to acute respiratory failure that is sometimes fatal. A lung biopsy may be necessary to make the diagnosis. Asymptomatic infiltrates found incidentally after radiation therapy need not be treated. However, prednisone should be administered to patients with fever or other symptoms. The dosage should be tapered slowly after the resolution of radiation pneumonitis, because abrupt withdrawal of glucocorticoids may cause an exacerbation of pneumonia. Delayed radiation fibrosis may occur years after radiation therapy and is signaled by dyspnea on exertion. Often it is mild, but it can progress to chronic respiratory failure. Therapy is supportive.

Classic radiation pneumonitis that leads to pulmonary fibrosis is due to radiation-induced production of local cytokines such as platelet-derived growth factor β, tumor necrosis factor, interleukins, and transforming growth factor β in the radiation field.

SBRT is a radiotherapy treatment method that has been applied to the treatment of stage I lung cancers in medically inoperable patients. SBRT accurately delivers a high dose of irradiation in one or few treatment fractions to an image-defined lung mass. Most of the acute changes after SBRT occur later than 3 months after treatment, and the shape of the SBRT-induced injury conforms more tightly to the tumor.

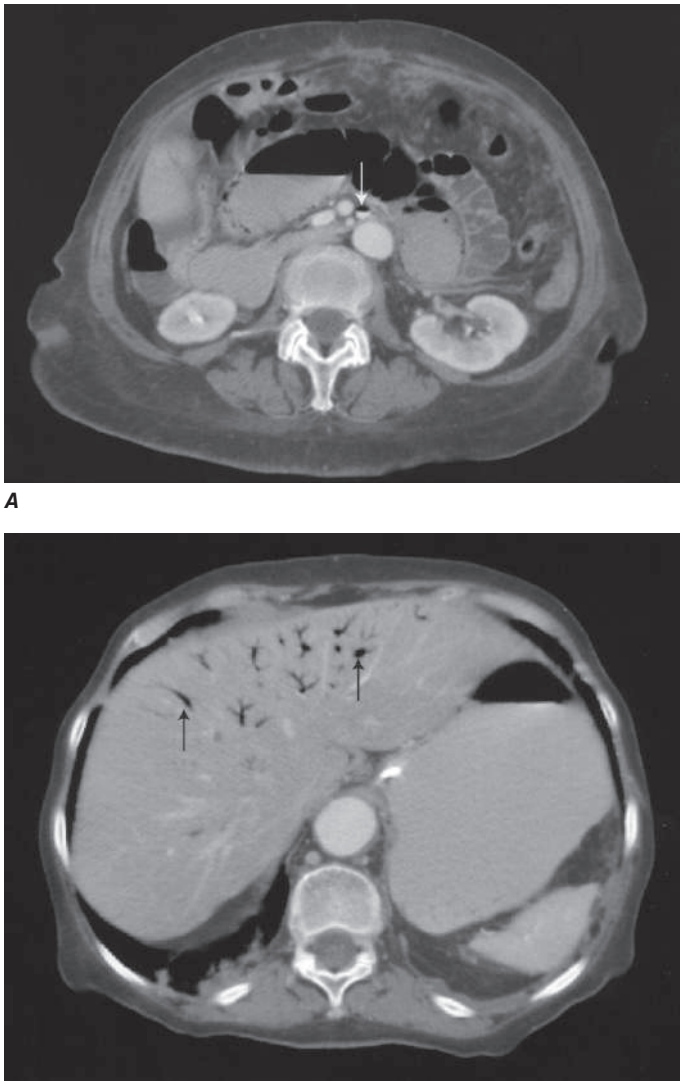

FIGURE 80-5 ***A.*** Computed tomography scan of a 63-year-old female with metastatic adenocarcinoma on nivolumab with immune check point inhibitor pneumonia showing interlobular septal thickening and diffuse ground-glass opacity to nivolumab. ***B.*** Computed tomography scan of a 68-year-old female with resected adenocarcinoma of lung and COVID-19 pneumonia showing peripheral and basilar predominant patchy ground-glass and consolidative opacity consistent with multifocal COVID pneumonia.

Pneumonia is a common problem in patients undergoing treatment for cancer (Chap 79). In patients with pulmonary infiltrates who are afebrile, heart failure and multiple pulmonary emboli are in the differential diagnosis.

NEUTROPENIC ENTEROCOLITIS

Neutropenic enterocolitis (typhlitis) is the inflammation and necrosis of the cecum and surrounding tissues that may complicate the treatment of acute leukemia. Nevertheless, it may involve any segment of the gastrointestinal tract including small intestine, appendix, and colon. This complication has also been seen in patients with other forms of cancer treated with taxanes, 5-fluorouracil, irinotecan, vinorelbine, cisplatin, carboplatin, sacituzumab govitecan, and high-dose chemotherapy (Fig. 80-6). It also has been reported in patients with AIDS, aplastic anemia, cyclic neutropenia, idiosyncratic drug reactions involving antibiotics, and immunosuppressive therapies. The patient develops right lower quadrant abdominal pain, often with rebound tenderness and a tense, distended abdomen, in a setting of fever and neutropenia. Watery diarrhea (often containing sloughed mucosa) and bacteremia are common, and bleeding may occur. Plain abdominal films are generally of little value in the diagnosis; CT scan may show marked bowel wall thickening, particularly in the cecum, with bowel wall edema, mesenteric stranding, and ascites, and may help to differentiate neutropenic colitis from other abdominal disorders such as appendicitis, diverticulitis, and *Clostridium difficile*–associated colitis in this high-risk population. Patients with bowel wall thickness >10 mm on ultrasonogram have higher mortality rates. However, bowel wall thickening is significantly more prominent in patients with *C. difficile* colitis. Pneumatosis intestinalis is a more specific finding, seen only in those with neutropenic enterocolitis and ischemia. The combined involvement of the small and large bowel suggests a diagnosis of neutropenic enterocolitis. Rapid institution of broad-spectrum antibiotics, bowel rest, and nasogastric suction may reverse the process. Use of myeloid growth factors improved outcome significantly. Surgical intervention is reserved for severe cases of neutropenic enterocolitis with evidence of perforation, peritonitis, gangrenous bowel, or gastrointestinal hemorrhage despite correction of any coagulopathy.

C. difficile colitis is increasing in incidence. Newer strains of *C. difficile* produce ~20 times more of toxins A and B compared to previously studied strains. *C. difficile* risk is also increased with chemotherapy. Antibiotic coverage for *C. difficile* should be added if pseudomembranous colitis cannot be excluded.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis is characterized by diffuse bladder mucosal bleeding that develops secondary to chemotherapy (mostly cyclophosphamide or ifosfamide), radiation therapy, bone marrow transplantation (BMT), and/or opportunistic infections. Both cyclophosphamide and ifosfamide are metabolized to acrolein, which is a strong chemical irritant that is excreted in the urine. Prolonged contact or high concentrations may lead to bladder irritation and hemorrhage. Symptoms include gross hematuria, frequency, dysuria, burning, urgency, incontinence, and nocturia. The best management is prevention. Maintaining a high rate of urine flow minimizes exposure. In addition, 2-mercaptoethanesulfonate (mesna) detoxifies the metabolites and can be coadministered with the instigating drugs. Mesna usually is given three times on the day of ifosfamide administration in doses that are each 20% of the total ifosfamide dose. If hemorrhagic cystitis develops, the maintenance of a high urine flow may be sufficient supportive care. If conservative management is not effective, irrigation of the bladder with alum or formalin solution may stop the bleeding in most cases. *N*-Acetylcysteine may also be an effective irrigant. Prostaglandin (carboprost) can inhibit the process. In extreme cases, ligation of the hypogastric arteries, urinary diversion, or cystectomy may be necessary.

In the BMT setting, early-onset hemorrhagic cystitis is related to drugs in the treatment regimen (e.g., cyclophosphamide), and late-onset hemorrhagic cystitis is usually due to the polyoma virus BKV or adenovirus type 11. BKV load in urine alone or in combination with acute graft-versus-host disease correlates with development of hemorrhagic cystitis. Viral causes are usually detected by polymerase chain reaction (PCR)–based diagnostic tests. Treatment of viral hemorrhagic cystitis is largely supportive, with reduction in doses of immunosuppressive agents, if possible. No antiviral therapy is approved, although cidofovir was reported to be effective in a small series. Hyperbaric oxygen therapy has been used successfully in patients with BKV-associated and cyclophosphamide-induced hemorrhagic cystitis during hematopoietic stem cell transplantation, as well as in hemorrhagic radiation cystitis that occurs in up to 5% of patients after pelvic radiation.

HYPERSENSITIVITY REACTIONS TO ANTINEOPLASTIC DRUGS

Many antineoplastic drugs may cause hypersensitivity reaction. These reactions are unpredictable and potentially life threatening. Most reactions occur during or within hours of parenteral drug administration. Taxanes, platinum compounds, asparaginase, etoposide, procarbazine, and biologic agents, including rituximab, bevacizumab, trastuzumab, gemtuzumab, cetuximab, and alemtuzumab, are more commonly associated with acute hypersensitivity reactions than are other agents. Hypersensitivity reactions to some drugs, such as taxanes, occur during the first or second dose administered. Hypersensitivity to platinum compounds occurs after prolonged exposure. Skin testing may identify patients with high risk for hypersensitivity after carboplatin exposure.

Premedication with histamine H_1 and H_2 receptor antagonists and glucocorticoids reduces the incidence of hypersensitivity reaction to taxanes, particularly paclitaxel. Despite premedication, hypersensitivity reactions may still occur. In these cases, rapid desensitization in the intensive care unit setting or re-treatment may be attempted with care, but the use of alternative agents may be required. Skin testing is used to assess the involvement of IgE in the reaction. Tryptase levels measured at the time of the reaction help to explain the mechanism of the reaction and its severity. Increased tryptase levels indicate underlying mast cell activation. Candidate patients for desensitization include those who have mild to severe hypersensitivity type I, with mast cell–mediated and IgE-dependent reactions occurring during a chemotherapy infusion or shortly thereafter.

81 Cancer of the Skin

Brendan D. Curti, John T. Vetto, Sancy A. Leachman

MELANOMA

Pigmented lesions are among the most common findings on skin examination. The challenge for the physician is to distinguish benign lesions from cutaneous melanomas and nonmelanoma skin cancers (NMSCs), both of which are increasing in frequency. Melanoma accounts for over half of the deaths resulting from skin cancer, although recent advances in immunotherapy and targeted therapy used in the neoadjuvant, adjuvant, and advanced disease settings have significantly improved survival. Genomic analysis of melanoma has improved our understanding of prognosis, and informed treatment and surveillance strategies beyond traditional surgical staging. Melanoma is an aggressive malignancy of melanocytes, pigment-producing cells that originate from the neural crest and migrate to the skin, meninges, mucous membranes, upper esophagus, and eyes. Melanocytes in each of these locations have the potential for malignant transformation, but most melanomas arise in the skin, facilitating detection when complete surgical excision can lead to cure. Cutaneous melanoma occurs in people of all ages and all colors. Noncutaneous melanomas have a different biology and a lower probability of response to the immunotherapy agents that have transformed the care of cutaneous melanoma. Examples of malignant melanoma of the skin, mucosa, eye, and nail are shown in **Fig. 81-1**.

RISK FACTORS AND EPIDEMIOLOGY

The epidemiologic patterns seen in melanoma reflect the genetic and biologic features of melanocytes and their response to environmental ultraviolet radiation (UVR). Clinical features that confer an increased risk for melanoma include: (1) vulnerability to sun damage (light/red coloration of skin, hair, or eyes; photodamaged skin; history of exposure to natural or artificial UVR; prior history of skin cancers of any type); (2) abnormal growth of melanocytes (increased absolute number of nevi, increased size of nevi, or atypical features of moles such as multiple colors, speckles, or shapes); and (3) immunosuppression (innate, functional, or drug-induced). **Table 81-1** summarizes melanoma risk factors and the relative risk associated with these factors.

The incidence and mortality rates are strongly influenced by ethnic, geographic, and environmental factors. For instance, the incidence of melanoma is 1/100,000 per year in populations with high skin eumelanin (a brown-black pigment that absorbs ultraviolet [UV] photons efficiently as they enter the epidermis) and up to 27/100,000 per year in populations with low skin eumelanin. Men are affected slightly more than women (1.4:1), and the median age at diagnosis is 66. Melanoma is one several cancer types with increasing incidence in the United States and is now the fifth leading cancer in men (59,170 new cases in 2024; probability 1:28) and the sixth leading cancer in women (41,460 new cases in 2024; probability 1:41). Although these rankings are based on the total number of new invasive melanoma cases in 2024, estimated at 100,640, an additional 99,700 cases of melanoma in situ (MIS) occurred in 2024.

Mortality rates begin to rise at age 55, with the greatest mortality in men age >65 years. In contrast to the increasing incidence, the mortality rates for melanoma are decreasing, though this trend appears less dramatic outside of the United States. The most likely reason for the decreased mortality is the influence of immunotherapy and targeted therapy on melanoma-specific survival. After U.S. Food and Drug Administration (FDA) approval of ipilimumab and vemurafenib in 2011, the 1-year relative survival rate increased from 42% (2008–2010) to 55% (2013–2015). The mortality rate from 2013 to 2017 dropped annually by 7% in those aged 20–64 years old and dropped 5–6% per year for individuals aged ≥65 years.

GLOBAL CONSIDERATIONS

The incidence of both nonmelanoma and melanoma skin cancers around the world has been increasing. Every year, between 2 and 3 million people develop NMSC, and in 2020, there were 324,635 cases of melanoma. A disproportionate number of cases and deaths occur in North America, Europe, Australia, and New Zealand. The highly variable melanoma incidence rates in different populations are due to the interplay between risk factors, including host genetics and environmental factors, which distribute risk unevenly across these populations and account for the absolute risk in different ethnic groups and geographic areas.

Dark-skinned populations (such as those of India and Puerto Rico), blacks, and East Asians also develop melanoma but at rates 10–20 times lower than those in whites. Cutaneous melanomas in dark-skinned populations are more often diagnosed at a higher stage, and patients tend to have worse outcomes. Surveillance, Epidemiology, and End Results (SEER) data (2016–2020) reveal that whites have the highest incidence of melanoma at 37.9 (men) and 25.2 (women) per 100,000 and that the incidence drops substantially in Hispanics (4.5 [men] and 4.3 [women] per 100,000), Native Americans (8.7 [men] and 7.8 [women] per 100,000), Asians/Pacific Islanders (1.3 [men] and 1.1 [women] per 100,000), and blacks (1 [men] and 0.9 [women] per 100,000). In nonwhite (Asian and dark-skinned) populations, the

frequency of non–sun-exposed melanomas, such as acral (subungual, plantar, palmar) and mucosal melanomas, is much higher; the incidence of melanoma in black and Hispanic populations is not associated with UV exposure. In China, ~20,000 new melanomas are reported each year, and in contrast to the United States, mortality is increasing. Non–sun-exposed melanomas have a different biology, have a lower probability of response to immunotherapy, and carry a poorer prognosis than cutaneous melanomas, thus accounting for the increase in mortality of this melanoma subgroup. Little is known about the effects of mixed ethnicity on melanoma risk.

GENETIC SUSCEPTIBILITY TO MELANOMA

Approximately 20–40% of hereditary melanomas (0.2–2% of all melanomas) are due to germline mutations in the cell cycle regulatory gene cyclin-dependent kinase inhibitor 2A (*CDKN2A*). In fact, 70% of all cutaneous melanomas have mutations or deletions affecting the *CDKN2A* locus on chromosome 9p21. This locus encodes two distinct tumor-suppressor proteins from alternate reading frames: *p16* and *ARF* ($p14^{ARF}$). The p16 protein inhibits CDK4/6-mediated phosphorylation and inactivation of the retinoblastoma (RB) protein, whereas *ARF* inhibits MDM2 ubiquitin-mediated degradation of p53. The loss of *CDKN2A* results in inactivation of two critical tumor-suppressor pathways, RB and p53, which control entry of cells into the cell cycle. Several studies have shown an increased risk of pancreatic cancer among melanoma-prone families with *CDKN2A* mutations. A second high-risk locus for melanoma susceptibility, *CDK4*, is located on chromosome 12q13 and encodes the cyclin-dependent kinase inhibited by p16. *CDK4* mutations, which also inactivate the RB pathway, are much rarer than *CDKN2A* mutations. Germline mutations in the melanoma lineage-specific oncogene microphthalmia-associated transcription factor (*MITF*), BRCA1-associated protein 1 (*BAP-1*), protection of telomeres 1 (*POT-1*), and telomerase reverse transcriptase (*TERT*) also predispose to familial melanoma with a not yet quantified high penetrance, based on families that have been tested.

The melanocortin-1 receptor (*MC1R*) gene is a moderate-risk inherited melanoma susceptibility factor. UVR stimulates the production of melanocortin (α-melanocyte-stimulating hormone [α-MSH]), the ligand for *MC1R*, which is a G-protein-coupled receptor that signals via cyclic AMP and regulates the amount and type of pigment produced by melanocytes. *MC1R* is highly polymorphic, and many among its ~80 variants result in partial or full loss of signaling and lead to the production of non-photoprotective red/yellow pheomelanins, rather than photoprotective brown/black eumelanins. The red hair color (RHC) phenotype produced by *MC1R* mutations includes lightly

TABLE 81-1 Melanoma Risk Factors and Relative Risk

RISK LEVEL	RISK FACTOR	RELATIVE RISK
Elevated	1 atypical nevus versus 0	1.5
	Total common nevi, 16+ versus <15	1.5
	Blue eye color versus dark	1.5
	Hazel eye color versus dark	1.5
	Green eye color versus dark	1.6
	Light brown hair versus dark	1.6
	Indoor tanning in any gender versus never	1.7
	Fitzpatrick skin type II versus IV	1.8
	Fitzpatrick skin type III versus IV	1.8
	History of sunburn versus no sunburn	2.0
	Blond hair versus dark	2.0
	2 atypical nevi versus 0	2.1
	Fitzpatrick skin type I versus IV	2.1
	High density of freckles versus none	2.1
	Total common nevi 41–60 versus <15	2.2
Moderately elevated	Family history of melanoma in 1 or more first-degree relatives	1.7–3.0
	3 atypical nevi versus 0	3.0
	Total common nevi 61–80 versus <15	3.3
	Red hair versus dark	3.6

	Indoor tanning in women aged <30 versus never	6.0
	5 atypical nevi versus 0	6.4
	Total common nevi 81–120 versus <15	6.9
	Personal history of melanoma	8.2–13.4
	CDK2NA mutation carrier	14–28

colored skin, red hair, freckles, increased sun sensitivity, and increased risk of melanoma. In addition to its weak UV-shielding capacity relative to eumelanin, increased pheomelanin production in patients with inactivating polymorphisms of *MC1R* also provides a UV-independent carcinogenic contribution to melanomagenesis via oxidative damage and reduced DNA damage repair.

Other more common, low-penetrance polymorphisms in genes related to pigmentation, nevus count, immune responses, DNA repair, metabolism, and the vitamin D receptor have small effects on melanoma susceptibility. In sum, ~50–60% of the genetic risk for hereditary melanoma can be attributed to known melanoma predisposition genes, with ~40% of the known genetic risk attributable to *CDKN2A*. The other components of inherited risk are most likely due to the presence of additional modifier genes and/or shared environmental exposures of the host.

PREVENTION AND EARLY DETECTION

Primary prevention of melanoma and NMSC is based on protection from the sun. Public health initiatives, such as the SunSmart program that started in Australia and is now operative in Europe and the United States, have demonstrated that behavioral change can decrease the incidence of NMSC and melanoma. Preventive measures should start early in life because damage from UV light begins early even though cancers develop years later. Early episodes of sunburns may be a greater risk than chronic tanning. Some individuals tan compulsively. There is now greater understanding of tanning addiction and the cutaneous-neural connections that may give rise to this behavior. Compulsive tanners exhibit differences in dopamine binding and reactivity in reward pathways in the brain, such as the basal striatum, resulting in cutaneous secretion of β-endorphins after UV exposure. Identifying individuals with tanning addiction may be another prevention method. Regular use of broad-spectrum sunscreens that block UV-A and UV-B with a sun protection factor (SPF) of at least 30 and protective clothing should be encouraged. Physical blockers such as zinc oxide and titanium dioxide have less likelihood of being absorbed or of generating an allergic reaction than chemical sunscreens. Avoidance of sunburns, tanning beds, and midday sun exposure is recommended.

Secondary prevention comprises education and screening with the goal of early detection and can be individualized based on risk factors. A full-body skin exam is warranted in populations at higher risk for melanoma such as patients with clinically atypical moles (dysplastic nevi) and those with a personal history of melanoma. Surveillance in high-risk patients should be performed by a dermatologist and include total-body photography and dermoscopy where appropriate. Individuals with three or more primary melanomas and families with at least one invasive melanoma and two or more cases of melanoma and/or pancreatic cancer, ocular melanoma, mesothelioma, or renal cell carcinoma among first- or second-degree relatives on the same side of the family may benefit from genetic testing. Atypical nevi and MIS should be completely removed with at least a 5-mm margin. Early detection of small lesions allows the use of simpler treatment modalities with higher cure rates and lower morbidity. Monthly self-screening augments provider-based screening. Patients should be taught to recognize the clinical features of melanoma and advised to report any change in a pigmented lesion. There is evidence supporting the ability of media campaigns to reduce cancer mortality in lung cancer, and results from Australia's skin cancer campaigns demonstrate improvement in attitude and behavior and a reduction in melanoma incidence. A benefit/cost analysis in Australia showed a return of $3.85 for every $1 invested. Although the U.S. Preventive Services Task Force states that there is insufficient evidence to recommend skin screening for the general population, additional research is anticipated to find best practices for skin cancer detection and prevention.

DIAGNOSIS

Early detection of melanoma before it becomes invasive and life-threatening metastases have occurred is essential and may be facilitated by applying the ABCDEs: *a*symmetry (benign lesions are usually symmetric); *b*order irregularity (most nevi have clear-cut borders); *c*olor variegation (benign lesions usually have uniform light or dark pigment); *d*iameter >6 mm (the size of a pencil eraser); and *e*volving (any change in size, shape, color, or elevation or new symptoms such as bleeding, itching, and crusting). In addition, any nevus that appears atypical and different from the rest of the nevi on that individual (an "ugly duckling") should be considered suspicious.

The entire skin surface, including the scalp and mucous membranes, as well as the nails should be examined in each patient. Bright room illumination is important, and a hand lens or dermatoscope is helpful for evaluating variation in pigment pattern. Any suspicious lesions should be biopsied, evaluated by a specialist, or recorded by chart and/or photography for follow-up. Dermoscopy employs low-level magnification of the epidermis with polarized light or water interface and permits a more precise visualization of patterns of pigmentation than is possible with the naked eye.

Biopsy Any pigmented cutaneous lesion that has changed on examination or has the other features previously discussed is a candidate for biopsy. An excisional biopsy with 1- to 3-mm margins (narrow-margin excision) is suggested. This facilitates histologic assessment of the lesion, permits accurate measurement of thickness if the lesion is melanoma, and constitutes definitive treatment if the lesion is benign. For lesions that are large or involving anatomic sites where excisional biopsy may not be feasible (such as the face, hands, and feet) or when suspicion of malignancy is low, an incisional biopsy (e.g. shave, saucerization, or punch) to include the most nodular or darkest area of the lesion is acceptable. Incisional biopsy does not appear to facilitate the spread of melanoma. For suspicious lesions, every attempt should be made to preserve the ability to assess the deep and peripheral margins and to

perform immunohistochemistry. All biopsies should be deep enough to include the deepest component of the entire lesion, and any pigment at the base of the lesion should be removed and included with the biopsy specimen. Punch biopsies are more likely to clear the deep margin but more likely to be positive at the radial margins; the opposite is true for shave biopsies. The choice of biopsy type should be guided by which is most likely to remove the entire lesion for histologic evaluation.

The biopsy should be interpreted by a pathologist experienced in pigmented lesions, and the report should include Breslow thickness, mitotic rate, presence or absence of ulceration, lymphatic/vascular/neural invasion, regression, microsatellitosis, and the status of the peripheral and deep margins. Breslow thickness is the greatest thickness of a primary cutaneous melanoma measured on the slide from the top of the epidermal granular layer, or from the ulcer base, to the bottom of the tumor. To distinguish melanomas from benign nevi in challenging cases, genetic expression profiles (GEPs), fluorescence in situ hybridization with multiple probes, or comparative genomic hybridization can be helpful. GEPs have also been developed to determine prognosis.

CLASSIFICATION AND PATHOGENESIS

Clinical More recent classifications of melanoma are based on association with cumulative solar damage and nine different pathways related to genomic attributes summarized in Table 81-2. This revised classification incorporates traditional histopathologic designations such as superficial spreading, lentigo maligna, acral lentiginous, and desmoplastic, among others, but more precisely incorporates the pathophysiology and genetic drivers of melanoma subtypes.

At present, genomic alteration pathways for melanomas are not incorporated into American Joint Committee on Cancer (AJCC) staging or prognostic considerations, yet characterizing the genomic and mutational profiles of melanoma has become increasingly common in clinical practice. It is anticipated that genomic pathway characterization will become increasingly important in determination of melanoma prognosis and may influence surveillance strategies, surgical decisions, and medical therapy.

Genomic The advent of next-generation sequencing has led to whole exome sequencing of thousands of cutaneous melanomas derived from nonglabrous (hair-bearing) skin. This has revealed very complex genomic changes resulting from both germline (see "Genetic Susceptibility to Melanoma" above) and somatic mutations. Cutaneous melanomas have one of the highest somatic mutation rates (>10 mutations/Mb) among all cancers; the majority (76% of primary tumors and 84% of metastatic melanomas) exhibit mutations indicative of UVR exposure. The mutation rate varies based on body site; melanomas arising in chronic sun-damaged skin harbor substantially more mutations than melanomas from non–sun-damaged skin.

Melanomas can harbor thousands of mutations, but only a few are "driver" mutations that promote cell proliferation or inhibit normal pathways of apoptosis or DNA repair and confer a growth advantage to the neoplastic cell. Some of the driver mutations for cutaneous melanoma are depicted in Fig. 81-2 along with the clinical evolution of melanoma lesions. Driver mutations are often found in combination with mutations to germline susceptibility genes such as *p16*, which affect cell cycle arrest, and *ARF*, which result in defective apoptotic responses to genotoxic damage. As melanocytes accumulate DNA damage, they can undergo malignant transformation characterized by invasion, metastasis, and angiogenesis.

A genomic classification of cutaneous melanoma has been proposed based on the pattern of the most prevalent mutated genes, *BRAF*, *RAS*, and *NF1*, along with a triple wild type (WT), lacking mutations in these three genes. The pattern of DNA mutations can vary with the site of origin and should be determined along with the histologic subtype of the tumor. The proliferative pathways affected by the mutations include the mitogen-activated protein (MAP) kinase and phosphatidylinositol 3′ kinase/AKT pathways. *RAS* and *BRAF*, members of the MAP kinase pathway, which mediates the transcription of genes involved in cell proliferation and survival, undergo somatic mutation in melanoma and thereby represent potential therapeutic targets. *NRAS* is mutated in ~20% of melanomas, and somatic activating *BRAF* mutations are found in most benign nevi and 40–50% of cutaneous melanomas. Neither mutation by itself appears to be sufficient to cause melanoma; thus, they often are accompanied by other mutations, such as in *TERT*. The *BRAF* mutation is most commonly a T→A point mutation that results in a valine-to-glutamate amino acid substitution (V600E). V600E *BRAF* mutations are more common in younger patients and are present in most melanomas that arise on skin with intermittent sun exposure and are less common in melanomas from chronically sun-damaged skin (i.e., those of older patients).

Melanomas may harbor mutations in *AKT* (primarily in *AKT3*) and *PTEN* (phosphatase and tensin homolog). *AKT* can be amplified, and *PTEN* may be deleted or undergo epigenetic silencing that leads to constitutive activation of the PI3K/AKT pathway and enhanced cell survival by antagonizing the intrinsic pathway of apoptosis. A loss-of-function mutation in *NF1*, which can affect both the MAP kinase and PI3K/AKT pathways, has been described in 10–15% of melanomas.

TABLE 81-2 Major Histologic Subtypes of Malignant Melanoma

TYPE	SITE	APPEARANCE	ASSOCIATED MUTATIONS
Lentigo maligna	Sun-exposed surfaces, particularly malar region and temple	In flat portions, brown and tan predominate, but whitish gray sometimes present; in nodules, reddish brown, bluish gray, bluish black.	*BRAF* 28% *NRAS* 15% *PTEN*
Superficial spreading	Any (more common on upper back and, in women, lower legs)	Brown mixed with bluish red, bluish black, reddish brown, and often whitish pink. The lesion border is often visibly and/or palpably raised.	*BRAF* 57% *NRAS* 18%
Nodular	Any	Reddish blue, purple, or bluish black; can be uniform or mixed with brown and black.	*BRAF* 47% *NRAS* 33%
Acral lentiginous	Palm, sole, nail bed, mucous membrane	In flat portions, dark brown; in raised lesions (plaques), brown-black or blue-black.	*NRAS* 25% *c-KIT* 5-10% *BRAF* 10%
Desmoplastic	Any (more common on head and neck)	Highly variable; pigmentation is frequently absent. Can mimic nodular basal cell carcinoma.	*MAPK* and *PI3K* 73% High tumor mutational burden, *BRAF* and *NRAS* uncommon
Uveal	Choroid, ciliary body, iris	Dome or mushroom shaped. Display low internal reflectivity on ocular ultrasound.	BAP1, GNAQ, GNA11
Mucosal	Oral cavity, conjunctiva, sinuses, alimentary tract including rectum and anus, vulva	Can display radial growth pattern with ABCDE features associated with cutaneous melanomas. Often present with advanced tumors infiltrating local tissues	KIT, NRAS, KRAS or BRAF NF1

Abbreviation: ABCDE, asymmetry (benign lesions are usually symmetric); border irregularity (most nevi have clear-cut borders); color variegation (benign lesions usually have uniform light or dark pigment); diameter >6 mm (the size of a pencil eraser); and evolving (any change in size, shape, color, or elevation or new symptoms such as bleeding, itching, and crusting).

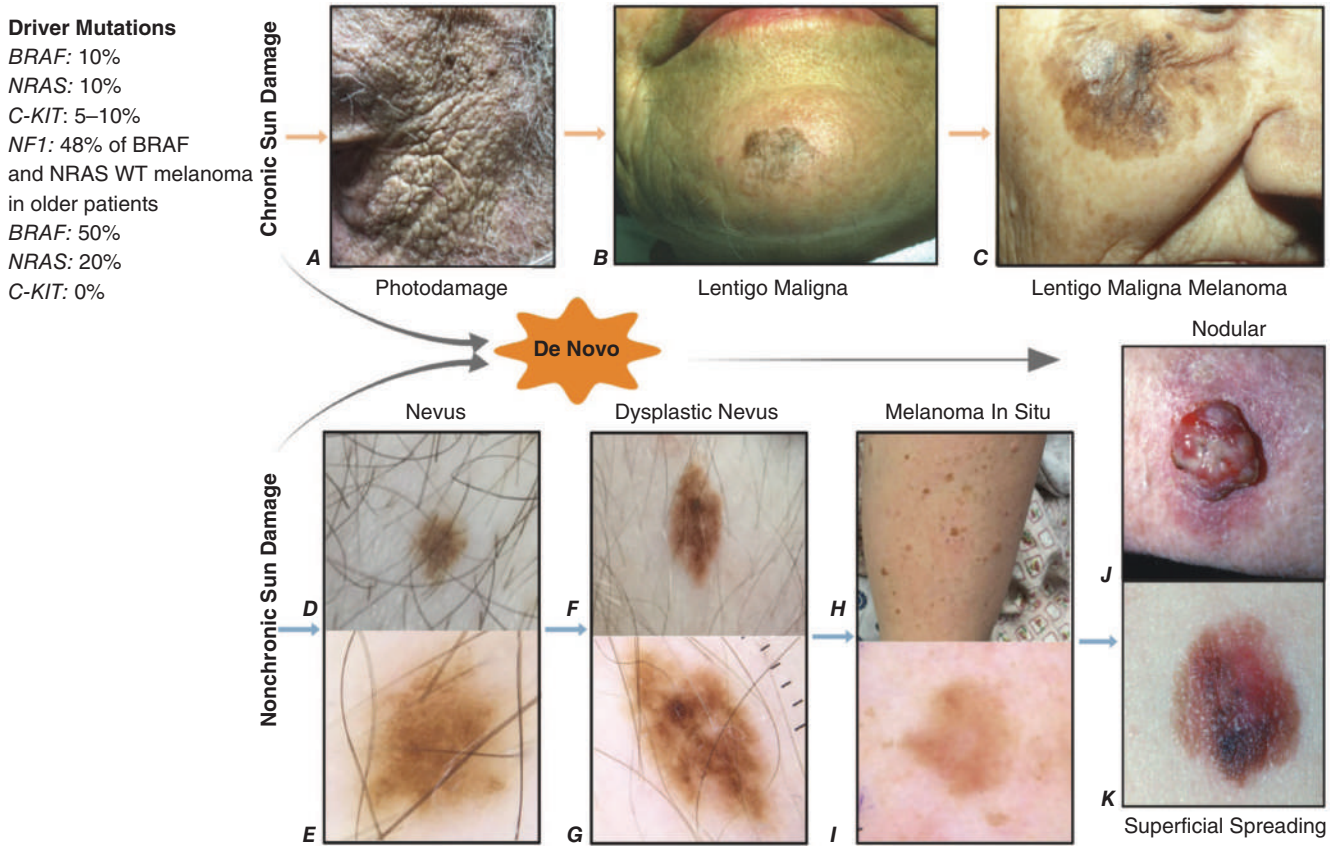

FIGURE 81-2 Cutaneous melanoma development and associated driver mutations. Chronic sun damage (with prominent solar elastosis) (***A***) predisposes to a lentigo maligna (in situ) (***B***), which can evolve into lentigo maligna melanoma (invasive) (***C***). Similarly, nonchronic sun damage can initiate melanoma de novo or in nevomelanocytes, where clinical and histologic changes of atypia may be seen prior to complete transformation. Nevi (***D, E***) can evolve into atypical lesions (***F, G***), in situ melanoma (***H, I***), and eventually invasive nodular (***J***) or superficial spreading melanomas (***K***). Images E, G, and I are dermascopic photos of images D, F, and H, respectively. *(Part A photo courtesy of Dr. Sancy Leachman, © Copyright 2022 Oregon Health & Science University [OHSU]. Parts B, C, J, and K photos courtesy of Dr. Leonard Swinyer Collection, © Copyright 2020 University of Utah and OHSU. Parts D–I photos courtesy of Dr. Elizabeth Berry, © Copyright 2022 OHSU.)*

In melanoma, these two signaling pathways (MAP kinase and PI3K/AKT) enhance tumorigenesis, chemoresistance, migration, and cell cycle dysregulation.

PROGNOSTIC FACTORS

The most important clinical prognostic factors for a newly diagnosed patient are incorporated in the AJCC staging classification. The best predictor of recurrence is Breslow thickness, followed by ulceration, which together make up the T stage for melanoma. The anatomic site of the primary tumor also influences prognosis; favorable sites are the forearm and leg, and unfavorable sites include the scalp, hands, feet, and mucous membranes. Women with stage I or II disease have better survival than men, perhaps in part because of earlier diagnosis; women frequently have melanomas on the lower leg, where self-recognition is more likely compared to the back, where melanoma is more likely in men.

Older individuals, especially men >60, have a tendency toward delayed diagnosis (and thus thicker tumors), have more head and neck and acral melanomas (which tend to have earlier vertical growth and distant metastases), and are more likely to develop melanomas in chronically UVR-damaged skin (which are more often *BRAF* wild type, with fewer options for therapy). All these factors help explain the worse prognosis in older males. Other important adverse factors include high mitotic rate and lymphatic/vascular invasion. Clinical features such as microsatellite lesions and/or in-transit metastases, evidence of nodal involvement, elevated serum lactate dehydrogenase (LDH), and certain sites of distant metastases (e.g., brain, liver, and bone) all portend a higher stage and worse prognosis.

GEPs and machine-learning algorithms that associate genomic changes with clinical outcomes have been used to estimate the prognosis of melanoma. A commercially available 31-gene GEP is available that predicts for all-site (particularly distant) relapse and incorporates the increased and decreased expression, as well as the dysregulation, of genes involved in many of the cellular processes leading to melanoma progression described earlier. Although this 31-gene GEP can estimate the probability of distant relapse, it has not supplanted the prognostic estimates derived from surgical staging. GEPs have been incorporated into management guidelines for breast, thyroid, and other cancers, but their use in cutaneous melanoma care is still under investigation.

STAGING

The purpose of staging is to estimate melanoma prognosis and determine treatment selection. The current melanoma staging criteria and estimated 10-year survival by stage are depicted in **Table 81-3**. The clinical stage is determined after the microscopic evaluation of the melanoma skin lesion and clinical and radiologic assessment. The pathologic stage incorporates the results from microscopic examination of clinically negative regional lymph nodes obtained at sentinel lymph node biopsy (SLNB), any enlarged nodes found on exam or imaging, and any suspected metastases amenable to open or image-guided biopsy.

All patients should have a complete history, with attention to symptoms that suggest metastatic disease, such as new palpable masses, malaise, weight loss, headaches, vision changes, alterations in bowel habits, hemoptysis, and pain. The provider should look for persistent melanoma at the biopsy site, dermal or subcutaneous nodules that could represent satellite or in-transit metastases, and lymphadenopathy. A complete blood count, complete metabolic panel, and LDH should be performed. Although these tests rarely lead to detection of occult metastatic disease, a microcytic anemia would raise the possibility of bowel metastases, elevated liver function tests can suggest liver metastases, and LDH is part of the AJCC system for stage IV disease. Abnormal test results should prompt a more extensive evaluation, including computed tomography (CT) scan or a positron emission tomography (PET) scan (or CT/PET combined). Magnetic resonance

TABLE 81-3 Staging and Survival

STAGE	TNM	10-YEAR MELANOMA-SPECIFIC SURVIVAL ESTIMATE
0	TisN0M0	>99%
IA	T1aN0M0, T1bN0M0	98%
IB	T2aN0M0	94%
IIA	T2b-T3aN0M0	88%
IIB	T3b-T4aN0M0	81–83%
IIC	T4bN0M0	75%
IIIA	T1a-T2aN1a-2aM0	71–88%
IIIB	T2b-T3aN1a-N2bM0	60–77%
IIIC	T3b-4bN1a-N3cM0	44–60%
IIID	T4bN3a-N3cM0	24–30%
IV M1a	Any T, any N, skin, soft tissue, or distant nodal sites	50% at 5 years
IV M1b	Any T, any N, lung + any M1a sites	35–50% at 5 years
IV M1c	Any T, any N, skin, non-CNS visceral disease, any M1a or M1b sites	~25% at 5 years
IV M1d	Any T, any N, CNS metastasis + any M1a,b,c sites	<5% at 5 years

Abbreviations: CNS, central nervous system; TNM, tumor-node-metastasis.

imaging (MRI) of the brain with contrast is recommended for the initial evaluation of patients who present with neurologic symptoms or have advanced disease on imaging or examination.

Despite all the above considerations, >80% of patients at presentation will have disease confined to the skin and a negative history and physical examination, in which case imaging is not indicated. One study suggests that imaging should be considered for node-negative low-stage melanoma with a high-risk GEP, but this is not yet standard. Imaging is sometimes done for very-high-risk primaries (e.g., >4 mm with ulceration, clinical stages IIB and IIC) in which the chance for occult distant metastases is higher than that for a positive SLNB, and the prognosis is worse compared to stage IIIA disease. Medical oncologists now routinely provide consultation for stage IIB and IIC patients to assess the potential value of adjuvant therapy (see "Treatment").

TREATMENT

Melanoma

MANAGEMENT OF CLINICALLY LOCALIZED MELANOMA (STAGE I, II)

For a newly diagnosed cutaneous melanoma, surgical wide excision (WE) of the lesion with a margin of normal skin is necessary to remove all malignant cells and minimize the probability of local recurrence. The National Comprehensive Cancer Network (NCCN), based on data from six randomized trials, recommends the following radial margins for a primary MIS, 0.5–1.0 cm; invasive up to 1 mm thick, 1 cm; >1.01–2 mm, 1–2 cm; and >2 mm, 2 cm. Smaller margins may be used for "anatomically constrained" locations such as the face, hands, feet, and genitalia due to the higher likelihood of surgical morbidity in these regions, and in some instances, Mohs with immunostaining is advantageous. In all instances, inclusion of subcutaneous fat in the surgical specimen facilitates adequate thickness measurement and assessment of surgical margins by the pathologist. When feasible, excision should go down to fascia, with fascial resection for thick (T4) lesions. Topical imiquimod, a toll-like receptor agonist, can stimulate skin macrophages to induce an immune response useful to treat lentigo maligna in cosmetically sensitive locations with narrow resection margins by promoting local immune response resulting in decreased local recurrence.

SLNB provides prognostic information to identify patients at high risk for relapse who may be candidates for adjuvant therapy. The first (sentinel) draining node(s) from the primary site is (are) located by injecting a blue dye and a gamma-emitting radioisotope around the primary site. The sentinel node(s) then is (are) identified using a handheld gamma detector brought sterilely into the operative field. The surgeon makes an incision of the area of uptake and looks for the blue-stained, "hot" node(s), which is (are) removed and subjected to histopathologic analysis with serial sectioning using hematoxylin and eosin and immunohistochemical stains (e.g., S100, HMB45, MART-1, and MelanA) to identify melanocytes.

NCCN guidelines recommend SLNB for patients with a 10% or greater chance of having tumor in the node. This includes patients with tumors >1 mm thick (T2) or T1 tumors that have ulceration (T1b). Patients with a 5–10% risk of node positivity (NCCN "Discuss and Consider" category), such as those with tumors measuring between 0.75 and 1.0 mm, transected tumors, regressed tumors, or lymphovascular invasion, should also be considered for SLNB. The NCCN does not recommend SLNB for patients with a risk of a positive SLNB ≤5% such as those with melanomas ≤0.75 mm thick and no high-risk features. In these patients, WE alone is the usual definitive therapy. There are computer nomograms that estimate the risk of sentinel lymph node involvement based on melanoma depth, clinical features (age, site), and histology (ulceration, mitotic rate, lymphovascular invasion). GEPs in combination with these other factors are being investigated as a sentinel lymph node risk assessment tool in ongoing prospective trials.

Patients with negative SLNB can either be followed or considered for adjuvant therapy if the primary lesion is considered high risk. Patients with thick and/or ulcerated stage IIB or IIC melanomas have a significant risk of recurrence after wide local excision and (negative) SLNB, estimated at 13–18% probability of death at 5 years using the AJCC melanoma database. Adjuvant anti-PD-1 immunotherapy using pembrolizumab or nivolumab for 1 year significantly reduces the risk of melanoma recurrence or death in stage IIB or IIC melanoma and has become a standard of care.

Patients with a positive sentinel lymph node should undergo CT or PET/CT imaging to rule out distant metastatic disease, and if none is found (i.e., stage III), adjuvant therapy should be offered (see next section). Complete lymphadenectomy following identification of a positive sentinel lymph node improves relapse-free but not overall survival, and therefore, it is no longer offered routinely, but should be considered in patients who cannot comply with follow-up and/or forgo adjuvant therapy. This avoids the morbidity of regional node dissection in most patients. However, patients not undergoing immediate completion node dissection should have nodal bed surveillance with physical examination and nodal bed imaging (ultrasound or CT) at 4- to 6-month intervals for approximately 3 years to rule out isolated nodal bed progression.

Mohs micrographic surgery (MMS) is an alternative to WE and is particularly useful in areas where tissue preservation is important (e.g., face, genitalia, hands) and for lesions with extensive MIS. MMS improves the probability of achieving negative margins, decreases local recurrence, and enhances cosmesis compared to WE in selected patients. It does not preclude SLNB, which can be done before the MMS procedure.

MANAGEMENT OF REGIONALLY METASTATIC MELANOMA (STAGE III)

Stage III melanoma comprises patients with a positive sentinel lymph node, resected regional nodal macrometastases, or resected locoregional disease (e.g., recurrences in the wide excision site, within 2 cm of the site ["satellite metastases"], or >2 cm from the site ["in-transit metastases"]). Even after complete resection of stage III disease, the risk of developing distant metastases (stage IV) may be high, and adjuvant systemic therapy should be offered. Melanomas may recur at the edge of the incision or graft, as satellite metastases, in-transit metastases, or most commonly, regional spread to a draining lymph node basin. Each of these presentations is managed surgically followed by postsurgical adjuvant systemic immunotherapy or targeted therapy (for *BRAF*-mutant tumors), after which

there is the possibility of long-term disease-free survival. Topical therapy with imiquimod has been useful for patients with low-volume dermal lesions, but survival benefit has not been confirmed with this approach. Talimogene laherparepvec is an engineered, oncolytic herpes simplex virus type 1 that is FDA approved for injection of primary or recurrent melanomas including cutaneous and subcutaneous lesions or lymph node deposits that cannot be completely removed by surgery.

Radiotherapy can reduce the risk of local recurrence after lymphadenectomy but does not improve overall survival. Patients with large nodes (>3–4 cm), four or more involved lymph nodes, or extranodal spread on microscopic examination should be considered for radiation as local recurrence in these high-risk patients has significant morbidity. Systemic adjuvant therapy can also be considered for patients with completely resected stage IV disease.

Current options for adjuvant systemic therapy include anti-PD-1 (nivolumab or pembrolizumab) or targeted therapy with BRAF/MEK inhibitors in melanomas that harbor a *BRAF* V600 mutation. Both anti-PD-1 and targeted therapy have been shown to confer disease-free and overall survival benefits in patients with stage III and stage IV melanoma (see below for further discussion).

A subset of patients with stage III melanoma has bulky disease (usually palpable nodal involvement) at presentation (stages IIIC and IIID) that may be difficult to resect with negative margins. Even if surgery is feasible and postsurgical adjuvant immunotherapy or targeted therapy is offered, the prognosis of these patients is poor. A recent randomized phase II study comparing neoadjuvant therapy followed by resection and adjuvant pembrolizumab versus resection followed by adjuvant pembrolizumab showed significant improvements in event-free and overall survival for the neoadjuvant approach. Other randomized phase II clinical trials investigating neoadjuvant plus adjuvant ipilimumab and nivolumab or relatlimab plus nivolumab in patients with palpable nodal disease at diagnosis have demonstrated a >50% probability of achieving a pathologic complete response with neoadjuvant treatment and a low probability of recurrence at 1 and 2 years. Neoadjuvant plus adjuvant targeted therapy in patients with stage IIIC or IIID *BRAF*-mutated melanoma has demonstrated a similar high probability of achieving pathologic complete response and improved event-free survival in single-arm phase II studies. Long-term follow-up data from randomized controlled studies of neoadjuvant immunotherapy are not yet mature, and comparisons of immunotherapy to targeted therapy in the neoadjuvant setting have not yet been performed. GEP may help to identify patients with stages II or III melanoma who are at *lower* risk of recurrence and could avoid the toxicity and expense of adjuvant therapy, although prospective data on this approach are needed.

TREATMENT

Metastatic Disease

At diagnosis, 84% of patients with melanoma will have stage I or II disease and 4% will present with metastases. Many others will develop metastases after initial therapy for locoregional disease; 60% of deaths from melanoma occur in patients who were initially diagnosed as stage I or II. The probability of recurrence is related to initial stage, ranging from <5% with stage IA to >90% for subsets of patients with stage IIID disease at presentation. Patients with a history of melanoma who develop signs or symptoms suggesting recurrent disease should undergo restaging imaging as described earlier. Distant metastases (stage IV) commonly involve skin and lymph nodes as well as viscera, bone, or the brain. The prognosis is better for patients with skin and subcutaneous metastases (M1a) than for lung (M1b) and worst for those with metastases to bone or other visceral organs (M1c) or brain (M1d). An elevated serum LDH is a poor prognostic factor and places the patient in stage M1c regardless of the metastatic sites. The 15-year survival of patients with stage IV melanoma was <10% before 2010; however, the development of targeted therapy and immunotherapy has improved disease-free and overall survival, especially for patients with M1a and M1b disease, in whom the 15-year survival is nearly 50%. Even patients with M1c disease may have prolonged survival, and those who are progression-free for >2 years after immunotherapy or targeted therapy have a high probability of living >5 years from the onset of metastasis; some of these individuals may be cured.

TABLE 81-4 Treatment Options for Metastatic Melanoma

Immunotherapy
Immune checkpoint blockade
Anti-PD-1: pembrolizumab or nivolumab
Anti-CTLA-4: ipilimumab
Combined ipilimumab and nivolumab
Combined relatlimab (anti-LAG-3) and nivolumab
T-cell engager
Tebentafusp (selected patients with uveal melanoma)
Cytokine-based immunotherapy
High-dose interleukin 2
Clinical trials investigating adoptive cellular therapy with tumor-infiltrating lymphocytes for advanced disease and personalized vaccine targeting neoantigens in high-risk resected melanoma
Oncolytic virus
Talimogene laherparepvec
Targeted therapies
BRAF inhibitors: vemurafenib, dabrafenib, encorafenib
MEK inhibitors: trametinib, cobimetinib, binimetinib
Local modalities
Surgery
Stereotactic radiation

FDA-approved agents since 2011 include three immune T-cell checkpoint inhibitors (ipilimumab, nivolumab, and pembrolizumab), combination immunotherapy (ipilimumab plus nivolumab or relatlimab plus nivolumab), six oral agents that target the MAP kinase pathway (the BRAF inhibitors vemurafenib, dabrafenib, and encorafenib, and the MEK inhibitors trametinib, cobimetinib, and binimetinib), and the oncolytic virus talimogene laherparepvec. Adoptive cellular therapy using tumor-infiltrating lymphocytes (TILs) administered with interleukin 2 is undergoing FDA review and may become a new standard of care for patients with progression on checkpoint immunotherapy **(Table 81-4)**.

Local modalities, such as surgery and stereotactic radiosurgery, should be considered for patients with a limited number of metastatic sites (oligometastatic disease) because they may experience long-term disease-free survival after metastasectomy or ablative high-dose-per-fraction radiation. Patients with solitary metastases are the best candidates, but local modalities can also be offered to patients with metastases at more than one site if a complete resection or treatment of all sites can be achieved with reasonable side effects. Patients rendered free of disease can be considered for adjuvant therapy or a clinical trial because their risk of developing additional metastases remains high. Surgery can also be used as an adjunct to systemic therapy if only one or a few oligometastases remain after systemic therapy. Surgery can be used to obtain tumor for mutational profile analysis or to harvest tumor for TIL therapy.

IMMUNOTHERAPY

Immune Checkpoint Blockade Immunotherapies are based on an understanding of the control mechanisms of the normal immune response. Inhibitory receptors or checkpoints, including CTLA-4, PD-1, and lymphocyte activation gene 3 (LAG-3), are upregulated on T cells after engagement of the T-cell receptor by cognate tumor antigen in the context of the appropriate class I or II human leukocyte antigen (HLA) molecules during the interaction between a T cell and antigen-presenting cell. Immune checkpoints are needed to ensure proper regulation of a normal immune response; however, the continued expression of inhibitory receptors during chronic

infection (hepatitis, HIV) and in cancer patients leads to exhausted T cells with limited potential for proliferation, cytokine production, or cytotoxicity. Ipilimumab, a fully human IgG1 antibody that binds CTLA-4 and blocks inhibitory signals, was the first drug shown in a randomized trial to improve survival in patients with metastatic melanoma. Anti-CTLA-4 monotherapy has been supplanted by anti-PD-1 monotherapy or checkpoint combinations due to higher objective response rates and longer durations of response.

The PD-1 blockers, nivolumab and pembrolizumab, have been approved to treat patients with advanced melanoma. Combination T-cell checkpoint therapy, blocking both inhibitory pathways with ipilimumab and nivolumab, leads to superior antitumor activity compared to treatment with either agent alone. Combined therapy with IV ipilimumab and nivolumab is administered in the outpatient setting every 3 weeks for four doses (induction), followed by nivolumab given every 2–4 weeks (maintenance) for up to 1 year, and is associated with an objective response rate of 56% and enhanced survival compared to ipilimumab monotherapy. Patients who have >5% expression of PD-1 on T cells in a melanoma biopsy sample derive a similar level of clinical benefit from nivolumab monotherapy, although using PD-1 expression to select therapy remains problematic as some patients whose melanoma has no detectable PD-1 expression can still respond to immunotherapy. Other elements of genomic analysis, including an estimate of tumor mutational burden (TMB), can be clinically useful as TMB is correlated with a higher probability of objective response and longer progression-free survival in patients treated with checkpoint antibody therapy in melanoma and other solid tumors. TMB appears to be a more robust predictor of response compared to PD-L1 expression in melanoma.

LAG-3 is another checkpoint present on CD4+ and CD8+ T cells and is upregulated after chronic antigen exposure. The combination of anti-LAG-3 using relatlimab and anti-PD-1 with nivolumab results in objective responses comparable to ipilimumab plus nivolumab with fewer side effects. Relatlimab plus nivolumab has been approved by the FDA for the first-line treatment of advanced melanoma, has activity after progression on other checkpoint inhibitors, and is being investigated in the neoadjuvant setting as detailed above.

T-cell checkpoint antibodies can also interfere with normal immune regulatory mechanisms, producing a novel spectrum of side effects. The most common immune-related adverse events were skin rash (discussed in depth in the Dermatology Drug Eruption section in **Chap. 63**) and diarrhea (sometimes severe, life-threatening colitis), but toxicity can involve almost any organ resulting in thyroiditis, hypophysitis, hepatitis, nephritis, pneumonitis, myocarditis, and neuritis. The severity and frequency of toxicity are greatest when anti-CTLA-4 and anti-PD-1 are combined, followed by anti-CTLA-4, anti-LAG-3 plus anti-PD-1, and then anti-PD-1 monotherapies. Vigilance, interruption of therapy, and early intervention with steroids or other immunosuppressive agents, such as anti–tumor necrosis factor antibodies or mycophenolate mofetil, can mitigate toxicity and prevent permanent organ damage. Using immunosuppressive agents to mitigate toxicity does not diminish antitumor activity, and benefit is manifest even in patients who must discontinue immunotherapy due to immune-mediated toxicity. Checkpoint immunotherapy can be administered safely to selected patients with preexisting autoimmune conditions using a multidisciplinary approach with input from endocrinology, rheumatology, and other specialty services as clinically necessary. The use of T-cell checkpoint antibodies for metastatic melanoma has become commonplace, but there is controversy about whether all patients need combined anti-CTLA-4 and anti-PD-1 and whether biomarkers can be used to select patients who may benefit from anti-PD-1 alone. There is also a significant economic impact with any anticancer therapy, which must be placed in the context of the survival benefit.

TARGETED THERAPY

The RAS-RAF-MEK-ERK pathway delivers proliferation and survival signals from the cell surface to the cytoplasm and nucleus and is mutated in approximately 50% of melanomas. Inhibitors of BRAF and MEK can induce regression of melanomas that harbor a *BRAF* mutation. Three BRAF inhibitors, vemurafenib, dabrafenib, and encorafenib, have been approved for the treatment of patients whose melanomas harbor a mutation at position 600 in *BRAF*. Monotherapy with BRAF inhibitors has been supplanted with combined BRAF and MEK inhibition to address the rapid adaptation of melanomas that use MAP kinase pathway reactivation to facilitate growth when BRAF is inhibited. Combined therapy with BRAF and MEK inhibitors (dabrafenib and trametinib, vemurafenib with cobimetinib, or encorafenib and binimetinib) improved progression-free and overall survival compared to monotherapy with a BRAF inhibitor. Long-term results of inhibition of the MAP kinase pathway confirm that some patients achieve long intervals of disease control, yet the major limitation of both monotherapy and combined therapy appears to be the acquisition of resistance. The mechanisms of resistance are diverse and reflect the genomic heterogeneity of melanoma; however, most instances involve reactivation of the MAPK pathway, often through *RAS* mutations or mutant *BRAF* amplification. Patients who develop resistance to BRAF and MEK inhibition are candidates for immunotherapy or clinical trials.

Targeted therapy is accompanied by manageable side effects that differ from those experienced during immunotherapy. Headache, pyrexia, and arthralgias are common. A class-specific side effect of BRAF inhibitor monotherapy is the development of hyperproliferative skin lesions, including well-differentiated squamous cell skin cancers (SCCs) in up to 25% of patients. Paradoxical activation of the MAP kinase pathway occurs from BRAF inhibitor–mediated changes in *BRAF* wild-type cells, and the activation is blocked by MEK inhibitor, which explains why these lesions are infrequent during combined therapy. Metastases from treatment-induced SCCs have not been reported, and BRAF and MEK inhibitors can be continued safely following simple excision of the SCCs. Cardiac and ocular toxicities, although infrequent, can occur with BRAF and MEK inhibitors and require medical evaluation, management, and usually discontinuation of targeted therapy.

Activating mutations in the c-kit receptor tyrosine kinase are found in a minority of cutaneous melanomas with chronic sun damage but are more common in mucosal and acral lentiginous subtypes. When activating mutations of *c-kit* are present, imatinib therapy can achieve clinically meaningful responses, similar to gastrointestinal stromal tumors. The probability of objective response in patients whose melanomas harbor a *c-kit* mutation is 29%, although most responses are transient. *N-RAS* mutations occur in 15–20% of melanomas. At present, there are no effective targeted agents for these patients, but *N-RAS* inhibitors are being investigated in clinical trials.

Targeting proteins that are differentially expressed on melanoma has been the basis for many clinical trials investigating vaccines and engineered biologics. An engineered bispecific fusion protein targeting gp100 on melanoma and CD3 on T cells, called tebentafusp, has garnered FDA approval for the treatment of metastatic uveal melanoma in patients who have the HLA-A*02.01 tissue type. Uveal melanoma is an aggressive melanoma subtype with a propensity for metastasis to the liver and a much lower probability of response to checkpoint immunotherapy than cutaneous melanomas. Objective response to tebentafusp is <10%, but overall survival and progression-free survival are significantly improved compared to checkpoint immunotherapy.

Other systemic therapies used to treat stage IV melanoma patients include high-dose interleukin 2, which is also associated with durable remissions in some patients. Chemotherapy using dacarbazine or taxanes is infrequently used and confers no survival benefit.

INITIAL APPROACH TO PATIENT WITH METASTATIC DISEASE

Upon diagnosis of stage IV disease, a sample of the patient's tumor should be submitted for molecular testing to determine whether a *BRAF* or *c-kit* mutation is present. Analysis of a metastatic lesion biopsy is preferred, but any sample will suffice because there is little discordance between primary and metastatic lesions. Treatment algorithms start with determining the melanoma's *BRAF* status.

For *BRAF* wild-type tumors, immunotherapy is recommended. The best sequence of targeted therapy and immunotherapy in patients with *BRAF*-mutated melanomas has been controversial. A randomized study that compared anti-CTLA-4 plus anti-PD-1 followed by BRAF/MEK targeted therapy at progression to the opposite sequence in patients with advanced melanoma showed that immunotherapy followed by targeted therapy conferred statistically significant better overall survival at 2 years and a trend toward better progression-free survival. Toxicities were similar comparing the treatment sequences. The patient's history, including sites of disease, symptom burden, and history of autoimmune conditions, influences the final recommendation for immunotherapy or targeted therapy, but survival data favor the initial use of combined checkpoint immunotherapy in the advanced disease setting. Despite improvements in therapy, most patients with metastatic melanoma will not be cured, so enrollment in a clinical trial is always an important consideration. Many will be poor candidates for therapy because of extensive disease burden, poor performance status, or concomitant illness; thus, the timely integration of palliative care and hospice remains an important element of care.

FOLLOW-UP AND SURVIVORSHIP

Skin examination and surveillance at least once a year are recommended for all patients with melanoma. Routine blood work and imaging for patients with stages IA–IIA (NCCN low risk) disease is not recommended unless symptoms are present. Surveillance diagnostic imaging can be considered in patients with stages IIB–III (NCCN high risk) disease but is mainly reserved for patients with signs or symptoms of recurrent disease or to follow response to therapy. The NCCN does not recommend surveillance imaging in asymptomatic patients who had advanced melanoma and are free of disease 5 or more years out from treatment. For stage-specific recommendations, please consult the NCCN guidelines (see "Further Reading").

The increasing incidence of melanoma has been met with more interest in advocacy and survivorship. Several national and international advocacy groups have called attention to issues such as genetic screening, sun awareness, and the care of chronic treatment-related side effects. These include, but are not limited to, skin changes (such as vitiligo), lymphedema, neuropathies, and gastrointestinal and endocrine disorders. Lymphedema can now be managed in specialty clinics that offer support, nonsurgical treatments, and newer surgical therapies such as lymphovenous bypass and vascularized lymph node transplants.

NONMELANOMA SKIN CANCERS

NMSCs (mostly SCCs and basal cell cancer [BCC]) are the most common cancers in the United States. Although tumor registries do not routinely gather data on the incidence of NMSCs, it is estimated that the annual incidence is more than 5.3 million cases in the United States; SCCs and BCCs account for 80 and 18%, respectively. While less common, the incidence of Merkel cell carcinoma (MCC) has tripled over the past 20 years. There are now an estimated 2600 cases per year with an annual increase in incidence of 8%. NMSCs can metastasize, but MCCs do this most commonly, with sentinel lymph node positivity rates of 25% (compared to 12–19% for melanoma) and mortality rates approaching 33% at 3 years. SCCs, particularly those with high-risk features, can also metastasize and account for 2400 deaths annually. Recent advances in systemic therapy using checkpoint antibodies have improved survival in patients with advanced NMSCs.

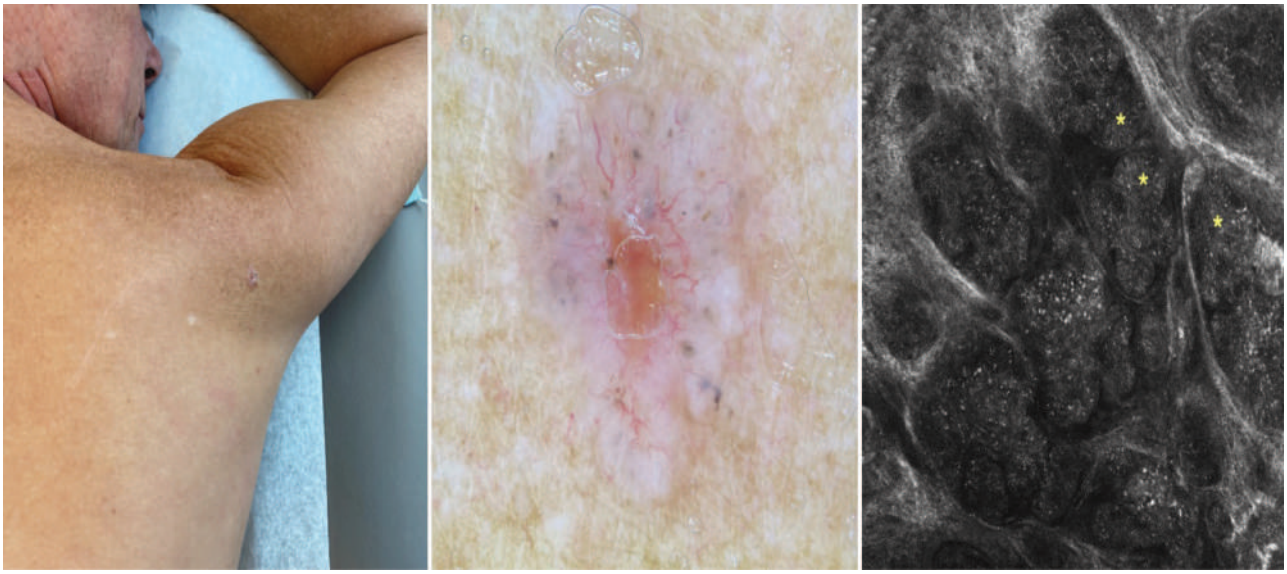
PATHOPHYSIOLOGY AND ETIOLOGY

Like melanoma, the most significant cause of NMSCs is UVR, with a dose-response relationship between tanning bed use and the incidence of NMSC. As few as four tanning bed visits per year confers a 15% increase in BCC and an 11% increase in SCC. The risk of lip or oral SCC is increased with cigarette smoking and, like SCC of the ear, has a worse prognosis than SCC found on other body sites. Human papillomaviruses and UVR may act as co-carcinogens. Inherited disorders of DNA repair, such as xeroderma pigmentosum, are associated with a greatly increased incidence of skin cancer and help to establish the link between UV-induced DNA damage, inadequate DNA repair, and skin cancer.

The genes associated with UV damage in SCC include *p53* and *N-RAS*, whereas BCC is primarily associated with damage to hedgehog signaling pathway (Hh) genes, which lead to basal cell proliferation. This is usually the result of loss of function of the tumor-suppressor patched homolog 1 (*PTCH1*), which normally inhibits the signaling of smoothened homolog (*SMO*).

Immunosuppression has also been associated with the development of NMSCs; chronically immunosuppressed solid organ transplant recipients have a 65-fold increase in SCC and a 10-fold increase in BCC. The frequency of skin cancer is proportional to the level and duration of immunosuppression and the extent of sun exposure before and after transplantation. SCCs in this population are particularly aggressive, demonstrating higher rates of local recurrence, metastasis, and mortality. Tumor necrosis factor (TNF) antagonist therapy of inflammatory bowel disease and autoimmune disorders, such as rheumatoid and psoriatic arthritis, may also confer an increased risk of NMSC.

Other risk factors for NMSCs include HIV infection, ionizing radiation, thermal burn scars, *BRAF* inhibitor monotherapy, and chronic ulcerations. Albinism, xeroderma pigmentosum, Muir-Torre syndrome, Rombo's syndrome, Bazex-Dupré-Christol syndrome, dyskeratosis congenita, and basal cell nevus syndrome (Gorlin syndrome) also increase the incidence of NMSC.



Although MCC is also clearly related to UV exposure, age, and immunosuppression, this neural crest–derived cancer also appears to have a viral etiology; an oncogenic Merkel cell polyomavirus (MCPyV) is present in 80% of tumors. In patients with MCPyV-positive tumors, there is inactivation of tumor-suppressor genes, specifically the *p53* transcription factor and retinoblastoma protein (*Rb*). In addition, the viral large T antigen is expressed on tumor cells, and many patients have detectable cellular or humoral immune responses to polyoma viral proteins, although this immune response is insufficient to eradicate the malignancy.

CLINICAL PRESENTATION

Basal Cell Carcinoma BCC arises from epidermal basal cells or the follicular bulge. The least invasive of BCC subtypes, superficial BCC, consists of often subtle, erythematous scaling plaques that slowly enlarge and are most commonly seen on the trunk and proximal extremities **(Fig. 81-3)**. This subtype may be confused with benign inflammatory dermatoses, especially nummular eczema and psoriasis or premalignant actinic keratoses. BCC also can present as a small, slowly growing, pearly nodule, often with tortuous telangiectatic vessels on its surface, rolled borders, and a central crust (nodular BCC). The occasional presence of melanin in this variant of nodular BCC (pigmented BCC) may lead to confusion with melanoma. Morpheaform (fibrosing), infiltrative, and micronodular BCC, the most invasive and potentially aggressive subtypes, manifest as solitary, flat or slightly depressed, indurated whitish, yellowish, or pink scar-like plaques. Borders are typically indistinct, and lesions can be subtle; thus, delay in treatment is common, and tumors can be more extensive than expected clinically.

Squamous Cell Carcinoma Primary *cutaneous SCC* is a malignant neoplasm of keratinizing epidermal cells that has a variable clinical course, ranging from indolent to rapid growth, with the potential to metastasize to regional and distant sites. Commonly, SCC appears as an ulcerated erythematous nodule or superficial erosion on sun-exposed skin of the head, neck, trunk, and extremities **(Fig. 81-4)**. It may also appear as a banal, firm, dome-shaped papule or rough textured plaque. It is commonly mistaken for a wart or callous when the inflammatory response to the lesion is minimal. Dotted or coiled vessels are a hallmark of SCC when viewed through a dermatoscope. The margins of this tumor may be ill defined, and fixation to underlying structures may occur ("tethering").

A very rapidly growing low-grade form of SCC, called keratoacanthoma (KA), typically appears as a large dome-shaped papule with a central keratotic crater. Some KAs regress spontaneously without therapy, but because progression to metastatic SCC has been documented,

A B C

FIGURE 81-3 Clinical, dermascopic, and confocal diagnostic findings of basal cell carcinoma. ***A.*** Typical basal cell carcinoma with skin-colored, slightly translucent rolled borders and a small central erosion on chronically sun-damaged skin of the lateral posterior shoulder. ***B.*** Dermoscopic image of the same lesion as in panel *A* clearly revealing the central erosion and classic gray, nonreticular globular structures of melanophages that characterize BCC. ***C.*** In vivo reflectance confocal microscopy of the same lesion as in panel *A* showing typical nests of dermal basaloid cells (*) with classic cleft formation around the nests. *(Photos courtesy of Dr. Alexander Witkowski and Dr. Joanna Ludzik, © Copyright 2022 Oregon Health & Science University [OHSU].)*

KAs should be treated in the same manner as other types of cutaneous SCC. KAs occur in 15–25% of patients receiving monotherapy with a BRAF inhibitor.

Actinic keratoses and *cheilitis* (actinic keratoses on the lip), both premalignant forms of SCC, present as hyperkeratotic papules on sun-exposed areas. Malignant transformation occurs in 0.25–20% of untreated lesions. SCC in situ, also called *Bowen's disease*, is the intraepidermal form of SCC and usually presents as a scaling, erythematous plaque. SCC in situ most commonly arises on sun-damaged skin but can occur anywhere on the body. Bowen's disease occurring secondary to infection with human papillomavirus can arise on skin with minimal or no prior sun exposure, such as the buttock or posterior thigh. Treatment of premalignant and in situ lesions reduces the subsequent risk of invasive disease.

Merkel Cell Carcinoma MCC, also known as cutaneous apudoma, primary neuroendocrine carcinoma of the skin, primary small-cell carcinoma of the skin, and trabecular carcinoma of the skin, arises from Merkel cells, which are neuroendocrine skin cells that act as pressure receptors. Like other skin cancers, MCCs most commonly arise as visible skin lesions, usually as raised, flesh-colored nodules or masses; they can also be red or blue in color and vary in size from 0.5 to >5 cm in diameter and may enlarge rapidly. Although MCCs may arise almost anywhere on the body, they are most often found in sun-exposed areas such as the head, neck, or extremities. They can also be found around the anus and on eyelids. The common clinical features of MCC can be summarized by the acronym AEIOU: *a*symptomatic/nontender, *e*xpand rapidly, *i*mmune suppression, *o*lder than 50 years, and *u*ltraviolet-exposed site.

NATURAL HISTORY

Basal Cell Carcinoma The natural history of BCC is that of a slowly enlarging, locally invasive neoplasm. The degree of local destruction and risk of recurrence vary with the size, duration, location, and histologic subtype of the tumor. Location on the central face, ears, or scalp may portend a higher risk. Small nodular, pigmented, cystic, or superficial BCCs respond well to most treatments. Large lesions and micronodular, infiltrative, and morpheaform subtypes may be more aggressive. The metastatic potential of BCC is low (0.1%) in immunocompetent patients, but the risk of recurrence or a new primary NMSC is about 40% over 5 years.

Squamous Cell Carcinoma The natural history of SCC depends on tumor and host characteristics. Tumors arising on sun-damaged skin have a lower metastatic potential than do those on non-sun-exposed areas. Cutaneous SCC metastasizes in 0.3–5.2% of individuals, most frequently to regional lymph nodes. Tumors occurring on the lower lip and ear develop regional metastases in 13 and 11% of patients, respectively, whereas the metastatic potential of SCC arising in scars, chronic ulcerations, and genital or mucosal surfaces is higher. Recurrent SCC has a 30% probability for metastatic spread. Large, poorly differentiated, deep tumors with perineural or lymphatic invasion, multifocal tumors, and those arising in immunosuppressed patients often behave aggressively.

Merkel Cell Carcinoma MCCs usually present locally yet have a high probability of spread to regional lymph nodes and distant sites. Molecular markers of neuroendocrine origin such as synaptophysin or chromogranin A are useful to diagnose MCC. Unlike other neuroendocrine tumors, such as small-cell lung cancer (SCLC), MCCs are not associated with measurable hormone secretion or endocrine syndromes.

Survival with MCC depends on extent of disease: 90% of patients with local disease are cured, whereas 52% with nodal involvement and 10% with distant disease survive. MCC has its own tumor-node-metastasis (TNM) staging system, which incorporates tumor size (<2 cm vs >2 cm), nodal status (which can be determined by SLNB for clinically negative nodes), and the presence of distant metastases.

Independent of stage, the prognosis of MCC is improved if the tumor cells contain virus, express RB protein, and exhibit intratumoral CD8+ T lymphocyte infiltration. p63 expression, lymphovascular infiltrative pattern, and concomitant immunosuppression (e.g., organ transplant, HIV infection, and certain cancers) portend a worse prognosis.

TREATMENT

Basal Cell, Squamous Cell, and Merkel Cell Carcinoma

BASAL CELL CARCINOMA

Treatment for BCC includes electrodesiccation and curettage (ED&C), excision, cryosurgery, radiation therapy (RT), laser therapy, MMS, topical 5-fluorouracil, photodynamic therapy (PDT), and topical immunomodulators, such as imiquimod. The choice

FIGURE 81-4 Progression of basal cell (BCC) and squamous cell carcinoma (SCC). ***A.*** Superficial BCC; note salmon pink color, rolled boarder, erosions, and a gray central globule. ***B.*** Nodular BCC; note shiny, slightly pearly character with prominent arborizing vessels. ***C.*** Eroded BCC with serous and sanguinous crusting. ***D.*** Multiple actinic keratoses; note flat lesions are early, and thicker lesions may require biopsy to discriminate between advanced actinic keratosis versus early SCC. ***E.*** Superficial SCC. ***F.*** Keratoacanthoma (well-differentiated SCC). ***G.*** Mucocutaneous SCC in a high-risk area on the lower lip. ***H.*** Cutaneous SCC. ***I.*** Large exophytic SCC on the wrist. *(Photos courtesy of the Dr. Leonard Swinyer Collection, © Copyright 2020 University of Utah and Oregon Health & Science University.)*

of therapy depends on tumor characteristics including depth and location, patient age, medical status, and patient preference. ED&C remains the most frequent treatment for superficial, minimally invasive nodular BCCs and low-risk tumors (e.g., a small tumor of a less aggressive subtype in a favorable location without terminal hairs). Wide local excision with standard margins is usually selected for invasive, ill-defined, and more aggressive subtypes of tumors or for cosmetic reasons. MMS, a specialized type of surgical excision that provides the best method for tumor removal while preserving uninvolved tissue, is associated with cure rates of >98%. It is the preferred modality for lesions that are recurrent, in high-risk or cosmetically sensitive locations (including recurrent tumors in these locations), and for which maximal tissue conservation is critical (e.g., the eyelids, lips, ears, nose, and digits). RT can cure patients not considered surgical candidates and can be used as a surgical adjunct in high-risk tumors. Imiquimod can be used to treat superficial and smaller nodular BCCs, although it is not FDA approved for nodular BCC. Topical 5-fluorouracil therapy should be limited to superficial BCC. PDT, which uses selective activation of a photoactive drug by visible light, has been used in patients with numerous tumors. Intralesional therapy (5-fluorouracil or interferon) can also be employed. Like RT, it remains an option for selected patients who cannot or will not undergo surgery. Systemic therapy with a targeted hedgehog pathway inhibitor, such as vismodegib or sonidegib, is indicated for patients with metastatic or advanced BCC that has recurred after local therapy and who are not candidates for surgery or RT. Targeted therapy does not cure patients with BCC but induces regression in approximately 50% of patients with a median duration of response of 9–12 months in patients with metastatic disease and ~2 years in patients with locally advanced disease. Checkpoint immunotherapy using cemiplimab can be offered to BCC patients who progress after targeted therapy.

SQUAMOUS CELL CARCINOMA

The principles for surgical management of SCC are the same as for BCC. Cemiplimab, a monoclonal antibody targeting PD-1, has become the systemic therapy of choice, inducing tumor regression in 47% of patients with advanced disease. Neoadjuvant cemiplimab has been given in stage II, III and IV SCC and is associated with a >50% probability of pathologic complete response and is becoming a standard of care in patients with very-high-risk presentations and/or who have disease that may be technically difficult to resect. SCC and KAs that develop in patients receiving BRAF-targeted therapy should be excised, after which BRAF therapy can be continued.

MERKEL CELL CARCINOMA

The epidemiology, clinical features, and treatments for MCC overlap those for melanoma and NMSC. Early-stage MCCs may be cured with wide local excision of the primary tumor and nodal staging with SLNB. Like SCLCs, MCC is sensitive to radiation, PD-1-directed immunotherapy, and platinum-based chemotherapy. RT is often used as postoperative adjuvant therapy at both the primary excision and SLNB sites, although its use may be withheld around sensitive areas such as the eyelids and hands and after a negative SLNB. For nonsensitive areas, RT may allow for primary excision margins smaller than the traditionally recommended 2-cm radial margins. When a positive sentinel node is found, adjuvant RT, close observation, and clinical trials investigating immunotherapy are favored over completion nodal dissection.

For patients with metastatic disease, immunotherapy has supplanted chemotherapy. Avelumab (anti-PD-L1) therapy led to objective responses in 33% of patients with advanced MCC; 82% of the responses were durable. Pembrolizumab has an objective response >50% in patients with MCPyV-associated and non-virus-associated advanced MCC resulting in a median duration of response approaching 2 years. Clinical trials should be offered to MCC patients who progress after checkpoint therapy and whose functional status can support additional treatment.

Follow-up of patients with MCC is based on stage and risk. Routine skin exams by a dermatologist familiar with MCC and regular examinations of the nodal basins are recommended. Antibody serum titers to MCPyV should be obtained in newly diagnosed MCC patients. The test can be used to follow patients for relapse if the titer is elevated at baseline and returns to normal after treatment. Conversely, if the titer is elevated but does not return to normal after treatment, imaging should be obtained to look for occult metastases.

PREVENTION

The principles for prevention are those described for melanoma earlier. Unique strategies for NMSC include active surveillance for patients on immunosuppressive medications or BRAF-targeted therapy. Chemoprophylaxis using synthetic retinoids and immunosuppression reduction when possible may be useful in controlling new lesions and managing patients with multiple tumors. Nicotinamide 500 mg BID may be used in patients with large numbers of actinic keratoses and SCCs to reduce the development and/or progression of disease. Field therapy with topical 5-fluorouracil (with or without calcipotriol), ingenol mebutate, or imiquimod can reduce transformation to SCC in patients with severely sun-damaged skin and numerous premalignant actinic keratoses. Older, immunosuppressed patients should be managed with the lowest doses of immunosuppression possible and encouraged to be particularly careful to minimize UV exposure. Earlier biopsy of unusual-appearing skin lesions may lead to better control of aggressive lesions.

OTHER NONMELANOMA CUTANEOUS MALIGNANCIES

Neoplasms of cutaneous adnexae and sarcomas of fibrous, mesenchymal, fatty, and vascular tissues make up the remaining 1–2% of NMSCs (Fig. 81-5). Lymphomas of B- or T-cell origin can also manifest in the skin and can mimic benign conditions such as psoriasis and eczema.

Extramammary Paget's disease is an uncommon apocrine malignancy arising from stem cells of the epidermis that is characterized

histologically by the presence of Paget cells. These tumors present as moist erythematous patches on anogenital or axillary skin of the elderly.

Outcomes are generally good with surgery, and 5-year disease-specific survival is 95% with localized disease. Advanced age and extensive disease at presentation confer poorer prognosis. RT or topical imiquimod can be considered for more extensive disease. Local management may be challenging because these tumors often extend far beyond clinical margins; surgical excision with MMS has the highest cure rates. Similarly, MMS is the treatment of choice in other rare cutaneous tumors with extensive subclinical extension such as *dermatofibrosarcoma protuberans*.

Kaposi's sarcoma (KS) is a soft tissue sarcoma of vascular origin that is induced by the human herpesvirus 8. The incidence of KS increased dramatically during the AIDS epidemic but has now decreased tenfold with the institution of highly active antiretroviral therapy.

82 Head and Neck Cancer

Everett E. Vokes

Epithelial carcinomas of the head and neck arise from the mucosal surfaces in the head and neck and typically are squamous cell in origin. This category includes tumors of the paranasal sinuses, the oral cavity, and the nasopharynx, oropharynx, hypopharynx, and larynx. Tumors of the salivary glands differ from the more common carcinomas of the head and neck in etiology, histopathology, clinical presentation, and therapy. They are rare and histologically highly heterogeneous. Thyroid malignancies are described in Chap. 397.

INCIDENCE AND EPIDEMIOLOGY

The number of new cases of head and neck cancers (oral cavity, pharynx, and larynx) in the United States was estimated at 66,920 in 2023, accounting for about 6% of adult malignancies; estimated deaths were 15,400. The worldwide incidence exceeds half a million cases annually. In North America and Europe, the tumors usually arise from the oral cavity, oropharynx, or larynx. The incidence of oropharyngeal cancers has been increasing in Western countries. Nasopharyngeal cancer is endemic in East Asia and some Mediterranean countries.

ETIOLOGY AND GENETICS

Alcohol and tobacco use are the most significant environmental risk factors for head and neck cancer, and when used together, they act synergistically. Smokeless tobacco is an etiologic agent for oral cancers. Other potential carcinogens include marijuana and occupational exposures such as nickel refining, exposure to textile fibers, and woodworking.

Some head and neck cancers have a viral etiology. Epstein-Barr virus (EBV) infection is frequently associated with nasopharyngeal cancer, especially in endemic areas. EBV antibody titers can be measured to screen high-risk populations and are under investigation to monitor treatment response. Nasopharyngeal cancer has also been associated with consumption of salted fish and indoor pollution.

In Western countries, the human papillomavirus (HPV) is associated with a rising incidence of tumors arising from the oropharynx, that is, the tonsillar bed and base of tongue. Over 50% of oropharyngeal tumors are caused by HPV in the United States, and in many urban centers, this proportion is higher. HPV-16 is the dominant viral subtype, although HPV-18 and other oncogenic subtypes are seen as well. Alcohol- and tobacco-related cancers, on the other hand, have decreased in incidence. HPV-related oropharyngeal cancer occurs in a younger patient population and is associated with increased numbers of sexual partners and oral sexual practices. It is associated with a better prognosis, especially for nonsmokers. Vaccination with the nine-valent HPV vaccine may prevent the disease but is not likely to result in a lower incidence for several decades due to long latency of the carcinogenic process.

Dietary factors may contribute. The incidence of head and neck cancer is higher in people with the lowest consumption of fruits and vegetables. Certain vitamins, including carotenoids, may be protective if included in a balanced diet. Supplements of retinoids, such as *cis*-retinoic acid, have not been shown to prevent head and neck cancers (or lung cancer) and may increase the risk in active smokers. No specific risk factors or environmental carcinogens have been identified for salivary gland tumors.

HISTOPATHOLOGY, CARCINOGENESIS, AND MOLECULAR BIOLOGY

Squamous cell head and neck cancers are divided into well-differentiated, moderately well-differentiated, and poorly differentiated categories. Poorly differentiated tumors have a worse prognosis than well-differentiated tumors. For nasopharyngeal cancers, the less common differentiated squamous cell carcinoma is distinguished from nonkeratinizing and undifferentiated carcinoma (lymphoepithelioma) that contains infiltrating lymphocytes and is commonly associated with EBV.

Salivary gland tumors can arise from the major (parotid, submandibular, sublingual) or minor salivary glands (located in the submucosa of the upper aerodigestive tract). Most parotid tumors are benign, but half of submandibular and sublingual gland tumors and most minor salivary gland tumors are malignant. Malignant tumors include mucoepidermoid and adenoid cystic carcinomas and adenocarcinomas.

The mucosal surface of the entire pharynx is exposed to alcohol- and tobacco-related carcinogens and is at risk for the development of a premalignant or malignant lesion. Erythroplakia (a red patch) or leukoplakia (a white patch) can be histopathologically classified as hyperplasia, dysplasia, carcinoma in situ, or carcinoma. However, most head and neck cancer patients do not present with a known history of premalignant lesions. Multiple synchronous or metachronous cancers can also be observed. In fact, over time, patients with treated

early-stage tobacco- and alcohol-related head and neck cancer are at greater risk of dying from a second malignancy than from a recurrence of the primary disease.

Second head and neck malignancies are usually not therapy induced; they reflect the exposure of the upper aerodigestive mucosa to the same carcinogens that caused the first cancer. These second primaries develop in the head and neck area, the lung, or the esophagus. Thus, computed tomography (CT) screening for lung cancer in heavy smokers who have already developed a head and neck cancer is recommended. Rarely, patients can develop a radiation therapy–induced sarcoma after having undergone prior radiotherapy for a head and neck cancer.

Much progress has been made in describing the molecular features of head and neck cancer. These features have allowed investigators to describe the genetic and epigenetic alterations and the mutational spectrum of these tumors. Early reports demonstrated frequent overexpression of the epidermal growth factor receptor (EGFR). Overexpression was shown to correlate with poor prognosis. However, it has not proved to be a good predictor of tumor response to EGFR inhibitors, which are active in only about 10–15% of patients as single agents. Complex genetic analyses, including those by The Cancer Genome Atlas project, have been performed. *p53* mutations are found frequently with other major affected oncogenic driver pathways including the mitotic signaling and Notch pathways and cell cycle regulation in HPV-negative tumors. HPV oncogenes act through direct inhibition of the *p53* and *RB* tumor-suppressor genes, thereby initiating the carcinogenic process. *HRAS* mutations are detected in 4–8% of patients with recurrent head and neck cancer and may be therapeutically targetable in a small patient subset. While overall mutation rates are similar in HPV-positive and carcinogen-induced tumors, the specific mutational signature of HPV-positive tumors differs, with frequent alteration of the PI3K pathway and occasional mutations in *KRAS*. Overall, these alterations affect mitogenic signaling, genetic stability, cellular proliferation, and differentiation.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Most tobacco-related head and neck cancers occur in patients older than age 60 years. HPV-related malignancies are frequently diagnosed in younger patients, usually in their forties or fifties, whereas EBV-related nasopharyngeal cancer can occur at all ages, including in teenagers. The manifestations vary according to the stage and primary site of the tumor. Patients with nonspecific signs and symptoms in the head and neck area should be evaluated with a thorough otolaryngologic examination, particularly if symptoms persist longer than 2–4 weeks. Males are more frequently affected than women by head and neck cancers, including HPV-positive tumors.

Cancer of the nasopharynx typically does not cause early symptoms. However, it may cause unilateral serous otitis media due to obstruction of the eustachian tube, unilateral or bilateral nasal obstruction, or epistaxis. Advanced nasopharyngeal carcinoma causes neuropathies of the cranial nerves due to skull base involvement.

Carcinomas of the oral cavity present as nonhealing ulcers, changes in the fit of dentures, or painful lesions and masses. Tumors of the tongue base or oropharynx can cause decreased tongue mobility and alterations in speech. Cancers of the oropharynx or hypopharynx rarely cause early symptoms, but they may cause sore throat and/or otalgia. HPV-related tumors frequently present with neck lymphadenopathy as the first sign.

Hoarseness may be an early symptom of laryngeal cancer, and persistent hoarseness requires referral to a specialist for indirect laryngoscopy and/or radiographic studies. If a head and neck lesion treated initially with antibiotics does not resolve in a short period, further workup is indicated; to simply continue the antibiotic treatment may be to lose the chance of early diagnosis of a malignancy.

Advanced head and neck cancers in any location can cause severe pain, otalgia, airway obstruction, cranial neuropathies, trismus, odynophagia, dysphagia, decreased tongue mobility, fistulas, skin involvement, and massive cervical lymphadenopathy, which may be unilateral or bilateral. Some patients have enlarged lymph nodes even though no primary lesion can be detected by endoscopy or biopsy; these patients are considered to have carcinoma of unknown primary **(Fig. 82-1)**. Tonsillectomy and directed biopsies of the base of tongue can identify a small primary tumor that frequently will be HPV related. If the enlarged nodes are located in the upper neck and the tumor cells are of squamous cell histology, the malignancy probably arose from a mucosal surface in the head or neck. Tumor cells in supraclavicular lymph nodes may also arise from a primary site in the chest or abdomen.

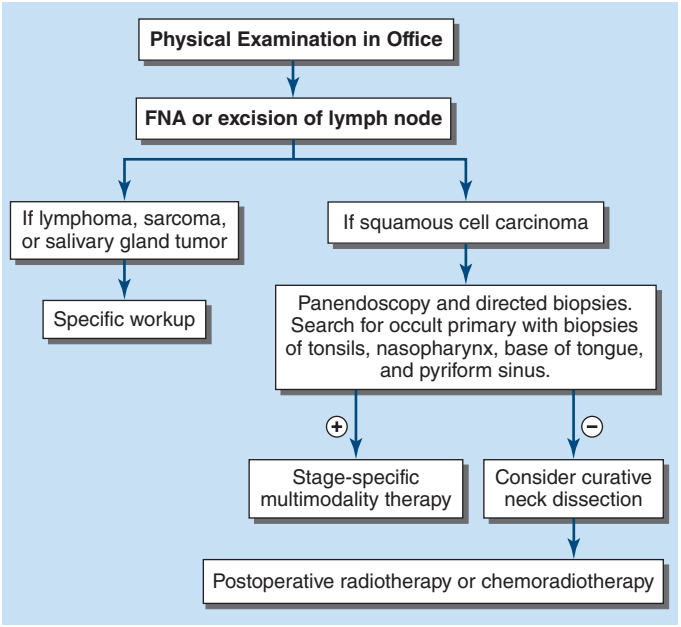

FIGURE 82-1 Evaluation of a patient with cervical adenopathy without a primary mucosal lesion; a diagnostic workup. FNA, fine-needle aspiration.

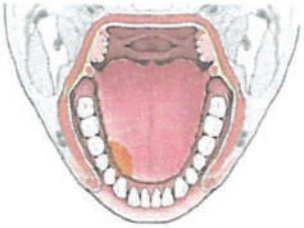
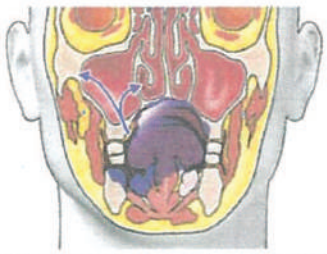
The physical examination should include inspection of all visible mucosal surfaces and palpation of the floor of the mouth and of the tongue and neck. In addition to a tumor, leukoplakia (a white mucosal patch) or erythroplakia (a red mucosal patch) may be observed; these "premalignant" lesions can represent hyperplasia, dysplasia, or carcinoma in situ and require biopsy. Further examination should be performed by a specialist. Additional staging procedures include CT or MRI of the head and neck to identify the extent of the disease. Patients with lymph node involvement should have CT scan of the chest and upper abdomen to screen for distant metastases. In heavy smokers, the CT scan of the chest can also serve as a screening tool to rule out a second lung primary tumor. A positron emission tomography (PET) scan can help to identify or exclude distant metastases. CT and PET scans may also be useful in evaluating response to therapy. The definitive staging procedure is an endoscopic examination under anesthesia, which may include laryngoscopy, esophagoscopy, and bronchoscopy; during this procedure, multiple biopsy samples are obtained to establish a primary diagnosis, define the extent of primary disease, and identify any additional premalignant lesions or second primaries.

Head and neck tumors are classified according to the tumor-node-metastasis (TNM) system of the American Joint Committee on Cancer (AJCC) **(Fig. 82-2)**. This classification varies according to the specific anatomic subsite. In general, primary tumors are classified as T1 to T3 by increasing size, whereas T4 usually represents invasion of another structure such as bone, muscle, or root of tongue. Lymph nodes are staged by size, number, and location (ipsilateral vs contralateral to the primary). Overt distant metastases are found in <10% of patients at initial diagnosis and are more common in patients with advanced lymph node stage; microscopic involvement of the lungs, bones, or liver is more common, particularly in patients with advanced neck lymph node disease. HPV-related oropharyngeal malignancies have consistently been shown to have a better prognosis, and in the eighth

DOI = depth of invasion





Definition of TNM			Stage groupings		
Stage I	**T1**  Tumor ≤2 cm in greatest dimension ≤5 mm depth of invasion (DOI)	**N0**  N0- No regional lymph node metastasis	**T1**	N0	M0
Stage II	**T2**  Tumor ≥2 cm but not more than 4 cm in greatest dimension OR DOI >5 mm and ≤10 mm	**N0**  N0- No regional lymph node metastasis	**T2**	N0	M0
Stage III	**T3**  Tumor ≥4 cm OR DOI >10 mm	**N1**  ≤3 cm N1- Metastasis in a single ipsilateral lymph node, ≤3 cm in greateast dimension	**T3** **T1** **T2** **T3**	N0 **N1** **N1** **N1**	M0 M0 M0 M0
Stage IVA	**T4a**  Tumor invades skin, mandible, ear canal, fascial nerve, and/or floor of mouth	**N2**  ≤6 cm N2a- Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm N2b- Metastasis in multiple ipsilateral lymph nodes, none >6 cm N2c- Metastasis in bilateral or contralateral lymph nodes, none >6 cm	**T4a** **T4a** **T1** **T2** **T3** **T4a**	N0 **N1** **N2** **N2** **N2** **N2**	M0 M0 M0 M0 M0 M0
Stage IVB	**T4b**  Tumor invades skull base and/or pterygoid plates and/or encases carotid artery	**N3**  >6 cm N3- Metastasis in a lymph node >6 cm in greatest dimension or clinically overt extranodal extension	**T4b** **Any T**	Any N **N3**	M0 M0
Stage IVC		**M1**	**Any T**	**Any N**	**M1**

FIGURE 82-2 Tumor-node-metastasis (TNM) staging system. *(Figure based on the AJCC Cancer Staging Manual, 8th edition.)*

edition of the AJCC staging manual, a separate staging system that takes into account the more favorable outlook of these patients has been included. According to this system, patients with advanced nodal stage can still be considered to have the equivalent of an overall early stage (and associated good prognosis).

In patients with lymph node involvement and no visible primary, the diagnosis should be made by fine-needle aspiration or by lymph node excision (especially if only a single node appears involved) (Fig. 82-1). If the results indicate squamous cell carcinoma, a panendoscopy should be performed, with biopsy of all suspicious-appearing areas and directed biopsies of common primary sites, such as the nasopharynx, tonsil, tongue base, and pyriform sinus. HPV-positive tumors especially can have small primary tumors that spread early to locoregional lymph nodes.

TREATMENT

Head and Neck Cancer

Patients with head and neck cancer can be grossly categorized into three clinical groups: those with localized disease, those with locally or regionally advanced disease (lymph node positive), and those with recurrent and/or metastatic disease below the neck. Comorbidities associated with tobacco and alcohol abuse can affect treatment outcome and define long-term risks for patients who are cured of their disease.

LOCALIZED DISEASE

Nearly one-third of patients have localized disease, that is, T1 or T2 (stage I or stage II) lesions without detectable lymph node involvement or distant metastases. These patients are treated with curative intent by either surgery or radiation therapy. The choice of modality differs according to anatomic location and institutional expertise. Radiation therapy is often preferred for laryngeal cancer to preserve voice function, and surgery is preferred for small lesions in the oral cavity to avoid the long-term complications of radiation, such as xerostomia and osteoradionecrosis and dental decay. Randomized data have shown that a prophylactic staging neck dissection should be part of the surgical procedure to eliminate occult nodal metastatic disease. Overall 5-year survival is 60–90%. Most recurrences occur within the first 2 years following diagnosis and are usually local.

LOCALLY OR REGIONALLY ADVANCED DISEASE

Locally or regionally advanced disease—disease with a large primary tumor and/or cervical lymph node metastases—is the stage of presentation for >50% of patients. Such patients can also be treated with curative intent, but not usually with surgery or radiation therapy alone. Combined-modality therapy, including surgery and/or radiation therapy and chemotherapy, is most successful. Chemotherapy can be administered as induction chemotherapy (chemotherapy before surgery and/or radiotherapy) or as concomitant (simultaneous) chemotherapy and radiation therapy. The latter is most commonly used and supported by the best evidence. Five-year survival rates exceed 50% in many trials, but part of this increased survival may be due to an increasing fraction of study populations with HPV-related tumors who carry a better prognosis. HPV testing of newly diagnosed tumors should be performed for patients with oropharyngeal tumors at the time of diagnosis. Clinical trials for HPV-related tumors are focused on exploring reductions in treatment intensity, especially radiation dose, in order to ameliorate long-term toxicities (fibrosis, swallowing dysfunction).

In patients with intermediate-stage tumors (stage III and early stage IV), concomitant chemoradiotherapy can be administered as a primary treatment for patients with unresectable disease, to pursue an organ-preserving approach especially for patients with laryngeal cancer (omission of surgery), or in the postoperative setting for smaller resectable tumors with adverse prognostic features.

Induction Chemotherapy In this strategy, patients receive chemotherapy (current standard is a three-drug regimen of docetaxel, cisplatin, and fluorouracil [5-FU]) before surgery and radiation therapy. Most patients who receive three cycles show tumor reduction, and the response is clinically "complete" in up to half of patients. This "sequential" multimodality therapy allows for organ preservation in patients with laryngeal and hypopharyngeal cancer and results in higher cure rates compared with radiotherapy alone.

Concomitant Chemoradiotherapy With the concomitant strategy, chemotherapy and radiation therapy are given simultaneously rather than in sequence. Tumor recurrences from head and neck cancer develop most commonly locoregionally (in the head and neck area of the primary and draining lymph nodes). The concomitant approach is aimed at enhancing tumor cell killing by radiation therapy in the presence of chemotherapy (radiation enhancement) and is a conceptually attractive approach for bulky tumors. Toxicity (especially mucositis, grade 3 or 4, in 70–80%) is increased with concomitant chemoradiotherapy. However, meta-analyses of randomized trials document an improvement in 5-year survival of 8% with concomitant chemotherapy and radiation therapy. Cisplatin is preferentially given weekly during a course of daily radiotherapy over a 6- to 7-week course. In addition, concomitant chemoradiotherapy produces better laryngectomy-free survival (organ preservation) than radiation therapy alone in patients with advanced larynx cancer. For patients with advanced nasopharyngeal cancer, the addition of neoadjuvant chemotherapy before concomitant chemoradiotherapy has been adopted as standard of care leading to 5-year survival rates exceeding 80% in a Southeast Asian study. The outcome of HPV-related cancers also seems to be favorable following cisplatin-based chemoradiotherapy. However, trials substituting cisplatin with the EGFR inhibitor cetuximab in that patient population have shown inferior survival. Similarly, the investigation of immune checkpoint inhibitors in this setting has not yet led to improved outcomes.

The success of concomitant chemoradiotherapy in patients with unresectable disease has led to the testing of a similar approach in patients with resected intermediate-stage disease as a postoperative therapy. Concomitant chemoradiotherapy produces a significant improvement over postoperative radiation therapy alone for patients whose tumors demonstrate higher risk features, such as extracapsular spread beyond involved lymph nodes, involvement of multiple lymph nodes, or positive margins at the primary site following surgery.

A monoclonal antibody to EGFR (cetuximab) increases survival rates when administered during radiotherapy compared with radiotherapy alone and has been considered for patients unable to tolerate concurrent chemoradiotherapy. The addition of cetuximab to standard chemoradiotherapy regimens has failed to show further improvement in survival and is not recommended.

TREATMENT APPROACHES FOR HPV-RELATED HEAD AND NECK CANCERS

Given consistent observations of high survival rates for patients with advanced HPV-related oropharyngeal tumors using combined-modality treatment strategies, de-escalation protocols have attracted widespread interest. The goal here is to decrease the long-term morbidity resulting from high-dose radiation therapy, including extensive neck fibrosis, swallowing problems, and osteoradionecrosis of the jaw. Current studies are investigating the use of lower radiation doses, the use of induction chemotherapy and subsequent omission of chemotherapy or administration of significantly reduced chemoradiation doses in very good responders, and other strategies. In addition, interest has increased in surgical approaches using robotic surgery, which allows better visualization of the base of tongue and tonsil. While technically feasible, a large number of patients with disease involving multiple lymph nodes will still require postoperative chemoradiotherapy, thus negating the goal of treatment de-escalation. At present, treatment guidelines for HPV-related tumors are identical to carcinogen-induced tumors. It is hoped that de-escalation approaches will be validated by ongoing controlled clinical trials.

RECURRENT AND/OR METASTATIC DISEASE

Five to 10% of patients present with metastatic disease, and 30–50% of patients with locoregionally advanced disease experience recurrence, frequently outside the head and neck region. Patients with recurrent and/or metastatic disease are, with few exceptions, treated with palliative intent. Some patients may require local or regional radiation therapy for pain control, but most are given systemic therapy.

Combination chemotherapy formerly was the first-line systemic therapeutic approach to patients with recurrent disease after prior curative intent surgery and/or chemoradiotherapy or those presenting initially with metastatic disease. In particular, a combination of cisplatin with 5-FU and cetuximab (the EXTREME regimen) was frequently used.

However, immunotherapies have proven to be of value in this setting. In particular, inhibitors of the immunosuppressive lymphocyte surface receptor (PD-1) pathway have shown activity in squamous cell cancers of the head and neck. A randomized trial evaluating the PD-1 inhibitor nivolumab versus traditional chemotherapy in the second-line treatment of patients with recurrent or metastatic disease showed a significant increase in 1-year survival rates with fewer severe treatment-related toxicities. In addition, some responses were of long duration, allowing a cohort of patients to live far beyond the historical median of <1 year. The PD-1 inhibitor pembrolizumab also demonstrated activity in a similarly designed randomized trial.

Pembrolizumab was also compared as single-agent therapy and in combination with cisplatin and 5-FU with prior standard chemotherapy alone (cisplatin, 5-FU, and cetuximab). In this trial, overall survival was improved with pembrolizumab versus chemotherapy as well as with the combination of chemotherapy plus pembrolizumab with the relative benefit correlating with the expression of PD-L1 in the tumor tissue. Patients with tumors high in expression (PD-L1 score >20%; i.e., expression of PD-L1 on 20% of tumor cells) had a marked survival benefit with pembrolizumab as single agent, whereas patients with lower PD-L1 expression had a less impressive but still statistically significant survival benefit. For the group expressing lower levels of PD-L1, the combination of pembrolizumab with chemotherapy showed more substantial benefit. Current standard treatment therefore frequently consists of combination chemoimmunotherapy for patients with low PD-L1 expression, whereas those with higher expression can be treated with immunotherapy alone, especially if overall tumor burden is limited. Patients with no PD-L1 expression may still be treated with the prior EXTREME chemotherapy standard. Patients who experience progression after first-line chemoimmunotherapy or immunotherapy can then be treated with additional single-agent or combination chemotherapy.

EGFR-directed therapies, including monoclonal antibodies (e.g., cetuximab) and tyrosine kinase inhibitors (TKIs) of the EGFR signaling pathway (e.g., erlotinib or gefitinib), have single-agent activity of ~10%. Side effects are usually limited to an acneiform rash and diarrhea (for the TKIs). Drugs targeting specific mutations are under investigation, and patients with *HRAS*-driven tumors can experience shrinkage with the farnesyltransferase inhibitor tipifarnib.

COMPLICATIONS

Complications from treatment of head and neck cancer are usually correlated to the extent of surgery and exposure of normal tissue structures to radiation. The extent of surgery can be limited or surgery can be completely replaced by use of chemotherapy and radiation therapy as the primary approach. Acute complications of radiation include mucositis and dysphagia. Long-term complications include xerostomia, loss of taste, decreased tongue mobility, second malignancies, dysphagia, and neck fibrosis. The complications of chemotherapy vary with the regimen used but usually include myelosuppression, mucositis, nausea and vomiting, and nephrotoxicity (with cisplatin).

The mucosal side effects of therapy can lead to malnutrition and dehydration. Many centers address issues of dentition before starting treatment, and some place feeding tubes to ensure control of hydration and nutrition intake. About 50% of patients develop hypothyroidism from the treatment; thus, thyroid function should be monitored.

SALIVARY GLAND TUMORS

Most benign salivary gland tumors are treated with surgical excision, and patients with invasive salivary gland tumors are treated with surgery and radiation therapy. These tumors may recur regionally; adenoid cystic carcinoma has a tendency to recur along the nerve tracks. Distant metastases may occur as late as 10–20 years after the initial diagnosis. For metastatic disease, therapy is given with palliative intent, usually chemotherapy with doxorubicin and/or a platinum agent by itself or in combination with a taxane. Identification of novel agents with activity in these tumors is a high priority. It is hoped that comprehensive genomic characterization of these rare tumors will facilitate these efforts.

83 Neoplasms of the Lung

Eric K. Singhi, Christine M. Lovly

Over 2.2 million people globally were diagnosed with lung cancer in 2020, ranking it as the second most frequently diagnosed cancer. Although maintaining its status as the leading cause of cancer-related deaths worldwide, claiming 1.8 million lives in the same year, a noteworthy decline in lung cancer fatalities has emerged. This shift is credited to advancements in screening and early detection methods, improved therapeutic strategies, and a reduction in tobacco usage.

Tobacco consumption, established as the primary cause of lung cancer in the mid-twentieth century, was solidified with the U.S. Surgeon General's 1964 report on the health effects of tobacco smoking. After the report, cigarette use declined in North America and parts of Europe, and with it, so did the incidence of lung cancer. Although tobacco smoking remains the leading global cause of lung cancer, accounting for about two-thirds of lung cancer deaths worldwide, ~65% of new lung cancer diagnoses in the United States are in individuals with a former smoking history (smoked ≥100 cigarettes per lifetime, quit ≥1 year) or individuals with no smoking history (smoked <100 cigarettes per lifetime), with one in five women and one in 12 men diagnosed having never smoked.

EPIDEMIOLOGY

Lung cancer is the most common cause of cancer death among American men and women. Approximately 235,000 individuals will be diagnosed with lung cancer in the United States in 2024, and >125,000 individuals will die from the disease. Lung cancer is less common below age 40, with rates increasing until age 80, after which the rate tapers off. The projected lifetime probability of developing lung cancer

is estimated at 1 in 16 for males and 1 in 17 for females as of 2023. Since 2006, there has been a steady decline in the incidence of lung cancer, with an annual decrease of 2.5% in men and 1% in women. Despite this positive trend, disparities persist. The incidence of lung cancer varies among racial and ethnic groups, with African Americans exhibiting the highest age-adjusted rates.

While the excess in age-adjusted rates among African Americans occurs only among men, examination of age-specific rates shows that below age 50, mortality from lung cancer is >25% higher among African-American women compared to their Caucasian counterparts. Additionally, African Americans face a 19% lower likelihood of receiving definitive surgical treatment, 11% higher likelihood of not receiving any treatment, and a 16% lower likelihood of surviving 5 years compared to their Caucasian counterparts. Incidence and mortality rates among Hispanics and Native and Asian Americans are ~40–50% of those among Caucasians. Consideration of these disparities prompts reflection on potential equitable improvements in lung cancer care.

RISK FACTORS

Persons who smoke have a 10-fold or greater increased risk of developing lung cancer compared to those who have never smoked. A large-scale genomic study suggested that one genetic mutation is induced for every 15 cigarettes smoked. The risk of lung cancer is lower among persons who quit smoking than among those who continue smoking. The size of the lung cancer risk reduction increases with the length of time the person has quit smoking, although even long-term former smokers have higher risks of lung cancer than those who never smoked. Cigarette smoking has been shown to increase the risk of all major types of lung cancer. Environmental tobacco smoke (ETS) or secondhand smoke is also an established cause of lung cancer. The risk from ETS is less than from active smoking, with about a 20–30% increase in lung cancer observed among never smokers married for many years to smokers, in comparison to the 2000% increase among continuing active smokers. The impact on the development of lung cancer among users of alternate nicotine delivery devices (e-cigarettes or vaping) is undefined. While one large, randomized study demonstrated the superiority of e-cigarettes compared to traditional nicotine replacement therapy in aiding smoking cessation, e-cigarette– or vaping-associated lung injury (EVALI) is an emerging phenomenon that poses risks that may counterbalance the potential benefit in helping patients reduce traditional cigarette consumption and lung cancer risk.

Although cigarette smoking is the cause of the majority of lung cancers, several other risk factors have been identified, including occupational exposure to asbestos, arsenic, bischloromethyl ether, hexavalent chromium, mustard gas, nickel (as in certain nickel-refining processes), and polycyclic aromatic hydrocarbons.

Ionizing radiation is also an established lung carcinogen, most convincingly demonstrated from studies showing increased rates of lung cancer among survivors of the atom bombs dropped on Hiroshima and Nagasaki and large excesses among workers exposed to alpha irradiation from radon in underground uranium mining. Prolonged exposure to low-level radon in homes might impart a risk of lung cancer equal to or greater than that of ETS. Prior lung diseases such as chronic bronchitis, emphysema, and tuberculosis have been linked to increased risks of lung cancer as well. The risk of lung cancer appears to be higher among individuals with low fruit and vegetable intake during adulthood. This observation led to hypotheses that specific nutrients, in particular retinoids and carotenoids, might have chemopreventative effects for lung cancer. However, randomized trials failed to validate this hypothesis.

Smoking Cessation Given the undeniable link between cigarette smoking and lung cancer, physicians must promote complete tobacco avoidance. Stopping tobacco use before middle age avoids >90% of the lung cancer risk attributable to tobacco. Importantly, smoking cessation can even be beneficial in individuals with an established diagnosis of lung cancer, as it is associated with improved overall survival, fewer side effects from therapy, and an overall improvement in quality of life. Consequently, it is important to promote smoking cessation even *after* the diagnosis of lung cancer is established. This remains a challenge as ~30% of patients continue to smoke even after receiving a diagnosis of lung cancer.

Physicians need to understand the essential elements of smoking cessation therapy. Self-help strategies alone only marginally affect quit rates, whereas individual and combined pharmacotherapies in combination with counseling can significantly increase rates of cessation. Therapy with an antidepressant (e.g., bupropion) and nicotine replacement therapy (varenicline, a $\alpha_4\beta_2$ nicotinic acetylcholine receptor partial agonist) are approved by the U.S. Food and Drug Administration (FDA) as first-line treatments for nicotine dependence. In a randomized trial, varenicline was shown to be more efficacious than bupropion or placebo. Prolonged use of varenicline beyond the initial induction phase proved useful in maintaining smoking abstinence. Clonidine and nortriptyline are recommended as second-line treatments. A role for e-cigarettes has not been definitively established **(Chap. 465)**.

Inherited Predisposition to Lung Cancer Exposure to environmental carcinogens, such as those found in tobacco smoke, induces or facilitates the transformation from bronchoepithelial cells to a malignant phenotype. The contribution of carcinogens to transformation is modulated by polymorphic variations in genes that affect aspects of carcinogen metabolism. Certain genetic polymorphisms of the P450 enzyme system, specifically CYP1A1, and chromosome fragility are associated with the development of lung cancer. These genetic variations occur at relatively high frequency in the population, but their contribution to an individual's lung cancer risk is generally low. However, because of their population frequency, the overall impact on lung cancer risk could be high.

First-degree relatives of lung cancer probands have a two- to threefold excess risk of lung cancer and other cancers, many of which are not smoking-related. These data suggest that specific genes and/or genetic variants may contribute to susceptibility to lung cancer. However, very few such genes have yet been identified. Individuals with inherited mutations in *RB* (patients with retinoblastoma living to adulthood) and *TP53* (patients with Li-Fraumeni syndrome) genes may develop lung cancer. Common gene variants involved in lung cancer have identified three separate loci that are associated with lung cancer (5p15, 6p21, and 15q25) and include genes that regulate acetylcholine nicotinic receptors and telomerase production. A rare germline mutation (T790M) involving the epidermal growth factor receptor (EGFR) maybe be linked to lung cancer susceptibility in never smokers. Likewise, a susceptibility locus on chromosome 6q greatly increases lung cancer risk among light and never smokers. A study involving 7700 patients diagnosed with primary lung cancer who underwent germline DNA sequencing and exon-level copy number analysis revealed that 14.9% of them had one or more clinically significant pathogenic germline variants; these variants were mainly found in DNA damage repair genes, suggesting a higher prevalence of pathogenic germline mutations in patients with primary lung cancer than previously suspected. Additionally, the Taiwan National Lung Cancer Early Detection Program, launched in July 2022, provided screening for nonsmoker patients with a positive family history of lung cancer in their first-degree relatives; this program demonstrated a 1.4% cancer detection rate among individuals with a family history of lung cancer. Despite this progress in identifying heritable risk factors for lung cancer, there is still significant work to be done. Currently, no molecular criteria are suitable for selecting patients for more intense screening programs or specific chemopreventive strategies.

PATHOLOGY

The World Health Organization (WHO) defines lung cancer as tumors arising from the respiratory epithelium (bronchi, bronchioles, and alveoli). The WHO classification system divides epithelial lung cancers into four major cell types: small-cell lung cancer (SCLC), adenocarcinoma, squamous cell carcinoma, and large-cell carcinoma; the latter three types are collectively known as non-small-cell carcinomas (NSCLCs) **(Fig. 83-1)**. Small-cell carcinomas consist of small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear

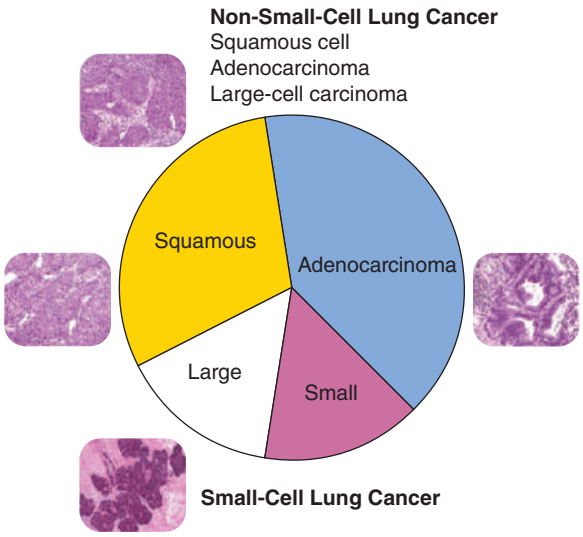

FIGURE 83-1 Histologic subsets of lung cancer.

chromatin, absent or inconspicuous nucleoli, and a high mitotic count. SCLC may be distinguished from NSCLC by the presence of neuroendocrine markers including CD56, neural cell adhesion molecule (NCAM), synaptophysin, chromogranin, and insulinoma-associated protein 1 (INSM1). Adenocarcinomas possess glandular differentiation or mucin production and may show acinar, papillary, lepidic, or solid features or a mixture of these patterns. Squamous cell carcinomas of the lung are morphologically identical to extrapulmonary squamous cell carcinomas and cannot be distinguished by immunohistochemistry alone. Squamous cell tumors show keratinization and/or intercellular bridges that arise from bronchial epithelium. The tumor consists of sheets of cells rather than the three-dimensional groups of cells characteristic of adenocarcinomas. Large-cell carcinomas compose <10% of lung carcinomas. These tumors lack the cytologic and architectural features of small-cell carcinoma and glandular or squamous differentiation. Together, these four histologic types account for ~90% of all epithelial lung cancers.

All histologic types of lung cancer can develop in current and former smokers, although squamous and small-cell carcinomas are more commonly associated with tobacco use. With the decline in cigarette consumption, adenocarcinoma has become the most frequent histologic subtype of lung cancer in the United States. In lifetime, never smokers or former light smokers (<10 pack-year history), women, and younger adults (<60 years), adenocarcinoma tends to be the most common form of lung cancer.

In addition to distinguishing between SCLC and NSCLC, because these tumors have quite different natural histories and therapeutic approaches (see below), it is necessary to classify whether NSCLC is squamous or nonsquamous. The classification system, developed jointly by the International Association for the Study of Lung Cancer, the American Thoracic Society, and the European Respiratory Society, provides an integrated approach to the classification of lung adenocarcinoma that includes clinical, molecular, radiographic, and pathologic information.

Even with advances in lung cancer screening and early detection, many lung cancers are still detected in an advanced stage and may be diagnosed based on small biopsies or cytologic specimens, rendering clear histologic distinctions difficult. In such cases, particularly in patients with advanced-stage disease, a repeat biopsy is recommended to obtain additional tissue for further clarification. The distinction between squamous and nonsquamous lung cancer is viewed as critical to optimal therapeutic decision-making, and a diagnosis of *non-small-cell carcinoma, not otherwise specified* is no longer considered acceptable. This distinction can be achieved using a single marker for adenocarcinoma (thyroid transcription factor-1 or napsin-A) plus a squamous marker (p40 or p63) and/or mucin stains. If tissue is limited and a clear morphologic pattern is evident, a diagnosis can be made without immunohistochemistry staining. In addition to determining histologic subtype, preservation of sufficient specimen material for appropriate molecular testing and programmed death ligand 1 (PD-L1) testing necessary to help guide therapeutic decision-making is recommended (see below).

The terms *adenocarcinoma in situ* and *minimally invasive adenocarcinoma* are now recommended for small solitary adenocarcinomas (≤3 cm) with either pure lepidic growth (term used to describe single-layered growth of atypical cuboidal cells coating the alveolar walls) or predominant lepidic growth with ≤5 mm invasion. Individuals with these entities experience 100% or near 100% 5-year disease-free survival with complete tumor resection. *Invasive adenocarcinomas*, representing >70–90% of surgically resected lung adenocarcinomas, are now classified by their predominant pattern: lepidic, acinar, papillary, and solid patterns. In general, lepidic-predominant subtype has a favorable prognosis, acinar and papillary have an intermediate prognosis, and solid-predominant has a poor prognosis. The terms *signet ring* and *clear cell adenocarcinoma* have been eliminated from the variants of invasive lung adenocarcinoma, whereas the term *micropapillary*, a subtype with a particularly poor prognosis, has been added. Because of prognostic implications, squamous cell carcinoma has also been modified to consist of keratinizing, nonkeratinizing, and basaloid, analogous to head and neck cancers.

IMMUNOHISTOCHEMISTRY

The diagnosis of lung cancer most often rests on the morphologic or cytologic features correlated with clinical and radiographic findings. Immunohistochemistry may be used to verify neuroendocrine differentiation within a tumor, with markers such as neuron-specific enolase (NSE), CD56 or NCAM, synaptophysin, chromogranin, and Leu7. Immunohistochemistry is also helpful in differentiating primary from metastatic adenocarcinomas; thyroid transcription factor-1 (TTF-1), identified in tumors of thyroid and pulmonary origin, is positive in >70% of pulmonary adenocarcinomas and is a reliable indicator of primary lung cancer, provided a thyroid primary has been excluded. A negative TTF-1, however, does not exclude the possibility of a lung primary. TTF-1 is also positive in neuroendocrine tumors of pulmonary and extrapulmonary origin. Napsin-A (Nap-A) is an aspartic protease that plays an important role in maturation of surfactant B7 and is expressed in cytoplasm of type II pneumocytes. In several studies, Nap-A has been reported in >90% of primary lung adenocarcinomas. Notably, a combination of Nap-A and TTF-1 is useful in distinguishing primary lung adenocarcinoma (Nap-A positive, TTF-1 positive) from primary lung squamous cell carcinoma (Nap-A negative, TTF-1 negative) and primary SCLC (Nap-A negative, TTF-1 positive). Cytokeratins (CK) 7 and 20 used in combination can help narrow the differential diagnosis; nonsquamous NSCLC, SCLC, and mesothelioma may stain positive for CK7 and negative for CK20, whereas squamous cell lung cancer often will be both CK7 and CK20 negative. p63 is a useful marker for the detection of NSCLCs with squamous differentiation when used in cytologic pulmonary samples. Mesothelioma can be easily identified ultrastructurally, but it has historically been difficult to differentiate from adenocarcinoma through morphology and immunohistochemical staining. Several markers in the past few years have proven to be more helpful including CK5/6, calretinin, and Wilms tumor gene-1 (*WT-1*), all of which show positivity in mesothelioma.

MOLECULAR PATHOGENESIS

As proposed by Hanahan and Weinberg, virtually all cancer cells acquire six hallmark capabilities: self-sufficiency in growth signals, insensitivity to antigrowth signals, evading apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. The order in which these hallmark capabilities are acquired is variable. Events leading to acquisition of these hallmarks vary widely, although broadly, cancers arise as a result of accumulations of gain-of-function mutations in oncogenes and loss-of-function mutations in tumor-suppressor genes. Further complicating the study of lung cancer, the sequence of events that leads to disease is clearly different for the various histopathologic entities.

For cancers in general, one theory holds that a small subset of the cells within a tumor (i.e., "stem cells") are responsible for the full malignant behavior of the tumor. As part of this concept, the large bulk of the cells in a cancer are "offspring" of these cancer stem cells. While clonally related to the cancer stem cell subpopulation, most cells by themselves cannot regenerate the full malignant phenotype. The stem cell concept may explain the failure of standard medical therapies to eradicate lung cancers, even when there is a clinical complete response. Disease recurs because therapies do not eliminate the stem cell component, which may be more resistant to therapy. Precise human lung cancer stem cells have yet to be identified.

Among lung cancer histologies, adenocarcinomas have been the most extensively catalogued for recurrent genomic gains and losses as well as for somatic mutations **(Fig. 83-2, Table 83-1)**. While multiple different kinds of aberrations have been found, a major class involves "driver mutations," which are mutations that occur in genes encoding signaling proteins that, when aberrant, drive initiation and maintenance of tumor cells. Importantly, driver mutations can serve as a potential Achilles' heels for tumors, if their gene products can be targeted appropriately. Several driver oncogenes have been described in NSCLC. These include activating mutations in receptor tyrosine kinases, including EGFR, ERBB2/HER2, and MET, and activating mutations in intracellular signaling proteins, such as KRAS and BRAF. Additionally, chromosomal rearrangements may also produce driver oncogenes in lung tumors, such as those chromosomal rearrangements leading to activation of the ALK, ROS1, RET, and NTRK tyrosine kinases. Each of these so-called "driver oncogenes" represents a distinct molecular cohort of lung cancer, with differing prevalence and varying levels of evidence regarding clinical actionability. So-called "targeted therapies" directed against these aberrantly activated oncogenes are discussed below. It is worth noting that most of these driver oncogenes are enriched in nonsquamous tumors.

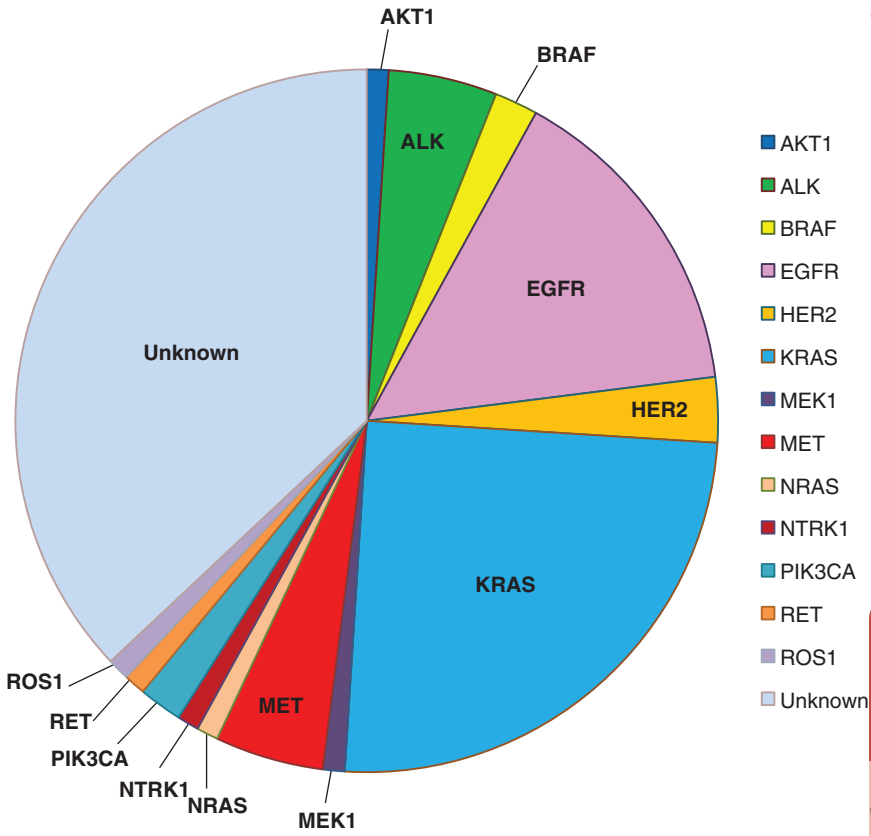

FIGURE 83-2 Driver mutations in lung adenocarcinomas.

Three potential molecular targets have been identified in squamous cell lung carcinomas: *FGFR1* amplification, *DDR2* mutations, and *PIK3CA* mutations/*PTEN* loss, as well as *BRAF* and *MET* (Table 83-1).

A large number of tumor-suppressor genes have also been identified that are inactivated during the pathogenesis of lung cancer. These include *TP53*, *RB1*, *RASSF1A*, *CDKN2A/B*, *LKB1* (*STK11*), and *FHIT*. Nearly 90% of SCLCs harbor mutations in *TP53* and *RB1*. Several tumor-suppressor genes on chromosome 3p appear to be involved in nearly all lung cancers. Allelic loss of this region occurs very early in lung cancer pathogenesis, including in histologically normal smoking-damaged lung epithelium.

EARLY DETECTION AND SCREENING

In lung cancer, clinical outcome is related to the stage at diagnosis, and hence, it is generally assumed that early detection of occult tumors will lead to improved survival. Early detection is a process that involves screening tests, surveillance, diagnosis, and early treatment. Screening refers to the use of tests across a healthy population in order to identify individuals who harbor asymptomatic disease. For a screening program to be successful, the target population must be a high-risk population; the test must be sensitive, specific, accessible, and cost effective; and effective treatment must be available that can reduce mortality. With any screening procedure, it is important to consider the possible influence of *lead-time bias* (detecting the cancer earlier without an effect on survival), *length-time bias* (indolent cancers are detected on screening and may not affect survival, whereas aggressive cancers are likely to cause symptoms earlier in patients and are less likely to be detected), and *overdiagnosis* (diagnosing cancers so slow growing that they are unlikely to cause the death of the patient).

Because a majority of lung cancer patients present with advanced disease beyond the scope of surgical resection, the value of screening for this condition is debated. Indeed, randomized controlled trials conducted in the 1960s to 1980s using screening chest x-rays (CXR), with or without sputum cytology, reported no impact on lung cancer–specific mortality in patients characterized as high risk (males age ≥45 years with a smoking history). These studies have been criticized for their design, statistical analyses, and outdated imaging modalities. In contrast to CXR, low-dose, noncontrast, thin-slice spiral chest computed tomography (LDCT) has emerged as an effective tool to screen for lung cancer. In nonrandomized studies conducted in the 1990s, LDCT scans were shown to detect more lung nodules and cancers than standard CXR in selected high-risk populations (e.g., age ≥60 years and a smoking history of ≥10 pack-years). Notably, up to 85% of the lung cancers discovered in these trials were classified as stage I disease and therefore considered potentially curable with surgical resection.

These data prompted the National Cancer Institute (NCI) to initiate the National Lung Screening Trial (NLST), a randomized study designed to determine if LDCT screening could reduce mortality

TABLE 83-1 Genetic Alterations with Existing Therapies in Non-Small-Cell Lung Cancer (NSCLC)

GENE	ALTERATION	FREQUENCY IN NSCLC	TYPICAL HISTOLOGY
ALK	Rearrangement	3–7%	Adenocarcinoma
BRAF	Mutation	1–3%	Adenocarcinoma
EGFR	Mutation	10–35%	Adenocarcinoma
HER2	Mutation	2–4%	Adenocarcinoma
KRAS	Mutation	15–25%	Adenocarcinoma
MET	Amplification	2–4%	Adenocarcinoma
NRAS	Mutation	1%	Adenocarcinoma
NTRK	Rearrangement	1–2%	Adenocarcinoma
RET	Rearrangement	1–2%	Adenocarcinoma
ROS1	Rearrangement	1–2%	Adenocarcinoma

from lung cancer in high-risk populations as compared with standard posterior anterior CXR. High-risk patients were defined as individuals between 55 and 74 years of age with a ≥30 pack-year history of cigarette smoking; former smokers must have quit within the previous 15 years. Excluded from the trial were individuals with a previous lung cancer diagnosis, a history of hemoptysis, an unexplained weight loss of >15 lb in the preceding year, or a chest computed tomography (CT) within 18 months of enrollment. A total of 53,454 persons were enrolled and randomized to annual screening yearly for 3 years (LDCT screening, n = 26,722; CXR screening, n = 26,732). Any noncalcified nodule measuring ≥4 mm in any diameter found on LDCT and CXR images with any noncalcified nodule or mass was classified as "positive." Participating radiologists had the option of not calling a final screen positive if a noncalcified nodule had been stable on the three screening examinations. Overall, 39.1% of participants in the LDCT group and 16% in the CXR group had at least one positive screening result. Of those who screened positive, the false-positive rate was 96.4% in the LDCT group and 94.5% in the CXR group. This was consistent across all three rounds. In the LDCT group, 1060 cancers were identified compared with 941 cancers in the CXR group (645 vs 572 per 100,000 person-years; relative risk [RR], 1.13; 95% confidence interval [CI], 1.03–1.23). Nearly twice as many stage IA cancers were detected in the LDCT group compared with the CXR group (40% vs 21%). The overall rates of lung cancer death were 247 and 309 deaths per 100,000 participants in the LDCT and CXR groups, respectively, representing a 20% reduction in lung cancer mortality in the LDCT-screened population (95% CI, 6.8–26.7%; $p = .004$). Compared with the CXR group, the rate of death in the LDCT group from *any* cause was reduced by 6.7% (95% CI, 1.2–13.6%; $p = .02$). The number needed to screen (NNTS) to prevent one lung cancer death was calculated to be 320.

The Nelson study was a second randomized trial comparing no screening to CT scans at baseline and in years 1, 3, and 5.5 in 13,195 men and 2594 women. Participants were 50–75 years of age and were current and former smokers with 10 years or less of cessation who smoked >15 cigarettes a day for >25 years or >10 cigarettes daily for >30 years. Participants were selected from four regions in the Netherlands or Belgium and were excluded if they were in moderate or bad self-reported health, were unable to climb two flights of stairs, had a body weight >140 kg, had a CT of the chest within the past year or a history of lung cancer <5 years ago or were still under treatment, or had current or past renal cell carcinoma, melanoma, or breast cancer. The hazard ratio for lung cancer mortality at 10 years was 0.74 (95% CI, 0.60–0.91; $p = .003$) and 0.61 (95% CI, 0.35–1.04; $p = .0543$) in men and women, respectively. These two trials have validated the use of annual CT scans for early detection of lung cancer in high-risk populations.

LDCT screening for lung cancer comes with known risks including a high rate of false-positive results, false-negative results, potential for unnecessary follow-up testing, radiation exposure, overdiagnosis, changes in anxiety level and quality of life, and substantial financial costs. One of the greatest challenges confronting the use of CT screening, in addition to its implementation, is the high false-positive rate. False positives can have a substantial impact on patients through the expense and risk of unneeded further evaluation and emotional stress. The management of these patients usually consists of serial CT scans over time to see if the nodules grow, attempted fine-needle aspirates, or surgical resection. At approximately $300 per scan (NCI estimated cost), the outlay for initial LDCT alone could run into the billions of dollars annually, an expense that only further escalates when factoring in various downstream expenditures an individual might incur in the assessment of positive findings. A formal cost-effectiveness analysis of the NLST demonstrated differences between sex, age, and current smoking status and the method of follow-up. Despite some questions, annual LDCT screening has been recommended for all patients meeting the following updated criteria from the U.S. Preventive Services Task Force as of 2021: individuals aged 50–80 years old with a 20-pack-year or greater smoking history who currently smoke or formerly smoked within the past 15 years. When discussing the option of LDCT screening, use of absolute risks rather than relative risks is helpful because studies indicate the public can process absolute terminology more effectively than relative risk projections. A useful guide has been developed by the NCI to help patients and physicians assess the benefits and harms of LDCT screening for lung cancer **(Table 83-2)**.

TABLE 83-2 The Benefits and Harms of LDCT Screening for Lung Cancer Based on NLST Data

	LDCT	CXR
Benefits: How did CT scans help compared to CXR?		
4 in 1000 fewer died from lung cancer	13 in 1000	17 in 1000
5 in 1000 fewer died from all causes	70 in 1000	75 in 1000
Harms: What problems did CT scans cause compared to CXR?		
223 in 1000 had at least 1 false alarm	365 in 1000	142 in 1000
18 in 1000 had a false alarm leading to an invasive procedure	25 in 1000	7 in 1000
2 in 1000 had a major complication from an invasive procedure	3 in 1000	1 in 1000

Abbreviations: CT, computed tomography; CXR, chest x-ray; LDCT, low-dose computed tomography; NLST, National Lung Screening Trial.

CLINICAL MANIFESTATIONS

Over half of all patients diagnosed with lung cancer present with locally advanced or metastatic disease at the time of diagnosis. The majority of patients present with signs, symptoms, or laboratory abnormalities that can be attributed to the primary lesion, local tumor growth, invasion or obstruction of adjacent structures, growth at distant metastatic sites, or a paraneoplastic syndrome **(Tables 83-3** and **83-4)**. A history of chronic cough with or without hemoptysis in a current or former smoker with chronic obstructive pulmonary disease (COPD) age 40 years or older should prompt a thorough investigation for lung cancer even in the face of a normal CXR. A persistent pneumonia without constitutional symptoms and unresponsive to repeated courses of antibiotics also should prompt an evaluation for the underlying cause. Lung cancer occurring in individuals who have never smoked is more prevalent in, though not limited to, women and East Asians. These patients also typically present at a younger age than their smoking counterparts at the time of diagnosis. The clinical presentation of lung cancer in never smokers tends to mirror that of current and former smokers.

Patients with central or endobronchial growth of the primary tumor may present with cough, hemoptysis, wheeze, stridor, dyspnea, or postobstructive pneumonia. Peripheral growth of the primary tumor may cause pain from pleural or chest wall involvement, dyspnea on a restrictive basis, and symptoms of a lung abscess resulting from tumor

TABLE 83-3 Presenting Signs and Symptoms of Lung Cancer

SYMPTOM AND SIGNS	RANGE OF FREQUENCY
Cough	8–75%
Weight loss	0–68%
Dyspnea	3–60%
Chest pain	20–49%
Hemoptysis	6–35%
Bone pain	6–25%
Clubbing	0–20%
Fever	0–20%
Weakness	0–10%
Superior vena cava obstruction	0–4%
Dysphagia	0–2%
Wheezing and stridor	0–2%

TABLE 83-4 Clinical Findings Suggestive of Metastatic Disease	
Symptoms elicited in history	• Constitutional: weight loss >10 lb • Musculoskeletal: pain • Neurologic: headaches, syncope, seizures, extremity weakness, recent change in mental status
Signs found on physical examination	• Lymphadenopathy (>1 cm) • Hoarseness, superior vena cava syndrome • Bone tenderness • Hepatomegaly (>13 cm span) • Focal neurologic signs, papilledema • Soft-tissue mass
Routine laboratory tests	• Hematocrit, <40% in men; <35% in women • Elevated alkaline phosphatase, GGT, SGOT, and calcium levels

Abbreviations: GGT, gamma-glutamyltransferase; SGOT, serum glutamic-oxaloacetic transaminase.

Source: Reproduced with permission from GA Silvestri et al: The noninvasive staging of non-small cell lung cancer. Chest 123:147S, 2003.

cavitation. Regional spread of tumor in the thorax (by contiguous growth or by metastasis to regional lymph nodes) may cause tracheal obstruction, esophageal compression with dysphagia, recurrent laryngeal nerve paralysis with hoarseness, phrenic nerve palsy with elevation of the hemidiaphragm and dyspnea, and sympathetic nerve paralysis with Horner's syndrome (i.e., enophthalmos, ptosis, miosis, and anhidrosis). Malignant pleural effusions can cause pain, dyspnea, or cough. Pancoast (or superior sulcus tumor) syndromes result from local extension of a tumor growing in the apex of the lung with involvement of the eighth cervical and first and second thoracic nerves, and present with shoulder pain that characteristically radiates in the ulnar distribution of the arm, often with radiologic destruction of the first and second ribs. Often Horner's syndrome and Pancoast syndrome coexist. Other problems of regional spread include superior vena cava syndrome from vascular obstruction; pericardial and cardiac extension with resultant tamponade, arrhythmia, or cardiac failure; lymphatic obstruction with resultant pleural effusion; and lymphangitic spread through the lungs with hypoxemia and dyspnea. In addition, lung cancer can spread transbronchially, producing tumor growth along multiple alveolar surfaces with impairment of gas exchange, respiratory insufficiency, dyspnea, hypoxemia, and sputum production. Constitutional symptoms may include anorexia, weight loss, weakness, fever, and night sweats. These parameters cannot clearly distinguish SCLC from NSCLC or even from neoplasms metastatic to lungs.

Extrathoracic metastatic disease is found at autopsy in >50% of patients with squamous carcinoma, 80% of patients with adenocarcinoma and large-cell carcinoma, and >95% of patients with SCLC. Approximately one-third of patients present with symptoms as a result of distant metastases. Lung cancer metastases may occur in virtually every organ system, and the site of metastatic involvement largely determines other symptoms. Patients with brain metastases may present with headache, nausea and vomiting, seizures, or neurologic deficits. Patients with bone metastases may present with pain, pathologic fractures, or spinal cord compression. The latter may also occur with epidural metastases. Individuals with bone marrow invasion may present with cytopenias or leukoerythroblastosis. Those with liver metastases may present with hepatomegaly, right upper quadrant pain, fever, anorexia, and weight loss. Liver dysfunction and biliary obstruction are rare. Adrenal metastases are common but rarely cause pain or adrenal insufficiency unless they are large.

Paraneoplastic syndromes are common in patients with lung cancer, especially those with SCLC, and may be the presenting finding or the first sign of recurrence. In addition, paraneoplastic syndromes may mimic metastatic disease and, unless detected, lead to inappropriate palliative rather than curative treatment. Often the paraneoplastic syndrome may be relieved with successful treatment of the tumor. In some cases, the pathophysiology of the paraneoplastic syndrome is known, particularly when a hormone with biologic activity is secreted by a tumor. However, in many cases, the pathophysiology is unknown. Systemic symptoms of anorexia, cachexia, weight loss (seen in 30% of patients), fever, and suppressed immunity are paraneoplastic syndromes of unknown etiology or at least not well defined. Weight loss >10% of total body weight is considered a bad prognostic sign. Endocrine syndromes are seen in 12% of patients; hypercalcemia resulting from ectopic production of parathyroid hormone (PTH) or, more commonly, PTH-related peptide is the most common life-threatening metabolic complication of malignancy, primarily occurring with squamous cell carcinomas of the lung. Clinical symptoms include nausea, vomiting, abdominal pain, constipation, polyuria, thirst, and altered mental status.

Hyponatremia may be caused by the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) or possibly atrial natriuretic peptide (ANP) **(Chap. 98)**. SIADH resolves within 1–4 weeks of initiating chemotherapy in the vast majority of cases. During this period, serum sodium can usually be managed and maintained above 128 mEq/L via fluid restriction. Demeclocycline can be a useful adjunctive measure when fluid restriction alone is insufficient. Vasopressin receptor antagonists like tolvaptan also have been used in the management of SIADH. However, the use of tolvaptan has significant limitations including liver injury and overly rapid correction of the hyponatremia, which can lead to irreversible neurologic injury. Likewise, the cost of tolvaptan may be prohibitive. Of note, patients with ectopic ANP may have worsening hyponatremia if sodium intake is not concomitantly increased. Accordingly, if hyponatremia fails to improve or worsens after 3–4 days of adequate fluid restriction, plasma levels of ANP should be measured to determine the causative syndrome.

Ectopic secretion of ACTH by SCLC and pulmonary carcinoids usually results in additional electrolyte disturbances, especially hypokalemia, rather than the changes in body habitus that occur in Cushing's syndrome from a pituitary adenoma **(Chap. 98)**. Treatment with standard medications, such as metyrapone and ketoconazole, is largely ineffective due to extremely high cortisol levels. The most effective strategy for management of the Cushing's syndrome is effective treatment of the underlying SCLC. Bilateral adrenalectomy may be considered in extreme cases.

Skeletal–connective tissue syndromes include clubbing in 30% of cases (usually NSCLCs) and hypertrophic primary osteoarthropathy in 1–10% of cases (usually adenocarcinomas). Patients may develop periostitis, causing pain, tenderness, and swelling over the affected bones and a positive bone scan. Neurologic–myopathic syndromes are seen in only 1% of patients but are dramatic and include the myasthenic Eaton-Lambert syndrome and retinal blindness with SCLC, whereas peripheral neuropathies, subacute cerebellar degeneration, cortical degeneration, and polymyositis are seen with all lung cancer types. Many of these are caused by autoimmune responses such as the development of anti-voltage-gated calcium channel antibodies in Eaton-Lambert syndrome. Patients with this disorder present with proximal muscle weakness, usually in the lower extremities, occasional autonomic dysfunction, and rarely, cranial nerve symptoms or involvement of the bulbar or respiratory muscles. Depressed deep tendon reflexes are frequently present. In contrast to patients with myasthenia gravis, strength improves with serial effort. Some patients who respond to chemotherapy will have resolution of the neurologic abnormalities. Thus, chemotherapy is the initial treatment of choice. Paraneoplastic encephalomyelitis and sensory neuropathies, cerebellar degeneration, limbic encephalitis, and brainstem encephalitis occur in SCLC in association with a variety of antineuronal antibodies such as anti-Hu, anti-CRMP5, and ANNA-3. Paraneoplastic cerebellar degeneration may be associated with anti-Hu, anti-Yo, or P/Q calcium channel autoantibodies. Coagulation or thrombotic or other hematologic manifestations occur in 1–8% of patients and include migratory venous thrombophlebitis (Trousseau's syndrome), nonbacterial thrombotic (marantic) endocarditis with arterial emboli, and disseminated intravascular coagulation with hemorrhage, anemia, granulocytosis, and leukoerythroblastosis. Thrombotic disease complicating cancer is usually a poor prognostic sign. Cutaneous manifestations such as dermatomyositis and acanthosis nigricans are uncommon (1%), as are the renal manifestations of nephrotic syndrome and glomerulonephritis (≤1%).

DIAGNOSING LUNG CANCER

Tissue sampling is required to confirm a diagnosis in all patients with suspected lung cancer. In patients with suspected metastatic disease, a biopsy of a distant site of disease is preferred for concurrent tissue and staging confirmation. Given the greater emphasis placed on molecular and PD-L1 testing for NSCLC patients, a core biopsy is preferred to ensure adequate tissue for analysis. Tumor tissue may be obtained via minimally invasive techniques such as bronchial or transbronchial biopsy during fiberoptic bronchoscopy, by fine-needle aspiration (FNA) or percutaneous biopsy using image guidance, or via endobronchial ultrasound (EBUS)-guided biopsy. Depending on the location, lymph node sampling may occur via transesophageal endoscopic ultrasound (EUS)-guided biopsy, EBUS-guided biopsy, or blind biopsy. In patients with suspected metastatic disease, a diagnosis may be confirmed by bronchoscopy, percutaneous biopsy of a soft tissue mass, lytic bone lesion, bone marrow, pleural or liver lesion, or an adequate cell block obtained from a malignant pleural effusion. In patients with a suspected malignant pleural effusion, if the initial thoracentesis is negative, repeat thoracentesis is essential. Although the majority of pleural effusions are due to malignant disease, particularly if they are exudative or bloody, some may be parapneumonic. In the absence of distant disease, such patients should be considered for possible curative treatment.

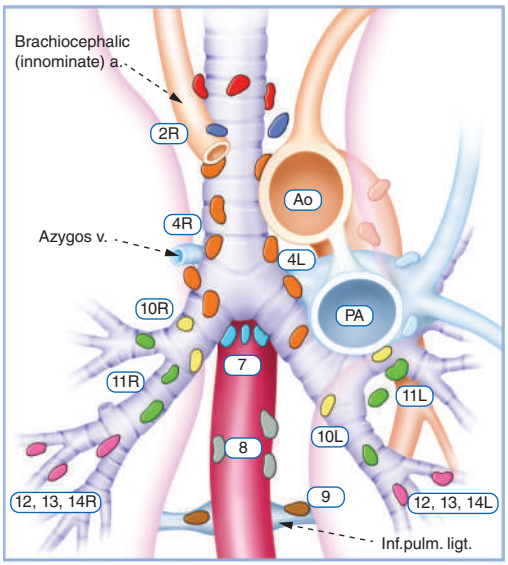
The diagnostic yield of any biopsy depends on several factors including location (accessibility) of the tumor, tumor size, tumor type, and technical aspects of the diagnostic procedure including the experience level of the bronchoscopist and pathologist. In general, central lesions such as squamous cell carcinomas, small-cell carcinomas, or endobronchial lesions such as carcinoid tumors are more readily diagnosed by bronchoscopic examination, whereas peripheral lesions such as adenocarcinomas and large-cell carcinomas are more amenable to transthoracic biopsy.

Biomarker testing in lung cancer plays an essential role in guiding a precision-based medicine approach for patient care. Ideally performed at the time of initial diagnosis, biomarker testing is recommended for all patients with advanced stage NSCLC by most current guidelines, with consideration for those with squamous histology. Biomarker testing aims to identify specific genetic alterations, or molecular markers, within the tumor cells. Traditionally, the gold standard process involves obtaining a tissue sample from the patient, which is then subjected to advanced techniques such as next-generation sequencing (NGS) to complete multigene sequencing. By completing this testing, clinicians can discern the presence of driver oncogenes to allow for tailored treatment approaches specific to the underlying molecular profile of the tumor such as with targeted therapies. Of note, immunohistochemical staining on tumor tissue should be employed for PD-L1 testing, quantified as tumor proportion score (TPS), as the level of PD-L1 expression serves as an additional crucial biomarker in lung cancer management.

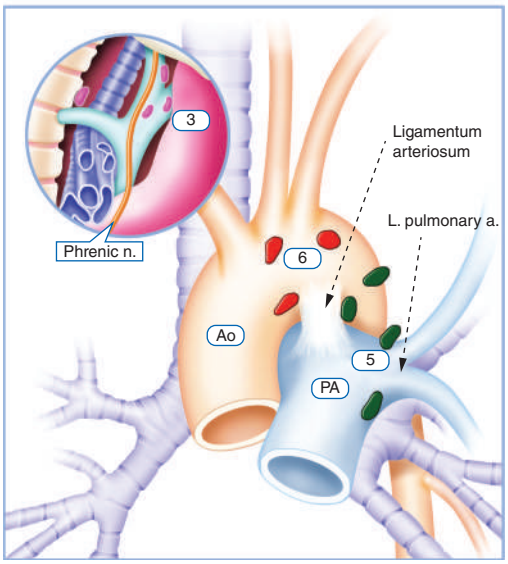
Advancements in the detection of circulating tumor DNA (ctDNA) have emerged as a noninvasive strategy to perform a "liquid biopsy" with a blood sample to assist in diagnosis and treatment monitoring. This strategy may be particularly useful to overcome tissue limitations, such as in cases where obtaining a tissue biopsy may be challenging or not feasible due to a tumor's location. The role of a liquid biopsy continues to evolve, especially as the sensitivity and specificity of this biopsy strategy continue to improve.

STAGING LUNG CANCER

Lung cancer staging consists of two parts: first, a determination of the location of the tumor and possible metastatic sites (anatomic staging), and second, an assessment of a patient's ability to withstand various antitumor treatments (physiologic staging). All patients with lung cancer should have a complete history and physical examination, with evaluation of all other medical problems, determination of performance status (i.e., standardized measure assessing a patient's physical functioning and ability to perform activities of daily living to determine their overall health and suitability for treatment), and history of weight loss. Staging with regard to a patient's potential for surgical resection is principally applicable to NSCLC.



ANATOMIC STAGING OF PATIENTS WITH LUNG CANCER



The accurate staging of patients with NSCLC is essential for determining the appropriate treatment in patients with resectable disease and for avoiding unnecessary surgical procedures in patients with advanced disease. All patients with NSCLC should undergo initial radiographic imaging with CT scan, positron emission tomography (PET), or preferably PET-CT. PET scanning attempts to identify sites of malignancy based on glucose metabolism by measuring the uptake of ^{18}F-fluorodeoxyglucose (FDG). Rapidly dividing cells, presumably in the lung tumors, will preferentially take up ^{18}F-FDG and appear as a "hot spot." To date, PET has been mostly used for staging and detection of metastases in lung cancer and in the detection of nodules >15 mm in diameter. Combined ^{18}F-FDG PET-CT imaging has been shown to improve the accuracy of staging in NSCLC compared to visual correlation of PET and CT or either study alone. PET-CT has been found to be superior in identifying pathologically enlarged mediastinal lymph nodes and extrathoracic metastases. A standardized uptake value (SUV) of >2.5 on PET is highly suspicious for malignancy. False negatives can be seen in diabetes, in lesions <8 mm, and in slow-growing tumors (e.g., carcinoid tumors or well-differentiated adenocarcinoma). False positives can be seen in certain infections and granulomatous disease (e.g., tuberculosis). Thus, PET should never be used alone to diagnose lung cancer, mediastinal involvement, or metastases. Confirmation with tissue biopsy is required. For brain metastases, magnetic resonance imaging (MRI) is the most effective method. MRI can also be useful in selected circumstances, such as superior sulcus tumors to rule out brachial plexus involvement, but in general, MRI does not play a major role in NSCLC staging.

If imaging is concerning for metastatic disease, biopsy of a distant site of disease is preferred for concurrent tissue diagnosis and confirmation of staging. In patients in whom distant metastatic disease has been ruled out, lymph node status needs to be assessed via minimally invasive techniques such as those mentioned above, including EBUS-guided mediastinal staging, and/or invasive techniques such as mediastinoscopy, mediastinotomy, thoracoscopy, or thoracotomy. Approximately one-quarter to one-half of patients diagnosed with NSCLC will have mediastinal lymph node metastases at the time of diagnosis. A standard nomenclature for referring to the location of lymph nodes involved with lung cancer has evolved **(Fig. 83-3)**. Lymph node sampling is recommended in all patients with enlarged nodes detected by CT or PET scan and in patients with large tumors or tumors occupying the inner third of the lung. The extent of mediastinal lymph node involvement is important in determining the appropriate definitive intent treatment strategy: neoadjuvant/perioperative therapy followed by surgical resection versus surgical resection followed by adjuvant therapy versus combined chemoradiation followed by immunotherapy consolidation (durvalumab).

In SCLC patients, current staging recommendations include a PET-CT scan and MRI of the brain (positive in 10% of asymptomatic patients). Bone marrow biopsies and aspirations are rarely performed now given the low incidence of isolated bone marrow metastases. Confirmation of metastatic disease, ipsilateral or contralateral lung nodules, or metastases beyond the mediastinum may be achieved by the same modalities recommended earlier for patients with NSCLC.

If a patient has signs or symptoms of spinal cord compression (pain, weakness, paralysis, urinary retention), a spinal CT or MRI scan should be performed. If metastases are evident on imaging, a neurosurgeon should be consulted for possible palliative surgical resection and/or a radiation oncologist should be consulted for palliative radiotherapy to the site of compression. If signs or symptoms of leptomeningeal disease develop at any time in a patient with lung cancer, an MRI of the brain and spinal cord should be performed, as well as a lumbar puncture, for evaluation and detection of malignant cells in the cerebrospinal fluid. If the lumbar puncture is negative, a repeat procedure should be considered. Leptomeningeal disease remains a clinical challenge, as there is currently no approved therapy for the specific treatment of leptomeningeal disease.

Superior mediastinal nodes

- 1 Highest mediastinal
- 2 Upper paratracheal
- 3 Prevascular and retrotracheal
- 4 Lower paratracheal (including azygos nodes)

N2 = single digit, ipsilateral
N3 = single digit, contralateral or supraclavicular

Aortic nodes

- 5 Subaortic (A-P window)
- 6 Para-aortic (ascending aorta or phrenic)

Inferior mediastinal nodes

- 7 Subcarinal
- 8 Paraesophageal (below carina)
- 9 Pulmonary ligament

N1 nodes

- 10 Hilar
- 11 Interlobar
- 12 Lobar
- 13 Segmental
- 14 Subsegmental

STAGING SYSTEM FOR NON-SMALL-CELL LUNG CANCER

The tumor-node-metastasis (TNM) international staging system provides useful prognostic information and is used to stage all patients with NSCLC. The various T (tumor size), N (regional node involvement), and M (presence or absence of distant metastasis) stages are combined to form different stage groups **(Tables 83-5 and 83-6)**. The eighth edition of the TNM staging system went into effect in 2018. T1 tumors are divided into tumors ≤1 cm (T1a), >1 cm and ≤2 cm (T1b), and >2 cm and ≤3 cm (T1c). T2 tumors are those that are >3 cm but ≤5 cm, involve the visceral pleura or main bronchus, or are associated with atelectasis; T2a tumors are >3 cm and ≤4 cm, and T2b are >4 cm and ≤5 cm. T3 tumors are >5 cm and ≤7 cm. T3 tumors also include tumors with invasion into local structures such as the chest wall and diaphragm and with additional nodules in the same lobe. T4 tumors include tumors >7 cm or tumors of any size with invasion into mediastinum, heart, great vessels, trachea, esophagus, or spine or with multiple nodules in the ipsilateral lung. Lymph node staging depends on metastasis to ipsilateral pulmonary or hilar nodes (N1), mediastinal or subcarinal nodes (N2), or contralateral mediastinal, hilar, or supraclavicular nodes (N3). Patients with metastasis may be classified as M1a (malignant pleural or pericardial effusion, pleural nodules, or nodules in the contralateral lung), M1b (single distant metastasis to a single organ; e.g., bone, liver, adrenal, or brain metastasis), or M1c (multiple metastases to a single organ or metastases to multiple organs). The ninth edition of the TNM classification is scheduled to be introduced sometime in 2024.

The effect of stage on survival is illustrated in **Fig. 83-4**. Approximately 15% of patients have localized disease that can be treated with curative attempt (surgery or radiotherapy), about a quarter have local or regional disease that may or may not be amenable to a curative attempt, and half have metastatic disease at the time of diagnosis. In 10%, the extent of disease is undefined.

STAGING SYSTEM FOR SMALL-CELL LUNG CANCER

In patients with SCLC, it is now recommended that both the Veterans Administration system and the American Joint Committee on Cancer/International Union Against Cancer eighth edition system (TNM) be used to classify the tumor stage. The Veterans Administration system is a distinct two-stage system dividing patients into those with limited- or extensive-stage disease. Patients with limited-stage disease (LD) have cancer that is confined to the ipsilateral hemithorax and can be encompassed within a tolerable radiation port. Thus, contralateral supraclavicular nodes, recurrent laryngeal nerve involvement, and superior vena caval obstruction can all be part of LD. Patients with extensive-stage disease (ED) have overt metastatic disease by imaging or physical examination. Cardiac tamponade, malignant pleural effusion, and bilateral pulmonary parenchymal involvement generally qualify disease as ED, because the involved organs cannot be encompassed safely or effectively within a single radiation therapy port. Sixty to 70% of patients are diagnosed with ED at presentation. The TNM staging system is preferred in the rare SCLC patient presenting with what appears to be clinical stage I disease (see above).

PHYSIOLOGIC STAGING

Patients with lung cancer often have other comorbid conditions related to smoking including cardiovascular disease and COPD. To improve their preoperative condition, correctable problems (e.g., anemia, electrolyte and fluid disorders, infections, cardiac disease, and arrhythmias) should be addressed, appropriate chest physical therapy should be instituted, and patients should be encouraged to stop smoking. Patients with a forced expiratory volume in 1 s (FEV_1) of >2 L or >80% of predicted may tolerate a pneumonectomy, and those with an FEV_1 >1.5 L may have adequate reserve for a lobectomy. In patients with borderline lung function but a resectable tumor, cardiopulmonary exercise testing could be performed as part of the physiologic evaluation. This test allows an estimate of the maximal oxygen consumption (VO_{2max}).

TABLE 83-5 TNM Staging System for Lung Cancer (Eighth Edition)

Primary Tumor (T)	
T1	Tumor ≤3 cm diameter, surrounded by lung or visceral pleura, without invasion more proximal than lobar bronchus
T1mi	Minimally invasive adenocarcinoma (pure lepidic pattern, <3 cm in greatest dimension and <5 mm invasion)—T1a (size ≤1 cm)—T1b (1 cm < size ≤ 2 cm)—T1c (2 cm < size ≤ 3 cm)
T2	Tumor >3 cm but ≤5 cm, or tumor with any of the following features: Involves main bronchus without carina, regardless of distance from carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor >3 cm but ≤4 cm
T2b	Tumor >4 cm but ≤5 cm
T3	Tumor >5 cm but ≤7 cm or any of the following: Directly invades any of the following: chest wall, pericardium, phrenic nerve Separate (satellite) tumor nodules in the same lobe
T4	Tumor >7 cm or any tumor with invasion of mediastinum, diaphragm, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina, or with separate (satellite) tumor nodules in a different ipsilateral lobe
Nodal Stage (N)	
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal or hilar lymph node(s); ipsilateral/contralateral scalene/supraclavicular lymph node(s)
Metastases (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; pleural/pericardial nodule/malignant effusion
M1b	Single extrathoracic metastasis, including single nonregional lymph node
M1c	Multiple extrathoracic metastases in one or more organs

Abbreviation: TNM, tumor-node-metastasis.

A VO_{2max} <15 mL/(kg.min) predicts for a higher risk of postoperative complications. Patients deemed unable to tolerate lobectomy or pneumonectomy from a pulmonary functional standpoint may be candidates for more limited resections, such as wedge or anatomic segmental resection, although such procedures are associated with significantly higher rates of local recurrence and a trend toward decreased overall survival. All patients should be assessed for cardiovascular risk using American College of Cardiology and American Heart Association guidelines. A myocardial infarction within the past 3 months is a contraindication to thoracic surgery because 20% of patients will die of reinfarction. An infarction in the past 6 months is a relative contraindication. Other major contraindications include uncontrolled arrhythmias, an FEV_1 of <1 L, CO_2 retention (resting PCO_2 >45 mmHg), DL_{CO} <40%, and severe pulmonary hypertension.

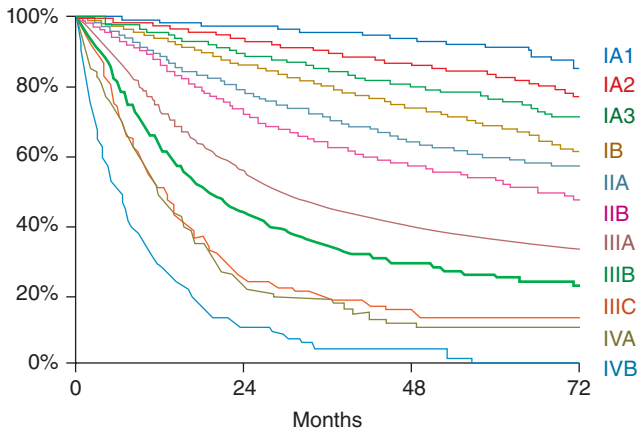
TREATMENT

Non-Small-Cell Lung Cancer



OCCULT AND STAGE 0 CARCINOMAS

Patients with severe atypia on sputum cytology have an increased risk of developing lung cancer compared to those without atypia. In the uncommon circumstance where malignant cells are identified in a sputum or bronchial washing specimen but the chest imaging appears normal (TX tumor stage), the lesion must be localized. More than 90% of tumors can be localized by meticulous examination of the bronchial tree with a fiberoptic bronchoscope under general anesthesia and collection of a series of differential brushings and biopsies. Surgical resection following bronchoscopic localization has been shown to improve survival compared to no treatment. Close follow-up of these patients is indicated because of the high incidence of second primary lung cancers (5% per patient per year).

SOLITARY PULMONARY NODULE AND "GROUND-GLASS" OPACITIES

A solitary pulmonary nodule is defined as an x-ray density completely surrounded by normal aerated lung with circumscribed margins, of any shape, usually 1–6 cm in greatest diameter. The approach to a patient with a solitary pulmonary nodule is based on an estimate of the probability of cancer, determined according to the patient's smoking history, age, and characteristics on imaging (**Table 83-7**). Prior CXRs and CT scans should be obtained if available for comparison. A PET scan may be useful if the lesion is >7–8 mm in diameter. If no diagnosis is apparent, Mayo investigators reported that clinical characteristics (age, cigarette smoking status, and prior cancer diagnosis) and three radiologic characteristics (nodule diameter, spiculation, and upper lobe location) were independent predictors of malignancy. At present, only two radiographic criteria are thought to predict the benign nature of a solitary pulmonary nodule: lack of growth over a period >2 years and certain characteristic patterns of calcification. Calcification alone, however, does not exclude malignancy; a dense central nidus, multiple punctuate foci, and "bull's eye" (granuloma) and "popcorn ball" (hamartoma) calcifications are highly suggestive of a benign lesion. In contrast, a relatively large lesion, lack of or asymmetric calcification, chest symptoms, associated atelectasis, pneumonitis, or growth of the lesion revealed by comparison with an old x-ray or CT scan or a positive PET scan may be suggestive of a malignant process and warrant further attempts to establish a histologic diagnosis. An algorithm for assessing these lesions is shown in **Fig. 83-5**.

Since the advent of screening CTs, small "ground-glass" opacities (GGOs) have often been observed, particularly as the increased sensitivity of CTs enables detection of smaller lesions. Many of these GGOs, when biopsied, are found to be atypical adenomatous hyperplasia (AAH), adenocarcinoma in situ (AIS), or minimally invasive adenocarcinoma (MIA). AAH is usually a nodule of <5 mm and is minimally hazy, also called nonsolid or ground glass (i.e., hazy slightly increased attenuation, no solid component, and preservation of bronchial and vascular margins). On thin-section CT, AIS is usually a nonsolid nodule and tends to be slightly more opaque than AAH. MIA is mainly solid, usually with a small (<5 mm) central solid component. However, overlap exists among the imaging features of the preinvasive and minimally invasive lesions in

Stage	24 months	60 months
IA1	97%	92%
IA2	94%	83%
IA3	90%	77%
IB	87%	68%
IIA	79%	60%
IIB	72%	53%
IIIA	55%	36%
IIIB	44%	26%
IIIC	24%	13%
IVA	23%	10%
IVB	10%	0%

the lung adenocarcinoma spectrum. Lepidic adenocarcinomas are usually solid but may be nonsolid. Likewise, the small invasive adenocarcinomas also are usually solid but may exhibit a small nonsolid component.

PREFACE TO MANAGEMENT OF LUNG CANCER

The landscape of lung cancer management, spanning from screening and early detection to addressing early-stage, locally advanced, and distant disease, is undergoing continuous evolution. The dynamic nature of this evolution is best exemplified by the approval of 12 drugs in the United States only between 2022 and 2023. Within the confines of this single chapter, presenting the most current and comprehensive management recommendations proves challenging, if not impossible, due to the accelerated pace of the evolving treatment armamentarium. Therefore, it is recommended to consult the latest professional guidelines for the most up-to-date best practices **(Table 83-8)**.

MANAGEMENT OF STAGES I AND II NSCLC

Surgical Resection of Stage I and II NSCLC Surgical resection, ideally by an experienced thoracic surgeon, is the treatment of choice for patients with clinical stage I and II NSCLC who are able to tolerate the procedure. Operative mortality rates for patients resected by thoracic or cardiothoracic surgeons are lower compared to general surgeons. Moreover, survival rates are higher in patients who undergo resection in facilities with a high surgical volume compared to those performing fewer than 70 procedures per year, even though the higher-volume facilities often serve older and less socioeconomically advantaged populations. The improvement in survival is most evident in the immediate postoperative period. In patients with stage I NSCLC, lobectomy is superior to wedge resection with respect to rates of local recurrence. There is also a trend toward improvement in overall survival. In patients with comorbidities, compromised pulmonary reserve, and small peripheral lesions, a limited resection, wedge resection, or segmentectomy (potentially by video-assisted thoracoscopic surgery) may be reasonable surgical options. Pneumonectomy is reserved for patients with central tumors and should be performed only in patients with excellent pulmonary reserve. According to the Surveillance, Epidemiology, and End Results (SEER) data from 2022, patients with localized disease have a 5-year survival rate of 63%.

Accurate pathologic staging requires adequate segmental, hilar, and mediastinal lymph node sampling. Ideally, this includes a mediastinal lymph node dissection. Although there are no evidence-based guidelines mandating the number of lymph nodes to be removed at surgery for adequate staging, the International Association for the Study of Lung Cancer staging manual states that suitable nodal staging generally includes sampling/dissection of lymph nodes from stations 2R, 4R, 7, 10R and 11R on the right side, and from stations 5, 6, 7, 10L, and 11L on the left side. Hilar lymph nodes are typically resected and sent for pathologic review, although it is helpful to specifically dissect and label level 10 lymph nodes when possible. On the left side, level 2 and sometimes level 4 lymph nodes are generally obscured by the aorta. Although the therapeutic benefit of nodal dissection versus nodal sampling is controversial, a pooled analysis of three trials involving patients with stages I to IIIA NSCLC demonstrated a superior 4-year survival in patients undergoing resection and a complete mediastinal lymph node dissection compared with lymph node sampling. Moreover, complete mediastinal lymphadenectomy added little morbidity to a pulmonary resection for lung cancer when carried out by an experienced thoracic surgeon.

TABLE 83-7 Assessment of Risk of Cancer in Patients with Solitary Pulmonary Nodules

	RISK		
VARIABLE	LOW	INTERMEDIATE	HIGH
Diameter (cm)	<1.5	1.5–2.2	≥2.3
Age (years)	<45	45–60	>60
Smoking status	Never smoker	Current smoker (<20 cigarettes/d)	Current smoker (>20 cigarettes/d)
Smoking cessation status	Quit ≥7 years ago or quit	Quit <7 years ago	Never quit
Characteristics of nodule margins	Smooth	Scalloped	Corona radiata or spiculated

Radiation Therapy in Stages I and II NSCLC There is currently no role for postoperative radiation therapy in patients following resection of stage I or II NSCLC with negative margins. However, patients with stage I and II disease who either decline or are not suitable candidates for surgery should be considered for radiation therapy with *curative* intent. Stereotactic body radiation therapy (SBRT) is a technique used to treat patients with isolated pulmonary nodules (≤5 cm) who are not candidates for or refuse surgical resection. Treatment is typically administered in three to five fractions delivered over 1–2 weeks. In uncontrolled studies, disease control rates are >90%, and 5-year survival rates of up to 60% have been reported with SBRT. By comparison, survival rates typically range from 13 to 39% in patients with stage I or II NSCLC treated with standard external-beam radiotherapy. Cryoablation is another

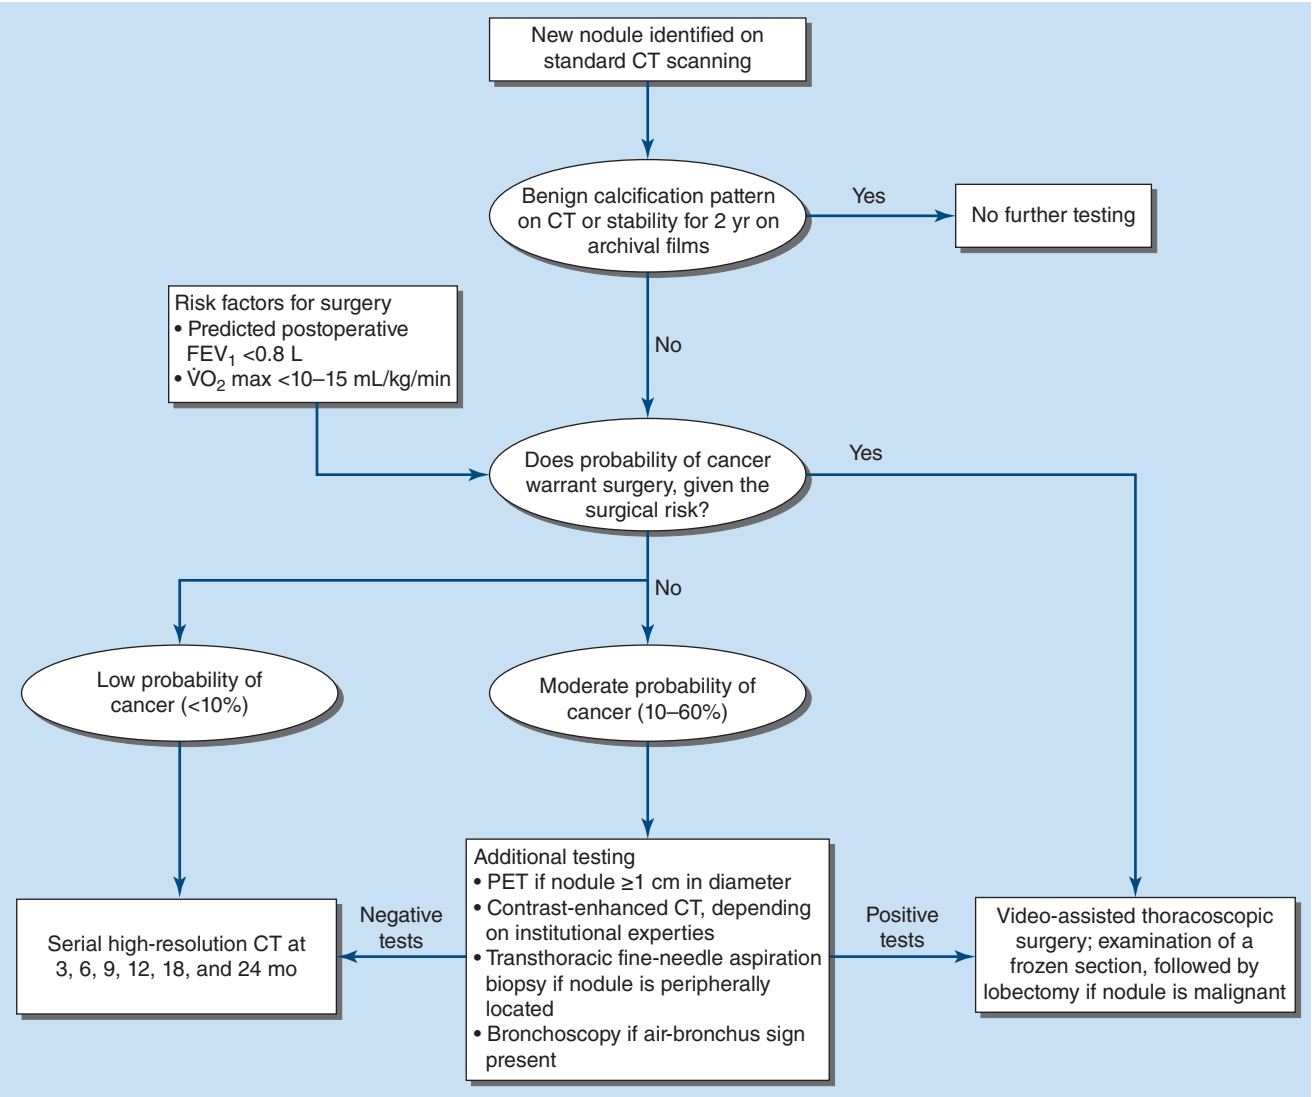

FIGURE 83-5 Approach to the solitary pulmonary nodule. FEV_1, forced expiratory volume in 1 s; PET, positron emission tomography.

technique occasionally used to treat small, isolated tumors (i.e., ≤3 cm). However, very little data exist on long-term outcomes with this technique.

Systemic Therapy in Stages I and II NSCLC For nearly two decades, chemotherapy has historically served as the cornerstone of adjuvant systemic therapy for patients with early-stage resected disease. The landmark meta-analysis of cisplatin-based adjuvant chemotherapy trials in patients with resected stages I to IIIA NSCLC (the Lung Adjuvant Cisplatin Evaluation [LACE] Study) published in 2008 demonstrated a 5.4% improvement in 5-year survival for cisplatin-based chemotherapy compared to surgery alone, thus becoming the standard-of-care adjuvant therapy recommendation. The survival benefit was seemingly confined to patients with stage II or III disease (Table 83-9). By contrast, survival was actually worsened in stage IA patients with the application of adjuvant therapy. In stage IB, there was a modest improvement in survival of questionable clinical significance, particularly for patients with a resected lesion ≥4 cm. Adjuvant chemotherapy was also detrimental in patients with poor performance status (Eastern Cooperative Oncology Group [ECOG] performance status = 2). These data suggest that adjuvant chemotherapy is best applied in patients with resected stage II or III NSCLC, with potential benefit for a select group of stage IB patients.

As with any treatment recommendation, the risks and benefits of adjuvant chemotherapy should be considered on an individual patient basis. If a decision is made to proceed with adjuvant chemotherapy, in general, treatment should be initiated 6–12 weeks after surgery, assuming the patient has fully recovered, and should be administered for no more than four cycles. Although cisplatin-based chemotherapy is the preferred treatment regimen, carboplatin can be substituted for cisplatin in patients who are unlikely to tolerate cisplatin for reasons such as reduced renal function, presence of neuropathy, or hearing impairment. A large cooperative group trial compared cisplatin-based chemotherapy with vinorelbine, pemetrexed, gemcitabine, or docetaxel with or without antiangiogenic therapy. The study found similar efficacy across all treatments. Therefore, no specific chemotherapy regimen is considered superior in this setting, and treatment selection may be based on cost and patient comorbidities.

From 2020 onward, systemic therapies, initially employed in the metastatic setting—such as targeted therapy and

immunotherapy—have been incorporated into the curative approach for patients with NSCLC (Table 83-10).

Osimertinib, an EGFR tyrosine kinase inhibitor (TKI), demonstrated improved disease-free survival in the adjuvant setting for patients with *EGFR* mutation (exon 19 deletion or L858R)–positive NSCLC treated for 3 years with or without chemotherapy; improved overall survival benefit with adjuvant osimertinib was also reported. Regulatory authorities including the U.S. FDA, the European Commission, and China's National Medical Products Administration have granted approval for adjuvant osimertinib in resected, stages IB–IIIA *EGFR*-mutant NSCLC. Furthermore, the exploration of additional targeted therapies in the adjuvant setting is ongoing, as seen for example in the phase 3 ALINA trial investigating oral alectinib for patients with *ALK* fusion oncogene–positive NSCLC. This highlights a dynamic landscape in the pursuit of enhanced treatment outcomes for patients with early-stage NSCLC.

TABLE 83-10 Select Therapeutic Strategies Incorporating Immunotherapy or Targeted Therapy In Early-Stage, Resectable Non-Small-Cell Lung Cancer (NSCLC)

TRIAL	STAGE AND DISEASE CHARACTERISTICS	REGIMEN	APPROVAL ENDPOINT
Neoadjuvant

Abbreviations: DFS, disease-free survival; EFS, event-free survival; EGFR, epidermal growth factor receptor; HR, hazard ratio; OS, overall survival; PD-L1, programmed death ligand 1.

Approved adjuvant immunotherapy regimens, using either atezolizumab or pembrolizumab, involve approximately 1 year of treatment following adjuvant chemotherapy. This treatment approach is supported by the disease-free survival benefit observed in the IMpower010 and KEYNOTE-091 trials. Notably, the association between treatment benefit and the level of PD-L1 expression varied.

Neoadjuvant chemotherapy, which is the application of chemotherapy administered *before* an attempted surgical resection, has been advocated by some experts on the assumption that such an approach will more effectively extinguish occult micrometastases compared to postoperative chemotherapy. In addition, there is thought that preoperative chemotherapy might render an inoperable lesion resectable. A meta-analysis of 15 randomized controlled trials involving >2300 patients with stage I–III NSCLC suggested there may be a modest 5-year survival benefit (i.e., ~5%) that is virtually identical to the survival benefit achieved with postoperative chemotherapy. Accordingly, neoadjuvant therapy may prove useful in selected cases (see below). A decision to use neoadjuvant chemotherapy should always be made in consultation with an experienced surgeon. Neoadjuvant immunotherapy combined with chemotherapy has gained approval for patients with stage IB–IIIA, resectable NSCLC, with neoadjuvant nivolumab plus chemotherapy for three cycles resulting in a pathologic complete response rate of 24% and statistically significant event-free survival benefit over chemotherapy alone (hazard ratio [HR] 0.63; $p = .005$) in the CheckMate 816 trial.

Various perioperative (i.e., before and after surgical resection) treatment strategies have been explored for patients with resectable NSCLC. This involves a neoadjuvant chemoimmunotherapy approach followed by adjuvant immunotherapy. A perioperative treatment approach with pembrolizumab in combination with chemotherapy has been approved for patients with stages II–IIIB, resectable NSCLC. This approval is based on the results of the KEYNOTE-671 phase 3 trial that demonstrated a significant overall survival and event-free survival benefit over preoperative chemotherapy alone.

All patients with resected NSCLC are at high risk of developing a second primary lung cancer or recurrence, most of which occur within 18–24 months of surgery. Thus, these patients should be followed with regular physical examinations and periodic imaging studies. Given the results of the NLST, periodic CT scans appear to be the most appropriate screening modality. Professional guidelines, such as those from the National Comprehensive Cancer Network (NCCN), recommend a chest CT scan every 3–6 months for the first 3 years after surgery, then every 6 months for 2 years, and then annually to monitor for recurrence.

MANAGEMENT OF STAGE III NSCLC

Management of patients with stage III NSCLC usually requires a combined-modality approach. Patients with stage IIIA disease commonly are stratified into those with "nonbulky" or "bulky" mediastinal lymph node (N2) disease. Although the definition of "bulky" N2 disease varies somewhat in the literature, the usual criteria include the size of a dominant lymph node (i.e., >2–3 cm in short-axis diameter as measured by CT), groupings of multiple smaller lymph nodes, evidence of extracapsular nodal involvement, or involvement of more than two lymph node stations. The distinction

between nonbulky and bulky stage IIIA disease is mainly used to select potential candidates for *upfront* surgical resection or for resection after neoadjuvant therapy. Many aspects of therapy of patients with stage III NSCLC remain controversial, and the optimal treatment strategy has not been clearly defined. Furthermore, because stage III disease is highly heterogeneous, no single treatment approach can be recommended for all patients. Key factors guiding treatment choices include the particular combination of tumor (T) and nodal (N) disease, the ability to achieve a complete surgical resection if indicated, and the patient's overall physical condition and preferences. For example, in carefully selected patients with limited stage IIIA disease where involved mediastinal lymph nodes can be completed resected, initial surgery followed by postoperative chemotherapy (with or without radiation therapy) may be indicated. By contrast, for patients with clinically evident bulky mediastinal lymph node involvement, the standard approach to treatment is concurrent chemoradiotherapy followed by a year of consolidation immunotherapy with durvalumab.

Absent and Nonbulky Mediastinal (N2, N3) Lymph Node Disease For the subset of stage IIIA patients initially thought to have clinical stage I or II disease (i.e., pathologic involvement of mediastinal [N2] lymph nodes is *not* detected preoperatively), surgical resection is often the treatment of choice. This is followed by adjuvant chemotherapy in patients with microscopic lymph node involvement in a resection specimen. Postoperative radiation therapy (PORT) may also have a select role for those with close or positive surgical margins. Patients with tumors exceeding 7 cm in size or involving the chest wall or proximal airways within 2 cm of the carina with hilar lymph node involvement (but not N2 disease) are classified as having T3N1 stage IIIA disease. They too are best managed with surgical resection, if technically feasible, followed by adjuvant chemotherapy if completely resected. Patients with T3N0 or T3N1 disease due to the presence of satellite nodules within the same lobe as the primary tumor are also candidates for surgery, as are patients with ipsilateral nodules in another lobe and negative mediastinal nodes (IIIA, T4N0 or T4N1). Although data regarding adjuvant chemotherapy in the latter subsets of patients are limited, it is often recommended.

Patients with T4N0-1 may have involvement of the carina, superior vena cava, or a vertebral body and yet still be candidates for surgical resection in selected circumstances. The decision to proceed with an attempted resection must be made in consultation with an experienced thoracic surgeon often in association with a vascular or cardiac surgeon and an orthopedic surgeon depending on tumor location. However, if an incomplete resection is inevitable or if there is evidence of N2 involvement (stage IIIB), surgery for T4 disease is contraindicated. Most T4 lesions are best treated with concurrent chemoradiotherapy followed by durvalumab.

The role of PORT in patients with completely resected stage III NSCLC is controversial. To a large extent, the use of PORT has historically been dictated by the presence or absence of N2 involvement and, to a lesser degree, by the biases of the treating physician. Using the SEER database, a meta-analysis of PORT identified a significant increase in survival in patients with N2 disease but not in patients with N0 or N1 disease. An earlier analysis by the PORT Meta-analysis Trialist Group using an older database produced similar results. However, two large, randomized phase 3 trials (PORT-C and Lung ART) have shown that PORT should not be routinely recommended as standard of care for patients given no improvement in disease-free survival and increased risk for cardiopulmonary toxicity.

Known Mediastinal (N2, N3) Lymph Node Disease When pathologic involvement of mediastinal lymph nodes is documented preoperatively, a combined-modality approach is recommended assuming the patient is a candidate for treatment with curative intent. These patients are at high risk for both local and distant recurrence if managed with resection alone. For patients with stage III disease who are not candidates for surgical resection, *concurrent* chemoradiotherapy is most commonly used as the initial treatment followed by durvalumab. Concurrent chemoradiotherapy has been shown to produce superior survival compared to *sequential* chemoradiotherapy; however, it also is associated with greater host toxicities (including fatigue, esophagitis, and neutropenia). Therefore, for patients with a good performance status, concurrent chemoradiotherapy is the preferred treatment approach, whereas sequential chemoradiotherapy may be more appropriate for patients with a performance status that is not as good. For patients who are *not* candidates for a combined-modality treatment approach, typically due to a poor performance status or a comorbidity that makes chemotherapy untenable, radiotherapy alone may provide a modest survival benefit in addition to symptom palliation.

For patients with potentially resectable N2 disease, it remains uncertain whether surgery after neoadjuvant chemoradiotherapy improves survival. In an NCI-sponsored Intergroup randomized trial comparing concurrent chemoradiotherapy alone to concurrent chemoradiotherapy followed by attempted surgical resection, no survival benefit was observed in the trimodality arm compared to the bimodality therapy. In fact, patients subjected to a pneumonectomy had a worse survival outcome. By contrast, those treated with a lobectomy appeared to have a survival advantage based on a retrospective subset analysis. Thus, in carefully selected, otherwise healthy patients with nonbulky mediastinal lymph node involvement, surgery may be a reasonable option if the primary tumor can be fully resected with a lobectomy. This is not the case if a pneumonectomy is required to achieve complete resection.

Advancements in neoadjuvant therapy, particularly in the realm of combination chemoimmunotherapy, have led to interest in exploring the benefits of such therapy for patients with N2 disease. The NADIM II phase 2 trial is an illustrative example that exclusively enrolled patients with stage IIIA–IIIB disease per American Joint Committee on Cancer eighth edition criteria; notably, two-thirds of these patients had N2 disease, including cases of multistation N2 disease. The trial demonstrated a pathologic complete response rate (pCR) of 36–42% with chemoimmunotherapy for patients with N2 disease, compared to 0–10% pCR rate for those who received neoadjuvant chemotherapy alone. Additionally, the study demonstrated the safety of a neoadjuvant chemoimmunotherapy approach in patients with N2 disease, without compromising the feasibility of surgical outcomes. Further investigation is warranted to better define the role of novel neoadjuvant therapeutic strategies for patients with N2 disease.

Superior Sulcus Tumors (Pancoast Tumors) Superior sulcus tumors represent a distinctive subset of stage III disease. These tumors arise in the apex of the lung and may invade the second and third ribs, the brachial plexus, the subclavian vessels, the stellate ganglion, and adjacent vertebral bodies. They also may be associated with Pancoast syndrome, characterized by pain that may arise in the shoulder or chest wall or radiate to the neck. Pain characteristically radiates to the ulnar surface of the hand. Horner's syndrome (enophthalmos, ptosis, miosis, and anhidrosis) due to invasion of the paravertebral sympathetic chain may be present as well. Patients with these tumors should undergo the same staging procedures as all patients with stage II and III NSCLC. Neoadjuvant chemotherapy or combined chemoradiotherapy followed by surgery is reserved for those without N2 involvement. This approach yields excellent survival outcomes (>50% 5-year survival in patients with an R0 resection). Patients with N2 disease are less likely to benefit from surgery and can be managed with chemoradiotherapy followed by durvalumab. Patients presenting with metastatic disease can be treated with radiation therapy (with or without chemotherapy) for symptom palliation.

SURGICAL MANAGEMENT OF NSCLC

Traditionally, in patients with NSCLC, the following have been relative contraindications to potential curative resection: extrathoracic metastases, superior vena cava syndrome, vocal cord and, in most cases, phrenic nerve paralysis, malignant pleural effusion,

cardiac tamponade, tumor within 2 cm of the carina (potentially curable with combined chemoradiotherapy), metastasis to the contralateral lung, metastases to supraclavicular lymph nodes, contralateral mediastinal node metastases (potentially curable with combined chemoradiotherapy), and involvement of the main pulmonary artery. In situations where it will make a difference in treatment, abnormal scan findings should be further investigated and require tissue confirmation of malignancy so that patients are not precluded from having potentially curative therapy. The role of surgical management of NSCLC continues to evolve, given emerging neoadjuvant/perioperative treatment strategies, and warrants multidisciplinary discussion.

MANAGEMENT OF METASTATIC NSCLC

Approximately 40% of NSCLC patients present with advanced, stage IV disease at the time of diagnosis. In addition, a significant number of patients who first presented with early-stage NSCLC will eventually relapse with distant disease. Patients who have recurrent disease have a better prognosis than those presenting with metastatic disease at the time of diagnosis. Standard medical management, the appropriate use of pain medications, and the pertinent use of radiotherapy and systemic therapy—which may consist of targeted therapy, immunotherapy, and/or traditional cytotoxic chemotherapy depending on the specific diagnosis as well as PD-L1 TPS and molecular subtype—form the cornerstone of management. Systemic therapy palliates symptoms, improves quality of life, and improves survival in patients with metastatic NSCLC, particularly in patients with good performance status. Of note, the early application of palliative care in conjunction with chemotherapy in patients with advanced NSCLC is associated with both improved survival and quality of life.

Targeted Therapies for Select Molecular Cohorts of NSCLC For a cohort of NSCLC patients, the presence of an oncogenic driver mutation allows the use of oral therapies with significant antitumor activity and improved survival compared to cytotoxic chemotherapy. These driver mutations occur in genes encoding signaling proteins that, when aberrant, promote the uncontrolled growth and metastasis of tumor cells. Importantly, driver mutations can serve as Achilles' heels for tumors, if their gene products can be targeted therapeutically with small-molecule inhibitors. All patients with advanced NSCLC should ideally undergo comprehensive molecular testing (i.e., multigene testing encompassing at least all biomarkers for which there are approved biomarker-matched therapies, including less common driver mutations) with broad panel-based testing techniques such as NGS as opposed to conventional, single-gene targeted testing strategies. Point mutations, insertions/deletions, chromosomal rearrangements (sometimes called "fusions"), and copy number variants have been reported in a number of genes including *ALK*, *BRAF, EGFR*, *ERRB2, KRAS, MET, NRAS, NRG1, NTRK, PIK3ca*, *RET*, and *ROS1,* with varying levels of clinical evidence. As our treatment armamentarium expands, knowledge of these mutations is critical for selection of appropriate therapy.

EGFR mutations have been detected in 10–15% of North American patients diagnosed with NSCLC. *EGFR* mutations are typically (but not exclusively) associated with younger age, light (<10 pack-year) and nonsmokers, and adenocarcinoma histology. Approximately 90% of these mutations are exon 19 deletions or exon 21 L858R point mutations within the EGFR tyrosine kinase domain, resulting in hyperactivation of both EGFR kinase activity and downstream signaling. Lung tumors that harbor activating mutations within the EGFR kinase domain display high sensitivity to small-molecule EGFR TKIs. Osimertinib, erlotinib, gefitinib, afatinib, and dacomitinib are FDA-approved oral small-molecule TKIs that inhibit EGFR. Several large, international, phase 3 studies have demonstrated improved response rates and progression-free survival in patients with *EGFR* mutation–positive NSCLC treated with an EGFR TKI as compared with standard first-line chemotherapy regimens (Table 83-11). Osimertinib was shown in a randomized phase 3 trial to have superior progression-free and overall survival in patients with *EGFR*-mutant NSCLC compared to earlier-generation EGFR TKIs (erlotinib or gefitinib) and to chemotherapy. Emerging combination strategies in the first-line setting, such as combining osimertinib with platinum-based chemotherapy, are also gaining traction. *EGFR* exon 20 insertion mutations are the third most common *EGFR* mutation. The anti-EGFR therapies described above are not approved for use in the context of tumors that harbor *EGFR* exon 20 insertion mutations. The current standard of care for *EGFR* exon 20–mutated lung cancer is a combination of platinum-based chemotherapy with amivantamab, which is an EGFR-MET bispecific antibody.

TABLE 83-11 Phase 3 Trials of EGFR TKIs in EGFR-Positive Non-Small-Cell Lung Cancer

TRIAL	THERAPY	NO. OF PATIENTS	ORR (%)	PFS (MONTHS)

Abbreviations: CbP, carboplatin and paclitaxel; CD, cisplatin and docetaxel; CG, cisplatin and gemcitabine; CP, cisplatin and paclitaxel; EGFR, epidermal growth factor receptor; ORR, overall response rate; PFS, progression-free survival; TKI, tyrosine kinase inhibitor.

HER2/ERBB2 mutations have also been detected in ~3% of nonsquamous NSCLC. HER2, like EGFR, is a member of the ERBB family of receptor tyrosine kinases. The most common *HER2* mutations in lung cancer encompass insertion variants within exon 20, which is part of the tyrosine kinase domain (so-called "exon 20 insertions"). The anti-HER2 monoclonal antibody-drug conjugate, trastuzumab deruxtecan, is approved for patients with previously treated, metastatic NSCLC harboring a mutation in HER2/ERRB2, with an objective response rate of ~50% and median progression-free survival of ~8 months.

Chromosomal Rearrangements in NSCLC Chromosomal rearrangements are found in ~10% of patients with NSCLC. Typically, although not exclusively, chromosomal rearrangements are associated with younger age, no smoking history, and adenocarcinoma histology. However, given the potential therapeutic impact, it is strongly recommended that all patients are tested. Given that the resultant fusion proteins include the entire tyrosine kinase domain, the most effective therapeutic strategy at this time is with TKIs.

TABLE 83-12 Results of Phase 3 Trials Comparing First-Line ALK Inhibitors in ALK-Positive NSCLC

Abbreviations: NSCLC, non-small-cell lung cancer; ORR, overall response rate; PFS, progression-free survival.

In NSCLC, chromosomal rearrangements involving the anaplastic lymphoma kinase (*ALK*) gene on chromosome 2 have been found in ~3–7% of patients with NSCLC. *ALK* rearrangements lead to hyperactivation of the ALK tyrosine kinase domain. Crizotinib is a first-generation ALK TKI, whereas alectinib, brigatinib, and ceritinib are second-generation ALK TKIs approved as first-line treatment options for patients with lung tumors harboring *ALK* rearrangements. Both alectinib and brigatinib have been found to have superior progression-free survival to crizotinib. Lorlatinib, a third-generation ALK TKI, is also approved for patients in the first-line setting and for patients who progress on a second-generation ALK TKIs **(Table 83-12)**. Unique adverse events of lorlatinib may include hyperlipidemia, weight gain, and cognitive effects. *ALK* testing may be performed via fluorescence in situ hybridization (FISH), immunohistochemistry (IHC), or NGS.

ROS1 fusions, detected by FISH or NGS, have been identified in ~1–2% of patients with NSCLC. Crizotinib, which inhibits both ROS1 and MET kinases, and the ROS1/TRK inhibitors entrectinib and repotrectinib have been FDA approved for patients whose tumors harbor a *ROS1* fusion. Entrectinib and repotrectinib offer improved blood-brain barrier penetration.

RET alterations typically occur as chromosomal rearrangements resulting in constitutive TKI activation. *RET* rearrangements may be detected by either FISH or NGS in ~1% of NSCLC patients. Analogous to capmatinib, pralsetinib and selpercatinib have demonstrated an excellent response rate; as many as 78–85% of treatment-naïve NSCLC patients with *RET* alterations responded.

NTRK fusions occur in members of the *NTRK* gene family (*NTRK1*, *NTRK2*, *NTRK3*) and result in constitutive protein kinase activation. *NTRK* fusions are rare, occurring in <1% of patients with NSCLC. Entrectinib and larotrectinib have demonstrated durable antitumor efficacy and are currently approved for *NTRK*-positive NSCLC.

Targeting the Mitogen-Activated Protein Kinase (MAPK) Pathway in NSCLC The MAPK pathway may be dysregulated in a subset of patients with NSCLC. For example, mutations within the *KRAS* GTPase are found in ~25% of lung adenocarcinomas, with mutations in *KRAS* G12C occurring in ~14% of adenocarcinomas. Agents targeting *KRAS* G12C such as adagrasib and sotorasib are now approved, with objective response rates of ~42 and ~37%, respectively. Defining mechanisms of acquired resistance to small-molecule inhibitors is a high research priority.

Oncogenic mutations in *BRAF* have been observed in ~2% of patients with NSCLC and, similar to *KRAS*, may serve as a key oncogene in the MAP kinase pathway. *BRAF* mutations may occur in both squamous and nonsquamous NSCLC and with an equal prevalence in patients with a history of smoking. This mutation is typically most targetable when it occurs at the 600th amino acid valine (V600). Combined inhibition with a BRAF and MEK inhibitor, dabrafenib plus trametinib or encorafenib with binimetinib, is a first-line or later therapeutic option in patients with *BRAF* V600–mutant NSCLC and appears to be superior to BRAF or MEK inhibition alone.

MET exon 14 skipping mutations have also been identified in ~3–5% of patients with NSCLC. Notably, *MET* exon 14 skipping mutations may occur in both squamous and nonsquamous NSCLC patients and those with a history of smoking. Pharmacologic inhibition of the overactive MET pathway with FDA-approved capmatinib or tepotinib resulted in response rates >70%, particularly in treatment-naïve NSCLC patients. A unique and challenging potential adverse event of oral MET inhibition with capmatinib and tepotinib is peripheral edema. All NCCN-supported targetable oncogenic driver mutations and potential therapeutic options are summarized in **Fig. 83-6**.

Immunotherapy Immune checkpoint inhibitors have significantly improved survival for a group of patients with locally advanced and metastatic NSCLC. These agents are used primarily in patients whose tumors do not express a targetable genetic lesion **(Fig. 83-7)**. Immune checkpoint inhibitors work by blocking interactions between T cells and antigen-presenting cells (APCs) or tumor cells that lead to T-cell inactivation. By inhibiting this interaction, the immune system is effectively upregulated and T cells become

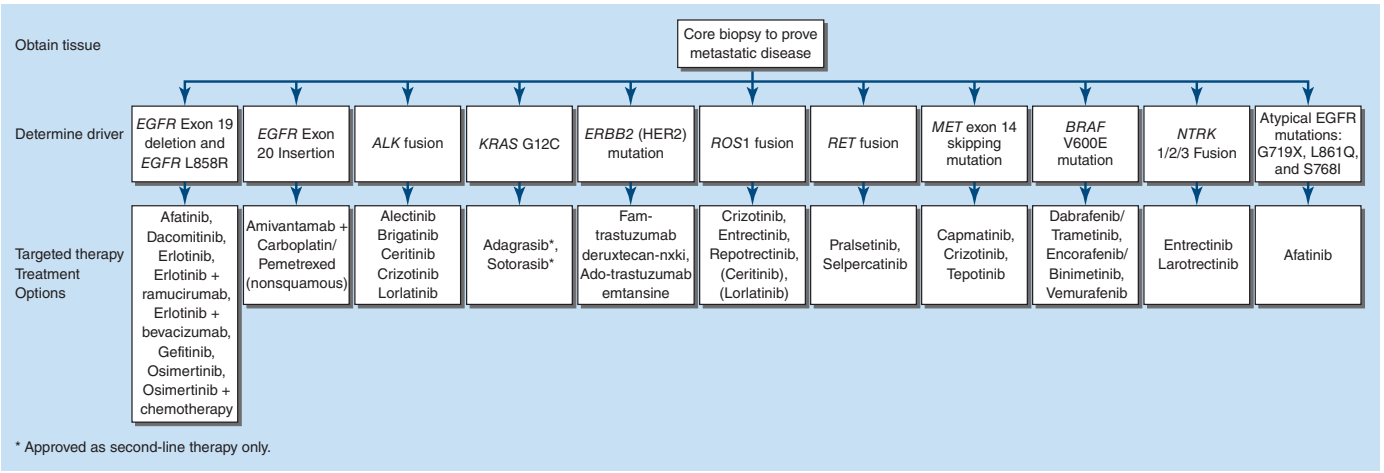

FIGURE 83-6 United States-centric approach to targeted therapy in non-small-cell lung cancer (NSCLC) based on drug approvals. Acknowledging regional variances in approvals. Drugs are listed alphabetically, not by author preference. Current as of June 2024.

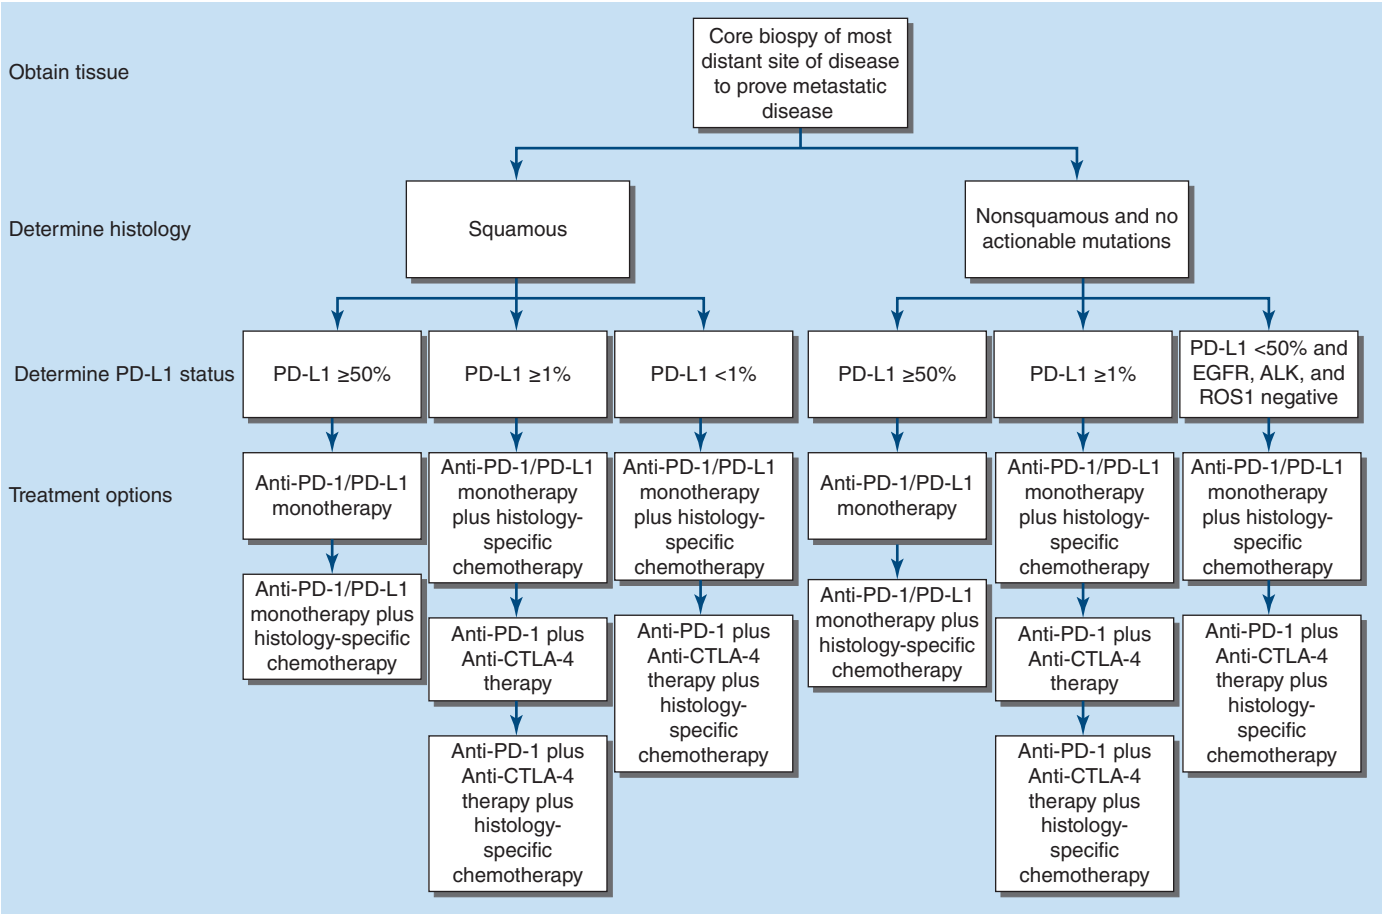

FIGURE 83-7 Approach to first-line therapy in a patient with stage IV, driver mutation–negative non-small-cell lung cancer (NSCLC).

activated against tumor cells. Several randomized studies have demonstrated superior overall survival in patients treated with pembrolizumab or atezolizumab monotherapy or nivolumab plus ipilimumab combination immunotherapy compared to chemotherapy in patients with metastatic NSCLC with PD-L1 expression in ≥50% of tumor cells (KEYNOTE-024, IMPOWER 110) and ≥1% of tumor cells (KEYNOTE-042, CheckMate 227) **(Table 83-13)**. The evidence supporting the use of single-agent immunotherapy in patients with tumor PD-L1 <50% remains unclear; current recommendations suggest the use of chemotherapy plus immunotherapy or immunotherapy combinations as the first-line treatment strategy in patients with metastatic NSCLC with tumor PD-L1 <50%. As discussed below, specific regimens vary by tumor histology (adenocarcinoma vs squamous cell carcinoma). Although PD-L1 has been identified as a biomarker that can predict response to immune checkpoint inhibitors, responses are observed in patients who do not appear to express the biomarker, and not all PD-L1-positive patients respond to checkpoint inhibition. Importantly patients with driver mutations such as *EGFR* and *ALK* appear to derive greater benefit from targeted therapy than immunotherapy and should be treated with a TKI, even in the presence of high PD-L1 expression. Further evaluation of these agents in the neoadjuvant and perioperative settings and combined with chemoradiotherapy is ongoing.

Cytotoxic Chemotherapy for Metastatic or Recurrent NSCLC

Cytotoxic chemotherapy is typically used in combination with immunotherapy as the initial treatment in patients with metastatic or recurrent NSCLC only when there is no contraindication to immunotherapy. Selected chemotherapy agents perform quite differently in squamous carcinomas versus adenocarcinomas. Patients with nonsquamous NSCLC have an improved survival when treated with cisplatin and pemetrexed compared to cisplatin and gemcitabine. By contrast, patients with squamous carcinoma have an improved survival when treated with cisplatin and gemcitabine. This survival difference is thought to be related to the differential expression between tumor types of thymidylate synthase (TS). Squamous cancers have a much higher expression of TS compared to adenocarcinomas, accounting for their lower responsiveness to pemetrexed. By contrast, the activity of gemcitabine is not impacted by the levels of TS.

Second-Line Therapy and Beyond Second-line therapy for advanced NSCLC relies on docetaxel; it improves survival compared to supportive care alone. Ramucirumab is a recombinant human IgG1 monoclonal antibody that targets VEGFR-2 and blocks the interaction of VEGF ligands and VEGFR-2. A phase 3 trial demonstrated a significant improvement in progression-free survival and overall survival when ramucirumab was combined with docetaxel as second-line therapy in patients who had progressed on platinum-based chemotherapy. Contrary to bevacizumab, ramucirumab was safe in patients with both squamous and nonsquamous NSCLC and is approved regardless of histology. Many new agents are being developed and tested in clinical trials for second-line and beyond therapy in the metastatic setting, including novel immune checkpoint agents, antibody-drug conjugates, and even cellular therapies. Improved therapies in this setting remain an area of great need for patients with lung cancer.

Supportive Care No discussion of the treatment strategies for patients with advanced lung cancer would be complete without a mention of supportive care. Coincident with advances in chemotherapy and targeted therapy was a pivotal study that demonstrated that the early integration of palliative care with standard treatment

strategies improves both quality of life and overall survival for patients with stage IV NSCLC **(Chaps. 13 and 74)**. Aggressive pain and symptom control are important components of optimal treatment of these patients.

TREATMENT

Small-Cell Lung Cancer

The overall treatment approach to patients with SCLC is shown in **Fig. 83-8**.

SURGERY FOR LIMITED-DISEASE SCLC

SCLC is a highly aggressive disease characterized by its rapid doubling time, high growth fraction, early development of disseminated disease, and dramatic response to first-line chemotherapy and radiation. In general, surgical resection is *not* routinely recommended for patients because even patients with LD-SCLC still have occult micrometastases. However, the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend surgical resection over nonsurgical treatment in SCLC patients with clinical stage I disease after a thorough evaluation for distant metastases and invasive mediastinal stage evaluation (grade 2C). After resection, these patients should receive platinum-based adjuvant chemotherapy (grade 1C). If the histologic diagnosis of SCLC is made in patients on review of a resected surgical specimen, such patients should receive standard SCLC chemotherapy as well.

CHEMOTHERAPY

In patients with limited-stage SCLC, concurrent chemoradiotherapy with cisplatin-etoposide for four cycles has remained standard of care for over 4 decades. Two randomized phase 3 trials have demonstrated that chemotherapy with either cisplatin or carboplatin plus either etoposide and a PD-L1 inhibitor, atezolizumab (IMPOWER 133) or durvalumab (CASPIAN), provides superior progression-free and overall survival compared to chemotherapy alone, making combination therapy the preferred choice in appropriate patients. Despite response rates to first-line therapy as high as 80%, the median survival ranges from 12 to 20 months for patients with LD and ~12 months for patients with ED. Regardless of disease extent, the majority of patients relapse and develop chemotherapy-resistant disease. The prognosis is especially poor for patients who relapse within the first 3 months of therapy; these patients are said to have *chemotherapy-resistant disease*. Patients are said to have *sensitive disease* if they relapse >3 months after their initial therapy and are thought to have a somewhat better overall survival. These patients also are thought to have the greatest potential benefit from second-line chemotherapy. Topotecan and lurbinectedin are FDA-approved agents for second-line therapy in patients with SCLC. Topotecan has only modest activity and can be given either intravenously or orally; it appears to have more efficacy in patients with chemotherapy-sensitive disease. Lurbinectedin has a 35% response rate and progression-free survival of 3.5 months, with a greater benefit in patients with chemotherapy-sensitive disease. Other agents with similar low levels of activity in the second-line setting include irinotecan, paclitaxel, docetaxel, vinorelbine, oral etoposide, and gemcitabine. The treatment of refractory SCLC is a pressing concern, prompting the investigation of various new targets and drugs. For example, at the time this chapter is being written, one of the most exciting advancements in SCLC is the development of delta-like ligand 3 (DLL3)-targeting agents. For example, in the phase 2 DeLLphi-301 study, tarlatamab, a bispecific T-cell engager immunotherapy targeting DLL3 and CD3, demonstrated a 40% objective response rate and a median progression-free survival of 4.9 months in the 10-mg group for patients with previously treated SCLC. Confirmatory evidence from the phase 3 study remains pending.

THORACIC RADIATION THERAPY

Thoracic radiation therapy (TRT) and concurrent chemotherapy with curative intent are standard for patients with limited-stage SCLC with suitable performance status. Without TRT, virtually

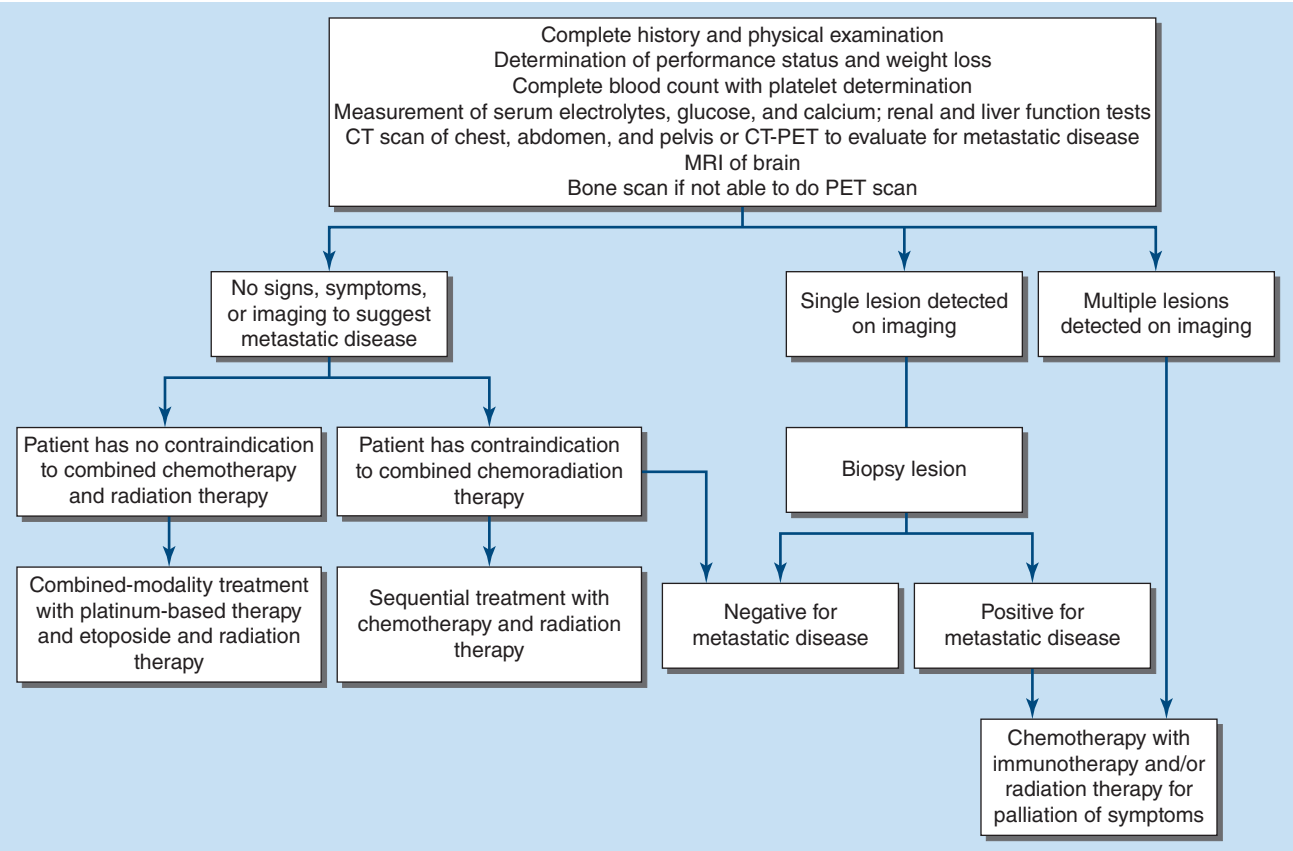

FIGURE 83-8 Algorithm for management of small-cell lung cancer. MRI, magnetic resonance imaging; PET, positron emission tomography.

all patients with limited-stage SCLC will progress on systemic therapy alone within 1 year. Meta-analyses indicate that chemotherapy combined with TRT improves 3-year survival by ~5% compared with chemotherapy alone. The 5-year survival rate, however, remains low at ~29–34%. Most commonly, TRT is combined with concurrent platinum and etoposide because of a better toxicity profile compared to anthracycline-based regimens. For limited-stage SCLC, concurrent chemoradiation is more effective than sequential chemoradiation but is associated with significantly more esophagitis and hematologic toxicity. Ideally, TRT should be administered by the second cycle of chemotherapy because later application appears slightly less effective. If for reasons of fitness or availability concurrent chemoradiation cannot be administered, TRT should follow induction chemotherapy in alignment with an extensive-stage SCLC paradigm. With respect to fractionation of TRT, twice-daily 1.5-Gy fractioned radiation therapy has been shown to improve survival in limited-stage SCLC patients but is associated with higher rates of grade 3 esophagitis and pulmonary toxicity. Patients should be carefully selected for concurrent chemoradiation therapy based on good performance status and adequate pulmonary reserve. The role of radiotherapy in ED-SCLC is mainly limited to palliation of tumor-related symptoms such as bone pain and bronchial obstruction. Notably, consolidation TRT has demonstrated a survival benefit in extensive-stage SCLC in prospective studies; however, translating these study findings into current clinical practice is challenging due to their completion before the introduction of immunotherapy in the first-line setting.

PROPHYLACTIC CRANIAL IRRADIATION

Prophylactic cranial irradiation (PCI) has historically been offered to all patients with SCLC without progression on initial treatment for limited-stage and extensive-stage disease. A meta-analysis including seven trials and 987 patients with limited-stage SCLC who had achieved a complete remission after upfront chemotherapy yielded a 5.4% improvement in overall survival for patients treated with PCI. However, the role of PCI has become controversial as these studies were conducted before brain MRIs for staging. In patients with ED-SCLC who have responded to first-line chemotherapy and had no CNS disease, patients randomized to observation had a higher incidence of brain metastases; however, use of PCI did not improve overall survival.

THYMIC TUMORS

Thymic tumors are rare malignancies, accounting for 0.5–1.5% of all malignancies in the United States with a higher incidence among Asian populations. They are particularly rare among children and young adults with incidence peaking in the fifth decade of life. There is no difference between sexes, and no clear risk factors have been identified.

CLINICAL MANIFESTATIONS

The majority of thymic tumors occur in the anterior mediastinum. Approximately 40% of patients with mediastinal masses will be asymptomatic with an incidental finding on chest imaging. In patients presenting with an anterior mediastinal mass, if appropriate, serum β-human chorionic gonadotropin (HCG) and α-fetoprotein (AFP) should be sent to rule out a germ cell tumor. A patient with a sign or symptom of thymoma or thymic carcinoma may present with chest pain, dyspnea, cough, or superior vena cava syndrome secondary to effects on adjacent organs or a paraneoplastic syndrome, most commonly myasthenia gravis, pure red cell aplasia, or hypogammaglobulinemia. More rare paraneoplastic syndromes include limbic encephalitis, aplastic anemia, hemolytic anemia, and autoimmune disease such as Sjögren's syndrome, polymyositis, rheumatoid arthritis, and ulcerative colitis, among others.

STAGING

Given the rarity of the tumor, patients with suspected thymoma should be evaluated by a multidisciplinary team including a surgeon, medical and radiation oncologist, and pathologist with experience in treating the disease. A CT scan of the chest with contrast is recommended to

TABLE 83-14 Staging Thymic Tumors	
MASAOKA STAGE	**DEFINITION**
I	Grossly and microscopically encapsulated
IIA	Microscopic transcapsular invasion
IIB	Macroscopic invasion into surrounding tissue excluding pericardium, lung, and great vessels
III	Macroscopic invasion into neighboring organs of the lower neck or upper chest
IVA	Pleural or pericardial dissemination
IVB	Hematogenous or lymphatic dissemination to distal organs
WHO	
A	Tumor with few lymphocytes
AB	Tumor with features of type A and foci rich in lymphocytes
B1	Tumor with features of normal epithelial cells with vesicular nuclei and distinct nucleoli and an abundant population of lymphocytes. Also known as cortical thymoma, lymphocyte-rich thymoma
B2	Thymoma with no or mild atypia with round or polygonal-shaped cells with small component of lymphocytes
B3	Well-differentiated thymic carcinoma with mild atypia
C	Thymic carcinoma with high atypia

determine if the mass is resectable based on relationship to surrounding structures. An MRI with contrast may be performed if clinically indicated. A PET scan may be useful in the evaluation of a patient with thymic tumors, although it may be less useful in the staging of thymoma compared to thymic carcinoma. A core needle biopsy is considered standard of care for obtaining a histologic diagnosis of an anterior mediastinal tumor. This may be obtained via CT or ultrasound imaging. However, in some circumstances, a mediastinoscopy or open biopsy may be required.

Thymomas are commonly staged using the Masaoka system or the WHO staging system, as described in Table 83-14. WHO types A, AB, and B1 tend to be more well-differentiated, types B2 and B3 are moderately differentiated, and type C is poorly differentiated.

TREATMENT

Surgical resection is the mainstay of treatment for patients with Masaoka type I and II thymic tumors. In patients with type III and IV who have potentially resectable thymic tumors, neoadjuvant chemotherapy may be given to decrease the tumor size and allow for a resection with negative margins. Surgery remains controversial and provides a limited role in the treatment of stage III and IV disease. No additional therapy may be required in patients with type I who have a resection with negative margins. Postoperative radiation therapy may be recommended based on extracapsular extension and the presence of positive margins in patients with type II or III thymic tumors or histologic evaluation WHO B3 and C. Radiation therapy may be beneficial in patients with locally advanced disease (type III or IV) or in patients with symptoms secondary to compression of surrounding structures. Chemotherapy with cisplatin, doxorubicin, and cyclophosphamide (CAP) remains the mainstay of therapy in the neoadjuvant and adjuvant setting as well as first-line therapy in patients with metastatic thymoma, whereas carboplatin and paclitaxel are often employed in patients with thymic carcinoma. Limited additional agents are recommended based on small phase 2 trials as second-line therapy and beyond.

SUMMARY

The management of SCLC and NSCLC has undergone major change in the past decade, resulting in a reduction in lung cancer mortality. For patients with early-stage disease, advances in radiotherapy and surgical procedures as well as new systemic therapies in the neoadjuvant and perioperative settings have greatly improved prognosis in all diseases. For patients with advanced lung cancer, major progress in understanding tumor genetics and tumor immunology has led to the development of rational targets and specific inhibitors, which have documented efficacy in specific subsets of NSCLC. Furthermore, increased understanding of how to activate the immune system to drive antitumor immunity has proven to be a successful therapeutic strategy for a subset of patients with advanced lung cancer. However, only a small subset of patients responds to immune checkpoint inhibitors, and the majority of patients treated with targeted therapies or chemotherapy eventually develop resistance, which provides strong motivation for further research and enrollment of patients onto clinical trials in this rapidly evolving area.

84 Breast Cancer

Nancy E. Davidson

Breast cancer is the most common nonskin cancer diagnosed in women in the world. In 2024, it is estimated that in the United States 310,000 women will be diagnosed with invasive breast cancer, >56,000 women will receive a diagnosis of ductal carcinoma in situ (DCIS), and about 42,250 women will die from breast cancer. Although largely a disease of women, about 2800 men will be diagnosed with and 530 men will die from breast cancer in 2024 in the United States. Thanks to advances in understanding of breast cancer biology, screening, diagnosis, treatment, and decreased use of hormone replacement therapy, 5-year relative survival in the United States is currently 91%. These advances have also made it possible to conceptualize the evolution of breast cancer and how available interventions can be applied across the continuum of changes to improve outcomes (Fig. 84-1).

EPIDEMIOLOGY AND RISK FACTORS

NONGENETIC RISK FACTORS

Female gender and increasing age are the most common risk factors for breast cancer. About 70% of breast cancer in the United States is diagnosed in women 55 years and older, and median age of diagnosis is 63. Incidence is highest in non-Hispanic whites followed by non-Hispanic blacks and is lower in Hispanic, Asian/Pacific Islander, and American Indian/Alaska Native women; in contrast, mortality is highest in non-Hispanic blacks followed by non-Hispanic whites and individuals of other race/ethnicity. Both incidence and mortality vary considerable around the globe, but studies of immigrant populations show that populations who migrate from low-incidence regions to high-incidence regions will attain the breast cancer risk of the higher incidence region within one or two generations.

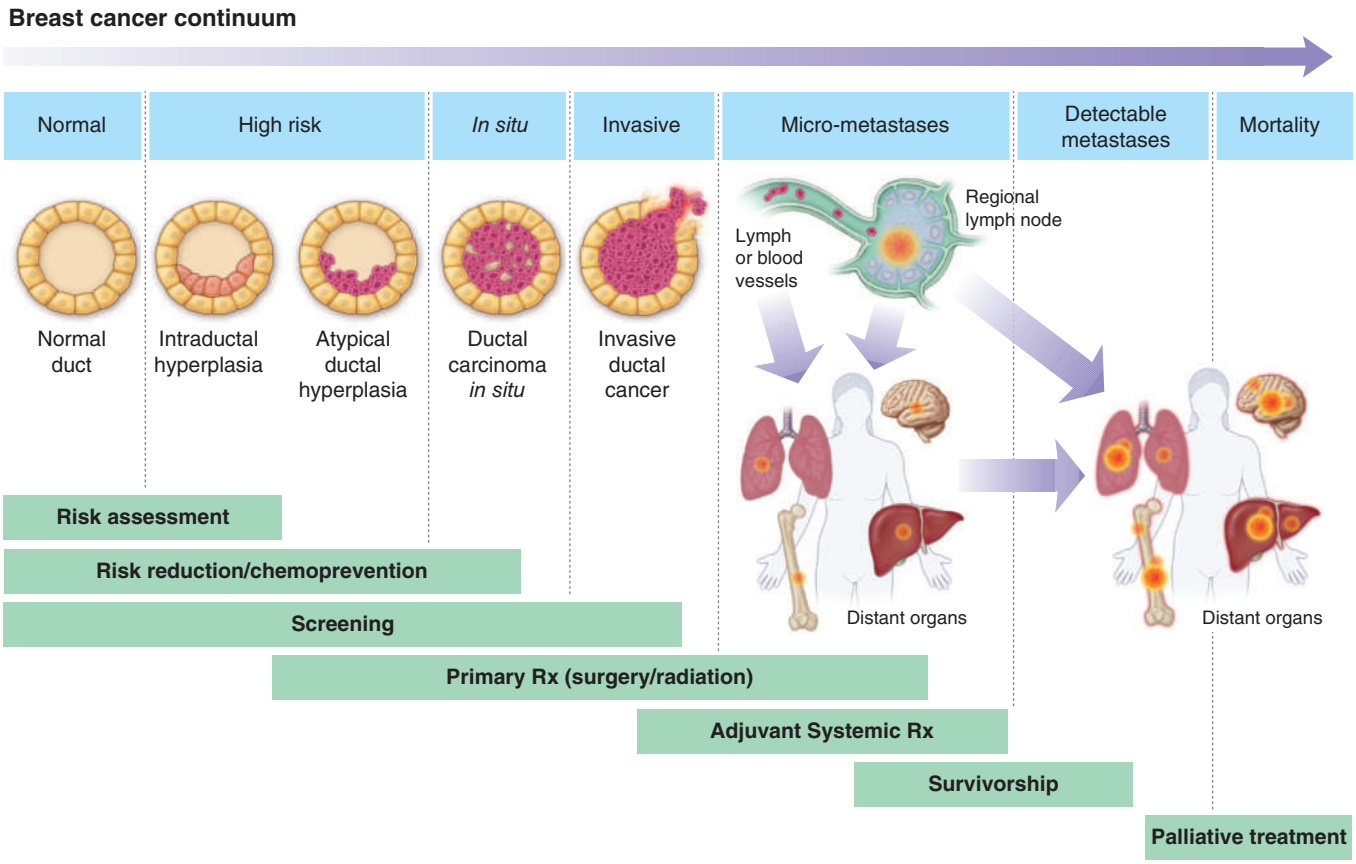

FIGURE 84-1 Breast cancer continuum conceptual model. Most breast cancers begin in epithelial cells within the lobules or ducts. They proceed through a continuum of atypia and hyperplasia to in situ malignancy to invasion into surrounding normal tissues followed by intravasation into lymph and blood channels to local lymph nodes and distant organs, culminating in distant metastases. This is a conceptual model. Not all metastatic breast cancers have progressed through these stages, and many lesions do not progress to the next.

Breast cancer is predominantly a disease resulting from prolonged exposure of the breast to estrogen. Thus, early menarche, late menopause, and late first pregnancy are known risk factors. Likewise, prolonged exposure to hormone replacement therapy (but paradoxically not estrogen replacement therapy) is associated with increased risk as is current use of oral contraceptives. Postmenopausal obesity (but not premenopausal obesity) is also a risk factor, likely because of increased estrogen exposure. Studies of diet and breast cancer risk have not been conclusive, but alcohol consumption is a risk factor.

The best documented exogenous risk factor for breast cancer is exposure to ionizing radiation during adolescence. Studies of other environmental factors such as pesticide or other chemical exposures have not been convincing.

Women diagnosed with some types of benign breast pathology also have a higher risk of subsequent invasive breast cancer diagnosis. In particular, the diagnosis of atypical ductal or lobular hyperplasia increases risk about four- to fivefold, whereas a diagnosis of lobular carcinoma in situ (LCIS) increases risk 7- to 12-fold. Recent studies also suggest that women with high breast density on mammography may be at increased risk of breast cancer.

GENETIC RISK FACTORS

Family history is a critical risk factor, although only 20% of women diagnosed with breast cancer have a family history. Diagnosis of breast cancer in a first-degree relative (parent, sibling, or daughter) doubles breast cancer risk. A personal diagnosis of previous invasive breast cancer also increases the risk of developing a new breast cancer in the ipsilateral or contralateral breast.

Prevention, diagnosis, and management of breast cancer have been revolutionized by the identification of a family of hereditary breast cancer susceptibility genes that account for 5–10% of breast cancers. These genes play a role in DNA damage repair, and inherited mutations, which are transmitted in an autosomal dominant fashion, generally lead to protein truncation and loss of function of DNA repair proteins. The most common mutations are in the *BRCA1* (located on chromosome 17q21) or *BRCA2* (located on chromosome 13q12) genes, and they impart a 50–80% risk of developing invasive breast cancer by age 80 years as well as a 30% risk of developing ovarian cancer. Germline mutations in other genes also lead to a higher risk of breast cancer including *TP53* (Li-Fraumeni syndrome), *PALB2*, *ATM*, *STK11* (Peutz-Jeghers syndrome), and *PTEN* (Cowden syndrome). Certain populations have a higher incidence of *BRCA* mutations, especially Ashkenazi Jews. Commercially available assays for germline, breast cancer susceptibility mutations have expanded from just the two originally discovered genes (*BRCA1/2*) to panels including these and the genes listed above to panels that include these and 20 or more additional genes. Two major concerns have arisen over time regarding the relative lack of clinical correlations inherent in these panels and the unknown association with risk, which have led to some confusion and discomfort among patients: (1) variants of unknown significance (VUS) in the genes known to be associated with increased risk; and (2) genes included in the panels about which little is known regarding clinical risk. Efforts to develop polygenic risk scores that evaluate single nucleotide polymorphisms (SNPs) in other genes are under study but are not yet ready for clinical application.

Testing for germline mutations is readily done using panel testing on DNA obtained from peripheral blood or saliva after appropriate counseling. It is not recommended for the general population. Evidence-based guidelines from the American Society of Clinical Oncology and Society of Surgical Oncology recommend consideration of testing for high-penetrance breast cancer susceptibility genes in individuals with a personal history of breast cancer with specific features including diagnosis ≤65 years. Older patients should be offered testing for clinical features such as Ashkenazi Jewish ancestry; multiple breast cancers; certain types of breast cancer, including breast cancer lacking expression of the estrogen and progesterone receptors and HER2 proteins

(triple-negative breast cancer [TNBC]) and lobular breast cancer with personal or family history of diffuse gastric cancer; or close blood relative with early-onset or male breast cancer, ovarian cancer, pancreatic cancer, or metastatic prostate cancer. Testing for individuals without a cancer diagnosis should be considered for those with a family member who tests positive or those with a family history as outlined above or those with higher risk based on existing risk assessment tools such as Tyrer-Cuzick score, BRCAPro, or CanRisk.

PREVENTION

Current strategies to prevent breast cancer include surgery, chemoprevention, and lifestyle modification; their use and impact will vary depending on the underlying risk of developing breast cancer.

PROPHYLACTIC SURGERY

Prophylactic mastectomy reduces risk of developing breast cancer by about 90% including in individuals who carry a germline breast cancer susceptibility gene mutation. Women who opt for prophylactic mastectomy in this setting should be counseled that breast cancer may develop in residual breast tissue. However, preventive mastectomy is not likely to improve outcomes in women with low or only modest risk and should be discouraged. Though the primary role for prophylactic oophorectomy is for ovarian cancer prevention in germline mutation carriers, it can also reduce breast cancer incidence in premenopausal women by about 50% because of reduction in estrogen exposure.

CHEMOPREVENTION

Ample evidence exists for the use of chemoprevention approaches that target estrogen signaling pathways in high-risk women. Tamoxifen reduces risk of invasive breast cancer in women at higher risk (≥60 years, diagnosis of LCIS, or younger women with risk of developing invasive breast cancer ≥1.67% over 5 years based on current risk assessment tools). Newer data suggest that low-dose tamoxifen for 3 years may be effective and well tolerated. Side effects include postmenopausal symptoms and increased risk for endometrial cancer and thromboembolic events, especially in women over 50. Raloxifene may be an alternative for postmenopausal women. Though less effective in reducing breast cancer risk than tamoxifen, it is associated with fewer uterine cancers. The aromatase inhibitors, exemestane or anastrozole, also reduce breast cancer incidence by about 50% in postmenopausal women who are at moderate-high risk for breast cancer. The U.S. Preventive Services Task Force recommends that clinicians offer risk-reducing medications like tamoxifen, raloxifene, or aromatase inhibitors to women who are at increased risk for breast cancer and at low risk for medication side effects. Uptake is low despite the substantial evidence that demonstrates a huge benefit.

LIFESTYLE MODIFICATION

Potential lifestyle modifications to reduce breast cancer risk include maintenance of a normal body mass index, avoidance of alcohol, and minimizing use of hormone replacement therapy. Regular exercise, especially during adolescence, may be associated with reduced risk. Long-term follow-up from the dietary substudy of the Women's Health Initiative showed that a low-fat diet in postmenopausal women who were cancer-free at the time of study enrollment resulted in a nonsignificant reduction in breast cancer incidence but appeared to reduce risk of death from breast cancer. The role of newer GLP-1 agents has not been studied.

SCREENING

Breast cancer screening has been an area of active investigation and controversy for decades. Issues include lack of consensus around the goal of screening, the target population (e.g., age, risk), and the type and frequency of screening. Multiple guidelines exist and continue to evolve. Initial trials focused on three modalities: breast self-exam, clinical breast exam (CBE), and mammography. Though widely promoted in the past, emphasis on breast self-exam has waned, in part because of two randomized clinical trials in China and Russia that showed no benefit. In contrast, a randomized trial in India of CBE every 2 years in women aged 35–64 years with no history of breast cancer indicated that CBE led to a significant reduction in the proportion of women diagnosed with stage III or IV disease and a nonsignificant 15% reduction in breast cancer mortality, largely in women ≥50 years.

Nine randomized trials have studied screening mammography. In aggregate, they demonstrated that screening mammography reduced breast cancer mortality by about 20–25% in women ≥50 years without an impact on overall mortality. The UK Age trial suggested a similar benefit for women who began screening at 40 years. Screening frequency has varied from 1–2 years across trials. Mammography techniques have evolved over the years, and a current U.S. trial is evaluating the role of tomosynthesis as a means of improving benefit from mammography. Multiple guidelines exist and continue to evolve. Most recommend that women aged 50–70 years have mammography every 1–3 years, and many recommend screening for women aged 40–50 years as well. When to stop is not known, but it is generally accepted that benefits are limited to women with a predicted life expectancy of at least 10 years.

The role of magnetic resonance imaging (MRI) as a screening modality is less well studied. MRI is more sensitive, less specific, and more complex to perform. Some guidelines suggest that it be used for women who have a lifetime predicted risk of ≥20%, which includes those with germline pathogenic mutations in the *BRCA* genes. Its use has also been suggested for those with very dense breasts on mammography, but clear evidence of benefit is lacking. Screening ultrasound has also been studied, but evidence supporting its routine use is lacking.

There is considerable interest in the use of multicancer early detection (MCED) tests using circulating DNA as a screening test for diseases like breast cancer. Initial studies have not shown that these tests can substitute for or augment conventional mammographic screening, and women who do have MCED assays performed should still undergo mammographic screening, even if the MCED test is negative.

DIAGNOSIS AND STAGING

Clinical signs and symptoms suggestive of breast cancer may include a breast lump or skin or nipple changes or palpable regional nodes. Thanks to mammographic screening, many patients present with abnormal mammographic findings including a mass, distortion, and/or suspicious microcalcifications without any symptoms or physical exam findings. **Figure 84-2** shows an algorithm for diagnostic evaluation of breast abnormalities noted on physical exam or imaging. Final diagnosis rests on pathologic confirmation, which is generally carried out by image-guided core biopsy to confirm diagnosis, assess tumor grade and morphology, and carry out biomarker evaluation for expression of estrogen receptor (ER) and progesterone receptor (PR) and HER2 proteins and potentially HER2 gene amplification. Suspicious axillary lymph nodes should also be biopsied via image-guided techniques. It is important to image both breasts because up to 3% of women with newly diagnosed breast cancer have unsuspected contralateral disease. Evaluation of the breasts with MRI after a biopsy-proven diagnosis is controversial. On the one hand, MRI is more sensitive than radiologic mammography and will commonly detect previously unidentified disease. On the other hand, this observation may lead to additional surgery, including mastectomy, without obvious improvements in outcomes.

Staging is a cornerstone for breast cancer management because it provides information about natural history and informs decisions about therapy. The traditional TNM (tumor-node-metastasis) staging system has evolved to consider molecular testing including biomarkers as above and certain genomic tests such as the Oncotype 21 gene assay. Staging may take place at time of diagnosis (c or clinical staging) or after surgery (p or pathologic staging) or after preoperative systemic therapy followed by surgery (designated with a "y" prefix). For most asymptomatic individuals presenting with early breast cancer, a careful history and physical exam will be sufficient, and testing can be limited to breast imaging and any testing needed to ensure a safe surgical procedure. Individuals who present with symptoms suggestive of metastatic disease or physical findings of more advanced disease (e.g., large

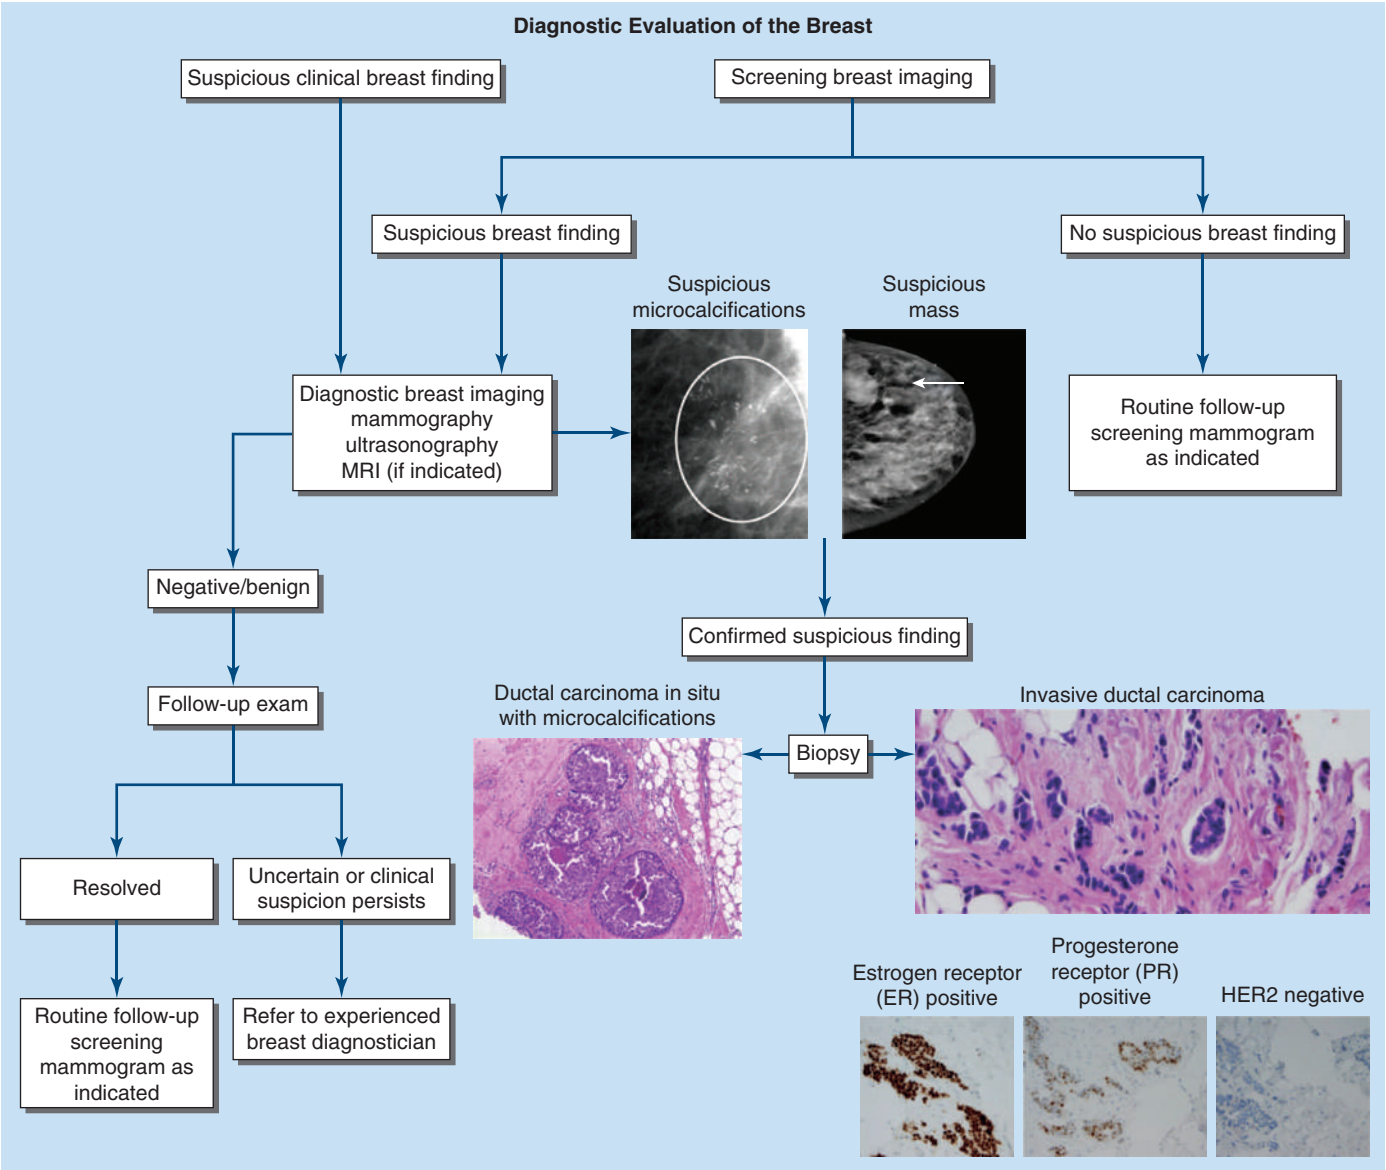

FIGURE 84-2 Evaluation and workup of breast lesions. For more extensive details, see *https://www.nccn.org/professionals/physician_gls/pdf/breast-screening.pdf. (Mammographic images courtesy of Drs. Mark Helvie and Colleen Neal, Department of Radiology, Michigan Medicine. Photomicrographs courtesy of Dr. Celina Kleer, Department of Pathology, Michigan Medicine.)*

tumor, skin changes, extensive regional adenopathy) should undergo radiologic imaging with computed tomography and radionuclide scanning to look for overt metastatic disease. Suspicious lesions should be biopsied whenever possible to confirm a diagnosis of metastatic breast cancer because of the implications for prognosis and selection of therapy. Less than 10% of patients present with de novo metastatic breast cancer.

Breast cancer staging is currently carried out according to the guidelines of the American Joint Committee on Cancer (AJCC) eighth edition. Conceptually, stages I and II represent early-stage disease, which is confined to breast and ipsilateral nodes, whereas stage III comprises locally advanced breast cancer and stage IV denotes de novo metastatic breast cancer, designated as M1 in the current staging system. Common sites for breast cancer metastasis include soft tissues, lung, bone, liver, and brain. One study suggested that M1 disease can be further divided into at least four subgroups with substantially different prognoses, based on sites and burden of disease as well as biological features. However, these findings have not yet been incorporated into the formal AJCC staging system. Outcomes are directly related to stage at presentation and vary by race and ethnicity in the United States, as shown in Table 84-1.

CURRENT UNDERSTANDING OF BREAST CANCER BIOLOGY AND CLINICAL IMPLICATIONS

It is now accepted that invasive breast cancer is in fact a disease with diverse subtypes, both histologic and molecular. Two decades of molecular analyses have documented multiple transcriptional, epigenetic, and genetic changes that characterize invasive breast cancer.

TABLE 84-1 Five-Year Breast Cancer Relative Survival Rate (%) by Stage at Diagnosis and Race/Ethnicity in United States from 2012–2018[a]

This has led to the division of invasive breast cancer into at least four major molecular subtypes. Luminal A and B subtypes both express ER and are viewed as generally likely to be responsive to antiestrogen strategies (also called hormonal or endocrine therapies). However, luminal B tumors are characterized by other findings such as reduced PR expression or increased proliferation, usually measured by expression of Ki67, and are associated with a poorer outcome than luminal A tumors. The HER2 subtype expresses HER2 protein at high levels and is more likely to benefit from the use of HER2-targeted therapies. Basal tumors tend to lack expression of ER, PR, and HER2 proteins (TNBC). TNBCs carry a poorer prognosis and are generally managed with chemotherapy and immunotherapy. TNBC can be further divided into at least six subtypes, which may also have therapeutic implications, especially in the metastatic setting.

Pathologic evaluation of a breast cancer specimen begins with an assessment of morphology. Most invasive breast cancers are ductal, but about 10–15% are lobular histologies. Lobular cancers are usually ER positive and HER2 negative. They are distinguished by absence of E-cadherin staining or function, and they have a different natural history, with a propensity to spread to serosal surfaces, including omentum, pleura, and meninges or to various parenchyma, such as ovaries and upper and lower gastrointestinal tracts. This curious site for metastatic recurrence may result in unusual clinical presentations that may delay diagnosis if metastatic disease is not considered. Other special subtypes are also recognized such as mucinous, medullary, papillary, and metaplastic histologies. Mucinous and pure medullary cancers (distinguished by high levels of lymphocytic invasion surrounding the tumor) are associated with very favorable prognoses with local therapy only. Metaplastic cancers may present as very poorly differentiated tumors or even as squamous or sarcomatoid differentiations. They are generally approached as ductal cancers but may be treated in a manner consistent with their relative subtypes, such as squamous or sarcoma-like differentiation. Tumor grade is also assessed using standard approaches such as Nottingham grade, ranging from grade 1 to 3; higher grade is generally associated with poorer prognosis.

Further profiling of the primary tumor specimens may follow depending on the clinical circumstances. Early-stage ER-positive breast cancers are often evaluated by genomic transcriptional profiling assays to identify patients with such a favorable prognosis that adjuvant chemotherapy in addition to endocrine therapy is not needed; five of these are recommended by the American Society of Clinical Oncology: Oncotype Dx (21 genes), MammaPrint (70 genes), ProSigna (50 genes), EndoPredict (12 genes), and Breast Cancer Index (two genes plus a proliferation signature). Although any one of these appears to be relatively accurate in terms of prognosis, they do not measure the same thing and they have not been compared head-to-head. Therefore, ordering more than one assay for a single case is discouraged. At present, more detailed molecular analysis is usually restricted to metastatic tumor specimens to identify molecular alterations that are associated with response to specific targeted therapies, as discussed in the section on treatment of metastatic breast cancer.

TREATMENT

Breast Cancer

MANAGEMENT OF IN SITU BREAST CANCER

Ductal Carcinoma In Situ (DCIS) Routine use of screening mammography has led to a marked increase in the diagnosis of DCIS and LCIS. Untreated DCIS (which is confined to the duct without evidence of invasion through the basement membrane into surrounding interstitial tissue) is associated with a 30% risk of developing a subsequent invasive cancer in the same breast. Therapy is generally focused on excision of the lesion to negative margins and to confirm absence of invasion; evaluation of axillary lymph nodes is not generally undertaken. Excision may be followed by radiotherapy to the ipsilateral breast and consideration of endocrine therapy if the DCIS expresses ER protein to reduce risk of breast recurrence or contralateral primary. Patients with extensive DCIS may require mastectomy, whereas those with a small disease burden may opt for excision alone with regular mammographic surveillance. Molecular assays that can predict lack of benefit from radiotherapy after excision are sometimes used.

Lobular Carcinoma In Situ (LCIS) LCIS is often an incidental finding on a breast biopsy done for abnormalities on physical exam or mammography. It is viewed as a marker for increased risk of developing invasive breast cancer as about 25–30% of women with LCIS subsequently develop invasive disease in either breast. The primary management is continued breast cancer screening and consideration of chemoprevention with tamoxifen or aromatase inhibitor to decrease risk of invasive disease. Bilateral prophylactic mastectomy is sometimes considered but should be generally limited to those who have other risk factors or concerns.

TREATMENT OF EARLY-STAGE BREAST CANCER

Multidisciplinary care is a cornerstone for optimal treatment of early breast cancer. The current approach to treatment of early-stage breast cancer reflects evolution from the initial concept of breast cancer as an orderly disease that spreads from breast to axillary nodes to systemic disease to our current understanding of breast cancer as a potentially systemic disease almost from onset. Therefore, treatment approaches incorporate surgery and radiation to treat local disease and systemic therapy to eliminate or suppress any microscopic distant disease. The goal of these treatments in early-stage disease is reduction of subsequent distant recurrence and mortality. They are given in a manner to optimize efficacy while minimizing toxicity and avoiding overtreatment.

Surgery Six randomized trials have demonstrated equivalent survival with the use of breast-conservation therapy (lumpectomy and, usually, radiotherapy to the remaining breast) or modified radical mastectomy for individuals with early-stage breast cancer. Contraindications to breast conservation include patient preference, poor cosmesis, multifocal disease, previous chest radiation, and ongoing pregnancy that prevents timely administration of radiotherapy. Though not an absolute contraindication, germline mutation in a member of the *BRCA* gene family can drive a decision for bilateral mastectomy because of the high risk of subsequent disease in either breast. Patients who require or choose mastectomy should be informed about availability of immediate or delayed reconstruction options using autologous tissue or implants as clinically appropriate. It is clear, though, that most women with early breast cancer are well served by a lumpectomy to negative margins with axillary management, followed by radiation as appropriate.

Management of the ipsilateral axilla continues to evolve as well. For patients with small tumors and clinically negative axillary nodes, sentinel node localization is used to identify clinically relevant nodes for removal and pathologic assessment to finalize staging and inform decisions about extent of radiotherapy and selection of adjuvant systemic therapy. Use of axillary dissection (removal of level 1 and 2 lymph nodes) is restricted to individuals with palpable lymph nodes or those with substantial pathologic involvement of sentinel lymph nodes. Randomized trials have shown excellent outcomes with omission of any sentinel node evaluation for older women with small biologically favorable tumors and clinically negative axilla who will take adjuvant endocrine therapy as well as omission of axillary dissection for women with low tumor burden in sentinel nodes who will receive radiation.

Radiation As with surgery, the use of postoperative radiotherapy to minimize breast recurrence and nodal recurrence has also changed as a result of data accumulated from serial clinical trials. Current treatment strategies are tailored to the individual based on age, tumor size, and nodal status. Options for external-beam radiotherapy include a standard scheme of daily whole breast radiotherapy (WBR) for 4–6 weeks, hypofractionated schedules lasting 5 days to 3 weeks, or partial breast radiation, usually given in

a hypofractionated regimen. Clinical trials of the latter have failed to demonstrate its benefit over WBR. Extension of the radiotherapy port to include regional and axillary nodes is also considered based on pathology and type of surgery. The safety of omitting radiotherapy for women older than 65 with low-risk ER-positive tumors who will take endocrine therapy has been demonstrated. Brachytherapy to apply a radiation source directly to the tumor bed is also employed in some cases as a way of shortening duration of therapy.

Patients who undergo mastectomy may also benefit from chest wall radiotherapy to reduce risk of both local and distant recurrence, thus improving survival. Potential candidates include those with large tumors or positive axillary lymph nodes, especially those with four or more involved nodes, while those with one to three positive nodes or close/minimally involved margins are also considered.

Systemic Therapy It has been recognized that breast cancer is often a systemic disease at time of diagnosis. Enhanced understanding of breast cancer biology, including the concept that resistant clones evolve as a function of random mutations over time, and the identification of multiple targets of therapy have greatly refined our understanding of the role of systemic therapy in early breast cancer. Such therapy may be given preoperatively (neoadjuvant) or postoperatively (adjuvant) and may take the form of cytotoxic chemotherapy, endocrine therapy directed toward ER, and other targeted therapies such anti-HER2, poly (ADP-ribose) polymerase (PARP) inhibitors in cancers with *BRCA1/2* mutations, and/or immunotherapy directed toward immune checkpoints. Treatment algorithms are constantly evolving based on results from clinical trials, and current evidence-based guidelines are available through groups like the National Comprehensive Cancer Network, American Society of Clinical Oncology, or European Society of Medical Oncology.

SELECTION OF NEOADJUVANT VERSUS ADJUVANT SYSTEMIC THERAPY

The primary goal of neoadjuvant therapy (also designated "preoperative" adjuvant therapy) compared to classic postoperative adjuvant therapy is to downsize tumor to make it more amenable to surgery. A second goal is to provide an in vivo assessment of tumor response to the selected systemic therapy and perhaps direct subsequent adjuvant therapy. Data suggest that individual patients who attain a complete pathologic response (pCR) to neoadjuvant therapy have a better outcome than those who do not, although randomized trials of adjuvant versus neoadjuvant therapy have not shown a difference in survival. At least one trial has demonstrated that patients who fail to experience a pCR to standard combination chemotherapy containing an anthracycline, an alkylating agent, and a taxane, especially those with TNBC, appear to benefit from subsequent capecitabine. Currently, neoadjuvant therapy with chemotherapy and anti-HER2 agents is considered for individuals with HER2-positive tumors that are ≥2 cm or node-positive disease, while neoadjuvant therapy with chemotherapy and possibly the checkpoint inhibitor pembrolizumab are considered for individuals with TNBC ≥2 cm or node-positive disease. Neoadjuvant endocrine therapy can be used for postmenopausal women with ER- or PR-positive breast cancer to reduce extent of surgery or perhaps avoid surgery for older women with multiple comorbidities. Women with small tumors of any subtype are often better served by initial surgery to establish pathologic stage followed by tailored selection of systemic therapy.

Types of Systemic Therapy for Early Breast Cancer Endocrine therapy is a mainstay for management of ER- and/or PR-positive invasive breast cancer; positive tumors are commonly defined as those with ≥1% staining by immunohistochemistry. Because of their mechanisms of action as blockers of interaction between estrogen ligand and ER, the selective ER modulators tamoxifen and toremifene can be used in women with any menopausal status. In contrast, estrogen deprivation approaches depend on menopausal status. The use of aromatase inhibitors, such as anastrozole, letrozole, and exemestane, as monotherapy is restricted to postmenopausal women. Ovarian suppression by gonadotropin hormone–releasing hormone (GnRH), such as the luteinizing hormone–releasing hormone (LHRH) agonists goserelin or leuprolide, or alternatively surgical oophorectomy, can be used to reduce circulating estradiol levels in premenopausal women to postmenopausal levels. These women can then also be treated either with tamoxifen or an AI. The CDK4/6 inhibitors abemaciclib and ribociclib may be used in combination with endocrine therapy for high-risk, early-stage, ER-positive breast cancer.

Multiple cytotoxic agents have shown efficacy for treatment of metastatic breast cancer and are now used in treatment of early-stage disease. The most common regimens include cyclophosphamide, doxorubicin, paclitaxel, docetaxel, 5-fluorouracil, methotrexate, and/or one of the platin salt compounds (cisplatin or carboplatin).

Several anti-HER2 therapies are also available. Two monoclonal antibodies, trastuzumab and pertuzumab, and two tyrosine kinase inhibitors, neratinib and lapatinib, are approved for use in early-stage breast cancer; multiple other agents are available for metastatic disease, as discussed below, and are undergoing testing for use in earlier stages of disease.

The role of immunotherapy with the checkpoint inhibitors is also under evaluation. At present, pembrolizumab for patients with TNBC is the only U.S. Food and Drug Administration (FDA)-approved agent for early-stage breast cancer, but others are under investigation.

A targeted agent, olaparib, an oral PARP inhibitor, is also used as an adjunct to chemotherapy for women with high-risk, germline *BRCA*-mutated, HER2-negative breast cancer who have completed (neo)adjuvant chemotherapy. It is particularly active in cancers with DNA repair pathway defects.

GENERAL GUIDELINES FOR (NEO)ADJUVANT SYSTEMIC THERAPY FOR EARLY BREAST CANCER

Approach to ER- and/or PR-Positive Breast Cancer Endocrine therapy is the foundation for adjuvant therapy for women with ER- and/or PR-positive breast cancer. Selection is based on menopausal status and consideration of side effect profiles. For premenopausal women with low-risk breast cancer, tamoxifen for 5–10 years is the standard. Premenopausal women with higher risk tumors are candidates for combined endocrine therapy with an LHRH agonist plus tamoxifen or aromatase inhibitor for 5 years. Multiple randomized trials have shown that aromatase inhibitors for 5 years provide modest but statistically significant superior outcome compared with tamoxifen for postmenopausal women. Women with ER-positive breast cancers are at risk for distant recurrence long after their original diagnosis, from 10–20 or more years. Some trials suggest that up to 10 years of endocrine therapy may be indicated for healthy postmenopausal women with higher risk tumors and good tolerance.

Given the chronic nature of adjuvant endocrine therapy, careful attention to side effects is warranted. Tamoxifen is associated with postmenopausal symptoms and a small chance of thromboembolic events or uterine cancer, especially in women over 50 years. Aromatase inhibitors are associated with postmenopausal symptoms, arthralgias, and bone loss, while LHRH agonists are associated with postmenopausal symptoms and bone loss. Although the three aromatase inhibitors appear to be equally effective, tolerance may vary; patients who are intolerant of one aromatase inhibitor may benefit from change to another member of the family or tamoxifen.

A critical decision in this setting is the value of chemotherapy in addition to endocrine therapy. Its absolute (as opposed to relative or proportional) benefit varies by menopausal status and nodal status. Genomic multigene expression testing of the tumor with assays like Oncotype, MammaPrint, ProSigna, EndoPredict, or Breast Cancer Index will identify a substantial portion of patients with zero to three positive nodes who would not benefit from adjuvant chemotherapy.

Neoadjuvant chemotherapy should be administered to healthy individuals with a large tumor burden or more than three positive nodes, especially premenopausal patients with a primary goal of reducing tumor size. However, in ER-positive disease, the likelihood of a pCR is low. Regardless, adjuvant chemotherapy (neoadjuvant or standard) is considered for healthy individuals with four or more positive lymph nodes as well as for those with lesser nodal burden who have high genomic signature score. Established chemotherapy regimens are outpatient based and use multiple agents for 3–6 months with appropriate supportive care including antiemetics and colony-stimulating factors as appropriate to reduce risk of febrile neutropenia. Long-term side effects can include premature menopause in premenopausal women and a small risk of doxorubicin-related cardiomyopathy, taxane-related peripheral neuropathy, or secondary leukemia, and possible cognitive dysfunction.

Women with node-positive or high-risk node-negative, ER- and/or PR-positive, HER2-negative breast cancer who have completed adjuvant chemotherapy should consider use of a CDK4/6 inhibitor in conjunction with endocrine therapy. Current information supports the use of abemaciclib for 2 years or ribociclib for 3 years; addition of palbociclib for 2 years did not improve outcomes. Those with HER2-negative germline *BRCA*-mutated breast cancer who have received (neo)adjuvant chemotherapy should consider a year of oral olaparib. When used in conjunction with chemotherapy or anti-HER2 therapy, endocrine therapy is generally delayed until completion of adjuvant chemotherapy to minimize toxicity.

Approach to HER2-Positive Breast Cancer Healthy individuals with tumor ≥3 cm or positive lymph nodes are candidates for neoadjuvant therapy with multiagent chemotherapy and trastuzumab with or without pertuzumab for 4–5 months. Those who achieve a pCR should receive further trastuzumab with or without pertuzumab therapy to complete a year. By contrast, those with residual invasive disease at surgery should switch to complete a year of the antibody-drug conjugate (ADC) trastuzumab emtansine (TDM-1). High-risk individuals who have completed a year of anti-HER2 therapy can also consider addition of oral neratinib for another year, although the benefits are incremental.

Toxicity of trastuzumab is relatively uncommon. Few patients have any side effects during treatment. However, the greatest risk is reduction of cardiac ejection fraction. Therefore, baseline cardiac evaluation with an echocardiogram should be obtained, and trastuzumab should not be given to those with low ejection fraction, or they should be evaluated by an experienced cardiologist if therapy is felt to be critical. Serial echocardiograms should be obtained during adjuvant trastuzumab therapy but are not indicated once therapy is discontinued if the patient has not had any evidence of cardiac dysfunction.

Pertuzumab is commonly associated with loose stools or diarrhea. This can be managed with conservative loperamide treatment. However, the added benefit of adjuvant pertuzumab to trastuzumab is modest, and if diarrhea is not easily controlled, trastuzumab should be continued alone.

Individuals who present with smaller tumors with clinically negative nodes should be considered for upfront surgery to establish pathologic stage. This is because women with pathologically node-negative tumors <3 cm have excellent outcomes with a regimen of single-agent weekly paclitaxel for 12 weeks in conjunction with a year of trastuzumab with or without pertuzumab.

Patients with HER2-positive tumors that are ER and/or PR positive should receive endocrine therapy as described above. Endocrine therapy is generally initiated after completion of any chemotherapy and can be given concurrent with anti-HER2 therapy. Neither CDK4/6 inhibitors nor PARP inhibitors have been tested as an adjuvant therapy in early-stage HER2-positive breast cancer.

Triple-Negative Breast Cancer (TNBC) Healthy patients with early-stage TNBC are frequently candidates for (neo)adjuvant chemotherapy. Those with tumors >2 cm or tumors >1 cm and positive axillary nodes should be considered for neoadjuvant multiagent chemotherapy, perhaps in conjunction with the checkpoint inhibitor pembrolizumab. If chemoimmunotherapy is utilized, then pembrolizumab is continued postoperatively to complete a year. Those who achieve a pCR receive pembrolizumab alone. Those patients who do not have a pCR may also consider further chemotherapy with capecitabine. In contrast, those with smaller tumors that are clinically node negative are best served by initial surgery to establish pathologic stage, which might permit a refinement of choice of chemotherapy regimen.

Follow-Up of Survivors of Early-Stage Breast Cancer Asymptomatic survivors of early-stage breast cancer should be followed regularly with history and physical examination to look for any evidence of recurrent disease and to assess for toxicities of prior or ongoing treatments. These exams are conducted every 3–6 months for the first 3 years and diminish in frequency over time. As noted, serial echocardiograms beyond 12 months of trastuzumab therapy are not needed. Annual breast imaging to look for ipsilateral or contralateral disease is the only routine testing needed. In the absence of symptoms or physical exam findings, routine imaging of other types or blood studies have not been shown to enhance well-being or outcome from breast cancer. Current research is focused on use of blood-based assays for circulating tumor cells (CTCs) or circulating free tumor DNA (ctDNA) as markers for early detection of recurrent disease, but these are investigational approaches at present. As many patients have long survival, routine follow-up by a primary care provider and adherence to age-appropriate general health guidelines are key.

Symptom management is a key aspect of follow-up, especially for those on adjuvant endocrine therapy as adherence is a crucial determinant of outcome. Hot flashes may be ameliorated by use of antidepressants like venlafaxine or gabapentin, while vaginal dryness should be addressed through topical agents or, if unsuccessful, vaginal estrogen. Avoidance of hormone replacement therapy is preferred. Aromatase inhibitor–associated musculoskeletal symptoms may be treated by switching from one aromatase inhibitor to another after a 4- to 6-week washout period, or they can be addressed by exercise, nonsteroidal anti-inflammatory agents, acupuncture, or the antidepressant duloxetine. Persistent taxane-related peripheral neuropathy is sometimes responsive to gabapentin.

Special Considerations in Management of Individuals with Early Breast Cancer

Use of Bisphosphonates Bone health can be compromised by breast cancer therapy, especially the estrogen-deprivation agents, aromatase inhibitors and LHRH agonists. Patients who receive these therapies may benefit from use of a bisphosphonate, zoledronate every 6 months for 3 years, or oral clodronate or ibandronate as a bone-strengthening agent. In addition, a meta-analysis suggests that this therapy is associated with decreased breast cancer recurrence, especially in bone. Data on denosumab are less compelling at present.

Pregnancy, Fertility, and Childbearing in Premenopausal Women The diagnosis of breast cancer during pregnancy can be difficult because of the evolving changes in the pregnant breast. Suspicious lumps or skin or nipple changes should be evaluated as above though imaging modalities of choice including ultrasound or MRI. If breast cancer is diagnosed and pregnancy is continued, the goal is to administer appropriate multimodality therapy to optimize maternal outcome from breast cancer and minimize toxicity to the fetus. Breast surgery can be safely undertaken during the second and third trimesters, but any therapeutic radiation must be delayed until after delivery. If indicated, certain chemotherapy agents such as doxorubicin and cyclophosphamide can be administered during the second and third trimesters, whereas others such as methotrexate and 5-fluorouracil should be avoided. In general, endocrine and targeted therapies should not be used until after delivery. Co-management by experienced multidisciplinary breast cancer and high-risk obstetrical teams is preferred.

Diagnosis of breast cancer in all premenopausal women necessitates discussion about fertility preservation and pregnancy with those women who desire later pregnancy. Premature menopause is a known consequence of adjuvant chemotherapy, and likelihood is related to type and duration of chemotherapy and age of patient. It is seen in <50% of women <40 years old but is common in those who are over 40. Patients are asked to avoid pregnancy while on adjuvant endocrine therapy. Thus, counseling about and implementation of fertility-preservation techniques are a priority in newly diagnosed premenopausal women if further childbearing is planned. A meta-analysis suggests that concurrent administration of an LHRH agonist to suppress ovarian function during adjuvant chemotherapy may help to preserve subsequent ovarian function without adverse breast cancer outcomes. Avoidance of oral contraceptives or hormone-based intrauterine devices is recommended for premenopausal breast cancer survivors who require contraception.

Though data are not extensive, pregnancy after early stage breast cancer diagnosis appears to be safe. There is no evidence of increased rate of recurrence compared to matched patients who did not become pregnant, nor is there evidence of increased fetal anomalies. A recent study has documented the safety and pregnancy success rate for women with treated early ER-positive breast cancer who stop adjuvant tamoxifen after 18–24 months of therapy and then resume after pregnancy to complete their prescribed course.

Male Breast Cancer Men with breast cancer usually present with a breast lump or other physical abnormality. Principles about diagnosis, staging, and local therapy are like those for women, although most men undergo mastectomy for primary management for anatomic reasons. Men with breast cancer should undergo genetic testing as germline *BRCA* mutation is seen in up to 14% of men with breast cancer. About 90% of male breast cancers express ER, and adjuvant endocrine therapy is standard. Tamoxifen is the drug of choice; if an aromatase inhibitor is indicated (as for example in an individual who has a history of thromboembolic disease), concomitant administration of an LHRH agonist is required. Guidelines for use of adjuvant chemotherapy are like those for postmenopausal women.

LOCALLY ADVANCED BREAST CANCER

In the United States, about 10% of patients present with locally advanced or stage III breast cancers, although this presentation is more common in less-resourced countries. These tumors are characterized by a large primary tumor, involvement of skin or chest wall, or fixed tumors or axillary lymph nodes, findings that make primary surgical resection difficult or impossible. Inflammatory tumors that present with rapid onset of erythema, swelling, and tenderness of the breast are a subset of locally advanced breast cancer and are sometimes confused with mastitis or other infection. Breast or skin biopsy is critical in the setting of breast inflammation that fails to resolve after antibiotics. Skin biopsy showing dermal lymphatic invasion with tumor cells is often associated with the diagnosis of inflammatory breast cancer. Because up to one-third of these patients have detectable metastasis at time of diagnosis, an evaluation for metastatic disease is recommended even in asymptomatic patients.

Combined-modality therapy begins with neoadjuvant systemic therapy, whose selection is guided by biomarker status as outlined above, to downstage tumor to permit resection. Mastectomy with axillary dissection is often required in the case of inflammatory or other T4 lesions because breast-conserving therapy has been associated with an unacceptably high incidence of locoregional recurrence. Postoperative radiotherapy is the norm in conjunction with systemic therapy with chemotherapy and/or anti-HER2 therapy and/or endocrine therapy tailored to the biological qualities of the tumor.

METASTATIC BREAST CANCER

Presentation and Evaluation About 20–25% of patients who are treated for early breast cancer subsequently develop metastatic disease, presumably because of micrometastatic disease at time of diagnosis that was or becomes resistant to adjuvant systemic therapy. Metastatic disease can be detected years to decades after primary diagnosis, especially in the setting of ER-positive disease, whereas it is most likely to be diagnosed within 3–7 years after treatment for TNBC or ER-negative/HER2-positive breast cancer. Only about 5% of patients present with de novo metastatic or stage IV breast cancer in the United States.

Patients may present with abnormal physical exam or symptoms suggestive of metastases. As shown in **Fig. 84-3**, careful evaluation of extent of disease with computed tomography and radionuclide imaging, routine blood studies, and measurement of tumor markers such as carcinoembryonic antigen (CEA) and either CA27/29 or CA15-3 should be undertaken. Wherever possible, it is critical to biopsy a suspicious lesion to confirm the diagnosis of metastatic breast cancer and assay tumor markers including ER, PR, and HER2 because they may have changed from the initial biopsy under the pressure of time or therapy. In addition, PD-L1 staining and tumor mutational burden should be assessed in tumor, and assays for *PIKC3A* and *ESR1* mutations should be performed in blood or tumor to delineate options for treatment. Next-generation sequencing of tumor may also be considered to simultaneously survey for any other targetable changes to guide selection of therapy or eligibility for a clinical trial.

Goals of Care and General Management Metastatic breast cancer is rarely curable, and the goals of therapy, which is chronic—to palliate or prevent symptoms without undue toxicity—should be explicitly discussed with the patient at the time of diagnosis of metastatic disease. Median survival is <3 years, although the range is wide. Some patients with favorable characteristics such as ER-positive disease, nonvisceral disease, long disease-free interval, and good performance status may survive using serial therapies for many years, whereas those with TNBC are more likely to progress sooner and succumb to their disease. Advances in our understanding of biology of ER- and HER2-positive and genetically mutated (e.g., *BRCA1/2*, *PIK3CA*) breast cancer and development of a myriad of targeted treatments have led to improved outcome for these subtypes in recent years.

Unlike in early breast cancer, the primary intervention in metastatic breast cancer is systemic therapy. Surgery is generally limited to excision of isolated local recurrence or a solitary brain metastasis or stabilization of a bone metastasis. Randomized trials suggest that patients who present with de novo metastatic breast cancer do not have improved outcomes with surgical treatment for the primary breast cancer in addition to systemic therapy and the focus should be on systemic therapy. Radiotherapy may be used at any time to palliate symptomatic localized disease such as bony or brain metastases.

All patients with metastatic breast cancer should have access to palliative therapy approaches in addition to antineoplastic therapy to maximize symptom control and quality of life. In addition, those with metastatic bone disease should be considered for regular administration of bisphosphonate or denosumab in addition to antineoplastic therapy to reduce the chance of skeletal morbidity including pain, fracture, and need for radiotherapy.

Patients with metastatic breast cancer require regular follow-up with history and physical exam to gauge response to therapy. Patient well-being and relief of symptoms are paramount, and use of imaging and blood studies should be personalized to the patient and therapy to adjust dose or schedule and to assist in decisions about efficacy and toxicity of therapy. Current algorithms suggest changes in therapy only if the patient has clear signs of disease progression or unacceptable toxicity. Studies to evaluate the role of serial liquid biopsies to track CTC or ctDNA as an indicator to switch therapy, and even to switch to a targeted therapy suggested by the mutational profile of the ctDNA, in the absence of clinical or radiologic evidence of disease progression are in progress.

Management of ER-Positive Metastatic Breast Cancer Whenever possible, serial use of endocrine therapy is the preferred approach

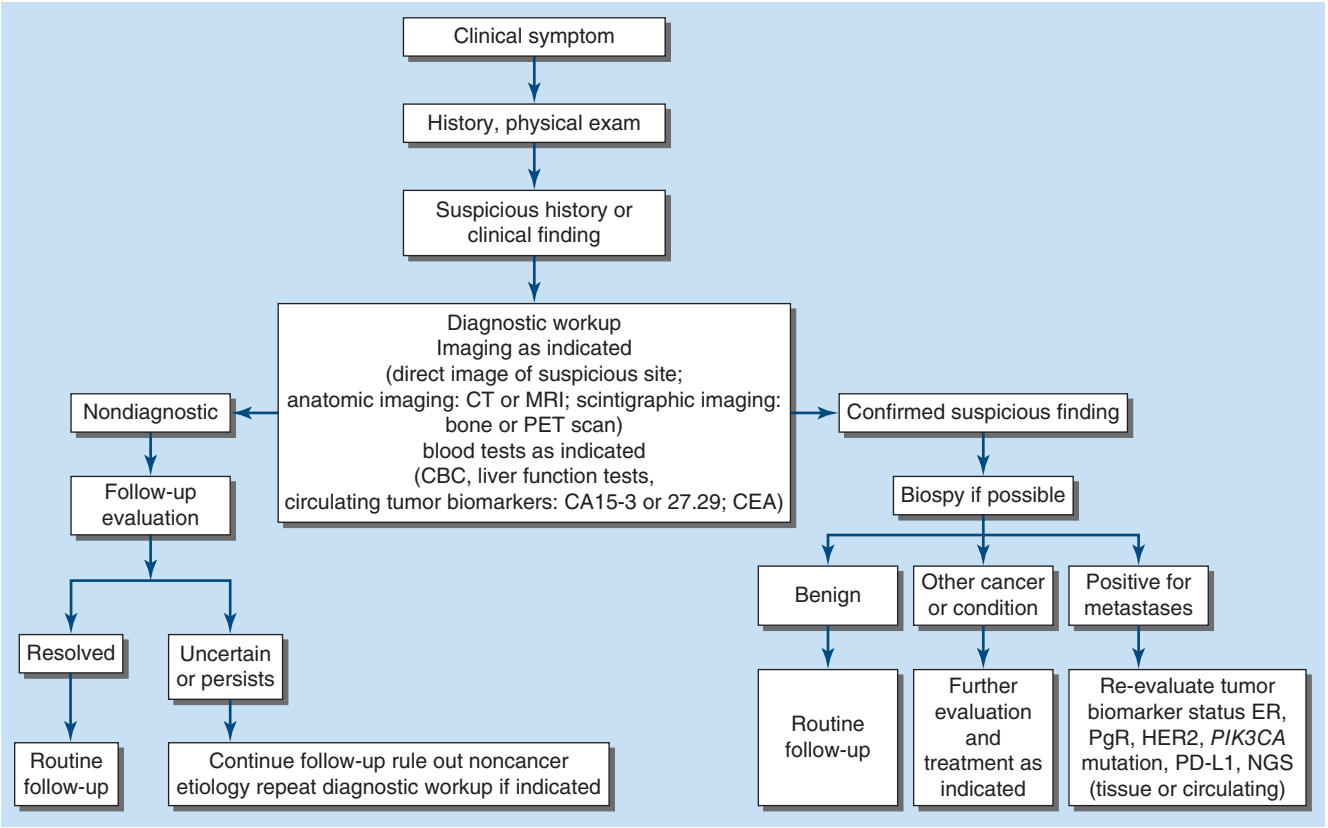

FIGURE 84-3 Evaluation of new signs or symptoms in a patient with prior history of early-stage breast cancer. See text for details. CBC, complete blood count; CEA, carcinoembryonic antigen; ER, estrogen receptor; NGS, next-generation sequencing; PET, positron emission tomography; PgR, progesterone receptor.

to patients whose recurrent tumor is ER and/or PR positive and whose clinical presentation is not dire. Use of chemotherapy can be reserved for those with life-threatening visceral disease like lymphangitic lung metastases or impending liver failure. However, a prospective trial has suggested that overall survival was the same in patients with apparent rapidly growing visceral disease randomly assigned to either chemotherapy or endocrine therapy and a CDK4/6 inhibitor. There is no value for concurrent endocrine therapy and chemotherapy for management of metastatic breast cancer. Selection of type of endocrine therapy will depend on menopausal status and previous adjuvant endocrine therapy. It may be paired with targeted therapy depending on the molecular profile of the cancer and clinical scenario.

For the uncommon patient who presents with untreated ER-positive metastatic breast cancer, therapy generally begins with aromatase inhibitor plus CDK4/6 inhibitor for postmenopausal women and LHRH agonist plus aromatase inhibitor plus CDK4/6 inhibitor for premenopausal women; median progression-free survival is about 2 years, and median overall survival is >3 years with this approach.

More commonly, patients present with recurrent disease diagnosed while on or after completing adjuvant endocrine therapy. For those who have received aromatase inhibitor, up to one-half will have evidence of *ESR1* mutation and may be candidates for the oral selective estrogen receptor degrading (SERD) agent elacestrant if they have also received a CDK4/6 inhibitor. Those without evidence of *ESR1* mutation are often treated with an alternate SERD, fulvestrant, which is administered monthly by intramuscular injection; this may be coupled with a CDK4/6 inhibitor if the patient has not previously received such an agent. The value of continuing or switching to another CDK4/6 inhibitor for those who have previously received adjuvant CDK4/6 inhibitor is not clearly defined in this setting.

For postmenopausal patients previously treated with endocrine therapy who are found to have a *PIKC3A* mutation by liquid or tissue biopsy, the use of alpelisib (a selective inhibitor of PI3Kα) with fulvestrant can be considered. Postmenopausal patients with *PIK3CA/AKT1/PTEN* alterations who have received one endocrine therapy for metastatic disease or recur within 12 months of completing adjuvant therapy can receive capivasertib (a pan-AKT inhibitor) with fulvestrant. The use of aromatase inhibitor plus everolimus, an mTOR inhibitor, can be considered for patients without targetable mutations as it, too, has been shown to increase progression-free survival over endocrine therapy alone. Each of these targeted agents carries a unique set of toxicities, and careful monitoring of clinical status and blood studies is needed for safe administration.

Other approaches, especially for patients who have demonstrated repeated and lengthy responses to serial hormone therapies, can include switch to another aromatase inhibitor or tamoxifen or administration of additive hormone therapies such as progestins, androgens, and estrogens. The latter category of agents is seldom used at present because of concerns about toxicity and the advent of newer more targeted therapies.

At some point, it will become apparent that a patient has tumor that is unresponsive to endocrine therapy, which necessitates a transition to other types of systemic therapy. The timing of this decision may be informed in part by the observation that likelihood of disease control and the duration of benefit are decreased by about one-half with each successive switch in endocrine therapy.

Management of Endocrine-Unresponsive ER-Positive, HER2-Negative Breast Cancer or TNBC Chemotherapy is the backbone of systemic therapy for individuals with metastatic HER2-negative breast cancer that is not responsive to endocrine therapy. Unlike in the setting of early breast cancer where multiagent chemotherapy is the norm, use of combination chemotherapy in metastatic breast cancer should be reserved for the uncommon situation of visceral crisis where a rapid reduction in tumor burden is desirable. For most patients, serial use of single-agent chemotherapy is associated with an acceptable likelihood of disease palliation without excess toxicity; combination chemotherapy does not improve overall survival over sequential monotherapy.

Many chemotherapeutic agents are active in metastatic breast cancer, and selection is based on previous adjuvant chemotherapy and patient preference about route and schedule of administration and side effects. The oral agent capecitabine is often used initially because of ease of administration and acceptable side effect profile. However, several studies have demonstrated that a small percentage of the population harbors deleterious mutations in the *DPYD* gene, which is responsible for converting capecitabine to its inactive metabolites for excretion. Such patients are prone to suffering extreme and, in some cases, lethal toxicities, and some guidelines call for routine testing for this gene before initiating capecitabine or other fluoropyrimidines, such as 5-fluorouracil. Other options include taxanes, anthracycline (depending on previous adjuvant exposure), vinorelbine, gemcitabine, cyclophosphamide, methotrexate, eribulin, ixabepilone, and platinum-based agents; the last is often considered in TNBC because of evidence of activity of platinums in that subtype. For patients with TNBC that expresses PD-L1, administration of paclitaxel with the checkpoint inhibitor pembrolizumab can be considered because the combination results in better outcomes than taxane alone; activity of other checkpoint inhibitors is under investigation.

ADCs are increasingly finding a role in treatment of metastatic breast cancer. Sacituzumab govitecan, an antibody targeted against TROP-2SN-38 coupled to an irinotecan metabolite, has shown activity against TNBC and endocrine-unresponsive ER-positive, HER2-negative breast cancer. A second ADC, trastuzumab deruxtecan, which couples trastuzumab with the cytotoxic deruxtecan (discussed in greater detail below in the HER2 section) is also active against tumors that express low levels of HER2 (1+ or 2+/fluorescence in situ hybridization [FISH] negative) and were initially labeled HER2 negative and thus ineligible for adjuvant anti-HER2 therapy using other anti-HER2 agents. Development and testing of novel ADCs are very vibrant areas in treatment of metastatic breast cancer, and findings are beginning to challenge some of our concepts about targeted therapy.

For patients whose tumors have evidence of germline or somatic *BRCA* mutation, use of single-agent PARP inhibitor with olaparib or taloparib should also be considered, perhaps before the transition to infusional therapies because of convenience.

Management of HER2-Positive Breast Cancer The landscape of treatment for metastatic breast cancer has changed substantially in the 25 years since the importance of HER2 protein expression as a predictor for response to anti-HER2 therapy was demonstrated. FDA-approved HER2-directed therapies now include monoclonal antibodies (trastuzumab, pertuzumab, margetuximab), small-molecule tyrosine kinase inhibitors (lapatinib, neratinib, tucatinib), and ADCs (ado-trastuzumab emtansine or TDM-1, trastuzumab-deruxtecan), and others are under development. Apart from trastuzumab-deruxtecan, their clinical benefit is seen only in individuals whose tumors express 3+ HER2 staining by immunohistochemistry or are gene-amplified by FISH.

The preferred first-line treatment for metastatic HER2-positive breast cancer is a combination of taxane, pertuzumab, and trastuzumab for several months; taxane chemotherapy may be stopped when disease stability is reached, and the anti-HER2 agents are continued as maintenance therapy. In some cases, this approach can lead to long-term remission, and an active area of research is how long to continue anti-HER2 therapy for those with complete response. A randomized clinical trial has established the superiority of trastuzumab-deruxtecan for second-line therapy. Thereafter, serial administration of anti-HER2 agents, in some cases in combination with single-agent chemotherapy, is pursued. Patients who have HER2-positive, ER- and/or PR-positive breast cancer may benefit from concomitant endocrine therapy as well.

HER2-positive breast cancers have a propensity for involvement of the central nervous system. Because control of systemic disease with anti-HER2 therapies can be excellent and penetration of the antibody-based agents across the blood-brain barrier is poor, patients with this disease subtype are often found to have brain metastasis and may require radiotherapy for local disease control. The small-molecule inhibitors may also offer disease control as they cross into the central nervous system.

85 Upper Gastrointestinal Tract Cancers

David Kelsen

Cancers of the upper gastrointestinal tract include malignancies of the esophagus, stomach, and small bowel. Esophageal, gastroesophageal junction (GEJ), and gastric cancers are among the most common of human malignancies, with 1.693 million global new cases diagnosed in 2020; as a measure of the gravity of such a diagnosis, there were an estimated 1.312 million deaths. In the United States, a lower-risk area, it is estimated that in 2023, esophageal cancer will be diagnosed in 21,560 people and cause 16,120 deaths; for gastric cancer, 26,500 new cases will be diagnosed and 11,130 deaths will occur. Small intestine cancers are rare.

ESOPHAGEAL CANCER

GLOBAL DIFFERENCES IN INCIDENCE AND CAUSATIVE FACTORS

Two distinct forms of cancer with different epidemiologies, causative factors, and genomic profiles arise within the esophagus: squamous cell cancers (SCCs), which occur more frequent in the upper and mid esophagus; and adenocarcinomas, which are almost always located in the lower esophagus and at the GEJ. The incidence of esophageal

cancer varies up to 20-fold in global geographic distribution: it is relatively uncommon in North America but has a high incidence in Asia (especially China), the Normandy coast of France, and Middle Eastern countries such as Iran. This marked global variation is likely due to different causative factors in the development of the malignancy, leading to two different cancer types within the same organ: globally, SCCs make up the majority of cases, as they are more common in high-incidence areas, usually with lower of the four-tier Human Development Index (HDI) scores (a measure of economic development that includes standard of living, health, and education). Overall, approximately 604,100 new cases of esophageal cancer were diagnosed globally in 2020; esophageal cancer was the tenth most common cause of malignancy and the sixth most common cause of cancer-related mortality, with an estimated 544,076 deaths.

The most established high-risk factors for the SCC subtype in Western countries are alcohol or tobacco abuse; concurrent alcohol and tobacco abuse further increases the risk. Ingestion of extremely hot substances (such as tea in Iran and mate [maté] in South America) has been proposed as a risk factor; in India, chewing the areca (betel) nut increases the risk of esophageal SCC. Less common risk factors include chronic achalasia, radiation therapy (such as is delivered for treatment of Hodgkin's lymphoma or breast cancer), lye ingestion, and Plummer-Vinson (Patterson-Kelly) syndrome (iron deficiency anemia, glossitis, cheilosis, and the development of esophageal webs). Adenocarcinoma of the lower esophagus and GEJ has been the predominant histologic subtype in the United States and Western Europe for several decades, now making up >75% of all incident cases. Risk factors for adenocarcinoma include chronic reflux esophagitis leading to inflammation and the development of Barrett's esophagus (the finding of glandular gastric type mucosa extending into the esophagus). Although obesity increases the risk of reflux esophagitis, a substantial number of patients with newly diagnosed adenocarcinoma of the esophagus and GEJ are younger and fit; Barrett's esophagus may still be found in these patients. In patients with adenocarcinoma of the lower esophagus in which Barrett's esophagus is not present, the disease may arise without Barrett's esophagus, or an extensive tumor found at diagnosis may obliterate previous areas of Barrett's. Genomic alterations may be identified even before the development of frank adenocarcinoma in patients with dysplasia associated with Barrett's esophagus. These include mutations of *TP53*, a gene critical in regulating uncontrolled cell division, and aneuploidy in dysplastic regions. Risk of progression of Barrett's esophagus to cancer is about 0.4–0.5% per year. **Management of Barrett's esophagus is discussed in Chap. 334.**

As opposed to other gastrointestinal malignancies, such as colorectal cancer, inherited cancer susceptibility genes are rarely associated with esophagus and GEJ cancers. An exception is the rare inherited cancer susceptibility gene driving tylosis palmaris and plantaris; a mutation in the *RHBDF2* gene is associated with an increased risk for SCC of the esophagus. Both Lynch syndrome and germline *BRCA* mutation carriers have a modestly increased risk of gastric and potentially GEJ adenocarcinomas. Identification of these germline mutations is important because it guides choices of systemic therapy, as well as counseling of family relatives (see below).

SCREENING AND SURVEILLANCE OF HIGHER RISK GROUPS

Because of its low incidence in North America and the absence of proven blood-based biomarkers for esophageal cancer assays, screening of the asymptomatic general population using, e.g., upper endoscopy is not currently recommended in the United States. Periodic endoscopy is used for surveillance of higher risk patients, such as those with Barrett's esophagus, especially with dysplasia, based on expert opinion guidelines.

Early-Onset GEJ and Gastric Cancers A marked increase in the incidence of early-onset gastrointestinal malignancies (EOGI; cancer occurring in people <50 years of age) has been noted over the past several decades. First noted were early-onset colorectal cancers, occurring particularly in the left-sided colon or rectum; the start of the steep increase was traced back to the mid-1990s. A similar trend has been noted in upper gastrointestinal tract cancers, particularly in women. The large majority of EOGI patients do not have inherited germline cancer susceptibility gene mutations or a family history of malignancy for colon cancer or small-bowel cancer or inflammatory bowel disease. Driving factors suggested for the steep increase include lifestyle changes such as being more sedentary (less exercise), dietary changes leading to obesity, use of alcohol and tobacco, changes in the microbiome, and exposure to an as not yet identified environmental agent, not previously used, which was introduced to the general population in the 1980s or 1990s. Because the absolute number of young people developing GEJ or gastric cancers is still small, surveillance upper endoscopy or imaging is not recommended (for colon cancer screening, current U.S. recommendations are to start at age 45 years). Efforts are underway to develop sensitive and specific early detection biomarkers such as blood-based assays. Because these cancers are uncommon in young patients, symptoms may be attributed to benign illnesses so that advanced stages are common at the time of diagnosis. Physicians should be aware that symptoms in a young person found more typically in older patients, such as dysphagia, odynophagia, or upper abdominal discomfort, may be related to malignancy, leading to the same diagnostic studies as performed in older patients.

GENOMIC ALTERATIONS

Genomic alteration analyses have revealed substantial genomic differences between adenocarcinomas and SCCs of the esophagus. The well-known integrated analysis involving several different genomic platforms, performed by The Cancer Genome Atlas (TCGA) Research Network investigators, demonstrated that esophageal SCC more closely resembled SCCs of other primary sites, such as the head and neck, than adenocarcinomas arising in the esophagus. Three molecular subclasses of SCC were identified (of note, as opposed to SCC of the head and neck, human papillomavirus was not identified in any of the three subgroups). Similarly, a study of 528 Chinese SCC patients, using whole genome sequencing, evaluated structural variations resulting in rearrangements; five types of structural variations were identified, and some of these may be of clinical significance. In adenocarcinomas, *HER2/ERBB2* is frequently amplified, and microsatellite instability can be found in both esophageal and GEJ adenocarcinomas. Epstein-Barr virus (EBV) infection is a driver in adenocarcinoma. The similar genomic profile for adenocarcinomas of the distal esophagus, GEJ, and cardia of the stomach suggests that proximal gastric and GEJ tumors may have a similar driving factor (see below). A genome-wide association study identified 27 risk loci for the development of adenocarcinomas of the esophagus or GEJ, with a difference between adenocarcinoma arising in Barrett's esophagus versus not. Other studies comparing transcriptomes of adenocarcinomas and SCC across organs (i.e., the same tumor histology arising in different organs, such as SCCs and adenocarcinomas from the esophagus, lung, and uterine cervix) found that the same histologies among the different organs showed more similarity than between the different histologies within the same organ. In addition to implications regarding driving factors in the initiation and progression of cancer, these genomic alterations are important for therapeutic decisions involving systemic agents given in the neoadjuvant or postoperative adjuvant setting or for advanced metastatic disease. For esophageal adenocarcinoma, genomic abnormalities that should be considered in prescribing drug-based therapy include analysis for *HER2/ERBB2* amplification, programed death ligand 1 (PD-L1) expression, and hypermutated tumors/microsatellite instability (see **Table 85-1**, and below). For SCC of the esophagus, the degree of PD-L1 expression may be of importance.

CLINICAL FEATURES

PRESENTING SYMPTOMS

The most common symptoms leading to suspicion of esophageal cancer are dysphagia or odynophagia and, less frequently, hematemesis or melena. More subtle symptoms include anorexia and weight loss, and

fatigue and shortness of breath if anemia from gastrointestinal bleeding is present. Because the symptoms of dysphagia or odynophagia are usually not perceived by the patient until substantial obstruction of the esophageal lumen has occurred, the large majority of patients with esophageal cancer are found with locally advanced if not metastatic disease. Patients with symptoms of dysphagia and/or odynophagia should undergo upper endoscopy to determine the presence or absence of malignancy; biopsy should be performed at the same setting to determine histology. Depending on the tumor stage, molecular diagnostic or next-generation sequencing (NGS) analysis to assist in determining potential therapies should be performed. PD-LI, which may guide use of immune modulation therapy, is assessed by immunohistochemistry (IHC). NGS requires adequate tumor cellularity, which may be difficult to achieve from endoscopic biopsy. NGS is currently probably the most efficient methodology for genomic analysis (other than PD-L1), and genomic analysis should be done on all patients with metastatic disease because it will guide therapy. Some high-volume U.S. centers routinely perform NGS on all specimens, including from all but the most early-stage primary tumors of patients without metastatic disease.

STAGING

Therapeutic strategy is currently based on the stage of the disease using a system such as the eighth version of the American Joint Committee on Cancer (AJCC) Staging Manual (for esophageal and gastric cancers, the ninth version is expected in 2024) tumor-node-metastasis (TNM) staging system. The T stage is based on the size of the tumor and depth of penetration through the esophageal wall (which for most of its course is not covered by serosa so that invasion through the muscle layer leads directly into periesophageal tissues) **(Fig. 85-1)**. Patients with regional lymph node metastases are still potentially curable. Metastatic disease is generally treated with palliative intent with rare exceptions. Because neoadjuvant (preoperative) therapy is widely employed for esophageal cancer to improve subsequent surgical outcomes, the AJCC TNM staging system includes clinical, pathologic (for patients undergoing initial surgery as first treatment), and ypTNM staging assessment for those treated with preoperative therapy. See **Table 85-2** for the TNM staging classification for gastric cancer, which is similar to esophageal cancer.

Determining tumor extent includes careful physical examination, which may reveal palpable lymphadenopathy or hepatomegaly; imaging studies including computed tomography (CT) and fluorodeoxyglucose (FDG) positron emission tomography (PET)-CT scan are used to assess for metastatic disease. If no metastatic disease is identified, endoscopic ultrasonography (EUS) is commonly performed to more definitively determine depth of penetration of the primary tumor (T) and regional lymph node involvement. Deep learning artificial intelligence methodology may assist the imaging analysis to improve the diagnostic sensitivity and specificity of EUS for both esophageal and gastric cancers. For tumors of the mid and upper esophagus (5% of esophageal cancers are in the upper third of the esophagus, 20% in the middle third, and 75% in the lower third), bronchoscopy may be performed to rule out invasion of the tracheobronchial tree. The finding of invasion of the trachea or bronchus rules out surgical intervention with curative intent. Regional lymph nodes may be biopsied under EUS guidance. For GEJ tumors, as for gastric cancers, laparoscopy is performed at many centers to assess for peritoneal involvement if the T stage is more advanced. If metastatic disease is suspected, biopsy to confirm tumor staging and to obtain adequate tissue for molecular and genomic alterations analysis should be performed. Assay of plasma ctDNA (circulating tumor DNA) can be used to detect genomic alterations before treatment if biopsy tissue is too limited to allow NGS or molecular diagnostics; ctDNA is being studied as a measure of minimal residual disease after definitive regional therapy (surgery or chemoradiation therapy). If systemic therapy is indicated as a portion of the treatment (for metastatic disease or for preoperative therapy for locally advanced cancers), serial FDG-PET/CT scans, using decrease in FDG avidity as a surrogate measure of effectiveness, are being used to guide whether the initial therapy should be continued or changed.

TREATMENT

Esophageal Cancer

Although the prognosis for patients with esophageal cancer (all stages) is still poor, a slow but steady improvement in 5-year survival has been noted. Because no cost-effective early detection methods exist in low-incidence countries, the number of U.S. patients found to have very-early-stage cancers at the time of diagnosis has not markedly increased; the modest improvement in survival is probably a combination of somewhat improved systemic therapy as well as decreased operative morbidity and mortality when surgery is performed by high-volume surgeons at high-volume centers, as well as improvements in the delivery of external-beam radiation therapy.

For patients without evidence of metastatic disease, the goal of therapy is cure, usually by employing combined-modality therapies. Except for patients with early-stage esophageal cancer, who might be treated by surgery alone (or for very-early-stage lesions [Tis or T1a], by endoscopic mucosal resection [EMR] or submucosal dissection [ESD] for smaller [<2 cm] tumors); EMR and ESD are also used as part of initial staging to determine more definitively T stage), preoperative treatment including systemic drug therapy is a standard of care option for patients with esophageal and GEJ cancers. For locally advanced adenocarcinomas of the esophagus and GEJ, systemic therapy alone may be indicated: in the ESOPEC trial, preoperative systemic FLOT chemotherapy resulted in improved survival compared to preoperative chemoradiation (using the CROSS regimen). For selected patients with adenocarcinomas (e.g., not able to tolerate regimens such as FLOT), and for patients with SCC of the esophagus, chemoradiation remains a standard of care option; for SCC, chemoradiation may be definitive therapy. If surgery is planned after preoperative chemoradiation, a prolonged delay before surgery has been associated with a poorer outcome. For selected patients with GEJ adenocarcinomas, systemic therapy alone may be given before definitive surgical resection. For patients with SCC of the upper and mid esophagus, combined chemotherapy plus concurrent radiation therapy is a standard option, with surgery reserved for patients not achieving a complete radiographic and endoscopic response. Radiation therapy alone is rarely given with curative intent, as chemotherapy plus concurrent radiation was superior to radiation therapy alone in several clinical trials. Increasingly, all systemic therapy with curative intent is given before operation, although if surgery is the initial therapy and the patient is found to have more locally advanced cancer at pathology (e.g., regional lymph node metastasis), postoperative systemic therapy is used in the adjuvant setting. Adjuvant chemotherapy is more frequently indicated in patients with adenocarcinoma than SCCs. The CheckMate 577 trial demonstrated that for esophageal or GEJ cancer patients who received preoperative chemoradiation therapy and underwent a R0 (negative margins) resection but who had residual tumor in the resection specimen (i.e., not ypT0N0M0), postoperative adjuvant therapy with nivolumab, an immune-modulating agent targeting PD-1, significantly improved survival. For patients with metastatic disease, the goal of therapy is symptom palliation and life extension. No randomized trials of supportive care only versus systemic therapy plus best supportive care have been reported in patients with esophageal cancers. For gastric cancer (an adenocarcinoma histology, as are most distal esophageal and GEJ tumors), clinical trials performed in the 1980s and 1990s indicated a modest improvement in 1- and 2-year survival when systemic therapy plus best supportive care was used versus best supportive care only. While the cytotoxic chemotherapy regimens used for palliation have not changed dramatically over the past 10 years (currently including, for first-line treatment, a platinum compound such as oxaliplatin and a fluorinated pyrimidine such as fluorouracil or capecitabine; the FLOT [fluorouracil, leucovorin, oxaliplatin, and docetaxel] regimen includes docetaxel and is used

Abbreviation: TNM, tumor-node-metastasis.

in very fit patients), subgroups of patients have been identified who benefit from therapies targeting specific genomic alterations (Table 85-3). Approximately 20–25% of patients with adenocarcinoma of the esophagus or GEJ are found to have amplified or overexpressed *HER2/ERBB2*; trastuzumab plus chemotherapy, or trastuzumab, chemotherapy, plus immune therapy using pembrolizumab (for progression-free survival), results in higher response rates and longer progression-free and overall survival compared to chemotherapy alone. For patients whose tumors do not express *HER2/ERBB2*, immune-modulating therapy using PD-1 inhibitors is a standard option as part of first-line therapy (in combination with chemotherapy) and as second-line palliative therapy for patients who have esophageal cancers expressing PD-L1. Patients whose tumors have high PD-L1 combined positive score (CPS) may have greater benefit. For patients with hypermutated or microsatellite-unstable tumors, immune therapy alone is considered, using agents such as pembrolizumab, or nivolumab plus ipilimumab. As noted above, molecular diagnostic or NGS genomic alteration analysis assays to identify these biomarkers should be performed routinely in patients with metastatic esophageal, GEJ, and gastric cancer to help guide therapy.

Supportive measures to improve nutrition and quality of life include placement of an endoluminal stent in the setting of high-grade obstruction; use of enteral nutrition can also be performed using a percutaneous gastrostomy. Photodynamic therapy and endoscopic laser therapy have been used to treat symptoms of endoluminal obstruction.

TUMORS OF THE STOMACH

ADENOCARCINOMA OF THE STOMACH

Incidence and Causative Factors Since the 1920s, the incidence of gastric cancer has steadily decreased; while the reason for this has not been definitively identified, it coincided with widespread use of refrigeration and a decreased need for food preservatives. In 2023, it is estimated that there will be 27,500 new cases of gastric cancer diagnosed in the United States; while now seen much less frequently, it remains a lethal disease, with 11,130 deaths. As noted above, globally, gastric cancer is the third most common cause of cancer mortality. High-incidence areas, as is the case for esophageal cancers, include large Asian countries such as China, Korea, and Japan; South American countries such as Chile; and Eastern European countries.

While the number of new cases of body and distal gastric cancers has decreased in Western, high-tier HDI countries, the incidence of adenocarcinomas of the GEJ has markedly increased in the same areas over the past several decades, including as described earlier in younger patients. For gastric cancer overall, a higher incidence in some countries may be due to the ingestion of high concentrations of nitrates found in dried, smoked, and salted foods. Chronic inflammation, caused by an infection, is a major cause of gastric cancer. *Helicobacter pylori* infection is a known driver in many cases of gastric cancer. While *H. pylori* is extremely common, occurring in approximately half of all humans, gastric cancer occurs in only a small subset of those infected. Higher cancer risk has been associated with certain strains of *H. pylori*; while analyses of *H. pylori* are identifying high-risk genomic factors, a specific human genomic profile increasing risk of gastric cancer in the setting of *H. pylori* has not yet been identified. *H. pylori* and ingestion of partially decayed bacterially contaminated food may lead to the generation of carcinogenic nitrites from nitrates. Supportive evidence that *H. pylori* infection is a causative factor in the development of gastric cancer includes prospective studies demonstrating that treatment of *H. pylori* infection decreases the overall risk of gastric cancer. For example, patients with *H. pylori* infection who had at least one first-degree relative with a history of gastric cancer (increasing their own risk of stomach cancer) were randomly assigned to placebo or treatment for *H. pylori*. The group receiving *H. pylori* eradication showed a significant decrease in the incidence of gastric cancer (especially for those in whom *H. pylori* was successfully eradicated) compared to the control group. Earlier studies had demonstrated that treatment of *H. pylori* in Korean patients who had a prior very-early-stage gastric cancer decreased the incidence of a second gastric cancer. These data suggest that treatment of asymptomatic *H. pylori* gastric infection should be considered for patients who have a first-degree relative who has had gastric cancer or who themselves have a prior history of an early-stage gastric cancer. The spectrum of the gastric microbiome beyond *H. pylori* may also be contributory to an increased risk of gastric cancer, with gastric cancer patients having a higher bacterial load than controls.

EBV has also been associated with an increased risk for gastric cancer, and gastric cancer EBV phenotype and genotype have been well described.

Another inflammation-driven cause is suspected to be reflux of gastric contents into the esophagus, particularly in obese people, increasing the

risk of GEJ and esophageal adenocarcinomas. Obesity alone is not the cause, as a substantial number of GEJ patients are fit and not overweight.

In addition to chronic inflammatory conditions, inherited cancer susceptibility genes increase the risk of gastric cancer. These include mutations of *CDH1*, which encodes for the cell cohesion gene e-cadherin; germline *CDH1* mutations markedly increase the risk for the diffuse cell (signet cell) gastric cancer subtype (see below for discussion of histologic subtypes). Prophylactic gastrectomy as a risk-reducing surgical procedure is an option for patients with an inherited deleterious *CDH1* mutation. *CDH1* mutations also increase the risk for lobular breast cancer. Germline mutations in the mismatch repair pathway (Lynch syndrome) and in the homologous repair pathway (*BRCA* mutations) slightly increase the risk for gastric cancer. Other inherited cancer susceptibility genetic syndromes that increase the risk of gastric cancer include familial adenomatous polyposis, juvenile polyposis, and Peutz-Jeghers syndrome. Surveillance programs for the early detection of gastric cancer for the higher risk germline cancer susceptibility genes (e.g., *CDH1*) should be employed. In addition, systemic therapy options for patients with certain germline mutations may be different from those with sporadic gastric cancer (e.g., for Lynch syndrome, immune modulation therapy; and for *BRCA*, use of DNA-damaging agents such as platinum compounds).

Gastric cancer stem cells, mostly located in the isthmus of individual gastric glands and possibly originating in the bone marrow, may play an important role in the development of gastric cancer. *H. pylori* may be an inciting factor for recruitment of such bone marrow gastric stem cells. If this hypothesis is confirmed, it may have important implications for therapy of gastric cancers.

Clinical Features • **SURVEILLANCE STRATEGIES** As is the case for esophageal cancer, the incidence of gastric cancer in Western patients is relatively low, and early detection methodologies such as endoscopy are not routinely employed. The development of a "pan-cancer" blood-based biomarker or a biomarker specific for gastric cancer would allow broader screening. At this time, the overwhelming majority of Western patients with gastric cancer are symptomatic at the time of diagnosis. Early detection programs in Japan and Korea, where gastric cancer has been among the most common of malignancies (although its incidence has been decreasing), include upper endoscopy; these programs have increased the number of patients found with early gastric cancer and decreased mortality rates. This strategy has not been cost effective in populations in which the incidence of gastric cancer is much lower, such as in the United States. As noted above, in high-incidence areas, treatment of symptomatic *H. pylori* is a preventive measure.

PRESENTING SYMPTOMS Presenting symptoms include vague upper abdominal discomfort, hematemesis or melena, anorexia and early satiety, and unexplained weight loss. For patients with esophagogastric junction cancers, dysphagia or odynophagia may be the presenting symptom. Anemia may be found due to occult bleeding. These symptoms and signs lead to upper (and if site of bleeding is uncertain, lower) endoscopy and biopsy. Occasionally, imaging using CT performed to evaluate abdominal symptoms may identify gastric thickening or a gastric mass leading to upper endoscopy. Physical examination can reveal left supraclavicular adenopathy (Virchow's node), a periumbilical mass (Sister Mary Joseph nodule), a pelvic mass on rectal exam (Blumer's shelf), ascites, or an ovarian mass (Krukenberg tumor). More commonly, physical examination is unrevealing.

Upper endoscopy may reveal an ulcer or ulcerated mass, biopsy of which shows adenocarcinoma. For the diffuse subtype of gastric cancer, a mass or ulceration may not be seen, but rather, thickened gastric rugae may be noted. Initial biopsy may not reveal diffuse gastric cancer, which may track below the mucosal surface. In these patients, EUS may guide biopsy.

Histopathology Classification of Primary Gastric Adenocarcinomas The large majority (~85%) of gastric malignancies are adenocarcinomas or subtypes of adenocarcinoma. Other malignancies, discussed below, include neuroendocrine tumors (carcinoid tumors), primary gastric lymphomas, gastrointestinal stromal tumors (GISTs), and other rare malignancies. Using the Lauren classification, pathologists classify adenocarcinomas on the basis of histopathology as intestinal (more common) or diffuse subtype (~20%). As noted above, the diffuse subtype is associated with inherited *CDH1* mutations; in addition, in the TCGA genomic analysis of gastric cancer and in other genomic analysis studies, approximately a third of diffuse subtype cases had somatic *CDH1* mutations. The intestinal subtype is associated with *H. pylori* infection and atopic gastritis. Histologic grade also influences the clinical course.

Genomic analysis performed by several groups has resulted in molecular classifications of gastric cancer that may, in the future,

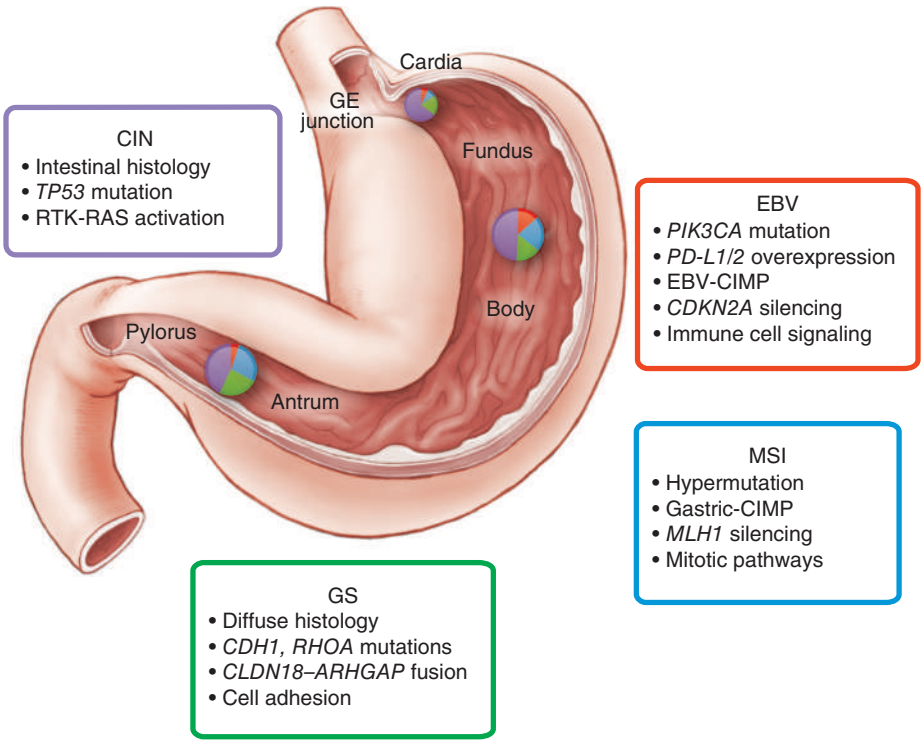

FIGURE 85-2 Molecular/genomic characterization of subtypes of gastric carcinomas. CIMP, CpG-island methylator phenotype; CIN, chromosomally unstable; EBV, Epstein-Barr virus-associated; GE, gastroesophageal; GS, genomically stable; MSI, microsatellite instability-associated.

inform staging systems; they already provide a better understanding of the driving factors in the development of gastric cancer and important information on treatment options as outlined above **(Fig. 85-2)**. For example, the TCGA group reported the results of a multiplatform analysis of 295 patients with previously untreated gastric cancer; both Western and Asian patients were included in the analysis. Four subtypes of gastric cancer were identified: high EBV burden, microsatellite unstable with hypermutation, genomically stable (associated with the diffuse subtype), and chromosomal unstable. The Asian Cancer Research Group (ACRG), studying primary tumors from 300 Korean patients, analyzed gene expression profiles and found four subtypes: mesenchymal, microsatellite unstable, microsatellite stable with *TP53* expressed, and microsatellite unstable with *TP53* mutated. Clinical outcome was correlated with genomic subtype in both studies, with microsatellite unstable tumors having the best outcome (in an era before use of immune modulation therapy) and genomically stable (TCGA) and mesenchymal (ACRG) types having the worst outcome.

In addition to histopathology, as is the case for esophageal cancer, molecular diagnostics and genomic alteration analysis using NGS are an important part of the pathology workup. The molecular subtypes have therapeutic implications; for example, as discussed above, ~20% of gastric cancer or GEJ cancer patients' tumors have overexpression or amplification of *HER2/ERBB2*, which would lead to the addition of agents such as trastuzumab-based therapy as part of systemic treatment for metastatic disease. Immune modulation therapy would be used in patients with hypermutated tumors, found by NGS (tumor mutation burden) or by polymerase chain reaction (PCR) for microsatellite instability (MSI). An evaluation for overexpression or amplification of *HER2/ERBB2*, quantification of PD-L1 by IHC, and assessment of MSI by PCR or deficient mismatch repair protein (dMMRP) expression should be a routine part of the pathology workup of patients with metastatic gastric cancer. Claudin 18.2 has recently been identified as a target for therapy; if agents targeting Claudin 18.2 are approved by the U.S. Food and Drug Administration (FDA), an assay for this factor should be included in the pathologic evaluation of metastatic gastric cancer. More controversial is whether these assays should also be routinely performed in patients with potentially operable gastric cancer because, for example, the addition of trastuzumab to neoadjuvant chemotherapy has not yet been shown to change outcome. In large-volume centers, NGS is routinely performed on pretreatment biopsies. Currently, the finding on pathologic assays of positive tumor EBV (identified in 8–10% of gastric cancer patients) does not change therapeutic options.

Staging Once a diagnosis of a primary gastric adenocarcinoma is made, algorithms for clinical evaluation of stage include physical examination and imaging studies (**Fig. 85-3**; Table 85-2). Tumor-related biomarkers such as carcinoembryonic antigen (CEA) or CA19-9 may be elevated but are nonspecific (may be elevated in a number of other gastrointestinal and other site cancers). Diagnostic CT scan of the chest, abdomen, and pelvis should be performed. If metastatic disease is suspected on imaging, a biopsy of a metastatic site should be strongly considered to confirm stage IV disease, which changes the goals of care from potentially curative to palliative treatment and provides tissue for molecular and genomic analyses. As is the case for esophageal cancer, FDG-PET/CT, which is more sensitive than diagnostic CT scan in identifying sites of metastatic disease, should be performed if the anatomic CT is negative for metastatic disease. Note, however, that FDG-PET may be noninformative (the primary tumor may not be FDG-avid, particularly in diffuse-type gastric cancer). If imaging does not reveal metastatic disease, EUS should be considered to determine depth of penetration of the primary tumor and the presence or absence of regional lymphadenopathy suspicious for metastasis. Lymph node biopsy and, on occasion, biopsy of left hepatic parenchymal lesions found on EUS can be performed at the same setting. Endoscopic biopsies usually provide enough tumor tissue for molecular diagnostic pathology testing for *HER2/ERBB2*, MSI/MMRP, and PD-L1 assessment; it may not provide enough tissue for NGS genomic alteration analysis. If neoadjuvant therapy is planned, laparoscopy should be considered to allow evaluation of the peritoneal cavity, with peritoneal washing for cytology if no peritoneal metastases are visible. The peritoneal cavity is a common site of metastases, especially from diffuse-type gastric cancer. The finding of peritoneal involvement either visibly or by positive cytology is staged as metastatic disease and generally rules out the chance for curative resection.

The AJCC staging classification for gastric cancer is summarized in Table 85-2. Three staging classifications are provided: cTNM clinical staging (before any therapy has been given), pTNM pathologic staging (for patients not undergoing preoperative therapy), and a post–neoadjuvant therapy classification staging (ypTNM). The three components take into account current standard-of-care options for therapy in which the AJCC prognostic stage groups from clinical staging guide therapeutic decisions. For example, after clinical evaluation, a large percentage of newly diagnosed patients will be found to have higher-stage primary cancers (penetrating through the gastric wall [T3 or T4] or lymph node–positive tumors), in which case perioperative (neoadjuvant) systemic therapy may be chosen. Pathologic examination of the resected specimen for prognostic stage classification must take into account exposure to preoperative therapies that may lead to downstaging (thus, ypTNM staging). Nomograms have been developed for predicting outcome in patients undergoing surgery as initial treatment.

TREATMENT

Gastric Cancer

POTENTIALLY CURABLE GASTRIC CANCER: SURGERY

Surgical removal of the primary tumor with negative microscopic margins (an R0 resection) and with resection of regional lymph nodes is currently the only curative therapy; with surgery alone, overall 5-year survival rates are approximately 25% (higher for very-early-stage tumors). If tumor cells are found at the margin of resection (R1) or if visible cancer is left at the time of surgical removal of the primary tumor (R2), surgery is palliative rather than curative. For patients with early-stage tumors (mostly clinical stage I), surgery without perioperative systemic therapy may be performed. For patients with more locally advanced tumors (clinical stages IIA, IIB, III), who compose approximately 70% of newly diagnosed operable patients, multimodality therapy (surgery and systemic chemotherapy) improves overall survival. Both neoadjuvant (preoperative) and postoperative systemic therapy are accepted approaches. If staging studies demonstrate a locally advanced cancer (or node positive), preoperative treatment is recommended in a medically fit patient. If surgery is performed first and a locally advanced cancer is found, postoperative chemotherapy or chemotherapy plus chemoradiation is recommended. For selected very-early-stage gastric cancers (primary tumors that are ≤2 cm in diameter, are well to moderately differentiated, do not invade the deep submucosa [T1], and do not show lymphovascular invasion or lymph node metastasis), which are not commonly found in the United States, EMR or ESD may be performed by experienced gastroenterologists in place of surgical resection, with favorable results in studies in high-incidence areas such as Japan.

For patients in whom the primary tumor is in the distal stomach, a subtotal gastrectomy is the preferred surgical procedure. For tumors of the proximal stomach, the options for resection include total gastrectomy or, alternatively, proximal gastrectomy. Esophagogastrectomy is performed for tumors involving the GEJ. In selected patients, a jejunostomy feeding tube may be placed if postoperative radiation therapy is part of the treatment plan.

As noted above, laparoscopy is commonly performed at high-volume centers before a final decision regarding the role of surgery. If staging has already demonstrated clinically suspicious lymph nodes or an advanced T stage tumor, but laparoscopy does not demonstrate peritoneal metastasis, perioperative chemotherapy is given before surgical resection.

Palliative resection of the primary tumor is usually performed only if symptoms such as uncontrollable bleeding or obstruction are present that cannot be relieved by other means.

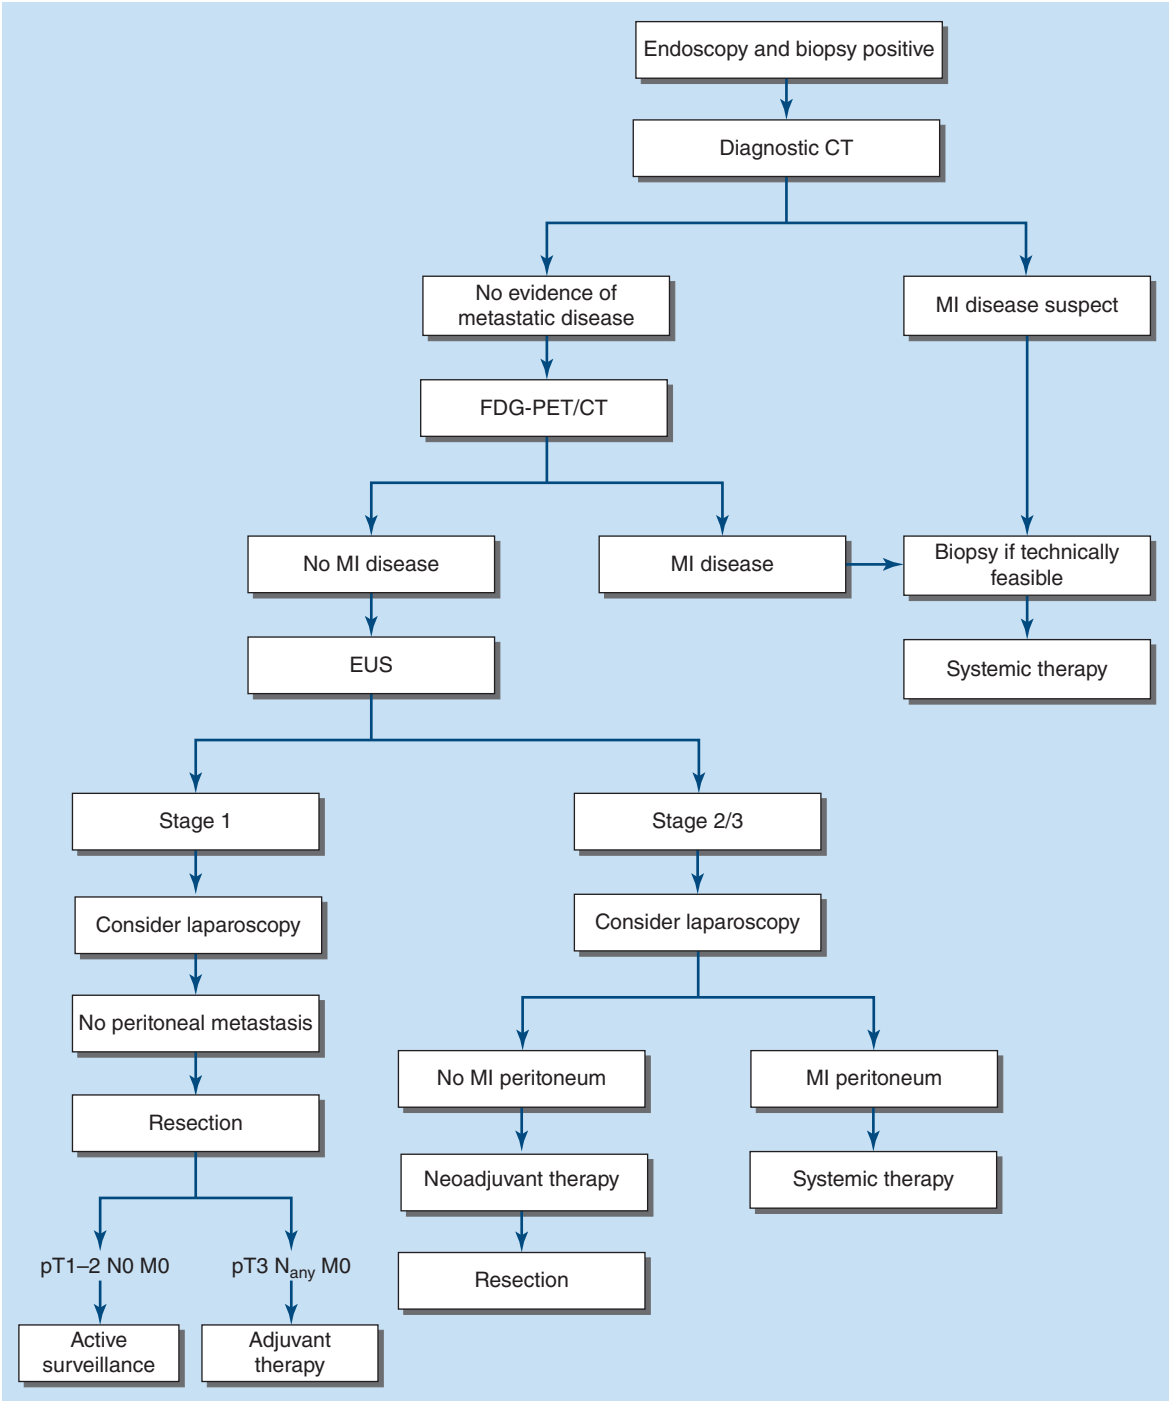

FIGURE 85-3 Staging for gastric adenocarcinoma. CT, computed tomography; EUS, endoscopic ultrasound; FDG-PET, fluorodeoxyglucose positron emission tomography.

As is the case for colorectal cancer, a correlation exists between the number of lymph nodes removed and sampled and outcome. Sentinel lymph node biopsy is not performed in gastric cancer outside of a research study setting. The goal is to examine at least 15 lymph nodes from the resected specimen; it is more controversial whether more extensive lymph node resection itself affects outcome; the extent of lymphadenopathy can be classified using a D0–D3 system with a higher number meaning more extensive lymphadenopathy. In the United States, a modified D2 (D1+) resection preserving the spleen and avoiding pancreatectomy is recommended but should be performed by experienced surgeons at high-volume centers. Japanese investigators and others have used very extensive lymph node dissections, but studies have not demonstrated an advantage for a D3 resection. Both resection of the primary tumor and its regional lymph nodes can be performed laparoscopically in appropriate patients.

In the hands of experienced surgeons, operative mortality would be anticipated to be ≤2%.

NEOADJUVANT AND POSTOPERATIVE ADJUVANT THERAPY FOR RESECTABLE GASTRIC CANCER

The large majority of potentially resectable Western gastric cancer patients have locally advanced tumors (cTNM stage IIA/B or III). Multimodality therapy using systemic chemotherapy plus surgery improves 5-year survival rates by 10–15% compared to surgery alone. An older but widely cited study, the MAGIC clinical trial, randomly assigned patients with potentially resectable disease to receive perioperative chemotherapy or to proceed directly to surgery. Five-year overall survival for patients undergoing surgery alone was 23%; for those receiving pre- and postoperative chemotherapy, it was 36%. On the basis of this and other clinical trials, for most medically fit patients with stage cTNM II and III resectable gastric cancers,

preoperative systemic chemotherapy followed by resection and, if tolerable, postoperative chemotherapy is a standard approach. Because it is challenging to give postgastrectomy systemic therapy using currently employed regimens (<50% of patients receive or complete postoperative treatment), total neoadjuvant therapy is favored at some centers. For patients with MSI/hypermutated tumors, immune modulation therapy (PD-1/PD-L1 or PD-1 plus CTLA-4 agents) can be considered in place of chemotherapy, although substantial pathologic response rates were seen in a small number of patients in the DANTE trial using FLOT alone. Preoperative chemoradiation as given for esophageal cancers is usually used for GEJ tumors. If an R1 or R2 resection is performed, postoperative chemoradiation can be considered. Use of postoperative chemoradiation therapy, with exceptions outlined above, did not improve outcome when compared to systemic chemotherapy alone. Preoperative chemotherapy followed by chemoradiation is under study. For patients being treated with multimodality therapy, close interactions among the surgeon, medical oncologist, and radiation oncologist are essential.

Clinical trials have compared different preoperative cytotoxic chemotherapy regimens, most of which include a platinum compound—either cisplatin or oxaliplatin. Currently, a platinum compound plus a fluorinated pyrimidine, such as fluorouracil or capecitabine, given for three to four cycles before surgery is a standard-of-care option. Drug combinations are favored; for very fit patients, a combination of FLOT may be chosen. An alternative is, for example, the FOLFOX regimen, which includes fluorouracil, leucovorin, and oxaliplatin. Addition of trastuzumab to preoperative chemotherapy has not improved outcomes for patients with *HER2*-positive cancers. Careful monitoring of chemotherapy-related toxicities with appropriate dose modifications is important. For patients receiving preoperative systemic chemotherapy and undergoing an R0 D2/D1+ dissection, postoperative chemoradiation therapy has not improved outcome.

For patients in whom the primary tumor has been resected and who did not receive preoperative chemotherapy, who are found to have stage II or III cancers, or who have <15 lymph nodes found in the resected specimen (less than D2 resection), postoperative chemotherapy or chemoradiation is a treatment option. Chemotherapy and chemoradiation therapy may also be given for unresectable cancers in selected patients. As noted above, plasma ctDNA as a measure of minimal residual disease (regional or metastatic cancer not identifiable by current imaging modalities) is being studied. Data from other gastrointestinal tumors suggest that conversion of a positive ctDNA assay to negative after systemic postoperative therapy is associated with a better outcome.

PALLIATIVE THERAPY FOR INCURABLE GASTRIC CANCER

Patients with clinical stage IV gastric cancers with an adequate performance status should be offered systemic drug therapies. Small clinical trials performed in the 1980s and 1990s showed a survival benefit for systemic therapy compared to best supportive care only. As discussed above, genomic and molecular diagnostic analysis has identified several distinct cohorts of gastric cancer patients. These analyses guide therapy. While the cytotoxic chemotherapy regimens most commonly employed are still based on a platinum compound and a fluorinated pyrimidine (e.g., FOLFOX, as is used in the perioperative setting), a major advance has been the demonstration that immune modulation therapy plus chemotherapy improves outcome (including overall survival) compared to chemotherapy alone. In the CheckMate 649 trial, 1581 patients with *HER2/ERBB2*-negative advanced gastric or GEJ cancers were randomly assigned to receive nivolumab plus chemotherapy (oxaliplatin plus capecitabine or FOLFOX) versus chemotherapy alone. Overall survival, progression-free survival, and response rates were significantly better for patients receiving nivolumab plus chemotherapy; this effect was most marked for patients with PD-L1 CPS of >5. CheckMate 649 and other data have led to guidelines recommending use of immune modulation therapy plus chemotherapy as an option for first-line treatment for patients with *HER2/EBB2*-nonexpressing, PD-L1 CPS >5 metastatic gastric and gastroesophageal cancers; chemotherapy plus immune modulation therapy may also have benefit for patients with lower PD-L1 CPS scores. Those whose tumors have overexpressed or amplified *HER2* should receive HER2-targeted agents such as trastuzumab or trastuzumab, pembrolizumab, plus cytotoxic chemotherapy. Beyond first-line therapy, additional HER2-targeted therapy using agents such as trastuzumab-deruxtecan, a monoclonal antibody-drug conjugate, is recommended for patients whose tumors have amplification of *HER2/ERBB2*. For patients with metastatic MSI/dMMRP gastric cancers, immune modulation therapy using either PD-1 inhibitors such as pembrolizumab or combinations such as nivolumab plus ipilimumab may be employed as first-line therapy; guidelines include the option of immune therapy plus chemotherapy.

When disease progresses after first-line treatment, other therapies include the combination of a VEGF receptor–targeted agent, ramucirumab, either alone or in combination with paclitaxel. Immune modulation inhibitors are an option for second-line therapy for patients whose tumors are microsatellite unstable (e.g., nivolumab plus ipilimumab if single-agent pembrolizumab was used as first-line therapy). For patients with microsatellite stable gastric cancers (the large majority), immune modulators are an option if not used in the first-line setting, if PD-L1 is positive. As above, for patients with *HER2/ERBB2*-amplified tumors, trastuzumab-deruxtecan can be used. Several other cytotoxic agents have activity in the third-line setting including trifluridine-tipiracil and irinotecan. Even with improvements in therapy including immune modulation therapy, the best results from clinical trials indicate overall survival for treated patients with stage IV disease is still only 12–15 months. Investigational studies include targeting Claudin 18.2, a cell surface type junction molecule that is overexpressed in ~50% of gastric cancers. In the SPOTLIGHT trial, previously untreated, *HER2/ERBB2*-negative patients assigned to zolbetuximab (targeting Claudin 18.2) plus FOLFOX chemotherapy had an improvement in survival compared to those receiving FOLFOX chemotherapy alone. Zolbetuximab plus chemotherapy may become another first-line option for advanced gastric cancer. Additional studies targeting Claudin 18.2 including those using chimeric antigen receptor (CAR) T cells are underway.

Radiation therapy using shorter regimens may be employed to palliate bleeding. For patients with advanced incurable disease, other supportive measures include placement of a duodenal stent to relieve gastric outlet obstruction; in selected patients, surgical procedures for gastric outlet obstruction may be performed. Radiation therapy might be used if not previously given. Enteral feeding using a jejunostomy tube may support nutritional needs.

GASTRIC LYMPHOMAS

Lymphomas of the stomach are an uncommon (~3%) but important subgroup of gastric malignancies. They are extranodal non-Hodgkin's lymphomas (NHL). The gastrointestinal tract is the most common site for extranodal NHL, and the stomach is the most common site within the gastrointestinal tract. The presenting symptoms can be similar to those of the much more common adenocarcinoma of the stomach described above, including pain, anorexia, and bleeding. Symptoms of fever and night sweats occur in 10–15% of patients with gastric NHL. Because the treatment options are so different, obtaining adequate tissue for definitive pathologic examination is crucial in diagnosing both gastric lymphomas (as opposed to adenocarcinoma) as well as defining the subtype of lymphoma. On occasion, this may be challenging because, similar to diffuse subtype adenocarcinoma, lymphomas may track below the mucosal surface. A fine-needle aspirate may not be sufficient; multiple deep biopsies or mucosal resection may be needed to provide enough tissue for definitive pathologic assessment.

Potential driving forces in the development of gastric lymphomas include active or prior *H. pylori* infection, which is associated with mucosa-associated lymphoid tissue (MALT) subtype gastric lymphomas and has been described as a potential driver in some patients with diffuse large B-cell lymphomas (DLBCLs). MALT lymphomas may

develop in nearly any organ, but the stomach is the most frequent primary site, accounting for ~35% of all MALT lymphomas. Identifying a MALT lymphoma is important because antibacterial therapy directed against *H. pylori* alone can be a highly effective treatment. Other infections should be considered either as driving factors or as risks from treatment, such as reactivation of hepatitis B virus (HBV); testing for HBV is recommended before initiation of lymphoma therapy. Hepatitis C infection has been associated with DLBCL and with marginal zone lymphomas. Other forms of NHL may involve the stomach either as primary gastric lymphoma or as a secondary site of disease, including both B-cell (e.g., mantle cell lymphoma, Burkitt's lymphoma, and follicular lymphoma) and T-cell lymphomas (e.g., enteropathy-associated T-cell lymphoma, anaplastic large-cell lymphoma, and peripheral T-cell lymphoma).

Staging is performed using similar imaging modalities as for gastric adenocarcinoma, but the staging systems are different (see below, and presented in more detail in the chapter on lymphomas [see Chap. 113]). As a staging study, FDG-PET/CT is performed, as well as a contrast-enhanced, diagnostic-quality CT. FDG-PET/CT is used both as an initial staging study and to assess response. EUS may be used to determine depth of invasion in patients in whom no evidence of metastatic disease is noted. Examination of the peripheral blood and bone marrow aspirate should be considered as part of the workup. In all patients with gastric lymphoma, *H. pylori* infection status should be evaluated. If *H. pylori* testing is negative by histopathology, noninvasive testing by either stool antigen test or urea breath test should be used.

STAGING

The TNM staging system is not employed for gastric lymphomas. Several classification systems are used for lymphomas, including the Lugano staging system (a modification of Ann Arbor staging), the revised World Health Organization (WHO) Fifth Edition of the WHO Classification of Haematolymphoid Tumours (WHOHAEM5), and the International Consensus Classification (ICC). These are discussed in **Chap. 113** on lymphomas. The Lugano staging system for gastrointestinal lymphomas is still widely used; it divides patient groups into stages I, II, III, and IV. Stage I tumors are limited to the gastric wall; stage II tumors have regional lymph node involvement or invasion of local structures; stage III tumors have lymph node involvement above and below the diaphragm. Stage IV tumors have either more extensive lymph node involvement or have distant metastasis, including to the bone marrow or other extranodal sites.

PATHOLOGIC CLASSIFICATION

The two most common histologic subtypes of gastric lymphoma are marginal zone B-cell lymphomas (gastric marginal zone B-cell lymphomas or MALT; ~40% of newly diagnosed patients) and DLBCLs (~55%). The distinction is critical because therapeutic options are different. The large majority of MALT cases are associated with *H. pylori* infection. The finding of a t(11;18) translocation identifies a subgroup less likely to respond to *H. pylori* eradication (or in non-*H. pylori*–associated MALT). This translocation may be detected using PCR or fluorescent in situ hybridization (FISH); it creates a chimeric protein composed of the amino terminal of *API1* (apoptosis inhibitor) and the carboxy terminus of *MALT1*, leading to activation of nuclear factor-κB signaling. Note that even *H. pylori*–negative MALT tumors may respond to anti–*H. pylori* therapy. Other, rarer subtypes of primary gastric lymphomas include those of T-cell lineage.

TREATMENT

Gastric Lymphoma

Unlike adenocarcinoma of the stomach, surgical resection has no role in the treatment of primary gastric lymphoma in the absence of complications of therapy such as perforation or uncontrollable bleeding. Resection of gastric lymphoma does not improve clinical outcomes.

For patients with MALT lymphoma, eradication of *H. pylori* with antibiotics is highly effective therapy. If tests for *H. pylori* are positive and t(11;18) translocation assay is negative, one of the currently accepted antibiotic regimens for treating *H. pylori* should be the initial therapy. *H. pylori* eradication is associated with high response rates including complete remissions in the majority of patients. Treatment with an anti–*H. pylori* regimen may induce remission even in patients in whom standard testing for *H. pylori*, described above, is negative. The time to remission may be prolonged (in some studies averaging 15–16 months); therefore, careful monitoring is important before determining that a MALT tumor is not responding to anti–*H. pylori* therapy. For patients in whom the t(11;18) translocation assay is positive, options for therapy include anti–*H. pylori* antibiotic therapy plus involved-field radiation therapy or, if radiation is contraindicated, the use of single-agent rituximab, a monoclonal antibody targeting CD20. For patients who are *H. pylori* negative, in whom anti–*H. pylori* therapy may have been used without response, moderate-dose (24–30 Gy) involved-site radiation therapy or single-agent rituximab is a treatment option. For selected, more advanced, stage IV MALT patients who have not responded to or who have progressed after receiving anti–*H. pylori* antibiotic therapy and/or rituximab, cytotoxic chemotherapy regimens such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone), dose-adjusted R-EPOCH (an infusional regimen of rituximab, etoposide, prednisolone, vincristine, cyclophosphamide, and doxorubicin), or rituximab and lenalidomide may be considered.

DLBCL may be a result of transformation from more indolent MALT lymphoma or may arise de novo. De novo tumors are more likely to be BCL2 and CD10 positive. MALT lymphomas that have transformed to DLBCLs are more frequently BCL2 and CD10 negative.

For patients with DLBCL, earlier-stage tumors may be treated by combination chemotherapy alone or chemotherapy plus involved-field radiation therapy. For more advanced gastric DLBCL tumors, chemotherapy using the R-CHOP or R-EPOCH regimen is standard therapy. Some reports have suggested that eradication of *H. pylori* is effective treatment for early-stage DLBCL when the patient also has *H. pylori*.

UNCOMMON TUMORS OF THE ESOPHAGUS AND STOMACH

GASTROINTESTINAL STROMAL TUMORS

GISTs are rare tumors of the gastrointestinal tract associated with activating somatic mutations in the *cKIT* (the majority) or *PDGFRA* genes; in a minority of cases, neither gene is mutated. GISTs arise from Cajal cells, which bridge between the autonomic nerves to the muscle layer of the bowel. The stomach is the most frequent primary site (~60%), followed by the small bowel in about 25%. As endoscopy for other indications has become more widely used, otherwise asymptomatic and probably clinically insignificant small GISTs have been identified more frequently; it is not clear that the actual incidence has substantially increased. Symptoms associated with GISTs include acute gastrointestinal bleeding leading to melena and/or hematemesis. Anemia may be reflected in generalized weakness. With larger tumors, abdominal distention and pain may be presenting symptoms. At endoscopy, a nonspecific smooth bulging mass covered by normal mucosa is the most frequent finding. Initial biopsy may not reveal a mesenchymal neoplasm. The radiologic features found on diagnostic CT scan (which may identify an asymptomatic tumor) may raise the question of a GIST tumor. EUS can be performed, but if biopsy is done, it may not provide an adequately cellular specimen to allow genomic sequencing, which is required to help guide systemic therapy (if needed).

Histologically, a spindle cell neoplasm is the most common subtype (~70%), with epithelioid cells making up 20%; 10% of cases are mixed histology. KIT expression is found in ~95% and *PDGFRA* in ~80% of cases. NGS is usually used to assess for gain-of-function *KIT, PDGFRA*, or other, rarer mutations.

For nonmetastatic GIST tumors, risk of recurrence assessment (guiding use of postoperative therapy) is based on the size of the primary tumor, mitotic index, and location in the gastrointestinal tract. For gastric GISTs, resected tumors ≤2 cm with a mitotic index of ≤5% have a near 0 risk of progression. For larger tumors, especially those ≥10 cm, with a mitotic index >5%, the risk is moderate to high. Postoperative adjuvant imatinib for 3 years is a standard-of-care option. Avapritinib is used for tumors with certain *PDGFRA* mutations. For patients with metastatic disease, imatinib (for *KIT* mutation–bearing tumors) or avapritinib (targeting *PDGFRA*) is used; the location of the *KIT* mutation (exon 11 vs 9) is associated with degree of effectiveness. However, resistance almost invariably develops, and the development of newer agents effective in tumors with secondary mutations is a high priority; ripretinib, which targets both *KIT* and *PDGFRA*, is now also FDA approved.

SMALL-BOWEL NEOPLASMS

Small-bowel neoplasms make up ~3% of gastrointestinal tumors; in 2023, 12,000 new cases are expected in the United States. The spectrum of malignant small-bowel neoplasms includes neuroendocrine tumors (NETs; carcinoid), adenocarcinomas, lymphomas, and GISTs. In the United States, NETs, which have increased in incidence, are slightly more frequent (40–45%) than adenocarcinomas (30–40%), with the remainder mostly lymphomas and ~8% GISTs. The duodenum is the most common portion of the small bowel in which malignancies develop (~50%), with ~30% occurring in the jejunum and 20% in the ileum. NETs are the most common benign and malignant tumors of the ileum. Risk factors for the development of small-bowel adenocarcinoma include inflammatory bowel disease (Crohn's disease); inherited germline mutation syndromes such as Lynch syndrome, familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome; and celiac disease (which is also associated with an increased risk for lymphomas).

While an asymptomatic small-bowel primary adenocarcinoma might be found during surveillance in patients at high risk (e.g., FAP), for many small-bowel tumors, the finding of positive stool occult blood, unexplained anemia, or small-bowel obstruction leads to the diagnosis. Both adenocarcinoma and lymphomas might present with perforation. Evaluation by diagnostic CT imaging may reveal a small-bowel lesion. CT and/or magnetic resonance enterography (CTE or MRE) have a high positive predictive value (for adenocarcinoma, MRE appears to be more accurate). A variety of endoscopic techniques are used for diagnostic evaluation of the small bowel, including device-assisted enteroscopy (DAE), e.g., double-balloon enteroscopy; small-bowel capsule endoscopy (SBCE) may also be employed. DAE allows tissue diagnosis; a tattoo helps localize the small bowel neoplasm (SBN) for resection; DAE may also allow stent placement for palliation of obstruction. SBCE is contraindicated in the setting of obstruction. As is the case for gastric imaging studies, deep learning artificial intelligence is being studied to improve the analysis of small-bowel imaging. For NETs, a gallium-68 or copper-64 DOTATATE scan may identify both the primary site as well as metastatic disease. Blood tumor biomarkers are nonspecific for the primary site (e.g., CEA or CA19-9 for adenocarcinoma); these assays are better used to monitor response or progression of disease rather than for diagnosis.

The median age at diagnosis for sporadic small-bowel adenocarcinoma is in the seventh or eighth decade of life, but genetically predisposed patients and those with inflammatory bowel disease may be diagnosed at a much earlier age. African Americans have a higher incidence of small-bowel cancer than whites. While systemic therapies are usually modeled on agents used to treat colorectal cancer, genomic analyses have indicated that small-bowel adenocarcinoma has distinct genomic alterations compared to either colorectal or gastric cancers. Genomic alterations less frequent in small-bowel than in colorectal cancers include *TP53*, *BRAF* V600E, and *APC* mutations, whereas the rate of *KRAS* mutations is similar to colorectal cancer (a genomic analysis of Chinese small-bowel cancer patients, mostly duodenal cancers, noted a somewhat different profile than U.S. patients). Within small-bowel sites, the most striking difference is the higher rate of *ERBB2* alterations (of which a minority are amplifications) in duodenal cancers. Not surprisingly, because Lynch syndrome increases the risk of small-bowel adenocarcinoma, 15–20% of these tumors are MSI high or mismatch repair deficient; small-bowel adenocarcinoma associated with celiac disease also may have an increased rate of MSI-high tumors. MSI/MMRP status should be assessed in all patients with small-bowel adenocarcinoma. Somatic tumor genomic analysis may suggest a germline mutation, but appropriate genetic testing for a germline driver mutation should be performed in all patients with small-bowel adenocarcinoma.

Small-bowel adenocarcinoma has its own staging classification in the eighth edition of the AJCC Cancer Staging Manual.

TREATMENT

Small-Bowel Adenocarcinomas

Surgical resection with negative microscopic margins (R0), as is the case for other gastrointestinal tumors, is the best chance for cure. For duodenal adenocarcinomas, a Whipple procedure may be needed; for more distal duodenal cancers and jejunal adenocarcinomas, a segmental resection with adequate margins should be performed. Distal ileal tumors may require right hemicolectomy.

Small-bowel cancers are frequently found with locally advanced disease at the time of diagnosis. If the tumor is resectable, postoperative adjuvant systemic therapy is currently recommended for lymph node–positive patients, using regimens such as those employed for colorectal cancer (capecitabine and oxaliplatin or FOLFOX). Benefit from adjuvant therapy has not yet been proven. Small-bowel cancers developing in patients with Lynch syndrome probably have a better prognosis; if colorectal cancer is a model, postoperative adjuvant therapy for patients with Lynch syndrome may include consideration of immune modulation therapy. For duodenal cancers, chemoradiation is considered if the resection margins are still positive.

For patients with advanced metastatic disease, in the absence of Lynch syndrome or a hypermutated tumor, similar cytotoxic regimens as deployed for gastric (duodenal) or colon cancers (jejunum or ileum) have been widely used. For tumors that are MSI high or dMMRP positive, immunotherapy is indicated; for tumors that are *HER2* amplified or *BRAF* mutated, targeted therapy may be useful.

SMALL-BOWEL GASTROINTESTINAL STROMAL TUMORS

Like small-bowel adenocarcinomas, small-bowel GISTs may present with obstruction or bleeding. Diagnostic techniques are those employed for other small-bowel neoplasms. While the pathological criteria for malignant potential are somewhat different than those used for gastric GISTs, postoperative management and treatment of metastatic disease are the same as those described above for gastric GIST.

BENIGN NEOPLASMS OF THE SMALL BOWEL

As is the case for malignant small-bowel tumors, benign neoplasms of the small bowel are rare. In addition to cancers, the precursor lesion adenomas or hamartomas (from which cancers develop) may be driven by inherited cancer susceptibility genes (e.g., FAP, Lynch syndrome, Peutz-Jeghers syndrome). Other benign neoplasms include lipomas, leiomyomas, neurofibromas, and benign lymphoid nodular hyperplasia.

Patients with benign small-bowel neoplasms not associated with an inherited cancer susceptibility gene (in which case, a benign tumor may be found during surveillance) are usually asymptomatic. A mass may be noted on an imaging study (usually a CT) ordered for another reason. Workup for occult or overt bleeding or intussusception of the bowel may lead to the discovery of a benign small-bowel neoplasm.

Diagnostic evaluation is similar to that described above for malignant tumors. In general, benign neoplasms, if found during surveillance, are removed endoscopically, if technically feasible, to decrease the risk of intussusception in Peutz-Jeghers syndrome. Mucosectomy may be used to treat bleeding hemangiomas.

NEUROENDOCRINE TUMORS OF THE ESOPHAGUS, STOMACH, AND SMALL BOWEL

Neuroendocrine neoplasms include NETs (more well differentiated, classified as grades 1–3) and neuroendocrine carcinomas (NECs). Neuroendocrine neoplasms including pancreas NETs are described in detail in **Chap. 89**. The following describes NET and NEC of the esophagus, stomach, and small bowel.

ESOPHAGEAL AND GASTRIC NEUROENDOCRINE TUMORS

NETs of the esophagus are rare, accounting for <1% of gastrointestinal NETs. Presenting symptoms are similar to those of SCC or adenocarcinoma of the esophagus, with dysphagia or odynophagia or with more nonspecific symptoms such as substernal discomfort or burning consistent with reflux esophagitis. A potential driving factor of NEC is smoking. The initial diagnostic evaluation includes upper endoscopy and biopsy. Pathology may reveal a well-differentiated NET (grades 1–3; grade guided by percent Ki-67 positivity) with a low to relatively low metastatic potential; at the other end of the spectrum are small-cell or large-cell NECs, which are fully malignant and frequently metastasize. In the absence of metastatic disease, EUS to assess depth of penetration and presence or absence of regional lymph node metastasis is frequently performed. Imaging studies include CT; for high-grade NEC, an FDG-PET/CT scan to assess for metastatic disease is done. For NET, somatostatin receptor imaging studies such as gallium-68 or copper-64 DOTATATE scans may be performed if metastatic disease is suspected.

Gastric NETs (also called gastric carcinoid tumors) represent 7–9% of gastrointestinal NETs but <1% of gastric neoplasms; several types have been described, based in part on whether there is associated achlorhydria and hypergastrinemia. For all gastric NETs, initial evaluation includes upper endoscopy and biopsy. EUS may be helpful in assessing depth of invasion for larger tumors and for assessing regional lymph node metastases in higher grade tumors. Somatostatin analogue imaging using DOTATATE scanning may be performed if metastatic disease is suspected. As is the case for other NETs, the finding of unresectable metastatic disease that is DOTATATE avid not only provides staging information but also guides potential therapy using somatostatin receptor–targeted therapy. See **Chap. 89** for a more detailed discussion.

TREATMENT

Esophageal Neuroendocrine Tumors

For early-stage, lower-grade NETs, endoscopic resection including EMR or ESD may be performed. Surgery may be employed for more advanced-stage locoregional but not metastatic NET. Small-cell or large-cell NECs that are not metastatic are usually treated with chemotherapy plus external-beam radiation therapy using chemotherapy regimens similar to those employed for small- and large-cell neuroendocrine cancers of the lung **(Chap. 83)**. For metastatic NETs, somatostatin receptor DOTATATE scans guide therapy. See below discussion for small-bowel NETs for discussion of use of somatostatin receptor blockade with agents such as octreotide or lanreotide and the use of peptide-related radiation therapy (PRRT). Systemic therapy for metastatic small- and large-cell esophagogastric NECs is also modeled on therapy for small- and large-cell thoracic NECs.

TREATMENT

Gastric Neuroendocrine Tumors

Type 1 tumors can be treated endoscopically with polypectomy or endomucosal resection. For larger tumors (>2 cm) or tumors invading through the muscularis or to regional lymph nodes, surgical resection is recommended. Type 2 tumors have a higher risk for regional lymph node metastasis and are usually treated surgically, although selected patients may have a combination of endoscopic resection and limited surgical resection. Type 3 tumors are not associated with elevated gastrin levels and have a higher propensity for regional lymph node metastasis and distant metastasis. Surgery is the treatment of choice for localized type 3 tumors, although EMR has been used in selected patients. Adenocarcinoma of the stomach may be found in 5–10% of type 3 tumors. The role of surgery in mixed NEC-adenocarcinoma neoplasms is not well established.

NEUROENDOCRINE TUMORS (CARCINOID) OF THE SMALL BOWEL

In the United States, NET are the most common small-bowel neoplasms. For not yet identified reasons, the incidence of small-bowel carcinoid tumors has markedly increased over the past several decades. A recent study found a 9% incidence of inherited germline cancer susceptibility genes in patients with small-bowel NET; however, it is unlikely that this is the cause of the increased incidence **(Chap. 89)**. Even with an increase in incidence, small-bowel NETs are still uncommon (~12 cases per million in the United States); the disease is more common in African Americans than whites.

Anatomically, the ileum is the most common part of the small bowel affected (~49%), followed by the duodenum and the jejunum. The same grading system, based on histology and the Ki-67 proliferative index or mitotic count, as for other gastrointestinal NETs is used. In the absence of metastatic disease to the liver in the subgroup of patients whose tumors are functional (i.e., produce a hormone, usually serotonin; a duodenal NET may produce gastrin), presenting symptoms may be vague abdominal discomfort until or unless small-bowel obstruction occurs. Carcinoid syndrome (including diarrhea and/or flushing) may occur in patients whose tumors are diagnosed with already established hepatic metastasis. Because the liver is very efficient at clearing serotonin on first pass, carcinoid syndrome as a result of small-bowel carcinoid tumors usually does not occur in the absence of hepatic metastasis.

Clinical evaluation includes a diagnostic-quality CT or MRI of the abdomen and pelvis. For duodenal NET, upper endoscopy with EUS is also performed. For ileal NET, colonoscopy with evaluation of the terminal ileum is performed. Imaging studies are similar to those used for diagnosis and localization of small-bowel adenocarcinomas. Somatostatin analogue imaging using gallium-68 or copper-64 DOTATATE PET/CT is helpful in assessing extent of disease in patients whose tumors are somatostatin analogue avid, as well as in identifying patients who may benefit from therapy targeting the somatostatin receptor. Plasma or urine assay for 5-hydroxyindoleacetic acid (5-HIAA) is performed to assess for a functional small-bowel NET. The AJCC Ninth Edition Cancer Staging Manual has a specific small-bowel NET TNM stage classification (for the duodenum and ampulla and for the jejunum and ilium).

The majority of patients present with locoregional disease, with approximately 40% having identified lymph node metastasis. Ten to 15% of patients have metastatic disease (usually to the liver) at the time of initial diagnosis.

Initial management should be surgical resection with curative intent; for patients with extensive adenopathy involving the root of the mesentery, vascular reconstruction may be required. Since small-bowel NETs may involve multiple tumors (15–30% of patients), the entire small bowel should be carefully examined at surgery. For patients with functional carcinoid tumors, somatostatin analogue therapy using agents such as octreotide should be given before the induction of anesthesia to avoid a carcinoid crisis. For patients with hepatic metastasis, resection or regional therapy including ablation or hepatic artery embolization for functional tumors may provide effective palliation. Carcinoid syndrome may also be palliated by somatostatin receptor–targeted therapy in the patients in whom DOTATATE scanning is positive (the majority of patients with carcinoid syndrome), including agents such as octreotide or lanreotide, or by peptide-directed radiation therapy using agents such as lutetium-177. Everolimus, an mTOR kinase inhibitor, has modest activity in metastatic small-bowel carcinoid tumors.

86 Colorectal Cancer

David P. Ryan

INCIDENCE

Colorectal cancer is the most common cancer of the gastrointestinal system in the United States. In 2024, 153,000 cases are expected, with ~106,000 cases in the colon and 46,000 cases in the rectum. It is the second most common cause of death from cancer (lung cancer is first) with 53,000 expected deaths. There is a slight male predominance in the incidence of colorectal cancer, and it is more common in black Americans than white Americans. Since 1985, there has been a steady decline in the incidence of colorectal cancer in both men and women likely due to the adoption of widespread screening guidelines for colonoscopy. This decline is seen in adults older than 50. However, a steady increase in the incidence of colorectal cancer has been seen in patients under the age of 50. While in older adults a gradual shift into predominantly right-sided cancer has been noted, a gradual increase in left-sided colon and rectal cancers has been seen in patients under the age of 50. This increase in incidence has resulted in an increase in mortality rates from colorectal cancer among young adults. Colon cancer is now the leading cause of cancer death for young men age 20–49 and the second leading cause of cancer death after breast cancer for women age 40–49.

ADENOMATOUS POLYPS

Most colorectal cancers arise from adenomatous polyps as opposed to a hyperplastic polyp, hamartomatous polyp, or a serrated polyp. While adenomatous polyps are clearly premalignant, only a minority of adenomatous polyps will ever develop into an adenocarcinoma. Adenomatous polyps are common in the United States and western societies, with approximately 25% of people having adenomatous polyps by age 50. The rate steadily rises as people age, and as many as 50% of 70-year-old people will have adenomatous polyps. Less than 5% of adenomatous polyps are expected to progress to an adenocarcinoma. The vast majority of adenomatous polyps are asymptomatic and do not bleed. The risk of progression to cancer is associated with size of the polyp and the histology. Villous adenomas develop into cancer threefold more often than tubular adenomas.

MOLECULAR PATHOGENESIS

The majority of colon cancers arise from a series of genetic and epigenetic events involving tumor suppressor genes and oncogenes. Three major types of molecular pathways are involved in sporadic colorectal cancer: the chromosomal instability (CIN) pathway, the mismatch repair (MMR) pathway, and the CpG island methylation pathway (CIMP). The CIN pathway is the most common molecular pathway associated with colon cancer and is characterized by early loss of the adenomatous polyposis coli (*APC*) gene, which is a tumor suppressor gene. Subsequent mutations in important oncogenes involving the MAP kinase pathway, such as *KRAS* and *BRAF*, are acquired sequentially. Finally, loss of *p53* tumor suppressor gene is a common final step.

The defects in the MMR pathway in sporadic colon cancer are often caused by hypermethylation of the promoters for mismatch repair genes. This results in a phenotype known as microsatellite instability high (MSI-high), which is characterized by altered sizes of various mono- and di-nucleotide repeat sequences. A defect in the MMR pathway is the etiology of Lynch syndrome, which involves a germline mutation in one of the genes encoding for the proteins involved in the MMR pathway. It is critical to test for MSI-high because these tumors are dramatically sensitive to immune checkpoint inhibition and less sensitive to chemotherapy. The third major molecular pathway is the CIMP phenotype. These tumors are often right sided and associated with methylation of MLH1. They can be either MSI-high or microsatellite stable (MSS). The three major pathways are not mutually exclusive, and often overlapping changes can be seen in individual cancers.

ETIOLOGY AND RISK FACTORS

Risk factors for the development of colorectal cancer are listed in Table 86-1.

HEREDITARY FACTORS AND SYNDROMES

Advances in germline genotyping have made this technology more widely available to the population of patients getting colon cancer. Approximately 10% of all patients with colorectal cancer will have an inherited, germline predisposition to colorectal cancer, and this rises to ~15% of young adults with colorectal cancer (Table 86-2). The germline mutations can be divided into high penetrance and moderate penetrance based on their risk of colon cancer development.

Familial Adenomatous Polyposis (FAP) FAP and its variants are due to a mutation in the *APC* gene located on chromosome 5q21-22. It is inherited in an autosomal dominant pattern, although a significant minority of cases are due to de novo mutations. FAP accounts for <1% of all colon cancer and is characterized by the development of hundreds to thousands of colonic polyps. It is diagnosed in childhood in the classical form of FAP, and colorectal cancer develops in virtually 100% of individuals if left untreated. An attenuated form of FAP is characterized by tens of polyps and cancers developing at a later age. FAP

Tobacco use

TABLE 86-2 Heritable (Autosomal Dominant) Gastrointestinal Neoplasia Syndromes

SYNDROME	DISTRIBUTION OF POLYPS	HISTOLOGIC TYPE	MALIGNANT POTENTIAL	ASSOCIATED LESIONS
Familial adenomatous polyposis	Large intestine	Adenoma	Common	—
Gardner's syndrome	Large and small intestines	Adenoma	Common	Osteomas, fibromas, lipomas, epidermoid cysts, ampullary cancers, congenital hypertrophy of retinal pigment epithelium
Turcot's syndrome	Large intestine	Adenoma	Common	Brain tumors
MYH-associated polyposis	Large intestine	Adenoma	Common	None
Lynch syndrome (nonpolyposis syndrome)	Large intestine (often proximal)	Adenoma	Common	Endometrial and ovarian tumors (most frequently), gastric, genitourinary, pancreatic, biliary cancers (less frequently)
Peutz-Jeghers syndrome	Small and large intestines, stomach	Hamartoma	Rare	Mucocutaneous pigmentation; tumors of the ovary, breast, pancreas, endometrium
Juvenile polyposis	Large and small intestines, stomach	Hamartoma, rarely progressing to adenoma	Rare	Various congenital abnormalities

can be associated with extracolonic manifestations such as desmoid tumors (Gardner's syndrome) or brain tumors (Turcot's syndrome).

Patients with classic FAP should undergo colectomy, as well as those patients with attenuated FAP that is too difficult to screen endoscopically. Colectomy patients with FAP should be followed for extracolonic tumors and manifestations. Chemoprevention with nonsteroidal anti-inflammatory drugs (NSAIDs) can be tried because it has been associated with polyp regression and delayed progression, but its overall effect on cancer prevention has not been established.

MUTYH-Associated Polyposis (MAP) MAP is an autosomal recessive polyposis syndrome caused by a biallelic mutation in the *MUTYH* gene. The *MUTYH* gene is a base excision repair gene, and failure of base excision repair leads to somatic CG-AT transversions in multiple genes. MAP accounts for <1% of colorectal cancers. The clinical presentation of MAP overlaps with attenuated FAP in that individuals may have tens of polyps that develop by the fifth or sixth decade of life. Individuals with MAP are at increased risk of duodenal cancers and thyroid cancer. Screening and colectomy guidelines for this syndrome are less clear than for polyposis coli, but annual to biennial colonoscopic surveillance is generally recommended starting at age 25–30 years.

Lynch Syndrome Lynch syndrome, previously known as hereditary nonpolyposis colon cancer, is the most common inherited predisposition to colorectal cancer, accounting for ~3% of all colorectal cancers, and confers an up to 17-fold risk of colorectal cancer. Lynch syndrome is due to a mutation in one of the MMR genes. The MMR genes are *MLH1* (Chr 3p22), *MSH2* (2p21-16), *MSH6* (2p16), and *PMS2* (7p22). Lynch syndrome can also occur due to deletion of the *EPCAM* gene, which causes loss of expression of *MSH2*. These mutations are inherited in an autosomal dominant fashion. The MMR system maintains genomic integrity by correcting base substitution mismatches, and failure of the MMR system results in the accumulation of a thousand-fold more mutations in genes that drive carcinogenesis compared with MMR-proficient tumors. Lynch syndrome has multiple extracolonic manifestations including increased risk of cancers of the ovary, endometrium, stomach, small bowel, pancreaticobiliary system, genitourinary system, brain, and skin.

Lynch syndrome may not be associated with multiple polyps and therefore is often unrecognized. Universal testing of colorectal tumors for defects in the MMR system is recommended and accomplished by either immunohistochemistry for MMR proteins in the tumor sample or evaluation for microsatellite instability on the tumor sample. For patients without a Lynch syndrome–associated cancer, family history is the most reliable way to recognize Lynch syndrome, and several family history criteria (Amsterdam Criteria and Revised Bethesda Criteria) have been developed. Germline testing is recommended for all patients with defects in the MMR system noted on the tumor sample or for those non-cancer-affected patients with an appropriate family history. Germline testing should be done in the context of appropriate pre- and posttest genetic counseling.

***BRCA1/2* Mutation** The hereditary breast and ovarian cancer syndromes due to mutations in the tumor suppressor genes *BRCA1* and *BRCA2* may carry an increased risk of colorectal cancer. In particular, *BRCA1* mutation may confer a 1.5-fold increased risk of colorectal cancer. Currently, the evidence is inconsistent, and therefore, guidelines do not recommend increased screening. Nevertheless, *BRCA* carriers may have an increased risk of young adult–onset colorectal cancer, and clinicians should be aware of these data.

Diet The etiology for most cases of large-bowel cancer appears to be related to environmental factors. The disease occurs more often in upper socioeconomic populations who live in urban areas. Mortality from colorectal cancer is directly correlated with per capita consumption of calories, meat protein, and dietary fat and oil as well as elevations in the serum cholesterol concentration and mortality from coronary artery disease. Geographic variations in incidence largely are unrelated to genetic differences because migrant groups tend to assume the large-bowel cancer incidence rates of their adopted countries. Furthermore, population groups such as Mormons and Seventh Day Adventists, whose lifestyle and dietary habits differ somewhat from those of their neighbors, have significantly lower-than-expected incidence and mortality rates for colorectal cancer. The incidence of colorectal cancer has increased in Japan since that nation has adopted a more "Western" diet. At least three hypotheses have been proposed to explain the relationship to diet, none of which is fully satisfactory.

ANIMAL FATS One hypothesis is that the ingestion of animal fats found in red meats and processed meat leads to an increased proportion of anaerobes in the gut microflora (the "microbiome"), resulting in the conversion of normal bile acids into carcinogens. This provocative hypothesis is supported by several reports of increased amounts of fecal anaerobes (*Fusobacterium nucleatum*, *Bacteroides fragilis*) in the stools of patients with colorectal cancer. Diets high in animal (but not vegetable) fats are also associated with high serum cholesterol, which is also associated with enhanced risk for the development of colorectal adenomas and carcinomas.

INSULIN RESISTANCE The large number of calories in Western diets coupled with physical inactivity has been associated with a higher prevalence of obesity. Obese persons develop insulin resistance with increased circulating levels of insulin, leading to higher circulating concentrations of insulin-like growth factor type I (IGF-I). This growth factor appears to stimulate proliferation of the intestinal mucosa.

FIBER Contrary to prior beliefs, the results of randomized trials and case-controlled studies have *failed* to show any value for dietary fiber or diets high in fruits and vegetables in preventing the recurrence of colorectal adenomas or the development of colorectal cancer.

The weight of epidemiologic evidence, however, implicates diet as being the major etiologic factor for colorectal cancer, particularly diets high in animal fat and in calories.

INFLAMMATORY BOWEL DISEASE (CHAP. 337)

Colon and rectal cancers (but not anal cancers) are more common in patients with inflammatory bowel disease (IBD). Most of the data supporting this come from patients with ulcerative colitis. The risk of colorectal cancer in a patient with IBD is relatively small during the first 10 years of the disease but then appears to increase at a rate of ~0.5–1% per year. Cancer may develop in 8–30% of patients. The risk is higher in patients with more extensive, more severe, and longer-lasting colitis. The data are less consistent with Crohn's disease, but this may be due to the difficulty in distinguishing the two entities and also the different amount of pancolitis in the two diseases. The molecular pathogenesis of colorectal cancer arising from IBD appears to be distinctly different from sporadic cancers. For instance, *K-ras* and *APC* mutations appear to be less common in colon cancers arising in IBD patients.

Cancer surveillance strategies in patients with IBD are unsatisfactory due to the lack of the classic polyp-to-cancer sequence. Symptoms such as bloody diarrhea, abdominal cramping, and obstruction, which may signal the appearance of a tumor, are similar to the complaints caused by a flare-up of the underlying inflammatory disease. Surveillance for colorectal cancer in patients with IBD is highly technical and requires management by physicians specializing in this area. In patients with longstanding ulcerative colitis, surgical removal of the colon (subtotal or total) eliminates or significantly reduces the risk of colorectal cancer depending on the extent of the operation. In patients undergoing subtotal colectomy with preservation of the rectum, continued surveillance of the remaining rectum is required.

OTHER HIGH-RISK CONDITIONS

Tobacco Use Cigarette smoking is linked to the development of colorectal adenomas, particularly after >35 years of tobacco use. No biologic explanation for this association has yet been proposed.

Alcohol Use Moderate to excessive alcohol consumption has been associated with an increased risk of colorectal cancer. It is difficult to tease out the effect compared with other lifestyle risk factors.

Obesity, Insulin Resistance, and Diabetes Mellitus Multiple studies demonstrate an increased risk of colorectal cancer in obese individuals. Additionally, diabetes is associated with an increased risk of colorectal cancer. This has led to a theory that metabolic syndrome and hyperinsulinemia are risk factors for the development of colorectal cancer.

Vitamin D Deficiency Multiple studies have demonstrated an association between low levels of vitamin D and colon cancer. Nevertheless, no evidence suggests that vitamin D supplementation results in fewer colon cancers.

PRIMARY PREVENTION

Several orally administered compounds have been assessed as possible inhibitors of colon cancer. The most effective class of chemopreventive agents is aspirin and other NSAIDs, which are thought to suppress cell proliferation by inhibiting prostaglandin synthesis. Regular aspirin use as demonstrated in randomized studies reduces the risk of colon adenomas. Regular aspirin use in cohort studies has demonstrated reduced incidence of colon cancer. However, prospective trials using aspirin to prevent colon cancer have had conflicting results in part due to the delayed effects of aspirin on colon carcinogenesis; prevention may increase with the duration and dosage of aspirin, and the effects may take years to manifest. Meta-analyses have suggested that regular aspirin use prevents colon cancer. However, given the potential side effects of aspirin, regular use of aspirin is an individualized decision.

Antioxidant vitamins such as ascorbic acid, tocopherols, and β-carotene are ineffective at reducing the incidence of subsequent adenomas in patients who have undergone the removal of a colon adenoma. Estrogen replacement therapy has been associated with a reduction in the incidence of colorectal cancer in women but not mortality from colorectal cancer.

SCREENING

The rationale for colorectal cancer screening programs is that the removal of adenomatous polyps will prevent colorectal cancer and that earlier detection of localized, superficial cancers in asymptomatic individuals will increase the surgical cure rate. It is important to note that screening studies did not take into account the presence of inherited predisposition and germline genetics. Due to the rise in incidence of colorectal cancer in younger adults, the U.S. Preventative Services Task Force updated their screening recommendations in 2021 and lowered the age for recommended screening to 45.

TABLE 86-3 Screening Strategies for Colorectal Cancer

Digital rectal examination
Stool testing
• Occult blood
• Fecal DNA
Imaging
• Contrast barium enema
• Virtual (i.e., computed tomography colonography)
Endoscopy
• Flexible sigmoidoscopy
• Colonoscopy

Screening strategies for colorectal cancer that have been examined during the past several decades are listed in Table 86-3.

The rationale for screening asymptomatic individuals has undergone change over many decades, and it is important to understand how that change influences our current approach. Initially, patients were screened for the presence of occult blood in the stool, which would then lead to colonoscopy. Unfortunately, even when performed optimally, the fecal occult blood test has major limitations as a screening technique. About 50% of patients with documented colorectal cancers have a negative fecal occult blood test, consistent with the intermittent bleeding pattern of these tumors. When random cohorts of asymptomatic persons have been tested, 2–4% have fecal occult blood–positive stools. Colorectal cancers have been found in <10% of these "test-positive" cases, with benign polyps being detected in an additional 20–30%. Thus, a colorectal neoplasm will not be found in most asymptomatic individuals with occult blood in their stool. Nevertheless, prospectively controlled trials have shown a statistically significant reduction in mortality rate from colorectal cancer for individuals undergoing annual stool guaiac screening. However, this benefit only emerged after many years of follow-up and was due to colonoscopic intervention, which likely provided the opportunity for cancer prevention through the removal of potentially premalignant adenomatous polyps because the eventual development of cancer was reduced by 20% in the cohort undergoing annual screening.

Due to the importance of endoscopic screening in preventing death from colon cancer, many societies shifted from testing stool for the presence of occult blood to offering endoscopic screening for the asymptomatic population. Colonoscopy evaluates the entire colon but is associated with more complications, the need for cathartics to remove stool from the colon, the need for sedation in most cases, and more overall expense. Sigmoidoscopy does not require an enema, is associated with less perforations and morbidity, does not require sedation, and can identify patients at high risk of needing a full colonoscopy if polyps or cancer is found in the rectum or sigmoid colon. The recommendation for the inclusion of flexible sigmoidoscopy is strongly supported by randomized studies evaluating a one-time sigmoidoscopy as opposed to usual standard of care. A reduction in both colorectal cancer incidence and colorectal cancer mortality is obtained for patients undergoing screening, and this effect persists for >15 years. One of the downsides of using screening sigmoidoscopy alone is that in the presence of a normal sigmoidoscopy, ~1.5% of individuals will have either a high-risk polyp or adenocarcinoma in the proximal colon. The issue of missing advanced neoplasms in the proximal colon when using only sigmoidoscopy was addressed by increased frequency of sigmoidoscopy (every 5 years instead of every 10 years for colonoscopy) and the use of annual fecal immunohistochemical test (FIT) for occult blood. While randomized studies evaluating the combination are

lacking, most professional societies offer this approach as an alternative to colonoscopy screening.

With the appreciation that the carcinogenic process leading to the progression of the normal bowel mucosa to an adenomatous polyp and then to a cancer is the result of a series of molecular changes, investigators have examined fecal DNA for evidence of mutations associated with such molecular changes as evidence of the occult presence of precancerous lesions or actual malignancies. A multitarget stool DNA test evaluates stool that is collected at home for DNA changes including methylation combined with a FIT test. This multitarget stool DNA test, when done in patients undergoing colonoscopy, has a >90% specificity and sensitivity for detecting a colorectal adenocarcinoma but a <50% sensitivity for detecting an advanced precancerous lesion.

The use of imaging studies to screen for colorectal cancers has also been explored. Air contrast barium enemas had been used to identify sources of occult blood in the stool prior to the advent of fiberoptic endoscopy; the cumbersome nature of the procedure and inconvenience to patients limited its widespread adoption. The introduction of computed tomography (CT) scanning led to the development of virtual (i.e., CT) colonography as an alternative to the growing use of endoscopic screening techniques. Virtual colonography requires use of colon cathartic bowel preparations and appears to have good accuracy at detecting large lesions (>10 mm) but has not been compared in a randomized study with colonoscopy. Two other disadvantages of virtual colonoscopy are that it may have interuser variability and any findings need to be followed up with a colonoscopy requiring a second bowel cathartic preparation.

Most professional societies agree that screening for colon cancer should begin at age 45 for patients at average risk. In the United States, there is ~60% compliance with screening and the emphasis is on getting patients screened initially with either direct observation using sigmoidoscopy or colonoscopy or indirect tests such as FIT or multitarget stool DNA. The best combination approach and frequency of screening likely will involve risk stratification factors in the future.

CLINICAL FEATURES

Presenting Symptoms Symptoms vary with the anatomic location of the tumor. Because stool is relatively liquid as it passes through the ileocecal valve into the right colon, cancers arising in the cecum and ascending colon may become quite large without resulting in any obstructive symptoms or noticeable alterations in bowel habits. Lesions of the right colon commonly ulcerate, leading to chronic, insidious blood loss without a change in the appearance of the stool. Consequently, patients with tumors of the ascending colon often present with symptoms associated with hypochromic, microcytic anemia, indicative of iron deficiency. As a result, the unexplained presence of iron-deficiency anemia in any adult (with the possible exception of a premenopausal, multiparous woman) mandates a thorough endoscopic and/or radiographic visualization of the entire large bowel **(Fig. 86-1)**.

Because stool becomes more formed as it passes into the transverse and descending colon, tumors arising there tend to impede the passage of stool, resulting in the development of abdominal cramping, occasional obstruction, and even perforation. Radiographs and CTs of the abdomen often reveal characteristic annular, constricting lesions ("apple-core") **(Fig. 86-2)**.

Cancers arising in the rectosigmoid are often associated with hematochezia, tenesmus, and narrowing of the caliber of stool. While these symptoms may lead patients and their physicians to suspect the presence of hemorrhoids, the development of rectal bleeding and/or altered bowel habits demands a prompt digital rectal examination and sigmoidoscopy.

Staging, Prognostic Factors, and Patterns of Spread The prognosis for individuals having colorectal cancer is related to the depth of tumor penetration into the bowel wall and the presence of both regional lymph node involvement and distant metastases. These variables are incorporated into a TNM classification method, in which T represents the depth of tumor penetration, N the presence of lymph node involvement, and M the presence or absence of distant metastases **(Fig. 86-3)**. Superficial lesions that do not involve regional lymph nodes and do not penetrate through the submucosa (T1) or the muscularis (T2) are designated as *stage I* (T1–2N0M0) disease; tumors that penetrate through the muscularis but have not spread to lymph nodes are *stage II* disease (T3–4N0M0); regional lymph node involvement defines *stage III* (TXN1–2M0) disease; and metastatic spread to sites such as liver, lung, or bone indicates *stage IV* (TXNXM1) disease. Unless gross evidence of metastatic disease is present, disease stage cannot be determined accurately before surgical resection and pathologic analysis of the operative specimens.

The majority of recurrences occur within the initial 5 years after resection. Occasionally tumors can recur between 5 and 10 years after resection, and this appears to be more common with rectal cancer

FIGURE 86-1 Double-contrast air-barium enema revealing a sessile tumor of the cecum in a patient with iron-deficiency anemia and guaiac-positive stool. The lesion at surgery was a stage II adenocarcinoma.

FIGURE 86-2 Annular, constricting adenocarcinoma of the descending colon. This radiographic appearance is referred to as an "apple-core" lesion and is always highly suggestive of malignancy.

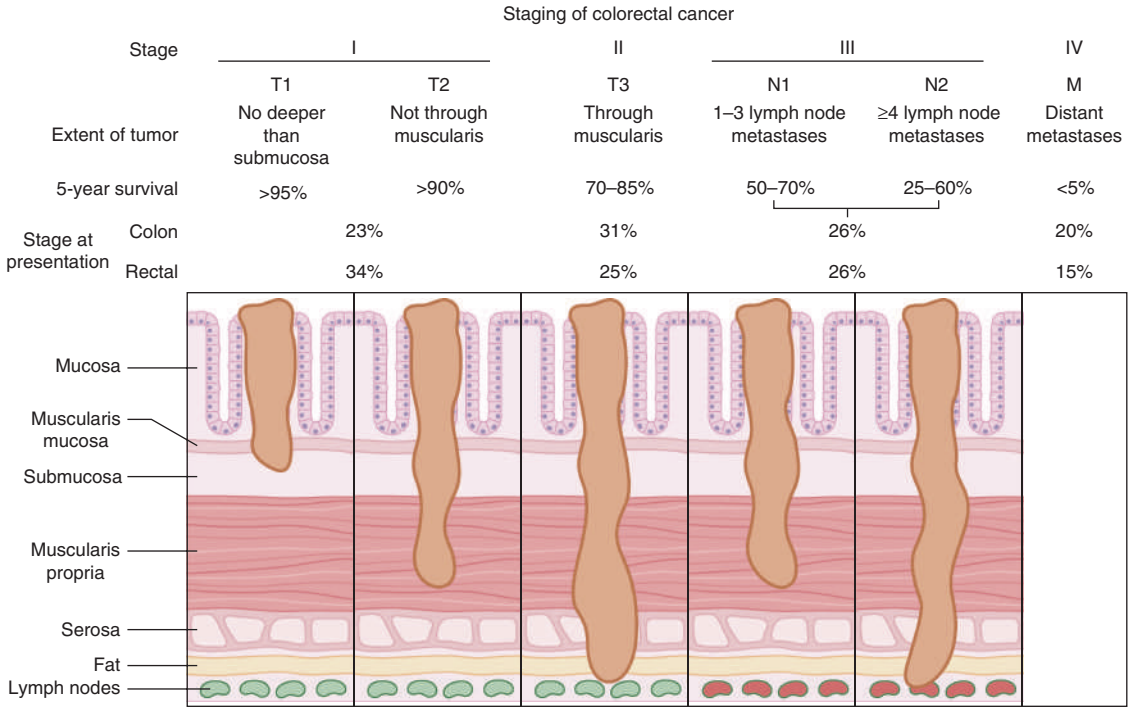

FIGURE 86-3 Staging and prognosis for patients with colorectal cancer.

than colon cancer. The likelihood for 5-year survival in patients with colorectal cancer is stage-related (Fig. 86-3), and the survival rates per stage have been improving in the past several decades. The most plausible explanation for improved survival is the more thorough evaluation for metastatic disease and the positive effects of chemotherapy for treatment of adjuvant and systemic disease. A minimum of 12 sampled lymph nodes is thought necessary to accurately define tumor stage, and the more nodes examined, the better reliability that a patient is either node negative or node positive. Other predictors of a poor prognosis after a total surgical resection include tumor penetration through the bowel wall into pericolic fat, poorly differentiated histology, perforation and/or tumor adherence to adjacent organs (increasing the risk for an anatomically adjacent recurrence), and venous invasion by tumor (Table 86-4). Tumors with microsatellite instability or defects in MMR have improved prognosis presumably due to an enhanced immune response against the tumor. Tumors arising in the left colon are associated with a better prognosis than those appearing in the right colon, likely due to differences in molecular patterns. In contrast to most other cancers, the prognosis in colorectal cancer is not influenced by the size of the primary lesion when adjusted for nodal involvement and histologic differentiation.

Colorectal cancer generally spreads to the liver, lungs, and peritoneal cavity. The liver represents the most frequent visceral site of metastasis; it is the initial site of distant spread in one-third of recurring colorectal cancers and is involved in more than two-thirds of such patients at the time of death. It can spread to the brain and bones but not typically as an initial site of metastatic disease, but rather after years of having systemic metastases. Nevertheless, prompt evaluation of signs and symptoms of bone and brain involvement should be efficiently done because lack of prompt treatment can have devastating consequences (e.g., cord compression, brain hemorrhage).

TABLE 86-4 Predictors of Poorer Outcomes Following Total Surgical Resection of Colorectal Cancer

Tumor spread to regional lymph nodes
Number of regional lymph nodes involved
Tumor penetration through the bowel wall
Poorly differentiated histology
Perforation
Tumor adherence to adjacent organs
Venous invasion
Preoperative elevation of CEA titer (>5 ng/mL)
Specific chromosomal deletion (e.g., mutation in the *b-raf* gene)
Right-sided location of primary tumor

Abbreviation: CEA, carcinoembryonic antigen.

TREATMENT

Colorectal Cancer

Staging should consist of a complete blood count, comprehensive metabolic panel, serum carcinoembryonic antigen (CEA), and a chest, abdomen, and pelvic CT scan. Additional imaging such as magnetic resonance imaging (MRI) and positron emission tomography (PET) scan can be dependent on the findings of the CT scan. When possible, a colonoscopy of the entire large bowel should be performed to identify synchronous neoplasms and/or polyps. While surgical resection is the standard of care for cure in patients with localized disease, initial treatment of colorectal cancer when possible should be delayed until MMR status or microsatellite stability status is known. MSI-high rectal cancers can be treated for cure with checkpoint inhibitors (PD-1 antibodies) without the need for surgery, radiation, and chemotherapy. Studies are underway involving management of MSI-high colon cancers with checkpoint inhibition.

LOCALIZED COLON CANCER

For the vast majority of patients with MSS colon adenocarcinoma, initial surgical resection is the standard of care. Surgery with minimally invasive techniques such as laparoscopy and robotic approaches has largely replaced open approaches. Following complete surgical resection, patients with stage I disease are considered cured. Patients with high-risk stage II and stage III colon cancer are considered for the appropriateness of adjuvant chemotherapy. The standard adjuvant approaches generally improve overall survival and cure rates by ~30%. Adjuvant chemotherapy for 3–6 months either with single-agent fluoropyrimidine (IV or oral) or in combination with oxaliplatin is considered the standard adjuvant treatment for MSS colon cancer.

Following recovery from a complete resection, patients should be observed carefully for 5 years using physical examinations and blood chemistry measurements at regular intervals. Some authorities favor measuring plasma CEA levels at 3-month intervals because of the sensitivity of this test as a marker for otherwise undetectable tumor recurrence. The value of periodically assessing plasma for the presence of circulating tumor DNA as a biomarker for residual or recurrent disease is under study. Subsequent endoscopic surveillance of the large bowel 1 year after resection and then usually every 3 years is indicated because patients who have been cured of one colorectal cancer have a 3–5% probability of developing an additional bowel cancer during their lifetime and a >15% risk for the development of adenomatous polyps. Anastomotic ("sutureline") recurrences are infrequent in colorectal cancer patients, provided the surgical resection margins were adequate and free of tumor. The value of periodic CT scans of the abdomen, assessing for an early, asymptomatic indication of tumor recurrence, is uncertain; however, CT has been recommended semi-annually to annually for the first 3 postoperative years.

LOCALIZED RECTAL CANCER

For the vast majority of patients with MSS rectal adenocarcinoma, surgical resection is considered the standard curative therapy. In addition to the staging above, pelvic MRI should be standard in staging for all patents with rectal cancer to assess mesorectal margin and nodal status. Surgical resection can either be a low anterior resection (LAR) or an abdominal-perineal resection (APR). An APR requires a permanent colostomy due to resection of the anal sphincter. Unlike colon cancer, rectal cancers (defined as tumor at or below the peritoneal reflection) have an increased risk of local recurrence after surgery. The risk of local recurrence increases with stage and closeness to the mesorectal border and decreases with distance from the anus. Thus, tumors requiring an APR have a high risk of local recurrence. The risk of local recurrence can be reduced with preoperative chemotherapy and radiation. Patients with stage II and III rectal cancer are deemed to have a risk high enough to warrant consideration of preoperative therapy.

Two new treatment paradigms have emerged for patients with rectal cancer in specific circumstances. The first situation involves patients in whom the consequences of radiation therapy are deemed unacceptable. Radiation is associated with the potential long-term side effects of radiation proctitis (increased risk in patients with IBD), small-bowel obstruction to adhesions, and malignancy (~1% risk after 10 years). Notably, radiation therapy in women causes infertility due to the effects of radiation on the uterus even when the ovaries are not included in the radiation field. Preoperative therapy with a fluoropyrimidine and oxaliplatin followed by surgical resection produces similar rates of local control to preoperative chemoradiation and can be considered for average-risk stage II and III rectal cancer patients.

The second circumstance involves patients with stage II and III rectal cancer treated with total preoperative therapy who experience a complete clinical response. Nonoperative management can be considered in these patients because 60–70% will be cured without an LAR or APR. It is important to note that 30–40% of patients will experience a recurrence so patients need to be followed intensively in the years following chemotherapy and radiation. The majority of patients who experience a local recurrence during nonoperative management can be cured with surgery.

METASTATIC COLORECTAL CANCER

The first principle to note is that complete resection of metastatic disease is considered curative for patients with colorectal cancer, particularly in the setting of metastases isolated to one site (liver, lungs, peritoneum). Consultation with the appropriate surgical specialists is preferred before starting systemic chemotherapy.

The detection of metastases should not preclude surgery to remove the primary tumor in patients with tumor-related symptoms such as gastrointestinal bleeding or obstruction but usually prompts the initiation of chemotherapy unless those symptoms are viewed to be life-threatening. Studies have demonstrated that resection of the primary tumor in the setting of unresectable metastatic disease does not improve overall survival and should be done only on an ad hoc basis.

Patients with MSI-high colon cancer should be treated with a checkpoint inhibitor as initial treatment. Long-term survival is possible in these patients, and some will have a complete response and may not ever have recurrence of their cancer. For the vast majority of patients with MSS colorectal adenocarcinoma who are not candidates for complete resection of metastatic disease, treatment with systemic chemotherapy is associated with marked improvement in overall survival compared with palliative care alone. A patient with metastatic disease lives on average for 2–3 years with systemic chemotherapy, and as many as 25% of patients will live for at least 5 years on and off chemotherapy.

The mainstays of therapy for patients with metastatic colon cancer are the following medications: 5-fluorouracil (5-FU; or capecitabine), irinotecan, oxaliplatin, and bevacizumab. These medications are used in combination all together (e.g., FOLFIRINOX-bevacizumab or FOLFOXIRI-bevacizumab) or in partial combination (e.g., FOLFOX-bevacizumab, FOFIRI-bevacizumab). 5-FU is an inhibitor of thymidylate synthase and is used in conjunction with folinic acid (leucovorin). It is metabolized by dihydropyrimidine dehydrogenase (DPD), which is deficient in ~1% of adults. Individuals with DPD deficiency can experience increased side effects from 5-FU, especially myelosuppression and mucositis. Testing for DPD gene mutations may identify patients at high risk of DPD deficiency and toxicity from 5-FU. Irinotecan is a topoisomerase I inhibitor and is metabolized by glucuronidation in the liver. Thus, patients with *UGT* mutations can experience decreased clearance and enhanced toxicity, principally myelosuppression. Oxaliplatin is a platinum analogue that is metabolized generally and can cause permanent peripheral neuropathy. Bevacizumab is a monoclonal antibody against vascular endothelial growth factor (VEGF). Side effects of bevacizumab include hypertension, nephrotic syndrome, and impaired wound healing. Untreated hypertension from bevacizumab has been associated with posterior reversible leukoencephalopathy syndrome.

Other agents with proven disease-altering effects in the metastatic setting include trifluridine-tipiracil, regorafenib, and fruquintinib. Trifluridine is a nucleoside analogue that is used with tipiracil, a thymidine phosphorylase inhibitor. Regorafenib is an oral multitargeted tyrosine kinase inhibitor, including VEGF. Fruquintinib is an oral VEFG tyrosine kinase inhibitor.

Molecular genotyping of the primary tumor should be done in all patients with metastatic colon cancer if possible. Patients without mutations of the RAS/RAF pathway can have excellent responses and prolonged survival with the addition of antibodies against epidermal growth factor (EGF), such as cetuximab and panitumumab. These agents are often given in combination with either FOLFOX or FOLFIRI. The effect of cetuximab and panitumumab appears to be limited to left-sided colon cancers because right-sided colon cancers have upregulation of receptor tyrosine kinases that create resistance to these antibodies. The main side effects of these two antibodies are the class effects of diarrhea and acneiform rash. Cetuximab, which is partially murine, is also associated with allergic reactions.

Patients who harbor *BRAF* V600E mutations may have a particularly virulent form of colon cancer that does not respond as well to standard chemotherapy. These mutations tend to occur more commonly in right-sided tumors and women. They often involve methylation of *MLH1* and can be MMR deficient. The BRAF inhibitor encorafenib is approved for use with cetuximab in patients with *BRAF*-mutant colorectal cancer.

HER2 overexpression can be seen in colorectal cancer, and consideration of anti-HER2–targeted therapy is warranted. Tucatinib (HER2 tyrosine kinase inhibitor) and trastuzumab (anti-HER2 monoclonal antibody) are approved in the United States for patients with HER2-positive colorectal cancers that lack a *RAS* mutation.

Rarely, *RET* fusions and *TRK* fusions can be seen in patients with metastatic colorectal cancer. These patients can have tremendous responses to the appropriate RET and TRK inhibitors with marked prolongation of survival.

CANCERS OF THE ANUS

Cancers of the anus account for 1–2% of the malignant tumors of the large bowel. Anal cancer by convention refers to squamous cell carcinomas arising in the anorectal region. Other types of cancers including melanoma, neuroendocrine cancer, lymphoma, and mesenchymal tumors can arise in these regions but are referred to by their histologic subtype and are not the subject of this chapter. True adenocarcinomas arising from the glands in the anal canal that are distinct from rectal adenocarcinoma can also arise but, for all intents and purposes, are indistinguishable from rectal adenocarcinoma and treated accordingly.

Most anal cancers arise in the anal canal, the anatomic area extending from the anorectal ring to a zone approximately halfway between the pectinate (or dentate) line and the anal verge. The dentate line can be quite variable in adults but, on average, is 4 cm from the anal verge. Squamous cell carcinomas are characterized as either nonkeratinizing or keratinizing. Older terms such as cloacogenic and basaloid are not used anymore, and these tumors are instead characterized as nonkeratinizing. Outcomes for keratinizing and nonkeratinizing squamous cell carcinoma of the anus are not different.

The development of anal cancer is associated with infection by human papillomavirus (HPV), the same virus etiologically linked to cervical and oropharyngeal cancers. The same HPV subtypes associated with cervical cancer are seen in anal cancer. The infection may lead to squamous intraepithelial lesions (SILs), which are classified as either low grade (LSIL) or high grade (HSIL). LSILs are associated with non–cancer-causing HPV subtypes, are not considered precancerous, and can spontaneously regress. HSILs are associated with HPV16 and are considered precancerous. Anal cancer risk is increased in both men and women with immunocompromised states including solid organ transplant patients, patients with chronic immunosuppression with glucocorticoids, and patients living with HIV, particularly with low CD4 counts. Anal cancers occur most commonly in middle-aged persons and are more frequent in women than men. At diagnosis, patients may experience bleeding, pain, sensation of a perianal mass, and pruritus. Examination of and attention to the inguinal lymph nodes on imaging is important because anal cancers often spread initially to the inguinal region rather than the iliac nodes like rectal cancer.

The standard treatment for anal cancers consists of 5-FU, mitomycin, and concurrent external beam radiation therapy. The majority of patients will experience a complete response to therapy. Some patients will have ongoing resolution of their cancer over the 6 months after completion of therapy. Therefore, the decision about whether a patient has had a complete response to therapy is not made until after 6 months following chemoradiation.

Patients who are considered primarily refractory to chemoradiation or those with locally recurrent disease can be cured with radical resection (i.e., APR). In addition to those experiencing a local recurrence, ~10% of patients may experience continued rectal incontinence due to the effects of radiation therapy and undergo a subsequent colostomy.

Metastatic anal cancer is considered incurable. It may respond well to carboplatin and paclitaxel. PD-1 antibodies have limited activity in patients with metastatic disease.

87 Tumors of the Liver and Biliary Tree

Josep M. Llovet

Liver cancer is the sixth most common cancer worldwide, the third leading cause of cancer-related deaths and the leading cause of death among cirrhotic patients. Liver cancer comprises a heterogeneous group of malignant tumors that range from hepatocellular carcinoma (HCC; ~85 cases), intrahepatic cholangiocarcinoma (iCCA; ~10%), and other malignancies, such as fibrolamellar HCC, mixed HCC-iCCA, epithelioid hemangiothelioma, and the pediatric cancer hepatoblastoma. The burden of liver cancer is increasing globally.

HEPATOCELLULAR CARCINOMA

EPIDEMIOLOGY AND RISK FACTORS

Overall, liver cancer accounts for 7% of all cancers (~900,000 new cases each year), and HCC represents 85% of primary liver cancers. The highest incidence rates of HCC occur in Asia and sub-Saharan Africa due to the high prevalence of hepatitis B virus (HBV) infection, with 20–35 cases per 100,000 inhabitants. Southern Europe and now North America have intermediate incidence rates (10 cases per 100,000), whereas Northern and Western Europe have low incidence rates of less than 5 cases per 100,000 inhabitants. In the United States, the incidence of liver cancer is 40,000 cases per year **(Fig. 87-1)**. HCC has a strong male preponderance, with a male-to-female ratio estimated to be 2.5:1. The incidence increases with age, reaching a peak at 65–70 years old. In Chinese and in black African populations (where vertical transmission of HBV occurs), the mean age is 40–50 years. By contrast, in Japan mean age in men is now around 75 years.

The main risk factors for HCC development are cirrhosis—an associated chronic liver damage caused by inflammation and fibrosis—of any etiology, chronic infection by HBV or hepatitis C virus (HCV) infection, alcohol abuse, metabolic syndrome, and hemochromatosis (associated to *HFE1* gene germline mutations) (Fig. 87-1). Cirrhotic patients represent 1% of the human population, and one-third of them will develop HCC during their lifetime. Long-term follow-up studies have established an annual risk of HCC development of 3–8% in HBV- or HCV-infected cirrhotic patients. HCC is less common (1–2% per year) in cirrhosis associated with alcohol, metabolic dysfunction–associated steatohepatitis (MASH, formerly known as nonalcoholic steatohepatitis or NASH), α_1-antitrypsin deficiency, autoimmune hepatitis, Wilson's disease, and cholestatic liver disorders. Predictors of liver cancer development among cirrhotic patients have been associated

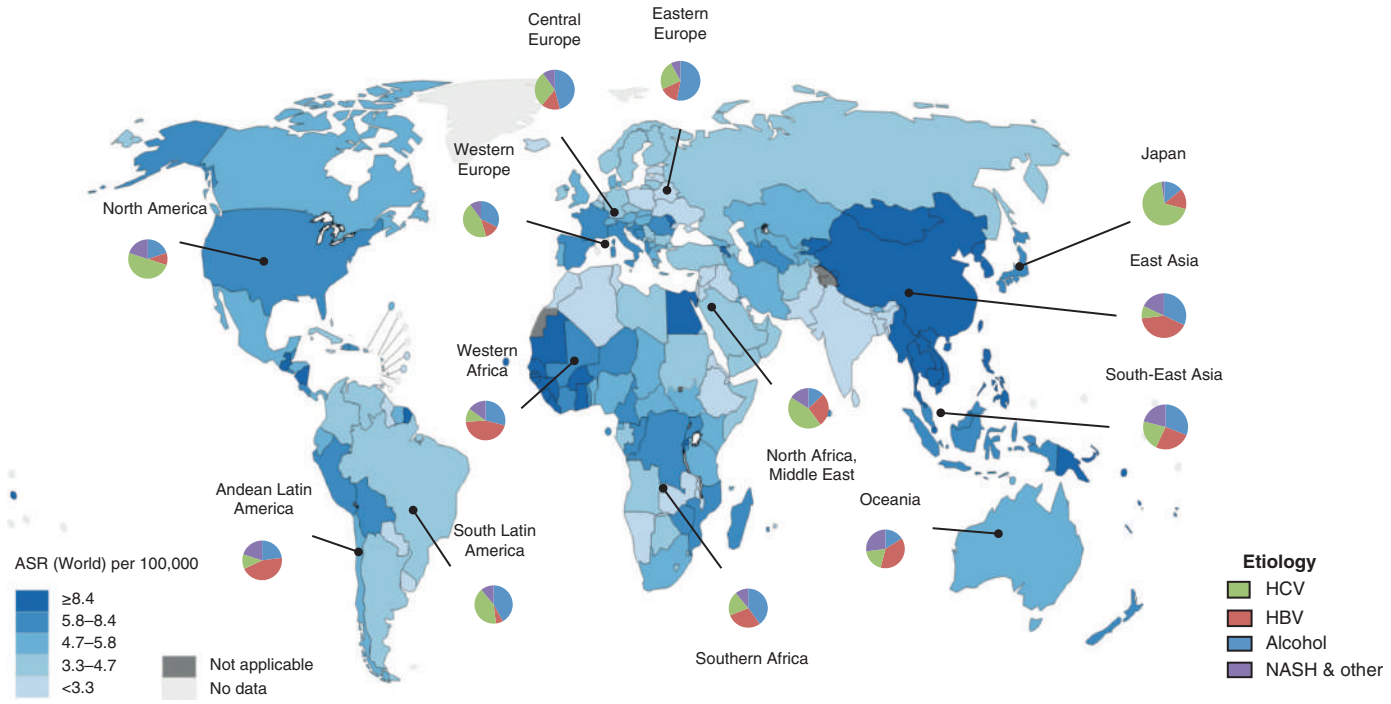

FIGURE 87-1 Distribution of hepatocellular carcinoma (HCC) incidence according to geographical area and etiology. HBV, hepatitis B virus; HCV, hepatitis C virus; NASH, nonalcoholic steatohepatitis. *(Reproduced with permission from JM Llovet et al: Hepatocellular carcinoma. Nat Rev Disease Primers 21:76, 2021.)*

with liver disease severity (platelet count of <100,000/μL, presence of portal hypertension), the degree of liver stiffness as measured by transient elastography, and liver gene signatures capturing the *cancer field effect*.

In terms of attributable risk fraction, HBV infection—a DNA virus that can cause insertional mutagenesis and affects ~300 million people globally—accounts for ~50% of HCC cases globally (60% in Asia and Africa and 20% in the Western world). Among patients with HBV infection, a family history of HCC, HBeAg seropositivity, high viral load, and genotype C are independent predictors of HCC development. HCV infection—an RNA virus that affects ~70 million people—is responsible for ~30% of cases and is the main cause of HCC in Europe and North America. Among patients with HCV infection, HCC occurs almost exclusively when relevant advanced liver damage and fibrosis are present, particularly if associated with HCV genotype 1b.

Alcohol consumption and metabolic syndrome due to diabetes and obesity are responsible for ~30% of cases. MASH is the fastest growing cause of cirrhosis in developed countries and currently represents ~15–20% of HCC cases in the West. The annual incidence of HCC in MASH-related cirrhosis (1–2%/year) justifies including cirrhotic patients in surveillance programs. Nonetheless, it has to be taken into account that 25–30% of MASH-associated HCCs occur in the absence of cirrhosis. A *PNPLA3* polymorphism is strongly associated with fatty and alcoholic chronic liver diseases and HCC occurrence. Finally, other cofactors contributing to HCC development in all etiologies are tobacco, aflatoxin B1 (a fungal carcinogen present in food supplies that induces *TP53* mutations), and aristolochic acid contained in Chinese medicine herbs.

MOLECULAR PATHOGENESIS

HCC development is a complex multistep process that starts with precancerous cirrhotic nodules, so-called low-grade dysplastic nodules (LGDN) that evolve to high-grade dysplastic nodules (HGDN) that can transform into early-stage HCC. Molecular studies support the pivotal role of adult hepatocytes as the cell of origin, either by directly transforming to HCC or by de-differentiating into hepatocyte precursor cells. Alternatively, progenitor cells also give rise to HCC with progenitor markers.

Genomic analysis has provided a clear picture of the main drivers responsible for HCC initiation and progression. This tumor results from the accumulation of around 40–60 somatic genomic alterations per tumor, among which 4–8 are considered driver cancer genes. HCC is a prototypical inflammation-associated cancer, where immune microenvironment and oxidative stress present in chronically damaged livers play pivotal roles in inducing mutations. In preneoplastic HGDN, mutations in telomere reverse transcriptase (*TERT*) gene (20% of cases) and gains in 8q have been described. Oncogenic transformation occurs upon additional genomic hits. The main molecular drivers of HCC are in the telomerase reverse transcriptase (*TERT*) promoter (56%), *TP53* (27%), and *CTNNB1* (26%), all of which are unactionable with molecular therapies. Genes commonly mutated in other solid tumors such as *EGFR*, *HER2*, *PIK3CA*, *BRAF*, or *KRAS* are rarely mutated in HCC (<5%) **(Table 87-1)**. Studies assessing copy-number alterations in HCCs have consistently identified: (1) high-level amplifications at 5–10% prevalence containing oncogenes in 11q13 (*CCND1* and *FGF19*) and 6p21 (*VEGFA*), *TERT* focal amplification, and homozygous deletion of *CDKN2A*; and (2) common amplifications containing *MYC* (8q gain). Overall, only ~20–25% of HCCs have at least one actionable mutation. Some risk factors have been associated with specific molecular aberrations. HBV integrates into the genome of driver genes, such as the *TERT* promoter, *MLL4*, and cyclin E1 (*CCNE1*). Alcohol abuse and HCV infection have been associated with *CTNNB1* mutations. *TP53* mutations are the most frequent alterations with a specific hotspot of mutation (R249S) in patients with aflatoxin B1 exposure.

Molecular and Immune Classes Genomic studies have revealed two molecular subclasses of HCC, each representing ~50% of patients. The proliferative subclass associated with poor outcomes, HBV-related etiologies, and overexpression of α-fetoprotein is enriched by activation of Ras, mammalian target of rapamycin (mTOR), and insulin-like growth factor (IGF) signaling and *FGF19* amplification. By contrast, the so-called nonproliferative subclass contains a subtype characterized by *CTNNB1* mutations and better outcome. Another classification based upon immune status has been proposed. It defines an inflamed HCC class in ~35% of cases (i.e., *hot* tumors), characterized by immune infiltrate with expression of PD-1/PD-L1, enrichment of T-cell activation, and better response to immunotherapies, and a noninflamed class (*cold* tumors), which includes the excluded subclass associated with activation of pathways related with immune escape (i.e., Wnt signaling) or absence of T-cell infiltrate. None of this molecular knowledge

has yet been translated into actual clinical benefits for any specific molecularly based subgroups, and thus, precision oncology is still an unmet goal of therapy.

PREVENTION AND EARLY DETECTION

Prevention Primary prevention of HCC can be achieved by vaccination against HBV and effective treatment of HBV and HCV infection. Universal vaccination against HBV infection is associated with a significant decrease of the incidence of HCC. Nowadays, HBV vaccination is recommended to all newborns and high-risk groups, following World Health Organization guidelines, and people with risk factors for acquiring HBV infection, such as health workers, travelers to areas where HBV infection is prevalent, injecting drug users, and people with multiple sex partners.

Effective antiviral treatments for patients with chronic HBV infection—achieving undetectable viral titers (circulating HBV-DNA)—result in 50–80% risk reduction of HCC development. Treatment of HCV with direct-acting antiviral agents (DAAs) yields >90% sustained virological response (SVR) rates after 12 weeks of treatment, thus significantly reducing HCC occurrence. Once cirrhosis is established, the incidence of HCC is lower for patients with SVR than for those with active viral disease, although they continue to have persistent HCC risk. Clinical practice guidelines recommend coffee consumption as a preventive strategy in patients with chronic liver disease. Aspirin, statins, and metformin have shown preventive effects but are not yet recommended as formal chemopreventive strategies.

Surveillance Surveillance programs aim to reduce cancer-related mortality. This is usually achieved through early detection that enhances the applicability and cost-effectiveness of curative therapies. U.S. and European guidelines recommend surveillance for patients at high risk for HCC on the basis of cost-effectiveness analyses.

Surveillance is recommended for cirrhotic patients owing to any cause, those with HCV-related advanced fibrosis, and patients with chronic HBV infection if Asian aged >40 years, African aged >20 years, family history of HCC, or patients with sufficient risk by risk scores such as PAGE-B. In terms of liver dysfunction, the presence of advanced cirrhosis (Child-Pugh class C) prevents potentially curative therapies from being employed, and thus surveillance is not recommended. As an exception, patients on the waiting list for liver transplantation, regardless of liver functional status, should be screened for HCC in order to detect tumors exceeding conventional criteria and to define priority policies for transplantation.

Ultrasonography every 6 months with serum α-fetoprotein (AFP) levels is the recommended method of surveillance. It has a sensitivity of ~65% and a specificity of >90% for early detection. A shorter follow-up interval (every 3–6 months) is recommended when a nodule of <1 cm has been detected. Computed tomography (CT) and magnetic resonance imaging (MRI) are not recommended as screening tools due to lack of data on accuracy, high cost, and possible harm (i.e., radiation with CT). Contrast-enhanced MRI can be considered in patients with obesity and fatty liver, where visualization with ultrasound is suboptimal. The accuracy of other serum biomarkers proposed, such as des-γ carboxyprothrombin (DCP) and the L3 fraction of AFP (AFP-L3), in early detection is not known.

Despite the fact that surveillance is cost-effective in HCC, the global implementation of such programs is estimated to engage ~50% of the target population in Europe and ~30% in the United States. Public health policies encouraging the implementation of such programs could lead to an increase in early tumor detection.

Diagnosis HCC is generally diagnosed at early or intermediate stages in Western countries but at advanced stages in most Asian (except Japan) and African countries. A surveillance program yields detection of early HCC in 70–80% of cases. At these stages, the tumor is asymptomatic, and diagnosis can be made by noninvasive (radiological) or invasive (biopsy) approaches. Without surveillance, HCC is discovered either as a radiological finding or due to cancer-related symptoms. If symptoms are present, the disease is already at an advanced stage, with a median life expectancy of <1 year. Symptoms include malaise, weight loss, anorexia, abdominal discomfort, or signs related to advanced liver dysfunction.

NONINVASIVE (RADIOLOGICAL) DIAGNOSIS Patients enrolled in a surveillance program are diagnosed by identification of a new liver nodule on abdominal ultrasound. Noninvasive criteria can only be applied to cirrhotic patients and are based on imaging techniques obtained by four-phase multidetector CT scan (four phases are unenhanced, arterial, venous, and delayed) or dynamic contrast-enhanced MRI. A flowchart of diagnosis and recall policy recommended by U.S. and European guidelines is summarized in **Fig. 87-2**. In nodules >1 cm or with AFP ≥20 ng/mL or rising AFP, multiphasic contrast-enhanced CT or MRI is recommended. Using these techniques, the typical hallmark of HCC consists of vascular uptake of the nodule in the arterial phase with washout in the portal venous or delayed phases. This radiological pattern captures the hypervascular nature characteristic of HCC and has a diagnostic specificity of ~95–100%, making a biopsy unnecessary. The Liver Imaging Reporting and Data System (LI-RADS) has been proposed as a way of classifying radiological findings. Essentially, nodules >10 mm visible on multiphase exams are assigned category codes reflecting their relative probability of being benign, HCC, or other hepatic malignant neoplasm. LI-RADS-1 lesions have a 0% probability of HCC, whereas lesions assigned to the LI-RADS-4 category are likely to be an HCC in 60–70% of cases and repeated imaging within 3–6 months or biopsy is recommended. Finally, LI-RADS-5 lesions have a ~95% probability of being HCCs. LI-RADS-M category comprises lesions that have malignant radiological features but are only HCC in ~35% of cases.

Nodules <1 cm in size are unlikely to be HCC and would be very difficult to diagnose, and thus ultrasound follow-up at 3–4 months is recommended. Contrast-enhanced ultrasound (CEUS) and angiography

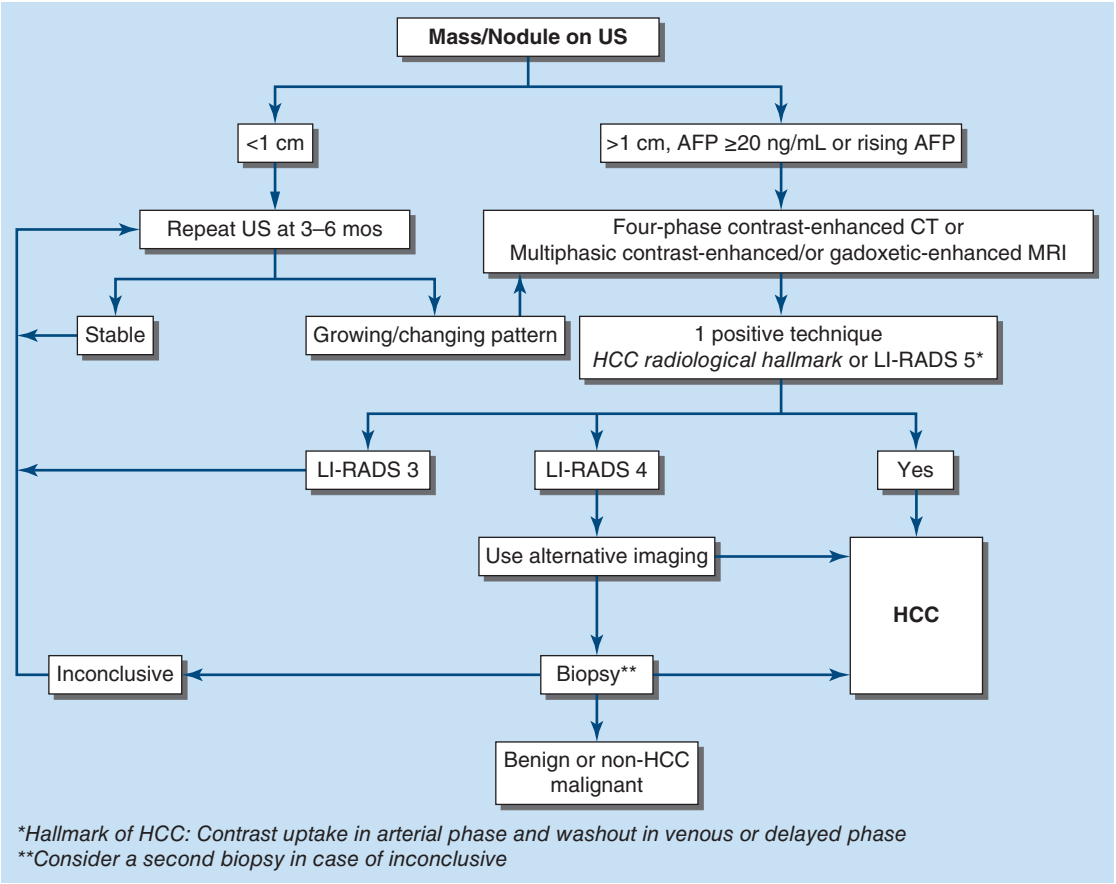

FIGURE 87-2 Recall diagnosis schedule for HCC (EASL). EASL, European Association for the Study of Liver Disease; HCC, hepatocellular carcinoma. *(Modified with permission from EASL. J Hepatology 69:182, 2018.)*

are less accurate for HCC diagnosis. Positron emission tomography (PET) scan performs poorly for early diagnosis. AFP levels ≥400 ng/dL are highly suspicious but not diagnostic of HCC according to guidelines.

PATHOLOGICAL DIAGNOSIS Pathological diagnosis is required: (1) in patients without cirrhosis, (2) if radiology is not typical in at least one of two imaging techniques (CT and MRI), and (3) for a LI-RADS-4 lesion. Biopsy has not been used as the gold standard in clinical practice, although with the advent of molecular therapies, some guidelines advocate obtaining tissue samples in the setting of all research studies in HCC, even if radiological criteria are met. Sensitivity of liver biopsies ranges between 70 and 90% for all tumor sizes but decreases to <50% in tumors 1–2 cm in size. The risk of complications, such as tumor seeding and bleeding, after liver biopsy is ~2–3%. Biopsies should be assessed by an expert hepatopathologist. The use of special stains may help to resolve diagnostic uncertainties. Positive staining in two of four markers (glypican 3 [GPC3], glutamine synthetase, heat shock protein 70 [HSP70], and clathrin heavy chain) is highly specific for HCC. Additional staining can be considered to detect progenitor cell features (K19 and epithelial cell adhesion molecule [EpCAM]) or assess neovascularization (CD34). A negative biopsy does not eliminate the diagnosis of HCC. A second biopsy is recommended in case of inconclusive findings or growth or change in enhancement pattern identified during follow-up (Fig. 87-2).

TREATMENT

Overview The landscape of management of HCC has substantially changed during the last decade. For early stages, resection, liver transplantation, and local ablation have substantially improved life expectancy, with median overall survival (OS) times beyond 5 years (Fig. 87-3). Adjuvant therapy with atezolizumab plus bevacizumab improves recurrence-free survival in patients at high risk of recurrence undergoing resection or ablation. For intermediate stages, transarterial chemoembolization (TACE) has improved the natural history of 16 months to ~30 months, and when combined with durvalumab plus bevacizumab, it improves progression-free survival. Systemic drugs for advanced tumors (atezolizumab plus bevacizumab, durvalumab plus tremelimumab, sorafenib, lenvatinib, regorafenib, cabozantinib, and ramucirumab) have improved median survivals from 8 months to even beyond 19 months in front-line and to 10 months in second-line treatment (Fig. 87-3).

Staging Systems and Treatment Allocation Staging systems are aimed at stratifying patients according to prognostic factors and outcome and allocating the best available therapies according to evidence. The most accepted staging system is the Barcelona Clinic Liver Cancer (BCLC) Classification, which is endorsed by U.S. and European clinical practice guidelines (Fig. 87-3). This staging system defines five prognostic subclasses and allocates specific treatments for each stage. The BCLC staging system has been externally validated by numerous studies. It is an evolving system that allows incorporation of new therapies and treatment-dependent variables as new evidence emerges. Several treatments improve survival in HCC, and thus have been incorporated in the therapeutic algorithm: surgical resection, liver transplantation, radiofrequency (RF) ablation, microwave, chemoembolization, and systemic therapies (atezolizumab-bevacizumab, durvalumab plus tremelimumab, sorafenib, lenvatinib, regorafenib, cabozantinib, and ramucirumab). The BCLC assigns each patient to a given treatment allocation. Treatment stage migration is also applied by this scheme, meaning that if patients are not candidates for the selected therapy, the next effective therapy at more advanced stages can be given.

In HCC, three parameters are relevant for defining treatment strategy: tumor status, cancer-related symptoms, and liver dysfunction. The BCLC staging captures all three variables and allocates patients to treatments according to evidence. Since >80% of patients have two diseases, HCC and cirrhosis, a clear measurement of liver dysfunction should be in place. The prognosis of chronic liver disease is commonly assessed using the Child-Pugh score, which uses five clinical

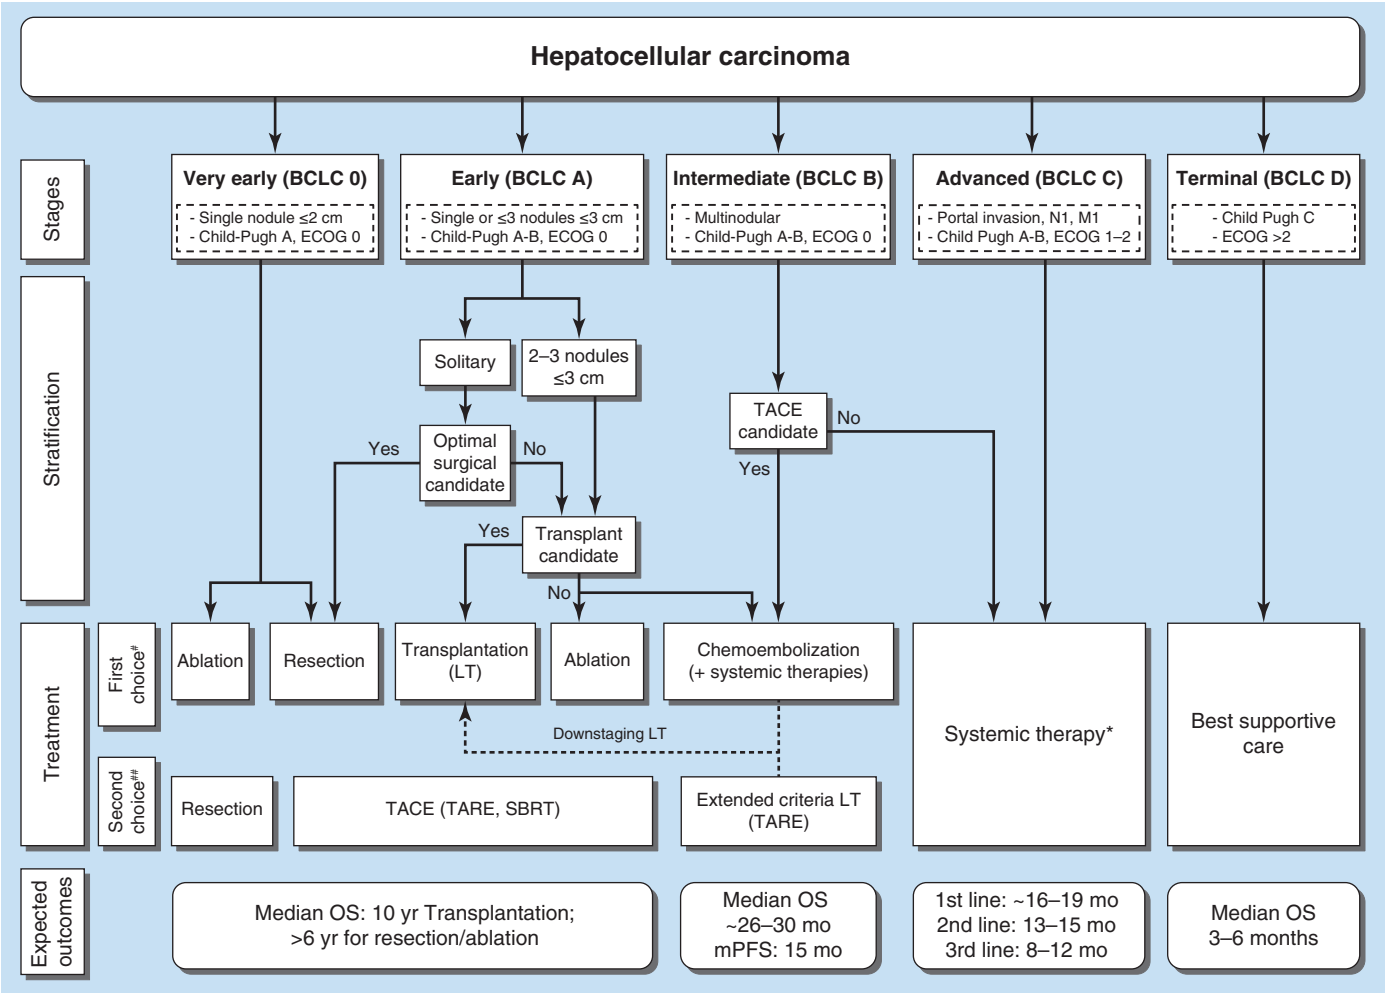

FIGURE 87-3 Staging system and therapeutic strategy. BCLC classification comprises five stages that select the best candidates for therapies according to evidence-based data. Patients with asymptomatic early tumors (stages 0 -A) are candidates for radical therapies (resection, transplantation, or local ablation). Asymptomatic patients with multinodular HCC (stage B) are suitable for transcatheter arterial chemoembolization (TACE), whereas patients with advanced symptomatic tumors and/or an invasive tumoral pattern (stage C) are candidates to receive systemic therapies. End-stage disease (stage D) includes patients with poor prognosis that should be treated by best supportive care. BCLC, Barcelona Clinic Liver Cancer; DDLT, deceased donor liver transplantation; EASL, European Association for the Study of Liver Disease; ECOG, Eastern Cooperative Oncology Group Performance Status; EORTC, European Organisation for Research and Treatment of Cancer; GRADE, grading of recommendations assessment, development, and evaluation; HCC, hepatocellular carcinoma; LDLT, living donor liver transplantation; OS, overall survival; PEI, percutaneous ethanol injection; RF, radiofrequency ablation; TACE, transcatheter arterial chemoembolization. *(Modified with permission from JM Llovet et al: Molecular pathogenesis and systemic therapies for hepatocellular carcinoma. *Around 70–80% of patients are expected to receive this regimen
#Based on high level evidence studies.
##Based on low or moderate level of evidence studies.

measures—total bilirubin, serum albumin, prothrombin time, ascites severity, and hepatic encephalopathy grade—to classify patients into one of three groups (A–C) of predicted survival rates. In brief, Child-Pugh class A reflects well-preserved liver function, Child-Pugh class B moderate liver dysfunction, and Child-Pugh class C severe liver dysfunction. Other measurements of liver dysfunction, such as the Model for End-Stage Liver Disease (MELD) score or the albumin-bilirubin score, are not integrated in this staging system. Performance status is assessed by Eastern Cooperative Oncology Group (ECOG) scale (a 5-point scale where higher numbers indicate greater disability), and presence of cancer-related symptoms (ECOG 1–2) is considered a sign of advanced stage.

Considering all these prognostic/predictive variables and evidence-based treatment efficacy, five BCLC stages have been defined (Fig. 87-3). Patients with liver-only neoplastic disease, no symptoms (ECOG 0), and mild to moderate liver dysfunction (Child-Pugh A-B) can be classified as very early (stage 0), early (stage A), or intermediate (stage B) stage depending on tumor size and number. Very early HCC (BCLC 0) is defined by single tumors ≤2 cm (if pathology is available, the tumors should be well-differentiated with absence of microvascular invasion or satellites). Early HCC (BCLC A) includes either single tumors or a maximum of three nodules of ≤3 cm in diameter. Intermediate stage (BCLC B) is defined by all other liver-only tumors. Conversely, HCC is considered at advanced stages (BCLC C) when patients present with cancer-related symptoms (ECOG 1–2) or tumors with macrovascular invasion (of any type, including branch, hepatic, or portal vein), lymph node involvement, or extrahepatic spread. Finally, end-stage disease (BCLC D) is considered in cases of severe impairment of quality of life or severe cancer-related symptoms (ECOG 3–4) or severe liver dysfunction (Child-Pugh C).

Around 40% of patients are diagnosed at stages 0 and A and hence are eligible for potentially curative therapies, resection, transplantation, or local ablation. These treatments provide median survival rates of 60 months and beyond, which are in sharp contrast with outcomes of 36 months reported in historical controls (Fig. 87-3, **Table 87-2**). Adjuvant therapy with atezolizumab plus bevacizumab is recommended in patients after resection or local ablation who are at high risk of recurrence. Patients at intermediate stage (stage B) with preserved liver function have a documented natural history of around 16 months. These patients benefit from TACE, as reported in two randomized studies and one meta-analysis and achieve an estimated survival of 25–30 months. Combination of durvalumab plus bevacizumab with TACE

TABLE 87-2 Summary of Key Results of Randomized and Cohort Studies in the Management of Hepatocellular Carcinoma (HCC)

TREATMENT OF EARLY AND INTERMEDIATE STAGE HCC				
TREATMENTS	**HCC STAGE**	**TREATMENT ARMS**		**OUTCOMES (OS)**
Treatments for early HCC				
Resection	Early	Optimal (single nodule; no portal hypertension)		5-year: 50–70%
		Suboptimal (multinodular or portal hypertension)		5-year: 35–55%
Resection + adjuvant	Early	Adjuvant atezolizumab + bevacizumab vs surveillance		12-month RFS: 78 vs 65%
Liver transplantation	Early	Milan (1 nodule <5 cm, 2–3 nodules ≤3 cm, no MVI, no EHS)		5-year: 70–80%
	Early/intermediate	Downstaged (1 nodule ≤6.5 cm, ≤3 nodules ≤4.5 cm and total diameter ≤8 cm, no MVI, no EHS)		5-year: 60–70%
Ablation	Early	RFA		Median: 50–60 months
Treatments for intermediate HCC				
Transarterial therapies	Intermediate	TACE		Median: 20–32 months Median PFS: 8 months
Locoregional + systemic	Intermediate	TACE + durvalumab + bevacizumab		Median PFS: 15.2 months
TREATMENT OF ADVANCED STAGE HCC				
STUDY NAME	**TREATMENT**	**MEDIAN OS, MONTHS (HR 95% CI)**	**MEDIAN PFS, MONTHS (HR 95% CI)**	**ORR mRECIST/RECIST**

Abbreviations: CI, confidence interval; EHS, extrahepatic spread; HCC, hepatocellular carcinoma; HR, hazard ratio; mRECIST, modified Response Evaluation Criteria in Solid Tumors; MVI, microvascular invasion; NA, not available; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; RFA, radiofrequency ablation; TACE, transarterial chemoembolization.

has shown benefits in progression-free survival compared with TACE alone. Patients progressing on TACE or at advanced stage (stage C) benefit from systemic treatments. First-line therapy for advanced HCC includes atezolizumab plus bevacizumab or durvalumab plus tremelimumab. Both combinations were superior to sorafenib in phase 3 trials. In patients with contraindications for immunotherapies, both sorafenib or lenvatinib are recommended Three additional targeted therapies have shown to improve survival compared to placebo in patients with HCC progressing on sorafenib: regorafenib, cabozantinib, and ramucirumab (only in patients with AFP >400 ng/mL). Therefore, these treatments have been adopted by guidelines and incorporated into the treatment algorithm. Patients with end-stage disease (BCLC D) should be considered for nutritional and psychological support and proper management of pain.

Although the BCLC establishes validated stages and treatment assignment according to evidence, clinical practice is not always aligned with this classification. In large cohort studies and surveys, only half of patients, or even less in Asia, are treated accordingly. Alternative staging or scoring systems have been proposed, such as the Hong Kong classification or the Japan Integrated Staging score. These systems capture extended indications for resection and TACE applied in clinical practice in Asia. Finally, the tumor-node-metastasis (TNM) staging system is not used in HCC since it does not incorporate the main prognostic variables related to liver function and performance status.

Due to the complexities of HCC diagnosis and management, it is recommended to refer patients to centers with multidisciplinary liver cancer programs that include a hepatologist, oncologist, hepatobiliary and transplant surgeons, interventional and body imaging radiologist, hepatopathologist, and specialized nurses.

SURGICAL THERAPIES

Resection Surgical resection is the first-line option for noncirrhotic patients with early-stage HCC (BCLC 0 or A) with solitary tumors (Fig. 87-3). In cirrhotic patients, ablation competes with resection for BCLC 0 tumors (<2 cm in diameter). Which is better is not defined. Cost-effectiveness approaches report a benefit for local ablation with RF. For single tumors >2 cm (BCLC A), resection remains the mainstay of treatment in patients with Child-Pugh A with normal bilirubin and absence of portal hypertension (no esophageal/gastric varices or platelet count >100,000/μL associated with splenomegaly). Anatomic resections following the functional segments of the liver are recommended to spare uninvolved liver parenchyma and to remove satellite tumors. Applying these criteria, resection is associated with perioperative decompensation rate of 5%, perioperative mortality of <1%, and 5-year survival of 60–70%, as opposed to ~35–55% for suboptimal candidates (Table 87-2). Macrovascular invasion, extrahepatic involvement, and liver dysfunction (Child-Pugh B-C) are major contraindications for resection.

Adjuvant Treatments Tumor recurrence represents a major complication of resection and local ablation (with 5-year rates of 50–70%). Predictors of recurrence are tumor size, tumor number, presence of microsatellites, or microvascular invasion at the specimen analysis. Most recurrences are intrahepatic metastases, but at least one-third are considered de novo tumors, new clones developing in the cirrhotic carcinogenic field. The type of recurrence can only be defined by molecular studies. An adjuvant regimen after resection or local ablation with atezolizumab plus bevacizumab for 12 months significantly improved recurrence-free survival in patients at high risk of recurrence and has been incorporated into the guidelines of practice.

Liver Transplantation Liver transplantation is the first treatment choice for cirrhotic patients with single tumors ≤5 cm and portal hypertension (including Child-Pugh B and C) or with small multinodular tumors (three or fewer nodules, each ≤3 cm) (Fig. 87-3). These so-called Milan criteria have been validated over the years and lead to median survival times of 10 years. Perioperative mortality rates have been reduced to <3%. Transplantation simultaneously cures the tumor and the

underlying cirrhosis, and it is associated with a low risk of recurrence, around 10–15% at 5 years. No immunosuppressive regimens or antitumor therapies after transplantation have demonstrated any preventive effect on recurrence. Milan criteria are integrated in the treatment strategy (BCLC 0 and A) and have also been adopted by the United Network for Organ Sharing (UNOS) pretransplant staging for organ allocation in the United States (stage T2). Aside from size and number, conventional contraindications for organ transplantation procedures (e.g., ABO incompatibility, comorbidities) are applied in this setting.

Liver transplantation has a couple of important limitations, such as cost and donor availability, that limit this procedure to <5% of HCC cases worldwide. The scarcity of donors represents a major drawback of liver transplantation. Donor scarcity varies geographically, and deceased liver donation is almost zero in some Asian countries. Due to the shortage of donors, median waiting times in Western programs is ~6–12 months, leading to 20% of candidates dropping off the list due to tumor progression before receiving the procedure. Neoadjuvant treatments with locoregional therapies are recommended when the waiting time exceeds 6 months.

Expansion of Milan criteria by using locoregional therapies to effectively downstage the tumor (i.e., UNOS-downstaging criteria) have reported good results. Since policies for enhancing organ donation have reached a ceiling during the past several years, alternatives to donation have emerged. Living donor liver transplantation represents a plausible alternative that accounts for ~5% of total transplantations performed globally. Outcomes reported are similar to those with deceased liver donors, and it is recommended as an alternative option in patients on a waiting list exceeding 6 months. The risks and benefits of this procedure should take into account both donor (death is estimated in 0.3%) and recipient, a concept known as *double equipoise*. Due to the complexity of this treatment, it must be restricted to centers of excellence in hepatobiliary surgery and transplantation.

LOCOREGIONAL THERAPIES

Local Ablation Thermal ablation with RF or microwave (MWA) is recommended as the primary ablative technique **(Fig. 87-4)**. The energy generated by RF ablation (heating of tissue at 80°–100°C) induces coagulative necrosis of the tumor, producing a *safety ring* in the peritumoral tissue, which might eliminate small undetected satellites. Treatment consists of one or two sessions performed using a percutaneous approach, although in some instances, ablation with laparoscopy is needed. HCC patients treated by RF ablation have 5-year survival rates of ~60% (Table 87-2). In tumors <2 cm, both RF and MWA ablation achieve complete responses in 90–100% of cases with good long-term outcome and compete with resection in terms of cost-effectiveness as a first-line option. For BCLC A cases, local ablation techniques are considered in patients with three tumors <3 cm in diameter unsuitable for surgical therapies.

For patients with unresectable HCC >3 cm in diameter who are not candidates for liver transplantation, transarterial radioembolization (TARE) with yttrium-90 and stereotactic body radiation (SBRT) are considered alternative options based on propensity-matched score studies and phase 2 investigations.

Chemoembolization TACE is the most widely used primary treatment for unresectable HCC worldwide and the first-line indication for patients with intermediate BCLC B stage (Fig. 87-3). Conventional chemoembolization (c-TACE) consists of local hepatic artery administration of chemotherapy (either doxorubicin 50 mg/m^2 or cisplatin) mixed with an emulsion of lipiodol followed by obstruction of the feeding artery with sponge particles. The best randomized phase 3 investigations have provided median survivals for TACE of 20–30 months in properly selected populations (compared to 16 months for pooled control arms). Median objective response rates are 50–70%. In randomized studies, the treatment is either performed at a regular schedule of 0, 2, and 6 months (median number of sessions is three) or on demand according to tumor response. TACE procedures should be stopped upon tumor progression or any other contraindication. Around 50% of patients present with a limited postembolization syndrome of fever and abdominal pain related to ischemic injury and release of cytokines. Less than 5% of patients have major complications (liver abscess, ischemic cholecystitis, or liver failure), and

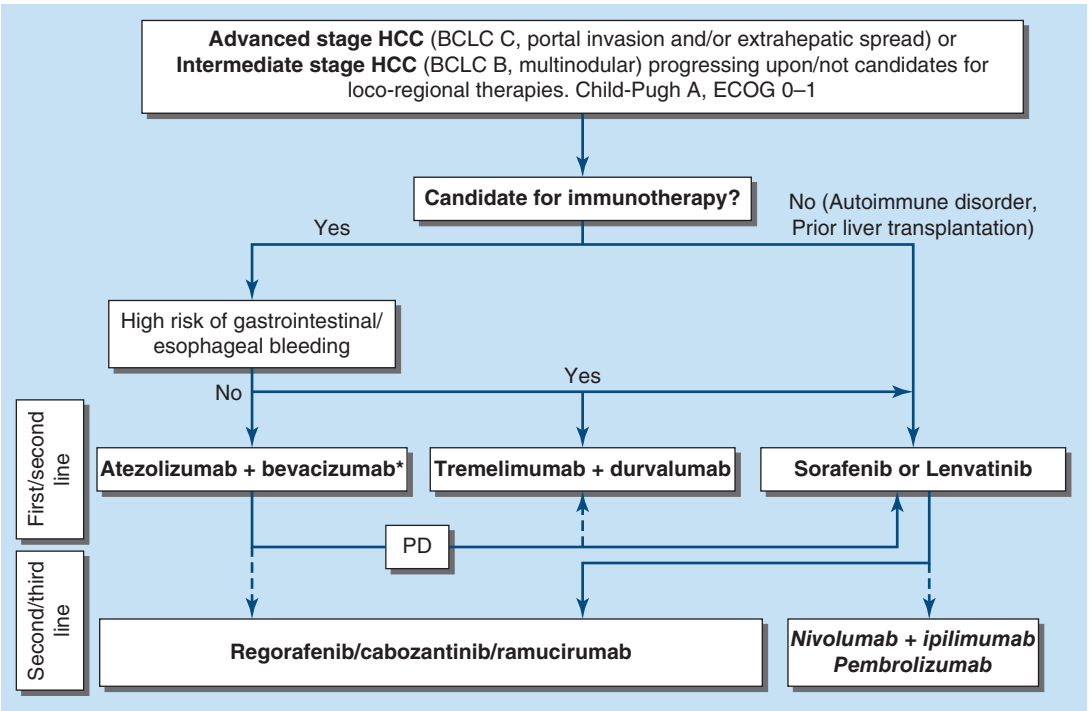

FIGURE 87-4 Treatment strategy for advanced hepatocellular carcinoma with systemic therapies. Drugs in bold have positive results from phase 3 trials with regulatory approval (atezolizumab plus bevacizumab, durvalumab plus tremelimumab, sorafenib, lenvatinib, regorafenib, cabozantinib, and ramucirumab). Drugs in bold italic have received accelerated approval from the Food and Drug Administration on the basis of promising efficacy results in phase 2 trials in second line (pembrolizumab and nivolumab ipilimumab). Key details of the patient populations are provided. BCLC, Barcelona Clinic Liver Cancer (classification); ECOG, Eastern Cooperative Oncology Group; PD, progressive disease. *(Modified from JM Llovet et al: Nat Rev Clin Oncol 15:599, 2018.)*

in <2% of cases, treatment-related death occurs. Drug-eluting bead chemoembolization (DEB-TACE) differs from c-TACE in the use of more standardized embolic spheres of regular size embedded with chemotherapy. This strategy achieves similar antitumor activity (objective responses of ~60%) as c-TACE and is associated with significantly fewer systemic toxic effects and better patient tolerance, but there are no clear differences in clinical outcomes.

Overall, TACE can only be applied to 50% of patients at intermediate stage, mostly as a result of the presence of liver failure (Child B or ascites or encephalopathy), technical contraindications to the procedure (i.e., impaired portal vein blood flow), or infiltrative/massive tumor burden (i.e., generally main tumor size >10 cm). Super-selective TACE minimizes the ischemic insult to nontumor tissue. According to guidelines, treatment stage migration allows performing TACE on patients at early stages not suitable for surgical or ablative therapies. TACE plus durvalumab plus bevacizumab significantly increases progression-free survival compared to TACE alone (median progression-free survival, 15.2 vs 8 months) with manageable treatment-related adverse events.

Radioembolization and Other Intra-arterial Therapies Transarterial radioembolization (TARE) using beads coated with yttrium-90 (Y-90)—an isotope that emits short-range β radiation—is the most promising alternative to TACE. Several phase II studies reported objective responses and overall outcome with a safe profile similar to TACE, and thus TARE has been endorsed by clinical practice guidelines. Radioembolization requires prevention of severe lung shunting and intestinal radiation before the procedure. Around 20% of patients experience liver-related toxicity, and <2% experience treatment-related death. Due to the minimally embolic effect of Y-90 microspheres, treatment can be safely used in patients with portal vein thrombosis, a setting where survival results in phase II studies were encouraging.

SYSTEMIC THERAPIES

Approximately 50–60% of patients with HCC are currently exposed to systemic therapies during their life span, either because they have been diagnosed at advanced stages or because they have progressed after locoregional therapies. In 2007, a phase III trial demonstrated survival benefits for patients with advanced-stage disease treated with sorafenib, thus becoming the first systemic therapy for HCC. Subsequently atezolizumab plus bevacizumab and durvalumab plus tremelimumab have demonstrated survival superiority compared to sorafenib, whereas lenvatinib showed noninferior effects (Fig. 87-4). In Asia, other combinations (i.e., carmelizumab plus rivoceranib) also were superior versus sorafenib in terms of survival. Three additional therapies, regorafenib, cabozantinib, and ramucirumab (only in patients with AFP >400 ng/mL), have been shown to benefit patients progressing on sorafenib. Of note, classical chemotherapy and radiotherapy have not resulted in benefits in survival. Similarly, due to the low prevalence of actionable molecular aberrations, precision oncology regimens are not yet available in HCC.

First-Line Therapies Atezolizumab (anti–PD-1 checkpoint inhibitor) plus bevacizumab (monoclonal antibody against VEGF-A) demonstrated survival differences compared to sorafenib (median OS, 19.2 vs 13.4 months) and has become the standard of care in first-line treatment (Fig. 87-4, Table 87-2). This combination treatment resulted in improved progression-free survival, patient-reported outcomes reflecting quality of life, and objective response rates (30 vs 12% for sorafenib). The combination had fewer adverse events compared to sorafenib (grade 3-4 adverse events, 36 vs 50%, respectively). The most common side effects associated with the combination are hypertension, proteinuria, and low-grade diarrhea, whereas autoimmune events are infrequent and manageable. Treatment-related adverse event rate leading to discontinuation of any drugs is 15%. Screening for varices with upper gastrointestinal endoscopies has become standard before first-line therapy in advanced HCC to mitigate the risk of bleeding associated with bevacizumab. In cases with varices, the use of one session of banding or carvedilol is recommended.

The combination of tremelimumab (a CTLA-4 inhibitor) and durvalumab (a PD-L1 inhibitor) (STRIDE regimen) has demonstrated a survival advantage versus sorafenib (median OS, 16.4 vs 13.7 months for sorafenib). No differences were identified regarding progression-free survival, and the response rate was 20.1% with the combination versus 5.1% with sorafenib. This regimen can be administered even in patients with portal hypertension or varices. STRIDE was associated with more immune-related adverse events, and 20% of patients required glucocorticoid treatments (Fig. 87-4).

Alternatively, sorafenib or lenvatinib is indicated for patients with advanced HCC with contraindications for immunotherapies (i.e., due to autoimmune disease or liver transplantation) (Fig. 87-4, Table 87-2). A phase 3 study comparing sorafenib (a multikinase inhibitor) versus placebo showed increased survival from 7.9 months to 10.7 months (hazard ratio [HR], 0.69; 31% reduction in risk of death). Patients with HCV-related HCC achieve significantly better outcomes with sorafenib, with a median survival of 14 months. Median treatment duration is about 6 months. Treatment is associated with manageable adverse events, such as diarrhea, hand-foot skin reactions, fatigue, and hypertension. These toxicities lead to treatment discontinuation in 15% of patients and dose reduction in up to half. It has been estimated that this therapy cannot be administered to approximately one-third of the targeted patients due to toxicity, advanced age, or liver failure (ascites or encephalopathy). Active vascular disease, either coronary or peripheral, is considered a formal contraindication. Median time to progression on sorafenib is 4–5 months in phase 3 trials.

Another alternative to sorafenib is the multikinase inhibitor lenvatinib, which was shown to be noninferior in a phase 3 investigation (Fig. 87-4). A phase 3 study comparing lenvatinib (an inhibitor of vascular endothelial growth factor receptor [VEGFR], fibroblast growth factor recepctor [FGFR], platelet-derived growth factor receptor [PDGFR], RET, and c-Kit) with sorafenib showed noninferiority of results in terms of OS (13.6 vs 12.3 months; HR, 0.92). Lenvatinib induces objective responses in 24% of cases. The main side effects are hypertension, proteinuria, asthenia, diarrhea, and weight loss. This treatment is associated with a 55% rate of grade 3-4 drug-related adverse events, resulting in a ~15% withdrawal rate.

Second-Line Therapies Three drugs (regorafenib, cabozantinib, and ramucirumab) have shown survival benefits versus placebo in patients progressing to sorafenib, and two additional treatments have been approved by the U.S. Food and Drug Administration (FDA) based on promising phase 2 data (pembrolizumab, and nivolumab plus ipilimumab) (Fig. 87-4). It is estimated that only half of patients progressing on sorafenib can be considered for second-line therapies, and their median survival with no treatment is 7–8 months (obtained from patients allocated to the placebo arm).

A phase 3 study comparing regorafenib (a more potent multikinase inhibitor than sorafenib, but targeting similar kinases) versus placebo in patients progressing to sorafenib reported an increase in survival from 7.8 to 10.6 months (HR, 0.62; 38% reduction in risk of death) **(Fig. 87-5)**. Response rate was 10% based on modified Response Evaluation Criteria in Solid Tumors. Median time on treatment was 3.5 months. Prevalence of toxicity (hand-foot reaction, fatigue, and hypertension) was higher compared with reported toxicity from sorafenib, but adverse events only led to treatment discontinuation in 10% of cases. Cabozantinib, a multikinase VEGFR inhibitor with activity against both AXL and cMET, improves survival compared to placebo after progression to sorafenib (10.2 months for cabozantinib vs 8.0 months in the placebo arm; HR, 0.76). Toxicity was manageable, with the most common grade 3–4 events being palmar-plantar erythrodysesthesia, hypertension, increased aspartate aminotransferase level, fatigue, and diarrhea. Ramucirumab, an anti–VEGFR-2 monoclonal antibody, is the only biomarker-guided therapy in HCC based on AFP levels. The randomized, placebo-controlled, phase 3 REACH-2 study studied patients with advanced HCC in second-line treatment with baseline AFP ≥400 ng/dL. This trial demonstrated positive survival results, and a further meta-analysis established a median survival for ramucirumab of 8.1 months compared to 5 months for patients receiving placebo. The most common grade 3–4 treatment-related adverse events were hypertension, hyponatremia, and increased aspartate

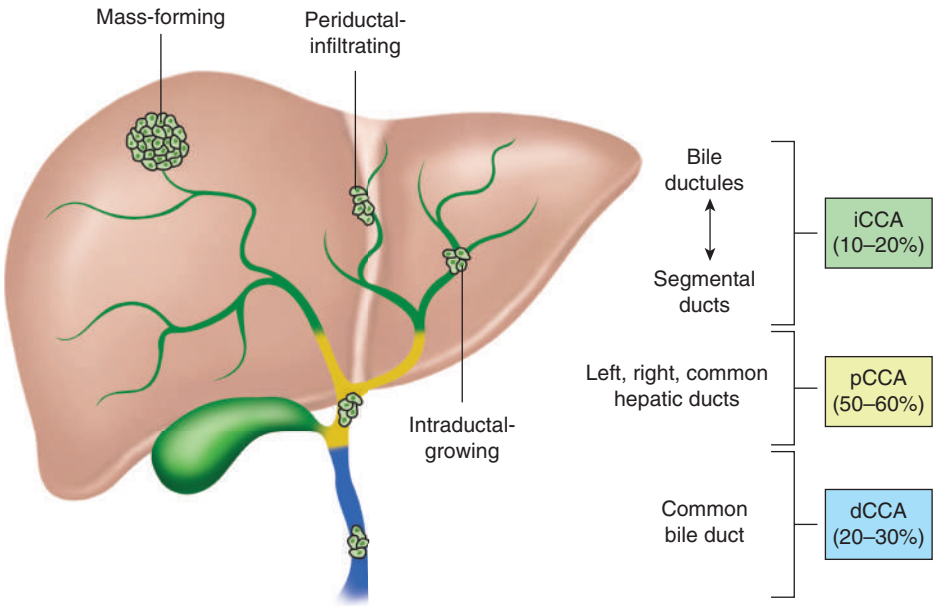

FIGURE 87-5 Anatomical classification of cholangiocarcinoma. Cholangiocarcinoma is classified as intrahepatic (iCCA) and extrahepatic (eCCA). eCCA can be subclassified as perihilar (pCCA) and distal (dCCA). *(Reproduced from JM Banales et al: Cholangiocarcinoma 2020: The next horizon in mechanisms and management. Nat Rev Gastroenterol Hepatol 17:557, 2020.)*

aminotransferase. Patients progressing after second-line therapy might be considered for third-line approaches. Patients with tumors at a BCLC D stage should receive best supportive palliative care, including management of pain, nutrition, and psychological support.

CHOLANGIOCARCINOMA

Cholangiocarcinoma (CCA) is classified according to its anatomic location as intrahepatic (iCCA; ~20–30%), perihilar (pCCA; ~50–60%), and distal (dCCA: ~20–30%). The latter two are also known as extrahepatic cholangiocarcinomas (eCCA), with the second-order bile ducts acting as the separation point (Fig. 87-5). The three subtypes of CCA differ in their anatomic location, epidemiology and risk factors, cell of origin, pathogenesis, and treatment. iCCA originates from adult cholangiocytes, transdifferentiation of adult hepatocytes, and hepatic progenitor cell–cholangiocyte precursors (Fig. 87-6), as opposed to HCC, which originates only from hepatic progenitor cells or adult hepatocytes. Mixed HCC-iCCA originates from hepatic progenitor cells, whereas eCCA arises from the biliary epithelium and peribiliary glands. Moreover, their mutational profile also differs. *FGFR2* fusions and *IDH1/2* mutations mostly occur in iCCA, whereas *ERBB2/3* amplifications and *SMAD4* aberrations are characteristic of eCCA. iCCA has been recognized as a distinct entity with specific clinical practice guidelines, which should be tailored according to each biological/anatomical subtype of CCA.

EPIDEMIOLOGY, RISK FACTORS, AND MOLECULAR TRAITS

CCA is the second most common liver cancer following HCC, with a 5-year survival of 10%. iCCA has globally increasing incidence and mortality rates. The incidence of iCCA varies according to exposure to risk factors, ranging from 1–2 cases per 100,000 inhabitants in Europe and North America to the highest incidence in some areas of Southeast Asia, particularly in Thailand (>80 cases/100,000 inhabitants). The male-to-female ratio is 1.2:1. Only 30% of patients with CCA have a known risk factor. The classical risk factors for CCA development include primary sclerosing cholangitis (PSC), biliary duct cysts, hepatolithiasis, and Caroli's disease. Parasitic biliary infestation with flukes (most common are *Opisthorchis viverrini* and *Clonorchis sinensis*) is a prevalent etiology in Asia that can be prevented with an antihelminth therapy, praziquantel. PSC is a clear risk factor for iCCA and pCCA development, with a lifetime incidence ranging from 5 to 10%. Surveillance in PSC patients is recommended with annual imaging techniques and CA 19-9 serum determination. Common risk factors for HCC, such as HBV and HCV infection and cirrhosis, have been associated with iCCA development. More recently, sweetened beverages were reported to constitute a risk factor in the development of eCCA and gallbladder carcinoma (GBC) in a population cohort study.

Molecular Classification and Actionable Drivers A morphological and molecular classification subclassifies iCCA into the large duct type, which is associated with *IDH* (15–20%) and *FGFR2* (15%) mutations and better prognosis, and the small duct type, which is associated with *KRAS* (15%) and *SMARD4* (<5%) mutations and poor prognosis. Overall, up to 40% of iCCAs have a targetable mutation. Similarly, a molecular classification of eCCA has been proposed, dividing tumors into four categories (metabolic, proliferation, mesenchymal, and immune) based on molecular traits. It has been suggested that the proliferation class with enrichment of *ERBB2/3* mutations might respond to monoclonal antibodies against this receptor, while the immune class might respond to checkpoint inhibitors, a fact that needs clinical confirmation. The most common mutations of pCCA/dCCA are *P53* (~30%) and *KRAS* (~25%), whereas *ERBB2* amplifications (~20%) are common in gallbladder cancer.

INTRAHEPATIC CHOLANGIOCARCINOMA

Surveillance, Diagnosis, and Staging Guidelines currently only recommend surveillance for early diagnosis in the following at-risk subpopulations: (1) patients with primary biliary sclerosis (PBS; surveillance is recommended with CA 19-9 and magnetic resonance cholangiopancreatography [MRCP] every 12 months) and (2) patients with cirrhosis or those infected with liver flukes (surveillance is recommended with abdominal ultrasound every 6 months). Otherwise, incidental diagnosis occurs due to cross-sectional imaging performed for other reasons. In most cases, iCCA is diagnosed at advanced stages when symptoms such as weight loss, malaise, abdominal discomfort, or jaundice are present. Diagnosis of iCCA requires pathological confirmation. Differential diagnosis should be established with metastatic adenocarcinoma (i.e., colorectal, breast, and lung cancer) and mixed iCCA-HCC tumors. Immunohistochemistry using K7, K19, and K20 is useful to confirm iCCA and to distinguish it from metastatic liver cancer. Hepatocytic markers such as Hep-Par-1, GPC3, and HSP70 may aid in pointing to a mixed HCC-iCCA tumor. Current guidelines recommend the use of abdominal MRI, chest and abdomen CT scan, and PET scan for establishing the disease extension once the pathological diagnosis has been confirmed. Meta-analysis has defined a role for PET scanning in identifying lymph node metastasis in patients with no apparent lymph node invasion with MRI and/or CT scan. Lymph node sampling by endoscopic ultrasound with fine-needle aspiration would be considered before resection in selected unclear cases. Tumor biomarker CA 19-9 at a cutoff level of 100 U/mL has prognostic significance but lacks accuracy (sensitivity and specificity of ~60%) for early diagnosis.

TREATMENT

The European Association for the Study of Liver Disease–International Liver Cancer Association (ILCA) guidelines for management of iCCA proposed an updated treatment algorithm, which has been adapted to the current accepted treatment modalities (Fig. 87-7). iCCA can be classified as early, intermediate, or advanced cases according to size of the nodules and invasion of lymph nodes (N1), metastasis, and ECOG

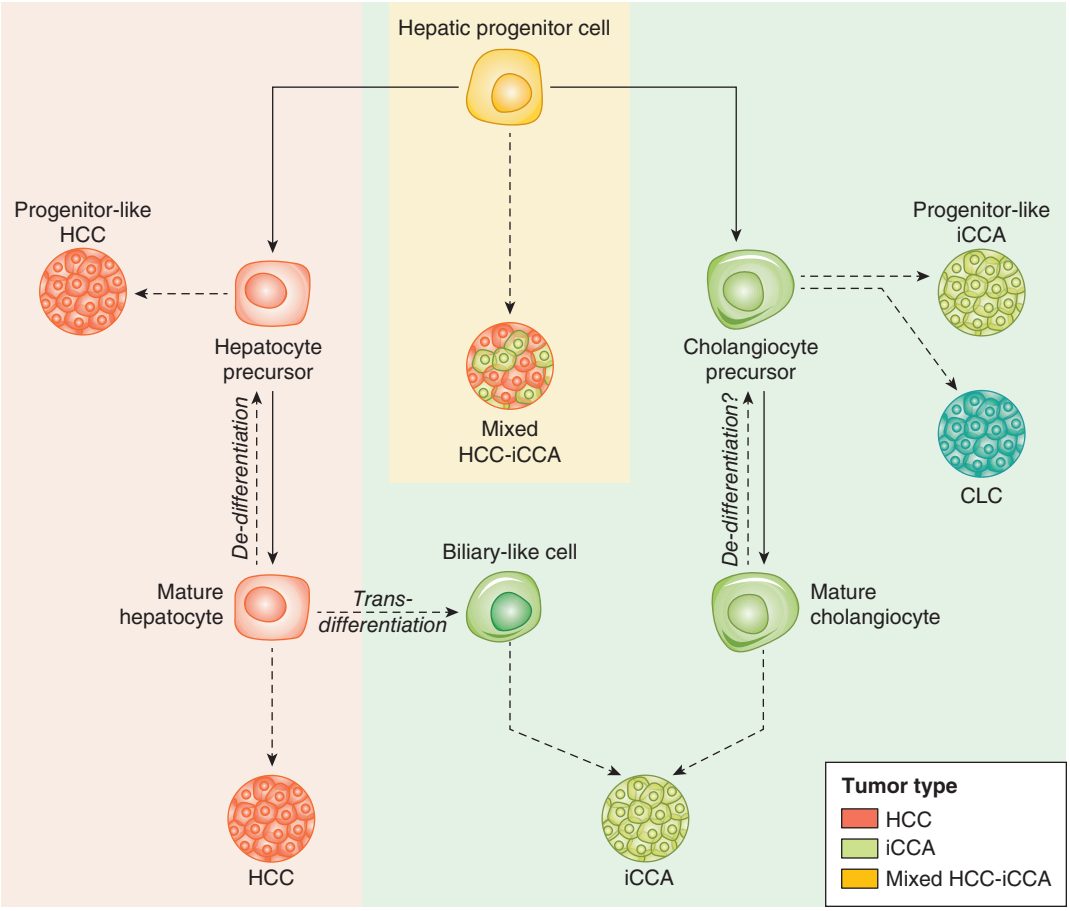

FIGURE 87-6 Cell of origin of liver cancer. Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCCA) can develop from the neoplastic transformation of mature hepatocytes and cholangiocytes, respectively. There is evidence showing that hepatic progenitor cells (HPCs), their intermediate states, or dedifferentiated hepatocytes can originate liver cancers with progenitor-like features, including mixed HCC-CCA (e.g., cholangiolocellular carcinoma [CLC]). Mature hepatocytes can be also reprogrammed into cells that closely resemble biliary epithelial cells and induce the onset of iCCA. *(Printed with permission from © Mount Sinai Health System.)*

performance status and liver dysfunction. Approximately 30–40% of iCCA cases are deemed resectable, and the median reported survival for single tumors is ~40–50 months, whereas survival decreases to ~20 months in intermediate/multinodular resectable tumors. The main predictors of recurrence (~50–60% at 3 years) and survival are identified at the pathological examination, including presence of vascular invasion, lymph node metastases, and poor differentiation degree. In terms of adjuvant therapy, a phase 3 trial (BILCAP trial) including all types of CCA in a prespecified per-protocol analysis reported improved survival (53 vs 36 months; adjusted HR, 0.75). Based on this trial, American Society of Clinical Oncology guidelines recommend adjuvant capecitabine for a period of 6 months. A small proportion of patients with early/intermediate tumors can have contraindications for resection, particularly in cirrhotic patients, and should be first considered for local ablation or even liver transplantation if the diameter of the main tumor is <2 cm.

Nonsurgical candidates have a dismal life expectancy. Overall, patients with multinodular unresectable tumors might be considered for locoregional therapies, such as chemoembolization or radioembolization, but the level of evidence is low and mostly based on cohort studies. A meta-analysis of 14 trials testing locoregional therapies reported median survival times of 15 months. External-beam radiation therapy is not recommended as standard therapy. At more advanced stages in patients with ECOG of 0–1, systemic chemotherapy with the combination of gemcitabine, cisplatin, and durvalumab showed significantly better survival and progression-free survival compared with gemcitabine plus cisplatin alone (12.8 vs 11.5 months) in the setting of the TOPAZ1 phase 3 trial including 685 patients. Objective response was 27%. Similar results were obtained with the combination of chemotherapy with pembrolizumab versus chemotherapy alone in a phase 3 trial including 1069 patients. The median OS was 12.7 months in the pembrolizumab group and 10.9 months in the placebo group (HR, 0.83; 95% CI, 0.72–0.95; one-sided p = .0034). Therefore, triplet therapy is now considered the standard for the management of CCA. In the second-line setting, a phase 3 study that randomized patients who had progressed on cisplatin and gemcitabine to mFOLFOX (leucovorin, fluorouracil, and oxaliplatin) versus best supportive care showed improvement in median OS of 5.3 to 6.2 months (adjusted HR, 0.69). In addition, three molecular and immune therapies have been approved in the second-line setting in iCCA patients with *IDH1/2* mutations, *FGFR2* aberrations, or deficient mismatch repair (dMMR) or microsatellite instability high (MSI-H). A phase 3 trial compared ivosidenib, an IDH-1 inhibitor, versus placebo in the second-line setting and demonstrated an improved primary end point of progression-free survival (2.7 vs 1.4 months; HR, 0.37) and improved OS in an adjusted analysis. A single-arm phase 2 study assessing pemigatinib (FGFR2 inhibitor) in iCCA patients with *FGFR2* fusions showed a median survival of 21 months with an objective response of 35%, leading to FDA accelerated approval. Similar results have been observed in phase 3 trials testing other FGFR2 inhibitors, such as infigratinib and futibatinib. Finally, regulatory agencies granted approval of pembrolizumab for MSI-H or dMMR solid tumors that progressed following prior treatment based on a basket tissue-agnostic trial. This recommendation excludes patients receiving durvalumab in first line.

Mixed HCC-iCCA is a rare neoplasm accounting for <0.5% of all primary liver cancers. Diagnosis is based on pathology. The 2010 World Health Organization classification defined two subtypes: the classical type and the stem cell feature type. Molecular data have also

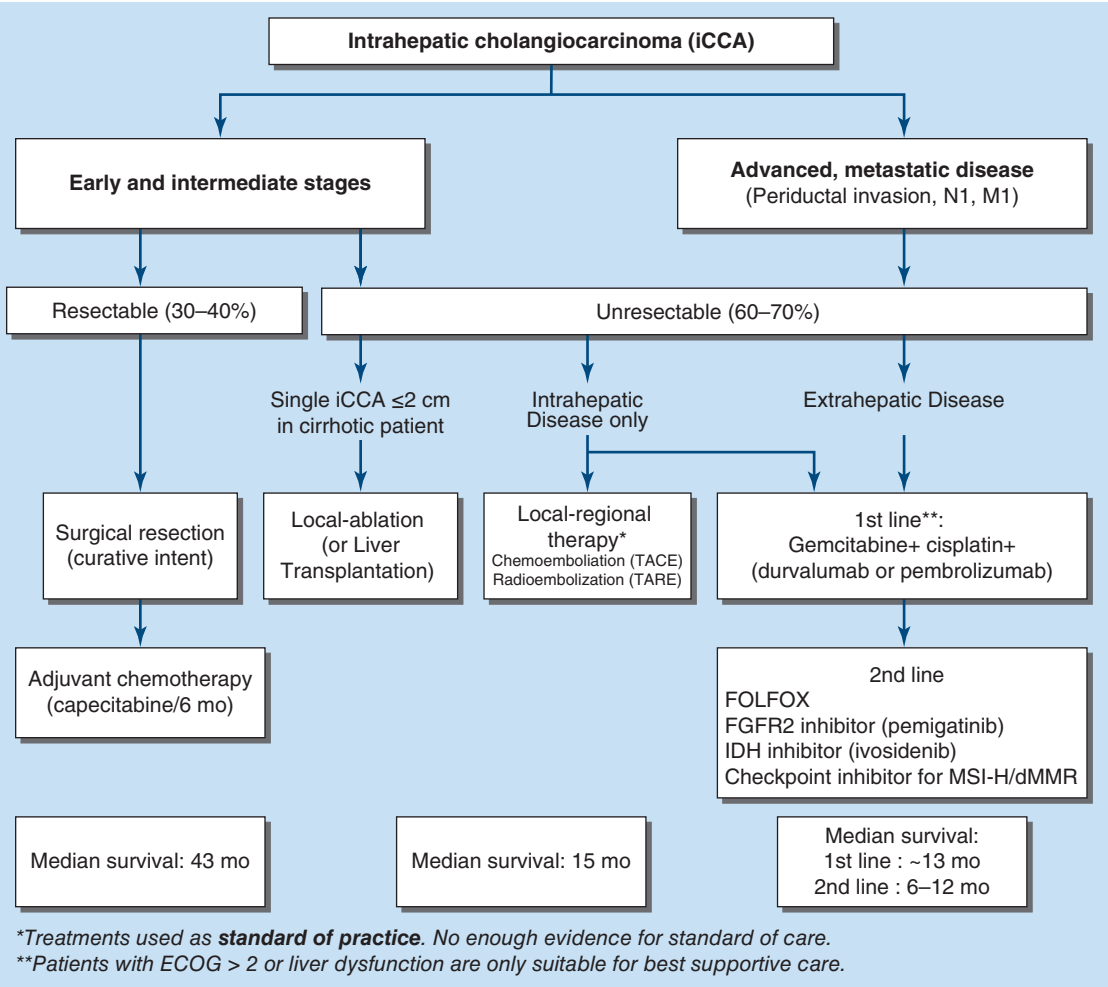

FIGURE 87-7 Staging and treatment schedule for intrahepatic cholangiocarcinoma (iCCA). *(Modified from EASL-ILCA Guidelines. J Hepatol 79:181, 2023.)*

characterized a third unique entity, cholangiolocellular carcinoma, with distinct molecular traits and better outcome. Due to their low incidence, the demographic features and clinical behavior of these tumors remain ill-defined. Survival and management are similar to iCCA.

EXTRAHEPATIC CHOLANGIOCARCINOMA

Perihilar and Distal Cholangiocarcinoma pCCA tumors arise between the second-order bile ducts up to the insertion of the cystic duct, whereas dCCAs arise from this point to the ampulla of Vater (Fig. 87-5). Thus, dCCA can be difficult to distinguish from early pancreatic cancer. Both entities have a similar diagnostic approach. Acute onset of painless jaundice occurs in 90% of patients with pCCA, and 10% of patients present with cholangitis. Primary biliary cholangitis with a cutoff for CA 19-9 >129 U/mL is suspicious for CCA. Imaging assessment starts with CT and MRI; they have a good sensitivity and specificity (>85%) for detecting the degree of bile duct involvement and hepatic and portal vein invasion. MRI cholangiography is optimal for defining the extent of the bile duct lesion. Ruling out IgG4 cholangiopathy by assessing serum IgG4 is mandatory. As a second step, endoscopic retrograde cholangiography with brushing to explore cytology and fluorescence in situ hybridization (FISH)—for exploring polysomy—are recommended. FISH enhances the sensitivity of cytology from 20 to ~40%.

Diagnosis is based on pathology. The treatment algorithm for pCCA indicates that in cases of a dominant stricture with positive cytology/biopsy or polysomy, a lymph node biopsy through endoscopic ultrasound should be obtained. pCCA with negative lymph node involvement is best treated by surgery, resection, or transplantation, the sole curative options. Staging laparoscopy is recommended to exclude metastatic disease prior to surgery, which occurs in 15% of cases. Resection entails hepatic and bile duct removal and Roux-en-Y hepaticojejunostomy with regional lymphadenectomy. Bilobular involvement is considered a surgical contraindication. Perioperative mortality rate is up to 10%, mostly as a result of liver failure. In a few referral centers, unresectable single pCCAs <3 cm without dissemination can be considered for liver transplantation with neoadjuvant chemoradiation. This procedure is associated with 5-year survival rates of ~70%. If lymph node involvement is present, systemic chemotherapy can be considered along with biliary tract stenting. Surgical resection (Whipple procedure) is the primary option for management of dCCA, a procedure that achieves a median survival of 24 months and 5-year survival rates of ~25%. Main contraindications for resection are presence of distant lymph node involvement, metastases, or major vascular invasion. At the pathological examination, perineural invasion, lymph node metastasis, R0 resection (absence of residual tumor at pathological examination), and tumor differentiation are predictors of survival. Adjuvant therapy with capecitabine for 6 months is accepted based on the BILCAP study, which has been previously discussed. For advanced cases, consensus statements endorse first-line (gemcitabine and cisplatin plus durvalumab or pembrolizumab) and second-line therapies (FOLFOX) similar to those for iCCA. No molecular targeted therapies are available for these entities.

GALLBLADDER CANCER

Gallbladder cancer is the most common cancer of the biliary tract worldwide. The estimated number of cases of gallbladder cancer in the United States in 2016 was 11,400, more than CCA. The female-to-male

ratio is 3:1. Cholelithiasis is the major risk factor, but <1% of patients with cholelithiasis develop this cancer. Gallbladder polyps at risk of transformation are those ≥10 mm in diameter. Early cases are discovered incidentally at routine cholecystectomy. Clinical symptoms, such as jaundice, pain, and weight loss, are associated with advanced stages. Staging of gallbladder cancer involves local disease (tumor confined to the gallbladder) and advanced disease (tumor outside gallbladder with lymph node or distant metastases). The most accurate technique to define staging and vascular and biliary tract invasion is the magnetic resonance cholangiopancreatography. CT and PET scan can also be useful for preoperative staging.

The mainstay of treatment is surgical resection, either simple or radical cholecystectomy (partial hepatectomy and regional lymph node dissection) for local disease. Only ~20% of patients are candidates for surgery with curative intent, and 5-year survival rates range from 60 to 90% depending on prognostic factors such as lymph node or tumor invasion beyond muscular layer. Adjuvant therapy with capecitabine is recommended in R0 cases. Gallbladder cancers at advanced stage are considered unresectable. For patients with ECOG of 0–1, chemotherapy with gemcitabine, cisplatin, and durvalumab is the standard of care based on the TOPAZ 1 phase 3 trial that included 171 patients with gallbladder cancer (25%). Overall, median survival is 10–12 months in advanced cases. Second-line therapy includes FOLFOX chemotherapy. Percutaneous transhepatic drainage is indicated in case of biliary obstruction. Radiotherapy is not effective.

OTHER MALIGNANT LIVER TUMORS

Fibrolamellar Hepatocellular Carcinoma Fibrolamellar hepatocellular carcinoma (FLC) is a rare form of primary liver cancer that typically affects children and young adults (10–30 years of age) without background liver disease. FLC accounts for 0.85% of all primary hepatic malignancies in the United States, and its incidence rate is 0.02 cases per 100,000 inhabitants. FLC is considered a unique entity with a specific fusion oncogene *PRKACA-DNAJB1* present in 80–100% of cases. Few additional mutations have been described in <10% of cases. FLC has a better prognosis than HCC, probably due to the absence of cirrhosis and the earlier age of presentation. Surgical resection is the mainstay of treatment, and indications are less restrictive than for HCC. A retrospective series of 575 FLC cases reported a median survival of 70 months after resection. At advanced stages, the expected outcome is <20 months. There is no standard systemic therapy, and clinical trials are focused on targeting the fusion protein with kinase inhibitors or immunomodulatory agents.

Hepatoblastoma Hepatoblastoma (HB) is the most frequent primary liver tumor in children. The incidence of the disease is 1.5 cases per 1,000,000, and onset of the disease occurs before the age of 3 years. Background liver disease is rare in these patients. WNT signaling plays a major role, with *CTNNB1* mutations (70%) as the most frequently reported molecular event. Overexpression of IGF2 and genes in the 14q32 *DLK1/DIO3* locus is also very prevalent. At diagnosis, ~30% of patients are amenable to surgery. Resection followed by chemotherapy with doxorubicin/cisplatin is the mainstay treatment strategy. Among the remaining 70% of patients, neoadjuvant chemotherapy achieved response in >90% of cases and enabled resection with good clinical outcomes. A study including 1605 patients randomized in eight clinical trials reported better outcome for patients with stage I–II of the PRETEXT (Pretreatment Extent of Tumor) classification (out of four stages), age <3 years, AFP >1000 ng/mL, and absence of metastases. As opposed to HCC, low AFP <100 ng/mL indicates poor prognosis. Overall, 5-year survival is 70% (ranging from 50 to 90% depending on PRETEXT stage).

BENIGN LIVER TUMORS

The most common benign liver tumors are hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (HCA). Most benign tumors are identified incidentally by abdominal ultrasound or other imaging techniques. *Hemangiomas* are present in ~5% of the general population and are diagnosed by ultrasound except in cirrhotic patients or oncology patients, in whom contrast-enhanced imaging (contrast-enhanced ultrasound, CT, or MRI) is required. Conservative management is appropriate, and follow-up is not recommended. Exceptionally, growing lesions causing symptoms by compression can be considered for resection. FNH is a benign tumor present in <2% of the population and occurring mostly in females aged 40–50 years. FNH is a polyclonal hepatocellular proliferation due to an arterial malformation. MRI has the highest diagnostic accuracy with a specificity of 100%, when typical imaging features are present (homogeneous enhancement in the arterial phase with a central scar). Atypical FNH requires biopsy for diagnosis. Treatment is not recommended because these tumors do not degenerate or cause complications. In exceptional cases of expanding symptomatic lesions, surgery is the treatment of choice.

Hepatic adenomas are clonal benign proliferations resulting from single-gene driver mutations. HCAs have a low prevalence of 0.001% of the population and are frequently diagnosed in women aged 35–40 years. The female-to-male ratio is 10:1, and the main risk factors are oral contraceptives in females and use of anabolic androgenic steroids in male body builders. HCAs have the potential for hemorrhage and HCC development, particularly when >5 cm. Nowadays, there is a clear understanding of the molecular classification of HCA in subtypes defined by *CTNNB1* mutations (10–20%), *HNF1A* inactivation, and activation of inflammatory pathways (50–60%) or Hedgehog signaling pathway. Diagnosis is based on MRI, which is able to correlate with molecular subtypes in 80% of cases (inflammatory and HNF-1A type). For defining HCA with *CTNNB1* mutations, biopsy is required. Upon diagnosis, discontinuation of oral contraceptives and weight loss are recommended. Resection is indicated in all cases >5 cm, in men, or with *CTNNB1* mutation. For HCA <5 cm, 1-year follow-up is recommended. In case of active HCA bleeding, embolization followed by resection is the treatment of choice. The presence of multiple HCAs is common, and guidelines endorse treating them based on the size of the main nodule.

88 Pancreatic Cancer

Eileen M. O'Reilly, Andrew M. Lowy, Daniel D. Von Hoff

Pancreatic cancer is the third leading cause of cancer-related mortality in the United States, with >66,000 Americans diagnosed and >51,000 dying from the disease each year. Pancreatic cancer is projected to be the second leading cause of death from cancer in the United States by 2030. Worldwide, pancreatic cancer is the eleventh most common cancer, with about half a million diagnoses per annum. Pancreatic cancer is the most lethal human cancer, with an overall 5-year survival of 13%. However, that situation is changing. In particular, (1) an enhanced understanding of the pathobiology and genomic landscape of pancreatic cancer is steadily giving rise to new therapeutic opportunities, (2) the integration of multimodality therapy for patients with localized disease has improved outcomes, and (3) increasingly more molecularly defined groups of patients are eligible for targeted therapy beyond cytotoxic therapy.

EPIDEMIOLOGY

Pancreatic cancer accounts for 3% of all new cancer cases in the United States and ~8.3% of all deaths from cancer in the United States. The lifetime risk of developing pancreatic cancer is ~1.7%; however, the incidence has been increasing about 1.1% per year overall, but notably in people <55 years of age, it has been increasing 2.36% per year in women and 0.62% per year in men. Pancreatic cancer is more common with increasing age and slightly more common in men than in women. The 5-year survival rate for all stages has increased from 3% in 1975 to 13% in 2024. The latest information from the U.S. Surveillance, Epidemiology, and End Results (SEER) database predicts that the 5-year survival is about 44% for patients with localized pancreatic cancer, 16% for those with regional disease, and 3.2% for patients with metastatic disease. Pancreatic cancer is more common in developed countries (although it tracks with the prevalence of smoking). The incidence is highest in Eastern (e.g., Hungary and Slovakia) and Western (e.g., Germany) Europe and North America followed by other areas in Europe, Australia, New Zealand, and Southcentral Asia.

RISK FACTORS

Age is one of the strongest risk factors for pancreatic cancer with median age at diagnosis of 71 years (the disease is most frequently diagnosed in the 65–79 age group; for men, 65–69; for women, 75–79). The number of new cases per 100,000 persons and the number of deaths per 100,000 persons are higher for males and for black people of both sexes. People who have a non-O blood type are at higher risk of developing pancreatic cancer.

Environment The greatest risk factor for pancreatic cancer is cigarette smoking. The risk correlates with the increased number of cigarettes smoked and persists for at least 10 years following smoking cessation. Twenty-five to 30% of pancreatic cancers are believed to be caused by smoking. Exposure to cadmium as part of cigarette smoking or via exposure to welding, soldering, or dietary exposure has been weakly associated with an increased risk of pancreatic cancer.

Dietary factors may contribute to risk, acknowledging confounding issues; however, high intake of fat or meat (particularly well-done barbequed meat) are risk factors. High intake of citrus fruits and vegetables are associated with a decreased risk of pancreatic cancer. Coffee and low-to-moderate alcohol consumption are not associated with an increased risk for pancreatic cancer, although consumption of sugary carbonated drinks has been associated with elevated risk.

Hereditary Factors, Genetics, and Screening Hereditary factors account for 10–16% of all pancreatic cancers. Family members of patients with pancreatic cancer and selected individuals with certain pathogenic germline variants should seek participation in an early detection program with genetic counseling, definition of risk, and if appropriate, periodic magnetic resonance imaging (MRI) screening and endoscopic ultrasound of the pancreas, ideally enrolled on a prospective registry. Table 88-1 summarizes the various germline variants along with familial cancer syndromes where there is known to be an increased risk for pancreatic cancer. For an average-risk individual (without any known predisposing factors), there is currently no recommended screening.

Knowing that an individual carries a *BRCA1/2* or *PALB2* germline variant or any of the above mutations requires referral of that person to an early detection or high-risk screening clinic. For patients with a *BRCA1/2* or *PALB2* pathogenic germline variant, a poly(ADP-ribose) polymerase (PARP) inhibitor should be considered (see below) as part of treatment for metastatic pancreatic cancer. Other pathogenic germline variants are under study to determine their increased risk of pancreatic cancer, including *CFTR, PRSS2, CDK4, FANCC, APC, ATM, BRIP1, BRCA1, EPCAM, MEN1, MLH1, MSH2, MSH6, NF1, PMS2, SMAD4, TP53, TSC1, TSC2,* and *VHL*. Some of these variants are also associated with pancreatic neuroendocrine tumors (Chap. 89).

In addition to recognized genetic syndromes from single gene variants, other individuals without any of these identifiable germline variants may be at higher risk for this cancer. For example, a family history of pancreatic cancer is associated with increased risk based on the number of affected relatives. Having one first-degree relative with pancreatic cancer, one's risk for developing the disease is increased 4.6-fold, having two first-degree relatives increases the risk 6.4-fold, and three or more first-degree relatives confers a 32-fold increased risk. The risk is also increased if a relative developed pancreatic cancer at <55 years old and is further compounded by smoking.

Medical Conditions Chronic pancreatitis that is nonfamilial is associated with an increased risk of pancreatic cancer (2.3–16.5-fold increase). Risk is also increased in people with chronic pancreatitis associated with cystic fibrosis or tropical pancreatitis.

A clear association exists between diabetes mellitus (both type 1 and type 2) and pancreatic cancer. Whether this is a causal association or whether the diabetes is the result of the cancer is not exactly clear. New-onset (particularly with concomitant weight loss) or unexpected worsening of type 2 (or type 3c) diabetes may be associated with pancreatic cancer, and research programs are evaluating screening in otherwise healthy individuals in this setting.

High body mass index (BMI) is considered a risk factor for pancreatic cancer. A high BMI of ≥30 is associated with a doubling of pancreatic cancer risk. As obesity is a risk factor for diabetes, the contribution of obesity alone is unclear. Interestingly, patients with severe obesity

TABLE 88-1 Germline Mutations, Familial Cancer Syndromes, and Fold Risk of Pancreatic Cancer

GERMLINE MUTATION	FAMILIAL CANCER SYNDROME	ESTIMATED INCREASED RISK (FOLD) OF PANCREATIC CANCER
BRCA2[a]	Familial breast/ovarian cancer and others	3.5–10
PALB2 (partner and localizer of *BRCA2*)	Familial breast cancer and others	~Sixfold

MLH1, MSH2, MSH6, PMS2	Heredity nonpolyposis colorectal syndrome or Lynch syndrome[d]	9–36

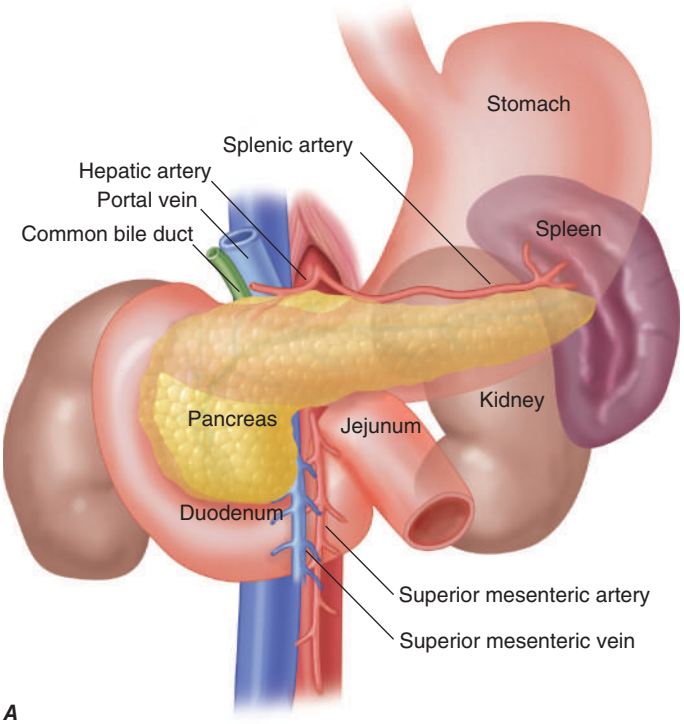
[a]Particularly common in individuals with Ashkenazi Jewish heritage. [b]Forty percent chance of pancreatic cancer by the age of 70. [c]Calculated at age 70. [d]Very important because this is associated with microsatellite instability, which is a marker for response to immune checkpoint blockade.

who undergo a bariatric intervention experience a reduction in the incidence of gastrointestinal cancers, including pancreatic cancer, by >30% in the first 3 years (along with a decrease in their hemoglobin A_{1c} and blood glucose level). Physical inactivity also has been associated with an increased risk of pancreatic cancer.

Other Considerations Most patients with pancreatic cancer relate that they have had developing symptoms over months to years before diagnosis. Efforts at early detection of the disease have not yet been fruitful, but this is an area of very active investigation.

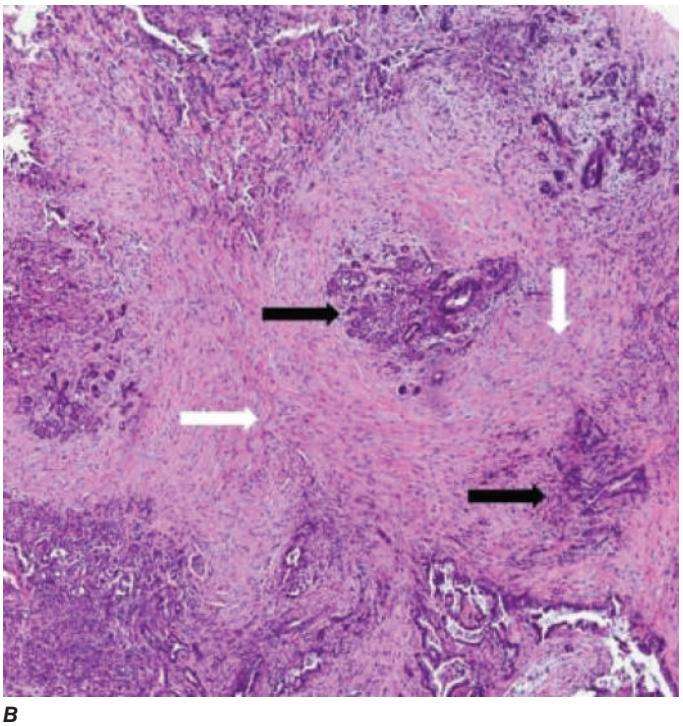
PATHOLOGY AND MOLECULAR CONSIDERATION

Location The posterior location of the pancreas in the abdomen is one of the issues that makes diagnosis more challenging **(Fig. 88-1*A*)**.



Pathology Cancers of the pancreas can be divided into neoplasms of the endocrine pancreas **(Chap. 89)** and those of the exocrine pancreas. The most common neoplasm of the exocrine pancreas and most lethal is ductal adenocarcinoma. These cancers arise in the head, body, or tail of the pancreas and are characterized by infiltrating desmoplastic stromal reactions **(Fig. 88-1*B*)**.

Other subtypes of nonneuroendocrine pancreatic cancers include acinar cell carcinoma (tumors of the exocrine enzyme producing cell), colloid carcinoma, medullary carcinoma, adenosquamous carcinoma, and other rare subtypes. Each of these is different in behavior and in their molecular characteristics and often requires other specific types of treatment. Occasionally, metastases to the pancreas occur secondary to renal, breast, lung, and urothelial carcinomas, melanoma, lymphoma, and other malignancies.



Molecular Characteristics The mutational landscape of pancreatic ductal adenocarcinoma is characterized by alterations in four genes that are commonly mutated or inactivated. The most common of these is the *KRAS* oncogene (mutations primarily in codon 12). It is increasingly important to identify the specific mutant *KRAS* allele as novel drugs targeting specific alleles now exist and others are in development. *KRAS* mutations are seen in 90–95% of pancreatic adenocarcinomas. A subset of pancreatic cancers is termed "*KRAS* wildtype," where no alteration in *KRAS* is observed. This form of pancreatic cancer is more frequently observed in patients <55 years of age, and often other therapeutically actionable findings are identified in these cancers, including mutations in *BRAF*, rare oncogenic targetable fusions (e.g., *NRG-1, NTRK1-3*), or microsatellite instability. *p16/CDKN2A* mutation or epigenetic silencing is present in >90% of invasive pancreatic adenocarcinomas. *TP53* is mutated in ~75% and *DPC4/SMAD4* is mutated in about half of these tumors. As a reference point, the *BRCA2* gene noted in Table 88-1 is mutated in 3.5–10% of pancreatic adenocarcinomas.

Precursor Lesions Most pancreatic cancers are believed to arise from pancreatic intraepithelial neoplasia (PanINs), which have varying degrees of dysplasia designated as PanINs 1–3 (and constitute a progression model for pancreatic cancer). Genetic alterations become more frequent as the PanIN grade increases (e.g., grade 3). Most PanIN lesions will never progress to invasive malignancy. An alternate precursor lesion is an intraductal papillary neoplasm (IPMN), which is usually noninvasive. Unfortunately, even high-grade PanIN lesions are not detectable by currently available imaging modalities. In contrast, some pancreatic adenocarcinomas arise from noninvasive cystic epithelial precursor lesions. These lesions can be seen on magnetic resonance imaging (MRI) and computed tomography (CT) imaging, and thus detection may permit early diagnosis of pancreatic cancer. As compared to main pancreatic duct IPMN, a side branch duct IPMN is more likely to be noninvasive. MRI and endoscopic ultrasound are commonly used to assess malignant potential based on risk factors such as size, growth rate, main pancreatic duct size, and the presence of mural nodularity.

One other rare pancreatic tumor is the mucinous cystic neoplasm; they may be seen as incidental findings on scans and are more common in the body and tail of the pancreas and tend to occur in women. These lesions are less likely to progress to malignancy. Clinical signs of concern include large size (>3 cm) and the presence of mural nodules and/or thickening. Even after rare progression to mucinous adenocarcinoma, they typically have a more favorable prognosis relative to typical ductal adenocarcinoma.

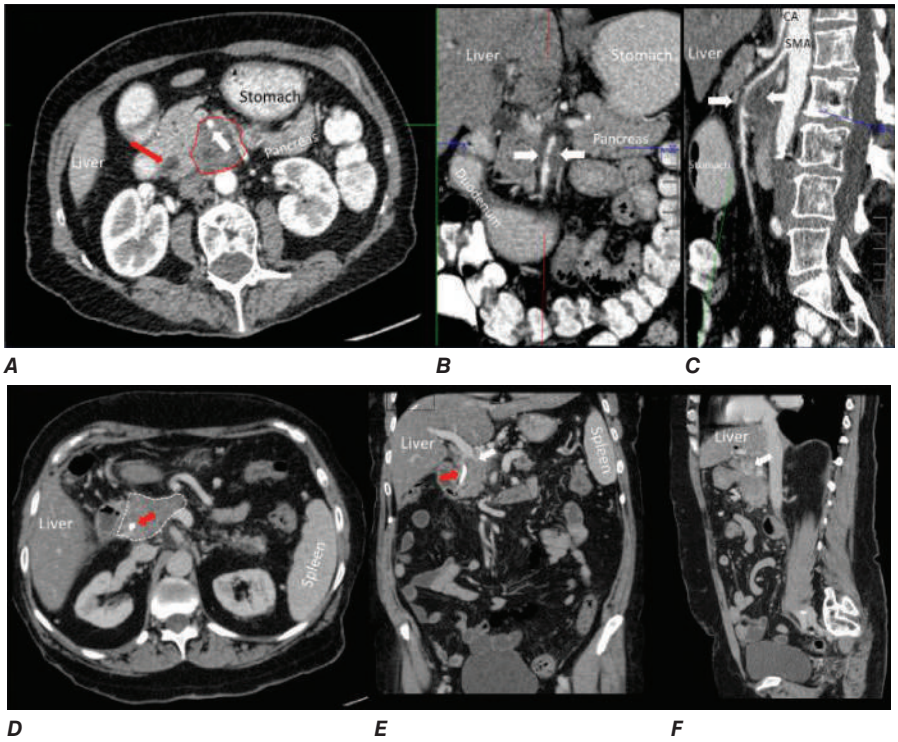

FIGURE 88-2 Selected images from contrast-enhanced computed tomography (CT) in patients with locally advanced adenocarcinoma of the pancreas. A high-quality contrast-enhanced CT scan (arterial phase in panels ***A–C*** and portal venous phase in panels ***D–F***) is required for optimal staging of pancreas cancer. Panel ***A*** demonstrates the typical features of adenocarcinoma of the pancreas on arterial phase axial CT scans (*dotted outline*) with tumor encasement of the superior mesenteric artery (*white arrow*). Note the dilatation of the common bile duct (*red arrow*). Panels ***B*** (magnified coronal) and ***C*** (sagittal) show reconstruction of CT images into additional orthogonal planes with exquisite details to confirm the unresectable nature of the tumor due to vascular encasement. Panel ***D*** demonstrates the typical features of adenocarcinoma of the pancreas on portal venous phase axial CT scans in a different subject. The dotted line outlines a pancreas cancer lesion in the pancreatic head, which is encasing the portal splenic confluence (*dotted outline*). Panels ***E*** (*white arrow*) and ***F*** show the pinched appearance of the portal splenic confluence by tumor abutment and invasion of the superior mesenteric vein (*white arrow*) on coronal and sagittal views. Note the presence of a stent in the common bile duct (*red arrow*) to help relieve biliary obstruction caused by the tumor. CA, celiac axis; SMA, superior mesenteric artery.

CLINICAL FEATURES

History and Physical A classic presentation for a patient with pancreatic cancer arising in the head of the gland is "painless" jaundice. Jaundice is visually detectable with a bilirubin of >2 mg/dL, and pruritus may also occur due to bile salt deposition in the skin. However, pain is also common in newly diagnosed patients and is typically mid epigastric (sometimes described as a "boring-like" pain) with radiation to the back (due to retroperitoneal invasion of the splanchnic nerve plexus). The pain may be exacerbated by eating or lying flat. In the presence of jaundice, light stool color from the absence of bile occurs (steatorrhea also causes malodorous stools). Other signs include the onset of diabetes (particularly with concomitant weight loss) or hyperglycemia/elevated hemoglobin A_{1c} in the preceding 1–2 years. The association of pancreatic cancer with depression remains controversial.

In addition to jaundice, physical signs of pancreatic cancer include evidence of weight loss, including loss of muscle mass, and a palpable gallbladder in the setting of biliary obstruction (Courvoisier's sign). Migratory superficial thrombophlebitis and presentation with both deep venous and arterial thromboses can occur (Trousseau's syndrome). Signs of late-stage disease include a lymph node palpable in the supraclavicular fossa (usually on the left where the thoracic duct enters the subclavian vein). This is referred to as Virchow's node. Occasionally, one can palpate subcutaneous metastases in the periumbilical area referred to as a Sister Mary Joseph's node—named after one of the operating room nurses from the Mayo Clinic who noted that when she prepped that area and felt those nodules, the patient often had peritoneal metastases.

The history and symptoms noted above lead to imaging as the next step, including ultrasonography (jaundice) and CT or MRI.

DIAGNOSTIC WORKUP

Imaging A key diagnostic tool is the use of a dual-phase contrast-enhanced CT using a pancreas cancer protocol, which allows arterial phase enhancement and portal venous phase enhancement and detailed visualization of tumor–blood vessel relationships to inform both resectability and staging. Figure 88-2 demonstrates such a CT scan (with vascular involvement). Figure 88-3 demonstrates the use of an ^{18}F-glucose positron emission tomography (PET) scan that can aid in the detection of otherwise occult metastatic disease.

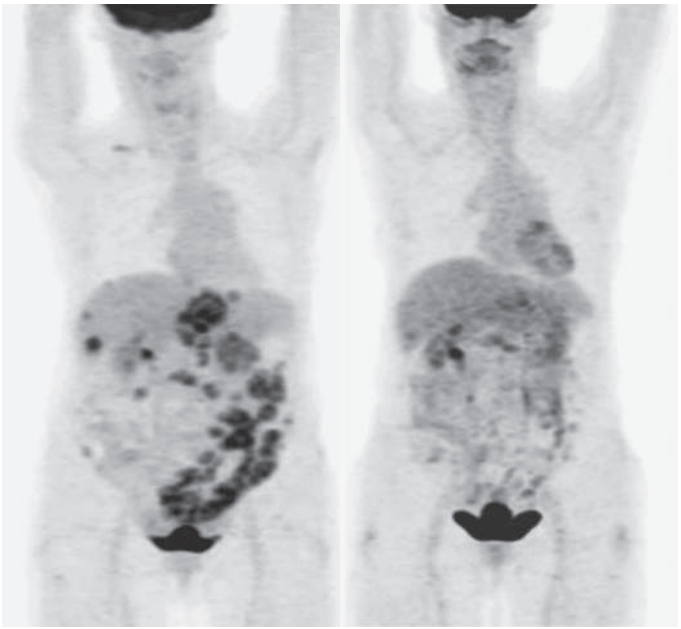

FIGURE 88-3 Positron emission tomography scan demonstrating metastatic disease—baseline and after 6 weeks of chemotherapy with partial resolution of liver metastases.

Histologic Diagnosis A histologic (tissue) diagnosis is essential and should be obtained with a Tru-Cut biopsy needle (fine-needle aspiration cytology is an acceptable but less preferred alternative). Obtaining adequate tissue not only secures a histologic/cytologic diagnosis but also facilitates molecular testing (next-generation sequencing for genomic alterations including *KRAS*) and microsatellite status. Increasingly subsets of patients based on genomic characterization are being identified and for whom therapies are available, making the need for adequate tissue sampling increasingly relevant to patient management.

A core needle (18- to 22-gauge) biopsy can be obtained via endoscopic ultrasound-guided technique for a tumor localized to the pancreas. To biopsy the liver or a lymph node, a larger (16- to 18-gauge) percutaneous needle biopsy by an interventional radiologist is typically undertaken.

Serum Markers Before treatment and, ideally, once the bilirubin level has normalized (biliary obstruction is associated with elevated CA19-9), a serum sample should be obtained for level of CA19-9, carcinoembryonic antigen (CEA), and CA125 (can be helpful for the 8–15% of patients with nondetectable CA19-9–Lewis antigen nonsecretors). Trends of these tumor markers over time can inform therapeutic decision-making.

IMPORTANT IMMEDIATE CONSIDERATIONS IN PATIENT CARE

During the life cycle of this cancer, biliary tract obstruction is a frequent occurrence for tumors arising in the head of the gland (and the attendant risk for sepsis from the biliary tree). A metallic biliary wall stent is typically placed endoscopically to alleviate jaundice and pruritus. If surgery is under consideration as the initial therapeutic step, biliary stent placement is not necessarily warranted; however, if neoadjuvant (preoperative) systemic therapy is planned, both a histologic/cytologic diagnosis and placement of a biliary wall stent are required (where the latter is medically indicated). Of important note, all patients with localized pancreatic cancer require multidisciplinary evaluation by surgical, medical, and radiation oncology to optimize therapeutic decision-making.

Patients with metastatic pancreatic cancer may have a hypercoagulable state and frequently have thrombophlebitis (Trousseau's sign) and deep vein thrombosis with pulmonary emboli and/or more rarely arterial thrombotic events. Anticoagulation using either a direct oral anticoagulant or low-molecular-weight heparin is required in these setting in the absence of a contraindication to anticoagulation.

Control of pain or of active cancer-related symptomatology including anorexia, weight loss, and malabsorption should be proactively treated. Pancreatic enzyme replacement therapy (PERT) is a critical measure to address symptoms of malabsorption, including abdominal cramping, bloating, steatorrhea, excess flatus, and weight loss. Early involvement of a supportive care team can help maximize symptom control, facilitate treatment readiness, and extend a better quality of life.

CLINICAL STAGING

The clinical staging of pancreatic cancer according to the American Joint Commission on Cancer staging is presented in **Table 88-2**.

Table 88-3 presents another clinical way to express extent of disease as well as therapeutic approaches (to be discussed later).

For optimal staging, a laparoscopy is selectively indicated either before or at the time of definitive surgery. If metastatic disease is identified at laparoscopy, curative intent surgery is not undertaken.

TREATMENT

Pancreatic Cancer

RESECTABLE DISEASE (10–20%)

For all patients with localized pancreatic cancer, multidisciplinary evaluation should be undertaken. A standard approach for resectable disease (10–15% of patients; as defined in Table 88-3) is upfront surgery. Neoadjuvant therapy (systemic therapy prior to surgery) is an option for patients with resectable disease. The rationales for preoperative chemotherapy include the following: (1) to control micrometastatic disease; (2) to assess tumor biology and response to the selected chemotherapy regimen (this allows patients with progressive disease to avoid nontherapeutic, morbid surgery); (3) to assure delivery of systemic therapy because therapy is better tolerated in the preoperative setting and is not subject to omission of drugs or altering doses due to delayed postoperative recovery; and (4) to achieve tumor downstaging to enhance the potential for a margin-negative surgical resection. The type of surgery for patients with tumors in the pancreatic head, neck, or uncinate process is typically a pancreaticoduodenectomy with or without pylorus preservation. For tumors in the body or tail, a distal subtotal pancreatectomy and splenectomy are performed. These operations may be performed using a traditional "open" surgical technique or using minimally invasive techniques. Clinical and pathologic findings of the resection are defined as either an R0 resection (no macroscopic or microscopic disease left after surgery) or an R1 resection, which refers to microscopic residual disease at the surgical margin. An R2 resection refers to gross residual disease remaining after surgery and is a highly undesirable oncologic outcome. The best outcomes are achieved in patients with a small tumor (<2 cm), no lymph node involvement (N0), and R0 (stage I), in whom 5-year survival ranges from 50 to 90% depending on actual tumor size and grade. Overall, only a small fraction of tumors are diagnosed when stage I; however, a key goal of screening is to "stage migrate" and increase the proportion of tumors that are diagnosed as early stage I lesions.

Several approaches are designed to maximize outcome for localized pancreatic cancer.

Postoperative Adjuvant Therapy A standard of care is 24 weeks of adjuvant treatment with the modified FOLFIRINOX regimen (folinic acid, 5-fluorouracil, irinotecan, oxaliplatin). The median survival was 54 months for modified FOLFIRINOX compared to 35 months for gemcitabine alone (hazard ratio [HR] 0.64; 95% confidence interval [CI] 0.48–0.86; $p = .003$) in the definitive trial supporting this therapy. Main side effects included fatigue, gastrointestinal toxicity, myelosuppression, and neuropathy.

Neoadjuvant Therapy A newer approach is the use of neoadjuvant chemotherapy (systemic therapy given before surgery) to shrink the tumor, eradicate micrometastatic disease, and normalize serum CA19-9 level. Neoadjuvant therapy is the standard approach for patients with borderline resectable or locally advanced disease. The role of radiation in the treatment of localized pancreatic cancer is controversial.

LOCALLY ADVANCED DISEASE (25–30% OF PATIENTS)

For patients with locally advanced disease (defined by tumor contact with arterial structures >180° and/or venous contact that does not permit resection/reconstruction), the median survival is poor (6–18 months). Complications from local disease progression can be significant and include pain, biliary and duodenal obstruction, vascular thromboses, varices, bleeding, and infection/sepsis. Typical treatment paradigms for locally advanced disease include systemic chemotherapy with or without radiation therapy. A proportion of patients with locally advanced disease (~20%) may be rendered operable following neoadjuvant therapy.

METASTATIC DISEASE (50–60% OF PATIENTS)

The mainstay of treatment for metastatic pancreatic cancer is systemic chemotherapy. Several treatment regimens including FOLFIRINOX, gemcitabine, albumin-bound paclitaxel, and, more recently, NALIFIRINOX (nanoliposomal irinotecan, 5-fluorouracil, leucovorin, oxaliplatin; NAPOLI-3) have all demonstrated a survival advantage compared to prior standards in untreated metastatic pancreatic cancer. In a previously treated setting, liposomal irinotecan and infusional 5-fluorouracil and leucovorin (NAPOLI-1) regimen has been shown to improve survival. Predictors of outcome in the

TABLE 88-2 Definition of Primary Tumor (T)

T CATEGORY	T CRITERIA
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ This includes high-grade pancreatic intraepithelial neoplasia (PanIn-3), intraductal papillary mucinous neoplasm with high-grade dysplasia, intraductal tubulopapillary neoplasm with high-grade dysplasia, and mucinous cystic neoplasm with high-grade dysplasia
T1	Tumor ≤2 cm in greatest dimension
T1a	Tumor ≤0.5 cm in greatest dimension
T1b	Tumor >0.5 cm and <1 cm in greatest dimension
T1c	Tumor 1–2 cm in greatest dimension
T2	Tumor >2 cm and ≤4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4	Tumor involves celiac axis, superior mesenteric artery, and/or common hepatic artery, regardless of size
N CATEGORY	**N CRITERIA**
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in one to three regional lymph nodes
N2	Metastasis in four or more regional lymph nodes
M CATEGORY	**M CRITERIA**
M0	No distant metastasis
M1	Distant metastasis

TABLE 88-3 Extent of Disease and Therapeutic Approach

DESIGNATION (MEDIAN SURVIVAL)	THERAPEUTIC APPROACHES
1. Resectable (localized): (18–23 mo) • No solid tumor contact with celiac axis, hepatic artery, or superior mesenteric artery (SMA), contact with superior mesenteric–portal veins of <180° • Patent superior mesenteric–portal veins • No extrapancreatic disease	Surgery followed by adjuvant therapy • mFOLFIRINOX or gemcitabine +/– capecitabine or nab-paclitaxel Neoadjuvant chemotherapy followed by surgery
2. Locally advanced: (6–18 mo) • Arterial involvement of >180° (superior mesenteric artery, others) • Venous occlusion (superior mesenteric vein [SMV] or portal) • No extrapancreatic disease	Chemotherapy Chemotherapy +/– radiation Evaluate for surgery following systemic therapy
3. Metastatic: (6–12 mo)	Chemotherapy with special consideration for tumors with specific targets (e.g., mismatch repair high, *BRCA1/2, BRAF*, etc.)

Abbreviation: mFOLFIRINOX, modified FOLFIRINOX (folinic acid, 5-fluorouracil, irinotecan, and oxaliplatin (T Conroy et al: N Engl J Med 379:2395, 2018).

metastatic setting include good physical functioning (performance status), favorable nutritional status, the absence of liver metastases, lung-only metastases, and the presence of select pathogenic germline variants. **Table 88-4** details combination regimens that have further improved survival modestly. Median overall survival ranges from 6 to 12 months. However, 1-year survival is improving, with subsets of patients whose survival with metastatic disease can reach a couple of years or longer.

PATIENTS WITH A SPECIFIC MOLECULAR PROFILE IN THEIR TUMOR/GERMLINE

PARP inhibitors have activity in patients with pathogenic germline or somatic (tumor-based) *BRCA2, BRCA1*, or *PALB2* (i.e., defective DNA repair proteins) variants. In addition, these tumors might be more sensitive to specific combinations of chemotherapy that include platinum agents (gemcitabine and cisplatin or FOLFIRINOX). About 1% of pancreatic cancers have microsatellite instability, typically with high numbers of mutations in their tumors, due to deficient mismatch repair, and these tumors are likely to benefit from immune checkpoint blockade with anti-PD-1 (pembrolizumab, nivolumab) and anti-CTLA-4 inhibitors. *KRAS* mutations occur ubiquitously in pancreatic cancer. Current treatment guidelines include drugs targeting *KRAS* G12C (~1% of pancreatic

TABLE 88-4 Combination Chemotherapy Regimens That Have an Impact on Survival in Stage IV Disease

STUDY DESIGN (AUTHOR/REF)	NO. OF PATIENTS	MEDIAN OVERALL SURVIVAL (MONTHS)

Nab-paclitaxel + gemcitabine vs gemcitabine (Von Hoff et al: N Eng J Med 369:1691, 2013)	861	8.5 vs 6.7 (HR 0.72; 95% CI 0.62–0.83; $p < .001$[a])
Nanoliposomal irinotecan, 5-fluorouracil + folinic acid vs nanoliposomal irinotecan monotherapy vs 5-fluorouracil + folinic acid (Wang-Gillam et al: Lancet 387:545, 2015)	417	6.1 vs 4.2 (HR 0.67; 95% CI 0.49–0.92; $p = .012$[b])
NALIRIFOX (nanoliposomal irinotecan, 5-fluorouracil, folinic acid, oxaliplatin) vs nab-paclitaxel and gemcitabine (Wainberg et al: Lancet 402:1272, 2023)	770	11.1 vs 9.2 (HR 0.83; 95% CI 0.70–0.99; $p = .036$)

[a]The 2-year survival rate with this regimen is 9%, and the 3+ year rate is 4%. Other studies have not reported on these parameters. [b]HR is for nanoliposomal irinotecan + 5-fluorouracil + folinic acid vs 5-fluorouracil + folinic acid.

Abbreviations: CI, confidence interval; HR, hazard ratio.

cancers); however, agents that target more common *KRAS* mutations (G12D, G12V, G12R) are being evaluated in clinical trials and have high potential to become part of standard treatment algorithms in the future. Other rare actionable alterations include oncogenic fusions in *RET, ALK, MET, NRG-1, ROS*, and *BRAF* V600E mutations, for which therapeutic agents are available and are in clinical trials.

MAINTENANCE THERAPY FOR PATIENTS RESPONDING TO TREATMENT

For patients with a germline *BRCA1* or *BRCA2* mutation whose metastatic pancreatic cancer has not grown during an initial platinum-based regimen, the PARP inhibitor olaparib has been shown to improve progression-free survival (7.4 vs 3.8 months; HR 0.53; 95% CI 0.35–0.82; $p = .004$) and maintenance of quality of life, both relative to placebo.

FUTURE DIRECTIONS

Multiple novel therapies are under development in pancreatic cancer. Immunotherapy using personalized neoantigen vaccines or using an antigenic target such as a "public" or shared neoantigen such as *KRAS* has demonstrated early promise following resection of pancreatic cancer as an adjunct to standard chemotherapy. Mid-phase trials are planned/underway to further explore these signals. *KRAS* has heretofore been considered nondruggable; however, developments in organic chemistry, biosynthesis, and other innovations have led to a series of therapeutics directly targeting *KRAS* with promise that these agents in the proximate future will be integrated as part of standard therapy for pancreatic cancer. Multiple therapeutic approaches targeting the tumor immune microenvironment are being explored, capitalizing on an increased understanding of the pathobiology of this cancer. Other important developments include innovation in clinical trial design, novel approaches to screening and surveillance utilizing "liquid" biomarkers (incorporating DNA fragments, methylation, and proteomic profiles), and other technologic developments.

89 Gastrointestinal Neuroendocrine Tumors

Matthew H. Kulke

Gastrointestinal (GI) neuroendocrine tumors (NETs) can be broadly grouped according to their site of origin as either extrapancreatic NETs, historically called carcinoid tumors, or pancreatic NETs. While NETs can pursue a broad range of clinical behaviors, they classically follow a course that is more indolent than many other malignancies. NETs also have the ability to synthesize peptides, growth factors, and bioactive amines that may be ectopically secreted, giving rise to a range of unique clinical syndromes.

INCIDENCE AND PREVALENCE

The diagnosed incidence of NETs has been steadily increasing over the past several decades. An analysis of data from the Surveillance, Epidemiology, and End Results (SEER) program, comprising population-based data in the United States from 1973 to 2012, showed that the overall incidence had increased 6.4-fold over this time period and that the estimated prevalence of patients who had been diagnosed with a NET was >170,000. Gastroenteropancreatic neuroendocrine tumors comprise the majority of neuroendocrine tumors, and recent analyses suggest the incidence in this subgroup has risen proportionately and continues to rise **(Fig. 89-1)**. These same studies have also found that overall survival durations for patients with NETs have improved significantly over time. The increasing incidence and improved survival durations for patients with NETs likely reflect, at least in part, advances in both diagnosis and treatment.

While environmental or other factors leading to an increased incidence of NETs cannot be excluded, common cancer risk factors such as tobacco or alcohol use and dietary patterns have not been clearly linked to NET development.

A minority of NETs develop in the context of autosomal inherited genetic syndromes associated with mutations in specific tumor-suppressor genes. The most common of these is multiple endocrine neoplasia type 1 (MEN 1), due to mutation and loss of function of the *menin* gene, located on chromosome 11q13 **(Chap. 400)**. Patients

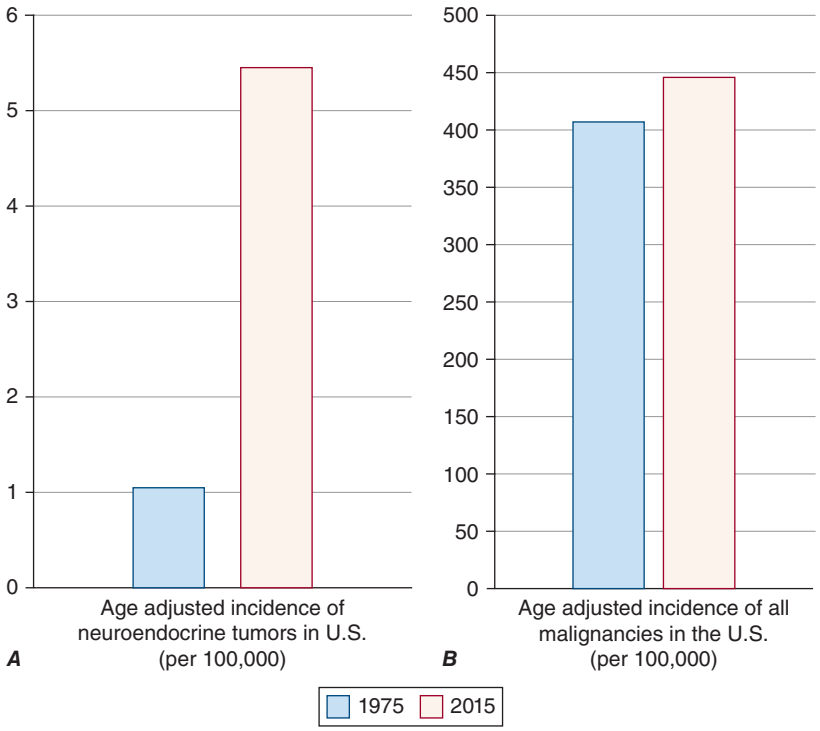

FIGURE 89-1 Incidence of gastroenteropancreatic neuroendocrine tumors (NETs). The incidence of gastroenteropancreatic neuroendocrine tumors has been increasing over the past several decades, an observation that has been attributed in part to improved diagnosis and classification. *(Adapted from Z Xu et al: Epidemiologic trends of and factors associated with overall survival for patients with gastroenteropancreatic neuroendocrine tumors in the United States. JAMA Network Open 4:e2124750, 2021, Figure 1A.)*

with MEN 1 are at risk for developing pancreatic NETs as well as hyperparathyroidism and pituitary adenomas; less commonly, they may develop bronchial and thymic NETs. Other inherited syndromes associated with NETs include von Hippel–Lindau disease (VHL), von Recklinghausen's disease (neurofibromatosis type 1), and tuberous sclerosis (Bourneville's disease). Inherited mutations in the VHL gene, located on chromosome 3p25, are associated with the development of cerebellar hemangioblastomas, renal cancer, and pheochromocytomas and, less commonly, pancreatic NETs. Mutations in neurofibromin (*NF1*) are associated with neurofibromatosis (von Recklinghausen's disease); patients with neurofibromatosis are at risk of developing both pancreatic and extrapancreatic NETs. Tuberous sclerosis is caused by mutations that alter either hamartin (*TSC1*) or tuberin (*TSC2*). Both hamartin and tuberin function as inhibitors of the phosphatidylinositol 3-kinase and the mechanistic target of rapamycin (mTOR) signaling cascades, and pancreatic NETs have been reported in these patients. Rare cases of familial small intestine NETs have also been reported; in these cases, multiple synchronous tumors generally arise within the small intestine. A characteristic inherited mutation has not been identified to date in the majority of these cases.

HISTOLOGIC CLASSIFICATION AND MOLECULAR FEATURES

The histologic features of NETs vary widely and are one of the most important determinants of both clinical behavior and treatment. NETs are classified based on the degree tumor differentiation (well or poorly differentiated), as assessed by a pathologist, and tumor grade (grades 1–3) (Table 89-1). Tumor grade closely correlates with mitotic count and Ki-67 proliferative index. Classic, well-differentiated NETs are composed of monotonous sheets of small round cells with uniform nuclei and only rare mitoses. Immunocytochemical staining for chromogranins and synaptophysin is typical. Ultrastructurally, these tumors contain electron-dense neurosecretory granules containing peptides and bioactive amines that may be ectopically secreted, giving rise to a range of clinical syndromes. These classic well-differentiated NETs have low-grade features and generally have a mitotic index of <2 mitoses per 10 high-power fields (HPFs) and a Ki-67 proliferative index of <3%. Less commonly, well-differentiated NETs have an intermediate histologic grade and pursue a somewhat more aggressive clinical course. Intermediate-grade tumors typically have a mitotic count of 2–20 per 10 HPF and a mitotic index of 3–20%. Well-differentiated high-grade tumors are rare and have mitotic counts that exceed 20 per 10 HPF and a Ki-67 proliferative index of >20%. Poorly differentiated high-grade tumors form the most clinically aggressive category; prognosis and treatment for these tumors differ markedly from their well-differentiated counterparts.

Whole exome sequencing of sporadic pancreatic NETs has shown that the most frequently altered gene was *MEN1*, occurring in 44% of tumors. In addition, 43% of tumors had mutations in genes encoding two subunits of a transcription/chromatin remodeling complex consisting of DAXX (death-domain-associated protein) and ATRX (α-thalassemia/mental retardation syndrome X-linked). Mutations in genes associated with the mTOR pathway were identified in 15% of tumors. In contrast, recurrent mutations in extrapancreatic NETs appear to be rare. In one study that evaluated 180 small intestinal NETs using a combination of whole exome and more targeted genome-sequencing analysis, recurrent mutations were only observed in the *CDKN1B* gene (cyclin-dependent kinase inhibitor 1B [$p27^{Kip1}$]) in 8% of cases. Loss of chromosome 18 is a common finding in small-bowel NETs. Small-intestinal GI carcinoids commonly have epigenetic changes; however, the clinical significance of these alterations remains uncertain.

CLINICAL PRESENTATION AND MANAGEMENT OF LOCALIZED PANCREATIC NEUROENDOCRINE TUMORS

Pancreatic NETs have been subcategorized as either "functional," meaning associated with symptoms of hormone secretion, or nonfunctional, in which case they may be clinically silent until they cause anatomic symptoms. The clinical presentation of functional pancreatic NETs depends on the type of hormone secreted and can sometimes lead to dramatic clinical presentations (Table 89-2). The most common functional pancreatic NETs are insulinomas, followed in incidence by glucagonomas and gastrinomas. Pancreatic NETs secreting other hormones, including somatostatin, vasoactive intestinal peptide (VIP), adrenocorticotropic hormone (ACTH), and parathyroid hormone (PTH), have also been described but are uncommon. Only ~20% of pancreatic NETs are associated with symptoms of hormone

TABLE 89-1 Histologic Classification of Neuroendocrine Tumors

CLASSIFICATION	DIFFERENTIATION	GRADE	MITOTIC COUNT	KI-67
Neuroendocrine tumor	Well differentiated	Low grade (grade 1)	<2 per 10 HPF	<3%
Neuroendocrine tumor	Well differentiated	Intermediate grade (grade 2)	2–20 per 10 HPF	3–20%
Neuroendocrine tumor	Well differentiated	High grade (grade 3)	>20 per 10 HPF	>20%
Neuroendocrine carcinoma	Poorly differentiated	High grade (grade 3)	>20 per 10 HPF	>20%

Abbreviation: HPF, high-power field.

TABLE 89-2 Clinical Presentation and Management of Secretory Syndromes Associated with Neuroendocrine Tumors

	CLINICAL SYMPTOMS AND MANIFESTATIONS	TREATMENT OPTIONS TO CONTROL SECRETORY SYMPTOMS
Pancreatic Neuroendocrine Tumors		
Gastrinoma (generally located in "gastrinoma triangle")	Zollinger-Ellison syndrome: gastroesophageal reflux, peptic ulcer disease, diarrhea	Proton pump inhibitors, somatostatin analogues
Insulinoma	Hypoglycemia leading to confusion, lethargy, coma; weight gain	Diazoxide, everolimus[a]
Glucagonoma	Skin rash (necrolytic migratory erythema), glucose intolerance, weight loss	Somatostatin analogues
VIPoma	Verner-Morrison syndrome: watery diarrhea, hypokalemia, achlorhydria	Somatostatin analogues
ACTHoma	Cushing's syndrome: hyperglycemia, weight gain, hypokalemia	Ketoconazole, metyrapone, consider adrenalectomy
Extrapancreatic Gastrointestinal Neuroendocrine Tumors		
Typically in setting of advanced disease from small intestine or appendiceal primary tumors	Carcinoid syndrome: flushing, diarrhea, right-sided valvular heart disease, mesenteric fibrosis	Somatostatin analogues, telotristat ethyl

[a]Successful use of monoclonal anti-insulin receptor antibodies to treat insulin-induced hypoglycemia has been reported but remains investigational.

Abbreviations: ACTH, adrenocorticotropic hormone; VIP, vasoactive intestinal peptide.

hypersecretion; the majority of pancreatic NETs are "nonfunctional" and are diagnosed either incidentally or after patients present with abdominal pain, weight loss, or other anatomic symptoms related to tumor bulk.

GASTRINOMA

Patients with gastrinoma typically present with Zollinger-Ellison syndrome (ZES) **(Chap. 335)**. The most common symptoms associated with this syndrome are abdominal pain, diarrhea, gastroesophageal reflux disease (GERD), and peptic ulcer disease. Peptic ulcer disease manifesting as multiple ulcers with associated diarrhea is a classic presentation. Up to 25% of patients with ZES have MEN 1, and a diagnosis of gastrinoma should prompt a family history as well as an assessment for concurrent hyperparathyroidism. Fasting hypergastrinemia is a nearly universal finding in patients with gastrinoma. Importantly, however, proton pump inhibitors (PPIs) can suppress acid secretion sufficiently to cause hypergastrinemia and can confound the diagnosis. Achlorhydria, usually in the context of chronic atrophic gastritis, will also elevate serum gastrin levels but can usually be easily distinguished from gastrinoma given the absence of other evidence of acid hypersecretion.

While often classified as pancreatic NETs, the majority of gastrinomas in fact arise in the "gastrinoma triangle," an anatomic region bounded by the duodenum, pancreas, and confluence of the cystic and common bile ducts. Most gastrinomas (50–90%) in sporadic ZES arise in the duodenum. They are frequently small and may be difficult to localize. Imaging studies generally include either computed tomography (CT) or magnetic resonance imaging (MRI); endoscopic ultrasound or somatostatin scintigraphy may also be helpful.

PPIs are generally highly effective in the treatment of symptoms related to gastrinoma and are considered the initial treatment of choice. Rapid resolution of both abdominal pain and diarrhea related to acid hypersecretion is common. Somatostatin analogues may also be helpful in controlling symptoms in refractory cases. Once symptoms are controlled, surgical resection is generally recommended for patients with sporadic gastrinomas, both to eliminate the cause of gastrin secretion and to decrease the risk of developing metastatic disease. The technique used for resection depends in large part on the precise location of the tumor. In some cases where preoperative imaging is not successful but a diagnosis is strongly suspected, exploratory laparotomy with intraoperative ultrasound may be undertaken. In gastrinoma patients who have underlying MEN 1, tumors are generally small and multiple; the role of routine surgery in this setting remains more controversial but generally is still recommended in patients with larger tumors measuring ≥1.5–2 cm in diameter.

INSULINOMA

Patients with insulinoma generally present with symptoms of hypoglycemia, which may include confusion, headache, disorientation, visual difficulties, irrational behavior, and even coma. In some cases, the diagnosis of insulinoma may not be immediately evident, and patients with insulinoma may initially be diagnosed with psychiatric illnesses that in retrospect were hypoglycemic symptoms. The diagnosis of insulinoma is generally confirmed with elevated fasting insulin levels in conjunction with elevated proinsulin and C-peptide. Fasting hypoglycemia can also be caused by severe liver disease, alcoholism, and poor nutrition. Postprandial hypoglycemia may also occur after gastric bypass surgery. Surreptitious use of insulin or hypoglycemic agents may be difficult to distinguish from an insulinoma. Evaluation of proinsulin and C-peptide levels, both of which should be normal in patients using exogenous insulin, and measurement of sulfonylurea levels in serum or plasma are helpful in such cases.

The hypoglycemia associated with insulinomas can be severe and challenging to manage. While somatostatin analogues are usually effective in treating symptoms of hormone hypersecretion associated with other types of NETs, they should be used with caution in patients with insulinoma. Somatostatin analogues may suppress counterregulatory hormones, such as growth hormone (GH), glucagon, and catecholamines, and precipitously worsen hypoglycemia. Diazoxide has historically been used in the initial management of patients with insulinoma and results in inhibition of insulin release, though it can also be associated with side effects including sodium retention and nausea. Everolimus, in addition to its antitumor effect (see below), is effective in improving glycemic control in patients with insulinoma. The benefits of everolimus in this setting may be related both to induction of insulin resistance and a direct antitumor effect. The use of anti-insulin receptor monoclonal antibodies may be highly effective in treating the hypoglycemia associated with insulinoma, although currently their use for this indication remains investigational Insulinomas may be difficult to localize, as they are less consistently avid on somatostatin scintigraphy than other pancreatic NETs. Insulinomas are also generally small, with the majority measuring <2 cm in diameter. Because of their generally small size, insulinomas are best localized with endoscopic ultrasound (EUS). In the absence of metastatic disease, surgical resection is usually recommended. The primary treatment for exophytic or peripheral insulinomas is enucleation. If enucleation is not possible because of invasion or the location of the tumor within the pancreas, then pancreatoduodenectomy for tumors in the head of the pancreas or distal pancreatectomy with preservation of the spleen for smaller tumors not involving splenic vessels may be considered.

GLUCAGONOMA

Patients with glucagonoma most commonly present with a characteristic dermatitis, called necrolytic migratory erythema **(Fig. 89-2)**. The rash usually involves intertriginous sites, especially in the groin or buttock, and can wax and wane. Other common presenting symptoms of glucagonoma include glucose intolerance and weight loss. The diagnosis of glucagonoma can be confirmed by demonstrating an increased plasma glucagon level, generally in excess of 1000 pg/mL. Somatostatin analogues are usually highly effective as an initial treatment to alleviate the symptoms and rash associated with glucagon hypersecretion. The majority of glucagonomas are large in size at presentation and arise in

FIGURE 89-2 Glucagonoma syndrome. Patients with glucagonoma may present with a classic skin rash, necrolytic migratory erythema (shown). Other presenting symptoms include glucose intolerance and weight loss.

the tail of the pancreas. For patients with localized disease, distal pancreatectomy and splenectomy are recommended. A hypercoagulable state has been reported in up to 33% of patients with glucagonoma, and perioperative anticoagulation should generally be employed.

SOMATOSTATINOMA

Patients with somatostatinoma typically present with diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea. Somatostatinomas occur primarily in the pancreas or duodenum, are usually large, and are commonly metastatic at presentation. They are only rarely associated with MEN 1. The diagnosis of somatostatinoma is based on the demonstration of elevated plasma somatostatin levels, and as such, the potential benefits of using somatostatin analogues as a treatment for patients with somatostatinoma are questionable. Surgery is recommended for patients with localized disease.

VIPOMA

VIPomas are associated with a distinct syndrome that has been variously called Verner-Morrison syndrome, pancreatic cholera, and WDHA syndrome (*w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria). VIP is a 28-amino-acid peptide that mimics the effects of the cholera toxin by stimulating chloride secretion in the small intestine and increasing smooth-muscle contractility, resulting in profound diarrhea. Treatment of dehydration, hypokalemia, and electrolyte losses with fluid and electrolyte replacement is the most critical initial treatment for patients with VIPoma. VIPomas are usually solitary and arise in the pancreatic tail. Elevated plasma levels of VIP are typical but should not be the only basis of the diagnosis of VIPomas because they can occur with some diarrheal states including inflammatory bowel disease, in the setting of small-bowel resection, and radiation enteritis. Chronic surreptitious use of laxatives/diuretics can be particularly difficult to detect clinically. Somatostatin analogues are usually highly effective in controlling the diarrhea; surgical resection is recommended for patients with localized disease.

OTHER SECRETORY PANCREATIC NETS

Pancreatic NETs secreting GH-releasing factor (GRF), calcitonin, ACTH, and PTH-related protein have also been described; it is also possible for pancreatic NETs to secrete more than one hormone or for the secretory profiles to evolve over time. Gastrinomas, in particular, may evolve and may be associated with secretion of ACTH, resulting in ectopic Cushing's syndrome. Tumors secreting these hormones may not be as responsive to treatment with somatostatin analogues as the more common pancreatic NETs and the associated hormonal symptoms may cause significant morbidity. As with other pancreatic NETs, patients with localized disease are generally treated with surgical resection. In patients with ACTH-secreting tumors, the associated symptoms of Cushing's syndrome can be alleviated with the use of metyrapone, an agent that directly inhibits cortisol synthesis. Adrenalectomy may also be considered if resection of the primary tumor is not possible or in the setting of metastatic disease.

PANCREATIC NETS ARISING IN THE SETTING OF MEN 1

Pancreatic NETs occurring in patients with MEN 1 are typically multiple and often pursue a relatively indolent course. Because of the high probability of multiple tumors, surgical resection of confirmed pancreatic NETs in patients with MEN 1 is usually undertaken with caution given the likelihood of tumors arising in the remaining pancreas if partial pancreatectomy is undertaken as well as the significant morbidities associated with total pancreatectomy. However, for symptomatic tumors or for growing tumors >2 cm in size, surgical resection may still be considered.

NONFUNCTIONING PANCREATIC NETS

As noted above, the majority of pancreatic NETs are not associated with symptoms of hormone hypersecretion and are considered "nonfunctional." As a result, they often remain clinically silent and either are diagnosed incidentally or are not diagnosed until widespread, metastatic disease is present resulting in anatomic symptoms. If they are localized at diagnosis, the general treatment recommendation is surgical resection; however, the management of small, asymptomatic pancreatic NETs is debated. Assuming tumors are low grade, patients with incidentally discovered, low-grade tumors measuring <1 cm in size can generally be safely followed. However, some studies have suggested that at least some tumors measuring <2 cm in size can pursue a more aggressive course and that surgical resection may be warranted in some cases. Management of small, incidentally discovered, asymptomatic, low-grade pancreatic NETs is therefore based on clinical judgement, taking into account surgical risk and patient comorbidities. For tumors measuring >2 cm in diameter, metastases pose a significant risk and surgical resection is generally recommended in patients for whom surgery is not contraindicated.

CLINICAL PRESENTATION AND MANAGEMENT OF LOCALIZED EXTRAPANCREATIC GASTROINTESTINAL NEUROENDOCRINE TUMORS

Extrapancreatic GI NETs, historically called carcinoid tumors, may arise virtually anywhere in the GI tract and differ significantly in their clinical characteristics depending on their location. The most common locations for extrapancreatic NETs are the stomach, distal small intestine, appendix, and rectum.

GASTRIC NETS

Gastric NETs can be categorized into three groups: type 1 (associated with chronic atrophic gastritis); type 2 (associated with gastrinomas and ZES), and type 3 (sporadic, gastric NETs). Type 1 gastric NETs are the most common of the three types. In type 1 gastric NETs, chronic atrophic gastritis results in loss of acid secretion with consequent loss of the negative feedback loop on gastrin-producing cells in the antrum of the stomach. Pernicious anemia is also commonly associated with this condition; classic laboratory findings are a markedly elevated gastrin level and low levels of vitamin B_{12}. Unchecked gastrin secretion in these patients results in hyperplasia of the endocrine cells in the gastric fundus. A typical finding on endoscopy is diffuse endocrine cell hyperplasia with multiple gastric carcinoid tumors **(Fig. 89-3)**. These

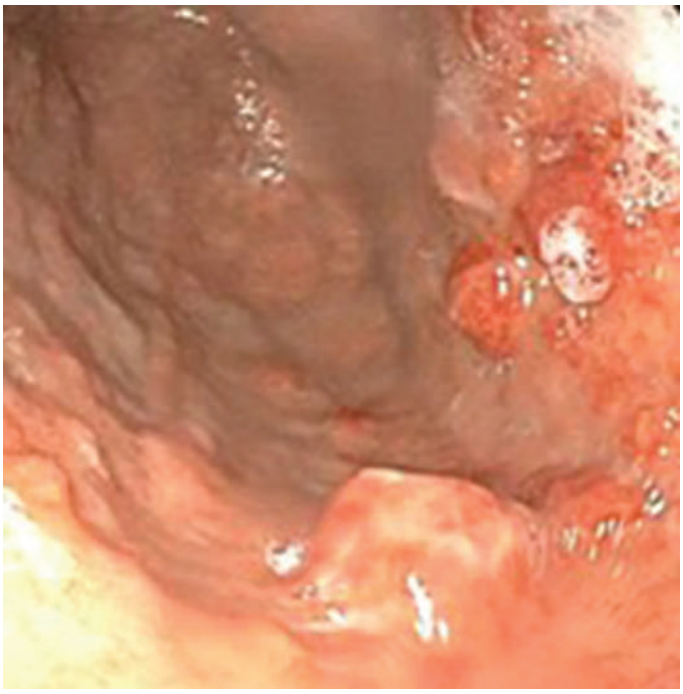

FIGURE 89-3 Multifocal gastric neuroendocrine tumor. *(Courtesy of Christopher Huang, MD, Boston Medical Center.)*

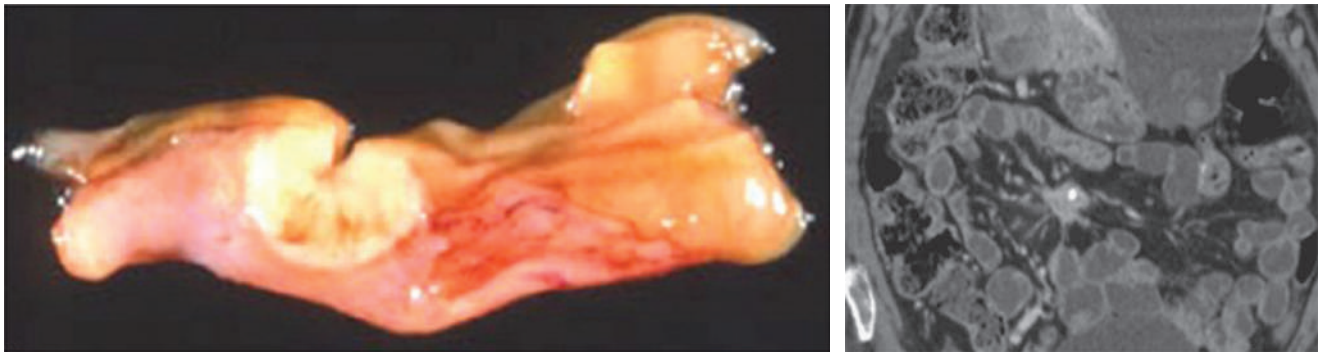
tumors generally pursue a benign course and can be monitored with serial endoscopy. In cases where tumors continue to grow or become symptomatic, antrectomy to remove the source of gastrin production can result in tumor regression. Type 2 tumors are rare and usually occur in the setting of gastrinoma; as with type 1 gastric NETs, elevated gastrin levels result in diffuse gastric neuroendocrine hyperplasia and multifocal gastric NETs. Resection of the gastrinoma, removing the source of gastrin production, is the treatment of choice.

In contrast to type 1 and type 2 gastric NETs, type 3 gastric NETs are generally solitary, arise in the setting of normal gastrin levels, and may pursue a far more aggressive course. For early-stage, smaller tumors, endoscopic or wedge resection may be performed. For larger tumors, partial gastrectomy with lymphadenectomy is recommended.

NETS OF THE SMALL INTESTINE

Small-bowel NETs occur most commonly in the terminal ileum and are notoriously difficult to diagnose at an early stage. One reason for this is that they arise within the muscularis, and their submucosal location makes them difficult to see during routine colonoscopy **(Fig. 89-4*A*)**. Small-bowel NETs are also often multifocal; multifocal tumors appear to arise independently throughout the small intestine, although the mechanisms underlying this phenomenon remain uncertain.



Small-bowel NETs are often associated with desmoplasia and mesenteric fibrosis, likely as a result of fibroblast proliferation stimulated by tumor serotonin secretion. Mesenteric fibrosis frequently results in intermittent small-bowel obstruction and, in some cases, bowel ischemia due to involvement of the mesenteric vessels. Patients may experience symptoms of intermittent abdominal pain and associated diarrhea, sometimes for months or years before diagnosis, that because of the difficulty in diagnosis are often attributed to irritable bowel syndrome. One classic finding that can aid in diagnosis is that the lymph node metastases associated with small intestine NETs are usually larger than the primary tumor and may be calcified, which, together with the tethering of the small intestine caused by the associated fibrosis, results in a classic "spoke and wheel" appearance on CT **(Fig. 89-4*B*)**.

Surgical resection of the primary tumor and associated metastases is recommended when feasible and is performed with curative intent when distant metastatic disease is not already present. Resection should also be considered in patients with metastatic disease experiencing intermittent obstruction or abdominal discomfort thought to be related to the primary tumor or associated mesenteric disease. Some have also advocated the routine resection of asymptomatic small-bowel primary tumors in patients with distant metastatic disease, with the rationale that this may be a way to prevent the future development of fibrosis and obstruction and preempt the development of unresectable disease due to tumor involvement of the mesenteric vessels. However, the available data on the benefits of resecting an asymptomatic primary tumor in this context are conflicting. Some studies have suggested that this practice results in an overall survival benefit, but the retrospective nature of these studies makes the data difficult to interpret given the high potential for selection bias in patients taken to surgery compared with those who were not. Other studies have suggested that prophylactic primary tumor resection confers no survival benefit and that surgery can be safely delayed until it is indicated based on the development of symptoms.

NETS OF THE APPENDIX

NETs are one of the most common tumors arising in the appendix. They are typically discovered incidentally in younger individuals undergoing appendectomy for acute appendicitis and not uncommonly are identified only at the time of pathology review. While the unexpected diagnosis of an appendiceal NET in such situations can cause considerable anxiety, in the majority of cases, the prognosis is excellent. Indeed, the clinical behavior of appendiceal NETs has been inferred from multiple large retrospective surgical series that suggest that the risk of lymph node or distant metastases from appendiceal NETs with well-differentiated histology and a tumor diameter measuring <2 cm is extremely low. In such cases, appendectomy alone is felt to be a sufficient surgical procedure.

In contrast, the risk of metastases for tumors measuring 2–3 cm is ~20–30% and is even greater for tumors measuring >3 cm. For patients with larger tumors, more formal staging studies with either

A ***B***

FIGURE 89-4 Small intestine neuroendocrine tumor. ***A.*** Small intestine neuroendocrine tumors arising in submucosal location. The submucosal location of small intestine neuroendocrine tumors, together with their location beyond the ileocecal valve in the terminal ileum, can make endoscopic detection challenging. ***B.*** Classic "spoke and wheel" appearance of calcified mesenteric mass associated with small intestine primary neuroendocrine tumor. Mesenteric fibrosis commonly leads to intermittent obstructive symptoms and can also lead to ischemia when the mesenteric vasculature is involved. *(Fig. B: Courtesy of Christina LeBedis, MD, Boston Medical Center.)*

cross-sectional imaging or somatostatin scintigraphy are generally recommended to assess for distant metastases, and a subsequent right colectomy to remove regional lymph nodes is performed if no distant metastases are observed. Whether right colectomy should be performed for tumors measuring <2 cm with features such as mesoappendiceal invasion or tumor origin at the appendiceal base, which in some series have suggested a poorer prognosis, remains uncertain. Additionally, tumors may arise in which neuroendocrine cells are admixed with mucin-producing cells or cells exhibiting features of frank adenocarcinoma. In such mixed neuroendocrine-adenocarcinoma tumors, sometimes termed "adenocarcinoids," treatment recommendations are generally dictated by the more aggressive component of the tumor and align with typical recommendations for colorectal adenocarcinoma.

RECTAL NETS

With the increased use of screening colonoscopy, the diagnosis of rectal NET has also become more common. For unclear reasons, the incidence of rectal carcinoid tumors shows geographic variation. In European studies, they compose up to 14% of all NETs, while in some Asian series (Japan, China, Korea), they compose up to 90% of all NETs. The majority of rectal NETs are small, measuring <1 cm in diameter, and have well-differentiated histology. These tumors rarely metastasize and can usually be safely removed endoscopically with subsequent endoscopic monitoring. In contrast, up to one-third of rectal NETs between 1 and 2 cm are associated with metastases, and those >2 cm, though uncommon, metastasize in >70% of patients. When identified early, these tumors generally require a surgical resection. In contrast to NETs of the appendix and small intestine, hormone secretion from rectal NETs, even when metastatic, is exceedingly rare.

CLINICAL PRESENTATION, DIAGNOSIS, AND EVALUATION OF PATIENTS WITH METASTATIC NEUROENDOCRINE TUMORS

While patients who undergo resection of localized NETs may be at risk of developing tumor recurrence or metastatic disease, postoperative treatment has not yet been shown to alter the risk of recurrence, and systemic adjuvant therapy is not recommended following resection of well-differentiated NETs, as it is for some other cancers. Whether adjuvant systemic therapy may be of benefit following resection of high-grade NETs is uncertain, and an approach utilizing platinum-based chemotherapy with or without external-beam radiation, analogous to that used in small-cell carcinoma, is sometimes considered.

The evaluation of patients with known or suspected metastatic disease generally includes both standard cross-sectional imaging such as CT or MRI and somatostatin scintigraphy. Somatostatin scintigraphy in this setting is based on the fact that >90% of NETs express somatostatin receptors. Gallium-68 (^{68}GA) dotatate, as well as ^{68}GA DOTATOC and copper-64 dotatate, are all radioligands bound to a somatostatin analogue and can be used as a nuclear medicine tracer to perform positron emission tomography (PET) scanning that is highly sensitive in detecting both primary NETs and metastases **(Fig. 89-5)**. Because of the sensitivity of these approaches, false-positive results can occur due to somatostatin receptor expression in other tissues. Physiologic uptake in the pancreatic uncinated process is common; uptake can also occur in the setting of sarcoidosis, in meningiomas, and in thyroid goiter or thyroiditis. Standard fluorodeoxyglucose (FDG) PET scans are often negative in well-differentiated NET due to their low metabolic activity but can show uptake in higher-grade tumors; conversely, rates of somatostatin expression tend to be lower in higher-grade tumors, and ^{68}GA dotatate scans may be negative in this setting.

The utility of blood-based tumor markers in NETs is controversial. The circulating tumor marker chromogranin A is commonly used as a screen for the presence of NETs and also to monitor for both recurrence and progression of disease in patients with known metastases. While chromogranin A is elevated in patients with metastatic NETs, it is neither particularly sensitive nor specific. A broad range of different assays for chromogranin A have also posed challenges in interpreting results in a standardized fashion. Chromogranin A is often elevated in a number of nonmalignant conditions, including in patients with impaired renal function and in patients who are taking PPIs. Elevated values of chromogranin A should be interpreted with caution in patients in whom a NET is being considered but in whom a diagnosis has not been established.

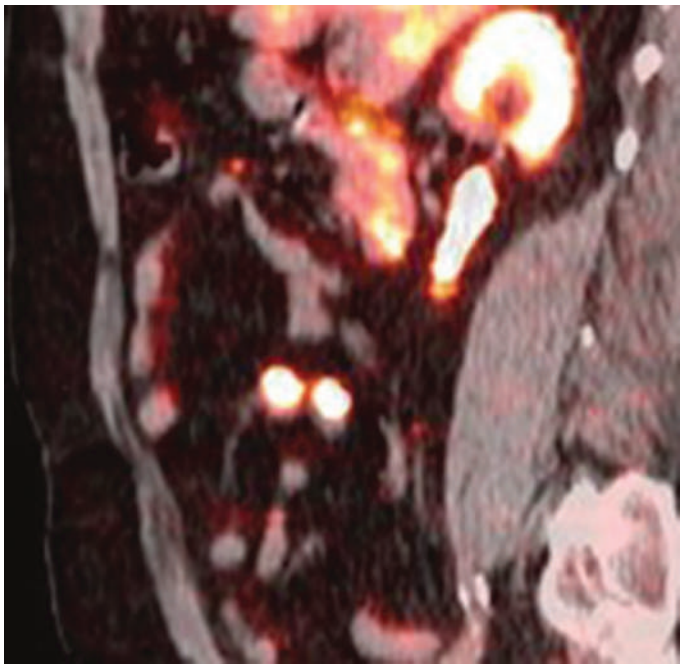


FIGURE 89-5 Gallium-68 dotatate positron emission tomography (PET) scan demonstrating a small-bowel neuroendocrine tumor and associated mesenteric mass. *(Courtesy of Sara Meibom, MD, Boston Medical Center.)*

The overall survival durations for patients with metastatic NETs vary significantly, depending on both the primary location of the tumor and the histologic grade. Median survival durations for patients with well-differentiated NETs have markedly increased in recent years, likely reflecting both earlier diagnoses and improved treatments. For example, in early analyses of the SEER database, the median survival for patients with advanced pancreatic NETs was ~2 years; this had increased to 4 years in a more recent analysis. Similar increases were observed in patients with advanced small intestine NETs, where the median survival for patients with well-differentiated small intestine NETs exceeds 5 years. The sometimes prolonged survival of patients with NETs can make it challenging to determine at what point to initiate treatment. In patients with symptoms of hormone secretion, decisions to initiate therapy are straightforward. In asymptomatic patients, on the other hand, observation off treatment can sometimes be appropriate. Nevertheless, the natural course of NETs is ultimately to progress, and if treatment is not initiated, close monitoring is essential to ensure patients maximize access to available treatment options over the course of their disease.

MANAGEMENT OF SYMPTOMS OF HORMONE HYPERSECRETION AND THE CARCINOID SYNDROME

Patients with advanced NETs may in some cases experience more symptoms from hormone hypersecretion than from tumor bulk. The management of hormonal symptoms associated with pancreatic NETs depends on the hormone being secreted (see above). Patients with GI NETs, particularly those with small intestine or appendiceal primaries, may develop the carcinoid syndrome. Flushing and diarrhea are the two most common symptoms associated with carcinoid syndrome. The characteristic flush is of sudden onset; it is a deep red or violaceous erythema of the upper body, especially the neck and face, often associated with a feeling of warmth. Flushes may be precipitated by stress, alcohol, exercise, and certain foods such as cheese. Flushing episodes initially are brief, lasting 2–5 min, though later in the disease course, they may last hours. The diarrhea associated with carcinoid syndrome

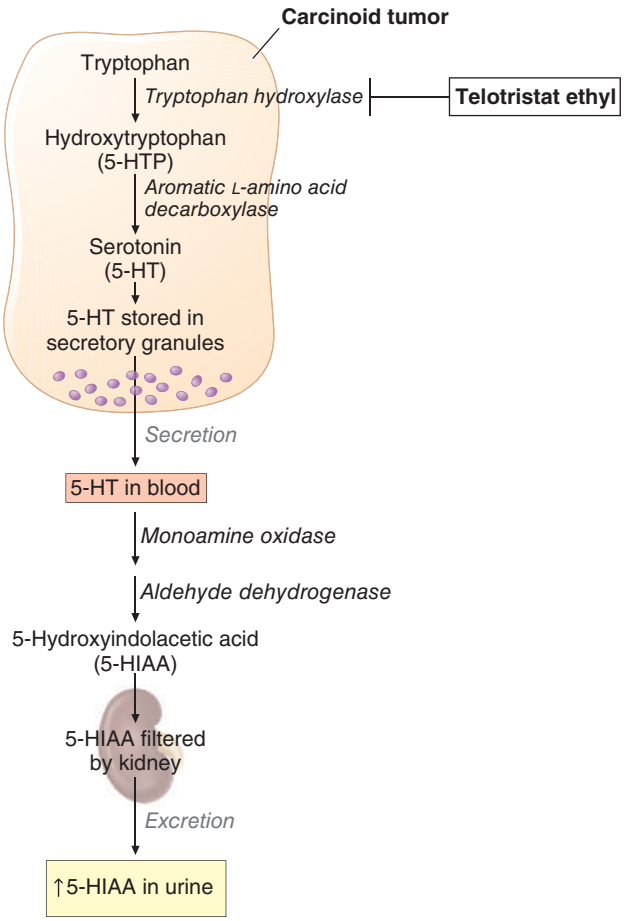

FIGURE 89-6 Serotonin synthesis and secretion in neuroendocrine tumors. Tryptophan is converted to hydroxytryptophan by tryptophan hydroxylase within the tumor cell and, subsequently, to serotonin (5-HT). Serotonin is subsequently converted to 5-hydroxyindole acetic acid (5-HIAA), which can be measured in a 24-h urine collection and can facilitate the diagnosis of carcinoid syndrome. Telotristat ethyl inhibits tryptophan hydroxylase and can be used as a treatment for carcinoid syndrome.

may or may not be associated with flushing and is described as watery in nature. Diarrhea can be profound, sometimes occurring in excess of 10 times daily and is one of the symptoms that most significantly interferes with activities of daily living. Less common manifestations of the carcinoid syndrome include wheezing or asthma-like symptoms. Impaired cognitive function has also been described in particularly advanced cases.

The main secretory product implicated in the carcinoid syndrome is serotonin (5-HT). Serotonin is synthesized from tryptophan by the enzyme tryptophan hydroxylase (Fig. 89-6). Up to 50% of dietary tryptophan can be used in this synthetic pathway by tumor cells, resulting in inadequate supplies for conversion to niacin; hence, some patients develop symptoms of niacin deficiency and pellagra-like lesions. Serotonin has numerous biologic effects, including the stimulation of intestinal secretion, increasing intestinal motility, and the stimulation of fibroblast growth. Other secreted products contributing to carcinoid syndrome symptoms are thought to include histamines and tachykinins, including substance P.

DIAGNOSIS AND TREATMENT OF THE CARCINOID SYNDROME

While the carcinoid syndrome can develop in patients with NETs from almost any site, it is most commonly associated with appendiceal or small intestine NETs. In these patients, the syndrome usually develops only after the development of hepatic metastases or retroperitoneal lesions, allowing entry of serotonin and other vasoactive substances into the systemic circulation. While serotonin levels can be measured in plasma, such measurements are frequently highly variable. Evidence of excess serotonin secretion can be more reliably confirmed by measuring levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA), either in plasma or using a 24-h urine collection. Urine collections can be challenging, and false-positive elevations may occur if the patient is eating serotonin-rich foods (e.g., salmon, eggs). As a result, elevated levels of 5-HIAA are suggestive but not diagnostic of the carcinoid syndrome. Patients with NETs may also experience symptoms of carcinoid syndrome related to other secreted products, including histamine, absent evidence of serotonin secretion. Conversely, patients without NETs may also describe symptoms analogous to carcinoid syndrome but due to other causes. The symptoms associated with systemic mastocytosis, in particular, can be easily confused with carcinoid syndrome.

The symptoms of carcinoid syndrome, including diarrhea, are generally refractory to standard antidiarrheals or other traditional medications but can often be well controlled with somatostatin analogues (Fig. 89-7). Somatostatin is a 14-amino-acid peptide that inhibits the secretion of a broad range of hormones. Due to its short half-life, administration of somatostatin itself is not therapeutically practical. Longer-acting somatostatin analogues, including octreotide and lanreotide, share an 8-amino-acid binding domain with naturally occurring somatostatin and bind primarily to somatostatin receptor subtypes 2 and 5. Both have been shown to be effective in the treatment of carcinoid syndrome.

The presence of somatostatin receptors on NETs is predictive of response to somatostatin analogues and can be easily confirmed with uptake on somatostatin scintigraphy such as ^{68}GA dotatate PET scan.

Somatostatin analogue side effects are generally mild. Mild nausea, abdominal discomfort, bloating, and loose stools occur in up to one-third of patients during the first month or two of treatment but usually subsequently subside. Patients with persistent symptoms of bloating or loose stools may be experiencing pancreatic insufficiency associated with use of somatostatin analogues; use of pancreatic enzyme supplements can ameliorate these symptoms. Mild glucose intolerance may also occur due to inhibition of insulin secretion. One of the more significant side effects associated with somatostatin analogues is impaired gallbladder contractility, resulting in delayed gallbladder emptying, and long-term administration of somatostatin analogues has been associated with an increased risk of cholelithiasis. For this reason, patients with advanced NETs in whom surgery is planned and for whom somatostatin analogue therapy is being considered should generally also undergo prophylactic cholecystectomy.

Over time, for reasons that remain uncertain, patients receiving somatostatin analogues for symptoms of hormone secretion may become refractory to treatment. Not uncommonly, such patients experience symptom exacerbation toward the final week of each treatment cycle. Such patients may benefit from an increased frequency of administration (i.e., every 3 weeks) or use of additional short-acting octreotide for breakthrough symptoms.

The association between high levels of circulating serotonin and symptoms of the carcinoid syndrome has also led to efforts aiming to directly inhibit serotonin synthesis (Fig. 89-6). This approach was first undertaken in the late 1960s with the drug para-chlorophenylalanine, which was reported to reduce symptoms of carcinoid syndrome but also caused significant central nervous system (CNS) side effects. Telotristat ethyl, a tryptophan hydroxylase inhibitor with minimal CNS penetration, was evaluated in a randomized trial that enrolled 135 patients with persistent carcinoid syndrome–related diarrhea while receiving somatostatin analogues. Treatment with telotristat ethyl was associated with a reduction in bowel movement frequency as well as significant decreases in urinary 5-HIAA compared to placebo, consistent with its mechanism of directly inhibiting serotonin synthesis. Thus, telotristat is a treatment option for patients with carcinoid syndrome who have persistent diarrhea despite treatment with somatostatin analogues.

CARCINOID CRISIS

Carcinoid crisis has been described in the setting of tumor manipulation during surgery and, less commonly, after other interventions such as hepatic artery embolization or radionuclide therapy. It may also occur as a result of exogenous administration of epinephrine or during

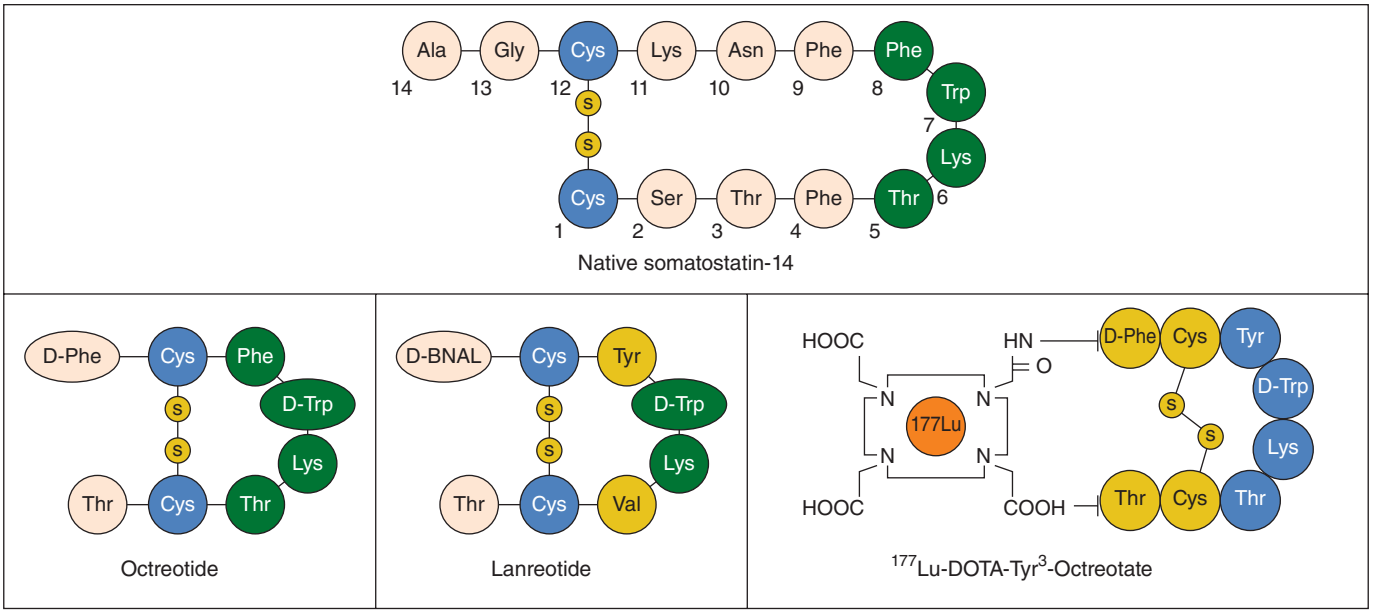

FIGURE 89-7 Somatostatin analogues. Commonly used somatostatin analogues include octreotide and lanreotide, which mirror the molecular structure of human somatostatin and bind to somatostatin receptors on neuroendocrine tumors. Somatostatin analogues inhibit tumoral hormone secretion and also have an antiproliferative effect. Radiolabeled somatostatin analogues such as ^{177}Lu-DOTA-octreotate, shown in the figure, share a similar molecular structure and are used therapeutically.

induction of anesthesia. It is most common in patients who already have significant symptoms of carcinoid syndrome and is thought to be caused by a sudden release of biologically active compounds from the tumor. Carcinoid crisis can be life-threatening and can manifest as either profound hypotension or hypertension. Prospective studies on the prevention and management of carcinoid crisis are limited; however, somatostatin analogues should be readily available during surgical procedures, and in some cases, continuous prophylactic intravenous administration of somatostatin analogues has been utilized as a way to mitigate risk.

CARCINOID HEART DISEASE

Carcinoid heart disease occurs in approximately two-thirds of patients with the carcinoid syndrome. Carcinoid heart lesions are characterized by plaque-like, fibrous endocardial thickening that classically involves the right side of the heart and often causes retraction and fixation of the leaflets of the tricuspid and pulmonary valves (Fig. 89-8). The fibrosis in carcinoid heart disease is thought to be directly related to exposure of heart valve fibroblasts to high circulating levels of serotonin. Lesions similar to those observed in carcinoid heart disease were observed in patients receiving fenfluramine, a drug also known to increase serotonin signaling, as well as in patients receiving ergot-containing dopamine receptor agonists for Parkinson's disease. Metabolites of fenfluramine, as well as the dopamine receptor agonists, have high affinity for serotonin receptor subtype 5-HT$_{2B}$ receptors, whose activation is known to cause fibroblast mitogenesis and which are normally expressed in heart valve fibroblasts. These observations support the hypothesis that serotonin overproduction in patients with carcinoid syndrome mediates the valvular changes by activating 5-HT$_{2B}$ receptors in the endocardium.

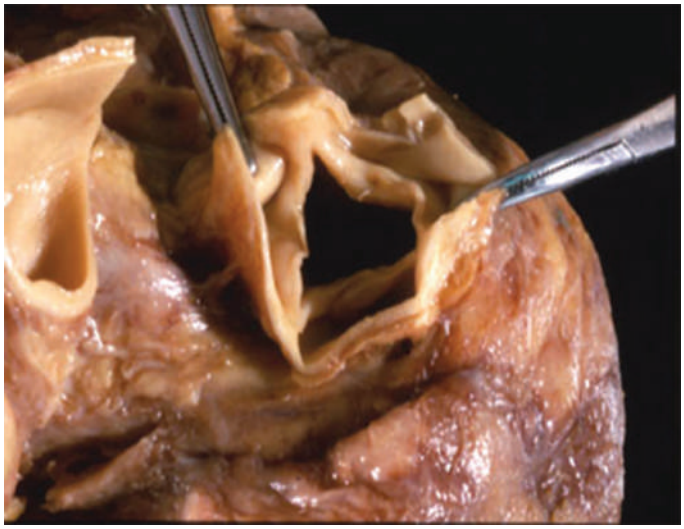

FIGURE 89-8 Carcinoid heart disease. Fibrosis secondary to elevated levels of circulating serotonin classically involves the tricuspid valve, resulting in valve retraction and tricuspid regurgitation.

Tricuspid regurgitation is a nearly universal feature of carcinoid heart disease; tricuspid stenosis, pulmonary regurgitation, and pulmonary stenosis may also occur. Left-sided heart disease occurs in <10% of patients and has been associated with the presence of a patent foramen ovale. The preponderance of lesions in the right heart is related directly to the fact that serotonin is secreted by liver metastases or retroperitoneal tumor deposits into the venous circulation and subsequently into the right atrium and right ventricle. The lower incidence of heart disease in the left heart is postulated to be due to the fact that serotonin is metabolized in the pulmonary vasculature before entering the left atrium and ventricle. Among patients with carcinoid syndrome, patients with heart disease exhibit higher levels of serum serotonin and urinary 5-HIAA excretion than patients without heart disease. Treatment with somatostatin analogues resulting in decreased serotonin secretion does not result in regression of cardiac lesions. Reduction of serotonin levels as a result of treatment with somatostatin analogues or with the tryptophan hydroxylase inhibitor telotristat ethyl seems likely to slow progression of carcinoid heart disease but has not been formally evaluated in clinical trials.

Right-sided heart failure in patients with carcinoid heart disease may lead to significant morbidity and mortality. The development of multiple new treatments to improve overall disease control in patients with advanced NETs has led to increased interest in valvular replacement, which may result in significant clinical benefit in appropriately selected patients with carcinoid heart disease. The appropriate timing of valve replacement in such patients can be challenging given the competing desires to perform surgery before the onset of severe right-sided heart failure, which can increase surgical morbidity, and the need to achieve adequate overall tumor control. However, advanced and less invasive techniques, including catheter-based valve replacement, have made valve replacement an increasingly attractive option for patients with this condition.

HEPATIC-DIRECTED THERAPY FOR METASTATIC NETS

The liver is one of the most common sites for metastases in patients with NETs and, in some cases, is the only site of metastatic disease. Hepatic-directed therapies can often be effective as a means of controlling, if not eliminating, metastases, particularly in patients who have more indolent tumors with well-differentiated histology. Common approaches for such patients include surgical resection, ablation or embolization, and orthotopic liver transplantation.

For patients with limited hepatic disease whose tumors have well-differentiated histology, surgical resection is generally considered the preferable option. While data are limited to retrospective series with the consequent risk of selection bias, long-term survival durations and symptomatic improvements reported in select populations of patients undergoing hepatic resection of neuroendocrine liver metastases compare favorably with outcomes associated with other management approaches, and 5-year survival rates approach 90% in some series. In patients in whom anatomy precludes resection or in whom a greater number of lesions are present, radiofrequency ablation or cryoablation can also be used, either as a primary treatment modality or as an adjunct to surgical resection. While ablation is considered to be less morbid than hepatic resection, it is generally utilized only in smaller tumors so that zones of ablation are limited.

In most cases, however, liver metastases are large, multiple, and involve both lobes of the liver. In such cases, the benefit of surgical resection and ablation is limited. Hepatic arterial embolization can be considered in these cases, assuming that extrahepatic disease remains relatively limited and that clinical benefit can be achieved by reducing hepatic tumor bulk. Hepatic artery embolization is based on the principle that tumors in the liver derive most of their blood supply from the hepatic artery, whereas healthy hepatocytes derive most of their blood supply from the portal vein. Multiple different embolization techniques have been explored, ranging from the simple infusion of gel foam powder into the hepatic artery (bland embolization) to the administration of chemotherapy or chemotherapy-eluting beads into the hepatic artery (chemoembolization) or the intra-arterial administration of radioisotope-tagged microspheres (radioembolization). Limited data suggest an optimal approach to embolization, and few studies have compared these approaches directly. Tumor response rates with all of these approaches generally exceed 50%. Specific approaches are therefore often tailored to the patient, taking into account tumor location, overall tumor burden, and comorbidities. Bland embolization, for example, may be associated with less morbidity, whereas chemoembolization or radioembolization may result in longer durations of response.

The role of orthotopic liver transplantation for the treatment of NETs remains uncertain. Data from available institutional series suggest that a small number of highly selected patients may achieve long-term survival. However, 5-year overall median survival durations in most series are ~50%, and the majority of patients undergoing hepatic transplantation develop tumor recurrence. Additionally, the widespread utility of hepatic transplantation is limited by organ availability. Decisions regarding proceeding with transplantation in patients with advanced NETs are therefore highly individualized.

SYSTEMIC TREATMENT TO CONTROL TUMOR GROWTH

While hepatic-directed therapies can be effective in the management of patients with liver-predominant disease, a majority of patients will either present with or ultimately develop more widespread metastases. A number of systemic treatment options have been developed and can be effective in treating such patients. These options include treatment with traditional somatostatin analogues, peptide receptor radioligand therapy, traditional cytotoxic chemotherapy, and an increasing array of molecularly targeted therapies targeting the mTOR or vascular endothelial growth factor (VEGF) pathways (Table 89-3). The choice and sequence of therapy depend in part on the type of tumor, the extent of disease, and patient symptoms and comorbidities.

TABLE 89-3 Selected Randomized Trials of Therapeutic Agents for the Treatment of Advanced Neuroendocrine Tumors (NETs)

TUMOR TYPE	NUMBER OF PATIENTS	PROGRESSION-FREE SURVIVAL
Pancreatic and Extrapancreatic NETs		
Lanreotide vs placebo (CLARINET)	204	65% vs 33% at 2 years (p <.001)
177-Lutetium dotatate vs octreotide (NETTER 2)	226 (limited to histologic grade 2 and 3 tumors)	22.8 vs 8.5 months (p <.0001)
Cabozantinib vs placebo (CABINET)	298 (203 extrapancreatic NETs [epNET] and 95 pancreatic NETs [pNET])	8.5 vs 4 months (epNET); 13.8 vs 4.5 months (pNET) (p <.0001 for both cohorts)
Pancreatic NET		
Everolimus vs placebo (RADIANT 3)	410	11 vs 4.6 months (p <.001)
Sunitinib vs placebo	171	11.4 vs 5.5 months (p <.001)
Surufatinib vs placebo	264	10.9 vs 3.7 months (p = .001)
Temozolomide/capecitabine vs temozolomide	144	22.7 vs 14.4 months (p = .021)
Extrapancreatic NET		
Octreotide vs placebo (PROMID)	85	14.3 vs 6 months[a]
Everolimus + octreotide vs octreotide (RADIANT 2)	429	16.4 vs 11.3 months
Everolimus vs placebo (RADIANT 4)	302	11 vs 3.9 months
Surufatinib vs placebo	198	9.2 vs 3.8 months (p <.0001)
Pazopanib vs placebo	171	11.6 vs 8.5 months (p <.0005)
177-Lutetium dotatate vs octreotide (NETTER 1)	230	65.2 vs 10.8% at 20 months (p <.001)

[a]Time to tumor progression.

SOMATOSTATIN ANALOGUES

Somatostatin analogues were originally developed as a treatment to reduce hormone secretion in NETs but are also effective in slowing tumor growth. The biologic mechanisms underlying this effect remain uncertain, but clinical studies have been definitive. The first of these studies, the PROMID study, randomized patients with metastatic small-intestinal NET to receive either octreotide LAR at a dose of 30 mg monthly or placebo. The median time to tumor progression in patients receiving octreotide was 14 months compared to only 6 months for patients receiving placebo. Because the study was limited to patients with small-intestinal NET, the generalizability of these results to patients with NETs of other origins, including pancreatic NET, was initially uncertain. This question was ultimately addressed by the phase 3 CLARINET trial, which compared lanreotide, a somatostatin analogue that is similar to octreotide in its somatostatin receptor–binding affinities, to placebo in 204 patients with a range of advanced well- or moderately differentiated gastroenteropancreatic NETs. Progression-free survival duration at 2 years was 65% in patients receiving lanreotide and 33% in patients receiving placebo, a difference that was statistically significant. One unusual aspect of the PROMID and CLARINET studies is the difference in progression-free survival durations in the placebo arms of the studies, which has been attributed to differences in patient selection. Either octreotide or lanreotide is currently considered an acceptable option for control of tumor growth in patients with advanced NETs.

The timing of initiation of somatostatin analogues in patients with advanced NETs remains uncertain. The variable clinical course of NETs means that tumors can remain indolent for years even without treatment. For patients with asymptomatic, small-volume disease, observation alone may be an appropriate initial option. However, for

patients with a larger disease burden, evidence of disease progression, or symptomatic disease, somatostatin analogues are generally used as an initial systemic treatment due to their ease of use and tolerability.

PEPTIDE RECEPTOR RADIOLIGAND THERAPY

Peptide receptor radioligand therapy employs the systemic administration of radiolabeled somatostatin analogues and is a treatment option for patients who require more aggressive treatment due to progression on traditional somatostatin analogues or other therapies (Fig. 89-7). Peptide receptor radioligand therapy may also be considered as an initial treatment in patients with significant symptoms or tumor burden. With this approach, a radioligand is coupled to a somatostatin analogue, using the somatostatin analogue to target the tumor. When bound to the tumor cell, the radioligand is then internalized, resulting in cell death. Due to its mechanism of action, peptide receptor radioligand therapy is only considered in patients whose tumors demonstrate uptake on somatostatin scintigraphy.

Several different radioligands have been evaluated, the most successful of which have been yttrium (^{90}Y) and lutetium (^{177}Lu). These two ligands differ from one another in terms of their particle energy and tissue penetration; of the two, ^{90}Y-DOTA-TOC emits higher-energy β particles and has deeper tissue penetration. ^{90}Y-DOTA-TOC has been evaluated in numerous series with overall tumor responses reported in approximately one-third of patients. Enthusiasm for this approach, however, has been tempered due to concerns about side effects including both renal and hematologic toxicity.

^{177}Lu-DOTA-octreotate emits both β particles and lower-energy γ particles and, in most studies, has been associated with less toxicity than ^{90}Y-DOTA-TOC. Initial single-center studies with ^{177}Lu-DOTA-octreotate showed promising antitumor activity, and based on these studies, a randomized trial of ^{177}Lu-dotatate in midgut GI NETs was undertaken. In this study (NETTER-1), 229 patients with inoperable, somatostatin receptor–positive midgut NETs were randomly assigned to receive either four doses of ^{177}Lu-dotatate administered intravenously every 8 weeks or treatment with high-dose octreotide LAR (60 mg) every 4 weeks. Treatment with ^{177}Lu-dotatate was associated with objective tumor responses in 18% of patients and also was associated with a significant improvement in progression-free survival: progression-free survival at month 20 was 10.8% for octreotide LAR alone and 65.2% in the ^{177}Lu-dotatate group. Subsequent analyses have also suggested improved overall survival associated with ^{177}Lu-dotatate treatment, as well as improvements in quality of life across a number of parameters, including global health status, overall physical functioning, fatigue, pain, and diarrhea.

One limitation of the NETTER-1 study was its restriction to patients with advanced small intestine NETs with low-grade histology. A subsequent study, NETTER-2, randomized 226 patients with a broader range of gastroenteropancreatic neuroendocrine tumors that were higher grade (grade 2 or 3) to receive treatment with ^{177}Lu-dotatate or octreotide alone. This study confirmed the activity of ^{177}Lu-dotatate in this patient population; median progression-free survival was 22.8 months for patients receiving ^{177}Lu-dotatate and 8.5 months for patients receiving octreotide alone.

The renal clearance of radiopeptides, including ^{177}Lu-DOTA-octreotate, poses a risk of renal toxicity; this risk can be mitigated with the coadministration of intravenous amino acids during treatment. Longer-term safety data are available from large institutional series that include >1000 patients. Reported toxicities from these series have included rare cases of acute leukemia and myelodysplastic syndrome, presumably associated with radiation exposure. Nevertheless, these studies generally support both the efficacy and safety of ^{177}Lu-dotatate as a treatment for patients with a range of somatostatin receptor–positive NETs.

ALKYLATING AGENTS

While the efficacy of traditional cytotoxic chemotherapy appears to be minimal in most extrapancreatic GI NETs, alkylating agents have a clear role in the treatment of advanced pancreatic NETs. Streptozocin-based combination therapy was historically used as treatment standard in such patients but has largely fallen out of favor due to both toxicity concerns and a cumbersome administration schedule. Temozolomide is an orally administered alkylating agent that has largely replaced streptozocin as a backbone in combination regimens used for the treatment of pancreatic NETs.

Initial studies evaluating temozolomide in combination with a range of different agents showed that temozolomide-based combination therapy was associated with tumor responses in 24–70% of patients. One of the most active combination regimens appeared to be temozolomide and capecitabine. This combination was subsequently compared to temozolomide alone in a prospective randomized study undertaken by the Eastern Cooperative Oncology Group (ECOG) that enrolled 144 patients with advanced pancreatic NETs. The overall response rates in the two arms were relatively similar; 33% of patients who received the combination of temozolomide and capecitabine experienced objective tumor responses as compared to 28% of the patients who received temozolomide as a single agent. However, progression-free survival was significantly longer in the combination arm (22.7 vs 14.4 months). Based on these results, the combination of temozolomide and capecitabine is now the preferred chemotherapy combination for advanced pancreatic NETs.

The reason that some pancreatic NETs respond to alkylating agents while others do not is uncertain. In patients with glioblastoma, methylation of the promoter region for methylguanine DNA methyltransferase (MGMT) is associated with decreased MGMT protein expression and is highly associated with temozolomide responsiveness. MGMT is an enzyme that is responsible for repairing DNA damage induced by alkylating agents. Reduced levels of MGMT presumably impair the ability of tumor cells to repair their DNA in response to treatment and enhance the cytotoxicity of temozolomide. Several retrospective studies, as well as data from the prospective ECOG study, have suggested that lack of MGMT expression in pancreatic NET may be associated with responsiveness to temozolomide-based therapy, although findings have not been definitive.

SMALL-MOLECULE TYROSINE KINASE INHIBITORS

The highly vascular nature of NETs combined with observations in preclinical models that disruption of signaling pathways associated with VEGF inhibits neuroendocrine cell growth prompted a number of clinical trials evaluating therapeutic agents that inhibit the VEGF pathway in both pancreatic and extrapancreatic NETs. The VEGF pathway is activated through the binding of VEGF to its cell surface receptor, which initiates an intracellular signaling cascade that promotes angiogenesis as well as cell growth, proliferation, and survival. Clinical trials of VEGF pathway inhibitors in NETs have included a number of small-molecule tyrosine kinase inhibitors that, while they differ to some extent in specificity, all have in common the property targeting VEGFR2, the receptor isoform most strongly implicated in promoting angiogenesis.

Sunitinib, a multitargeted tyrosine kinase inhibitor that inhibits a range of growth factor receptors including VEGFR2, was one of the first agents in this class found to have activity in pancreatic NETs. In an initial phase 2 trial, sunitinib was administered to 109 patients with either pancreatic or extrapancreatic NET. Of 61 patients with pancreatic NET enrolled in the study, 11 had evidence of an objective tumor response. Based on these observations, sunitinib was evaluated in an international, randomized trial in which continuous administration of sunitinib (37.5 mg daily) was compared with placebo in 171 patients with advanced, progressive pancreatic NET. The median progression-free survival was significantly longer in patients treated with sunitinib compared with patients treated with placebo (11.4 vs 5.5 months). Common side effects associated with sunitinib included hypertension, proteinuria, and fatigue.

A second VEGFR-targeted tyrosine kinase inhibitor, surufatinib, was evaluated in a randomized trial in which 264 patients with advanced pancreatic NETs from 21 centers in China were randomized to receive either surufatinib, administered at a dose of 300 mg daily, or placebo. Patients receiving surufatinib experienced a median progression-free survival duration of 10.9 months, as compared to 3.7 months in

patients receiving placebo, closely mirroring the results of the earlier sunitinib study. Cabozantinib, a tyrosine kinase inhibitor with activity against not only VEGFR but also c-MET and related growth factor receptors, was evaluated against placebo in a randomized trial led by the ALLIANCE cooperative group that included both pancreatic and extrapancreatic NETs. Among the 95 pancreatic NET patients in the study, median progression-free survival was 13.8 months for those receiving cabozantinib and 4.5 months for those receiving placebo. Other small-molecule tyrosine kinase inhibitors that have been evaluated in smaller, single-arm studies and have shown activity in pancreatic NETs, include sorafenib, pazopanib, and axitinib.

Small-molecule tyrosine kinase inhibitors targeting the VEGF pathway have also been evaluated in patients with advanced nonpancreatic GI NET. In most of these studies, objective tumor response rates are lower than those seen in pancreatic NET, though many of these initial studies also revealed low rates of tumor progression and encouraging progression-free survival durations, suggesting that these agents had antitumor activity. Pazopanib was compared to placebo in a randomized study undertaken by the ALLIANCE cooperative group, which enrolled 171 patients with nonpancreatic NETs. Patients treated with pazopanib in this study had a superior progression-free survival compared to those who received placebo (11.6 vs 8.5 months), a difference that was statistically significant. Surufatinib was used in a randomized study of 198 patients with extrapancreatic NETs; the median progression-free survival was 9.2 months in patients receiving surufatinib and 3.8 months in those receiving placebo. The strongest results to date have come from a randomized study of cabozantinib (see above) that included 205 patients with extrapancreatic GI NET. In this study, median progression-free survival was 8.5 months in the cabozantinib arm as compared with 4 months in the placebo arm. Taken together with the results in the pancreatic NET cohort (above), these results provide a strong rationale for considering cabozantinib as a treatment option for patients with both advanced pancreatic and nonpancreatic GI NET.

mTOR INHIBITORS

mTOR is an intracellular protein kinase that has been implicated in the regulation of a number of processes regulating cell growth in both normal and malignant cells. It functions as a downstream component of the PI3-AKT-mTOR pathway. This pathway is negatively regulated by the tuberous sclerosis complex, comprising TSC1 and TSC2. An association between the development of pancreatic NETs and inherited mutations in *TSC2* in patients with tuberous sclerosis complex was a contributing factor to initial interest in exploring mTOR inhibition as a therapeutic approach in this setting.

Following initial evidence of antitumor activity associated with everolimus (10 mg daily) in an international, multicenter, phase 2 trial of 160 patients, everolimus monotherapy (10 mg daily) was compared with best supportive care alone in the RADIANT-3 trial that enrolled 410 patients with advanced progressing pancreatic NET. While overall objective responses were uncommon, treatment with everolimus was associated with a significant prolongation in median progression-free survival (11.0 vs 4.6 months) compared to placebo, supporting its use as a standard treatment to control tumor growth in patients with advanced pancreatic NET. Common toxicities associated with everolimus are generally mild and can include stomatitis and rash; a more severe but less common side effect is pneumonitis.

Everolimus was also associated with promising activity in early phase 2 studies enrolling patients with extrapancreatic NET. The first large, randomized study evaluating everolimus was the RADIANT-2 trial; 429 patients with advanced GI NETs were randomly assigned to receive octreotide LAR (30 mg intramuscularly every 28 days) with or without everolimus (10 mg daily). Treatment with everolimus in this study was associated with an improvement in median progression-free survival (16.4 vs 11.3 months), but the difference in this study was of only borderline statistical significance. A second study, the RADIANT-4 study, enrolled 302 patients with advanced NETs of either GI (excluding pancreatic) or lung origin, randomizing them to receive either everolimus or placebo. In this study, treatment with octreotide was not required. As in the RADIANT-3 study, objective tumor responses were uncommon; however, median progression-free survival in patients who received everolimus was significantly longer than in those who received placebo (11 vs 3.9 months). Based on the results of this study, everolimus is considered a standard treatment for control of tumor growth in extrapancreatic NETs.

OTHER SYSTEMIC TREATMENTS FOR CONTROL OF TUMOR GROWTH

Interferon α has been used as a treatment for advanced NETs for several decades. With the development of newer approaches, its routine use has diminished. The use of interferon α was based primarily on observations in large, retrospective series where low-dose interferon α was reported to both reduce symptoms of hormonal hypersecretion and slow tumor progression. Interferon can be myelosuppressive, requiring dose titration, and in some patients can induce both fatigue and depression. Antitumor activity has also been reported with oxaliplatin-based chemotherapy regimens. A combined analysis of two phase 2 trials examining oxaliplatin-fluoropyrimidine chemotherapy plus bevacizumab in advanced NET suggested antitumor activity for these regimens; the benefit appeared to be greatest in patients with intermediate-grade rather than low-grade tumors.

Treatment with immune checkpoint inhibitors has been found to be effective across multiple cancer types. The role of immune checkpoint inhibitors for the treatment of neuroendocrine tumors has not yet been clearly established and appears to depend at least in part on tumor grade. Immunohistochemical and transcriptomic profiling in well-differentiated neuroendocrine tumors has revealed only low levels of PD-1 and PD-L1 expression together with high levels of immunosuppressive gene expression in tumor-associated myeloid cells. The KEYNOTE-158 study investigated the efficacy of pembrolizumab, a monoclonal antibody targeting the checkpoint marker PD-1, in multiple cancers, including 107 patients with neuroendocrine tumors of various sites. The overall tumor response rate in the neuroendocrine tumor cohort was only 3.7%. Other immunotherapeutic approaches, including use of chimeric antigen receptor T cells for the treatment of neuroendocrine tumors, remain investigational.

SYSTEMIC THERAPY FOR HIGH-GRADE NEUROENDOCRINE CARCINOMA

High-grade NETs are relatively uncommon and tend to pursue an aggressive clinical course. In contrast to well-differentiated neuroendocrine tumors, high-grade neuroendocrine carcinomas may, at least in some cases, be quite responsive to immunotherapeutic approaches. A basket trial evaluating a combination of the anti-CTLA-4 monoclonal antibody ipilimumab together with the anti-PD-1 monoclonal antibody nivolumab enrolled 32 patients with poorly differentiated nonpancreatic neuroendocrine tumors; the overall tumor response rate was 44% in this cohort. Apart from these more recent immune-based approaches, chemotherapy for advanced high-grade neuroendocrine carcinoma has historically followed a paradigm analogous to that used for small-cell carcinoma of the lung, with combinations of either cisplatin or carboplatin administered together with etoposide generally considered the preferred first-line approach. One of the most important elements in determining the optimal chemotherapeutic approach is assessing the Ki-67 proliferative index. A large retrospective series that evaluated 252 patients with high-grade neuroendocrine carcinoma found that the activity of platinum-based therapy was greatest in patients who had a Ki-67 proliferative index of 55% or higher; in these patients, the overall tumor response rate was 42%. In contrast, the overall response rate in patients in whom the Ki-67 proliferative index was <55% was only 15%.

90 Renal Cell Carcinoma

Robert J. Motzer, Martin H. Voss

Renal cell carcinomas account for 90–95% of malignant neoplasms arising from the kidney. Notable features include frequent diagnosis without symptoms, resistance to cytotoxic agents, robust activity of angiogenesis-targeted agents, immune infiltration commonly rendering tumors susceptible to checkpoint-directed immunotherapy, and a variable clinical course for patients with metastatic disease, including anecdotal reports of spontaneous regression. Most of the remaining 5–10% of malignant neoplasms arising from the kidney are transitional cell carcinomas (urothelial carcinomas) originating in the lining of the renal pelvis. See **Chap. 91** for transitional cell carcinomas.

EPIDEMIOLOGY

The incidence of cancers of the kidney and renal pelvis rose for three decades, reached a plateau of approximately 64,000 cases annually in the United States between 2012 and 2018, but has since increased to approximately 81,000 cases annually, resulting in close to 15,000 deaths per year. It is the seventh most common cancer overall in the United States, the sixth most common in males, and the ninth most common in females; the male-to-female ratio is 2:1. Although this malignancy may be diagnosed at any age, it is uncommon in those under 45 years, and incidence peaks between the ages of 55 and 75 years. Many factors have been investigated as possible contributing causes; associations include cigarette smoking, obesity, and hypertension. Risk is also increased for patients with polycystic kidney disease that has been complicated by chronic renal failure.

Most cases of renal cell carcinoma (RCC) are sporadic, although familial forms have been reported **(Table 90-1)**. One well-established example includes clear cell RCC arising in the context of von Hippel-Lindau (VHL) syndrome, an autosomal dominant disorder. Genetic studies identified the *VHL* gene on the short arm of chromosome 3. Individuals with VHL syndrome have a 70% estimated lifetime risk of developing clear cell RCC. Other *VHL*-associated neoplasms include retinal hemangioma, hemangioblastoma of the spinal cord and cerebellum, pheochromocytoma, and neuroendocrine tumors. Belzutifan, an oral inhibitor of hypoxia-inducible factor (HIF-2α), is approved for treatment of *VHL*-associated cancers. Birt-Hogg-Dubé syndrome is a rare human autosomal dominant genetic disorder characterized by fibrofolliculomas (benign tumors arising in hair follicles), pulmonary cysts, and RCCs of varying histologies, most commonly the chromophobe type, occurring in about a third of patients. This disorder is associated with mutations in the *FLCN* gene, which codes for folliculin. Other hereditary syndromes are summarized in Table 90-1.

PATHOLOGY AND GENETICS

Renal cell malignancies represent a heterogeneous group of tumors with distinct histopathologic, genetic, and clinical features **(Table 90-2)**. Categories include clear cell carcinoma (70% of cases), papillary RCC (10–15%), chromophobe RCC (≤5%), molecularly defined entities such as *TFE3*-rearranged RCC (<5%), and other less common variants. Papillary tumors can be bilateral and multifocal. Chromophobe tumors tend to have a more indolent clinical course. *TFE3*-rearranged RCC, rare in adult patients, is the predominant histology in children. *SMARCB1*-deficient RCC, previously called renal medullary

TABLE 90-1 Hereditary Renal Cell Tumors

SYNDROME	CHROMOSOME(S)	GENE	PROTEIN	KIDNEY TUMOR TYPE	ADDITIONAL CLINICAL FINDINGS
von Hippel-Lindau syndrome	3p25	*VHL*	von Hippel-Lindau protein	Clear cell	Hemangioblastoma of the retina and central nervous system; pheochromocytoma; pancreatic and renal cysts; neuroendocrine tumors
Hereditary papillary RCC	7p31	*MET*	MET	Papillary	Bilateral and multifocal kidney tumors
Hereditary leiomyomatosis and RCC (HLRCC syndrome)	1q42	*FH*	Fumarate hydratase	FH-deficient/HLRCC syndrome–associated RCC	Leiomyoma; uterine leiomyoma/leiomyosarcoma
Birt-Hogg-Dubé syndrome	17p11	*FLCN*	Folliculin	Chromophobe; clear cell; oncocytoma	Facial fibrofolliculoma; pulmonary cysts
Tuberous sclerosis	9q34 16p13	*TSC1* *TSC2*	Hamartin Tuberin	Angiomyolipomas; TSC-associated lymphangioleiomyomatosis; rare RCC with variety of histologic appearances including eosinophilic solid and cystic (ESC) RCC	Angiofibroma, subungual fibroma; cardiac rhabdomyoma; adenomatous small intestine polyps; pulmonary and renal cysts; cortical tuber; subependymal giant cell astrocytomas
BAP1 tumor predisposition syndrome	3p21	*BAP1*	BAP1	Mostly clear cell, but chromophobe and papillary have also been reported	Atypical Spitz tumors; uveal melanoma; cutaneous melanoma; basal cell carcinoma; malignant mesothelioma

Abbreviations: ESC, eosinophilic solid and cystic; FH, fumarate hydratase; HLRCC; hereditary leiomyomatosis and RCC; RCC, renal cell carcinoma; TSC, tuberous sclerosis.

TABLE 90-2 Classification of Malignant Epithelial Neoplasms Arising from the Kidney

CARCINOMA TYPE	CHARACTERISTIC GROWTH PATTERN	CHROMOSOMAL EVENTS	GENES WITH RECURRENT SOMATIC ALTERATIONS
Clear cell	Varying growth patterns, including acinar, solid and sarcomatoid	3p–, 5q+, 14q–, 9p–	*VHL, PBRM1, BAP1, SETD2*
Papillary	Papillary or sarcomatoid	+7, +17, 9p–	*MET, CDKN2A* (focal deletions)
Chromophobe	Solid, tubular, or sarcomatoid	Whole arm losses (1, 2, 6, 10, 13, 17, and 21)	*TP53, PTEN, TERT* promotor
TFE3-rarranged and *TFEB*-altered renal cell carcinomas	Mimicking clear cell and papillary variants	Xp11.2 translocations; t(6;11) translocations	*TFE3* gene fusions, *TFEB* gene fusions
SMARCB1-deficient renal medullary carcinoma	Varying growth patterns, including cribriform, reticular, sarcomatoid, adenoid, and microcystic	+8q, 22q–, 22q translocations	*SMARCB1* (focal deletions, mutations, gene fusions), *SETD2*

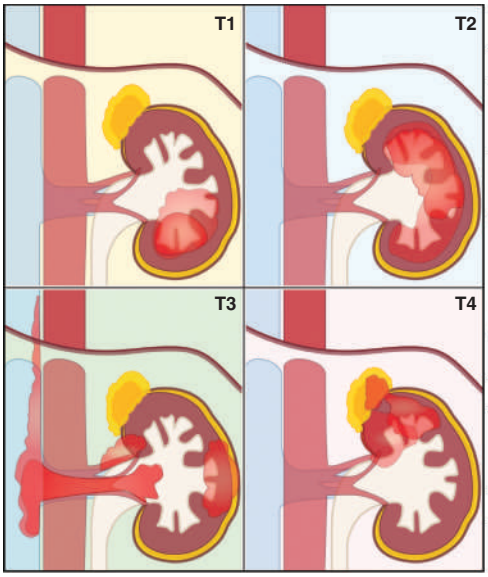
carcinoma, is rare, very aggressive, and associated with sickle cell trait. Tumors that do not meet criteria for defined variants are generally referred to as "unclassified" with variable clinical courses.

Clear cell tumors, the predominant histology, are found in >80% of patients who develop metastases and arise from the epithelial cells of the proximal tubules. Loss of chromosome 3p is uniformly seen as the earliest event in the development of these cancers. This leads to loss of heterozygosity for a number of relevant 3p genes, including *VHL*, *PBRM1*, *BAP1*, and *SETD2*, which can be functionally silenced through secondary events in the remaining allele. *VHL* encodes a tumor-suppressor protein that is involved in regulating the transcription of vascular endothelial growth factor (VEGF) and a number of other effectors through ubiquitination of hypoxia-inducible factors (HIF). Inactivation of *VHL*, through upregulation of VEGF signaling, promotes tumor angiogenesis and growth, ultimately rendering clear cell RCC cells susceptible to antiangiogenesis therapy.

Large-scale sequencing efforts have helped elucidate recurrent patterns of genomic evolution that correlate with distinct clinical phenotypes, e.g., varying levels of aggressiveness or specific patterns of metastatic spread. For example, early loss of chromosome 9p appears to confer a high risk for early metastatic dissemination and correlates with poor cancer-specific survival.

A growing number of other RCC variants are well defined (see Table 90-2 for examples) yet can further vary by molecular features. For instance, up to 15% of RCCs are of the papillary subtype, and variant features can be distinguished by light microscopy but also molecular assays. Activating mutations in the *MET* oncogene or gain of chromosome 7 (where *MET* is located) are hallmark events of certain papillary variants and considered actionable via targeted MET inhibitors. Tumors of the less common chromophobe subtype originate from the distal nephron. They are typically characterized by aneuploidy with common loss of an entire chromosome copy for chromosomes 1, 2, 6, 10, 13, and 17.

CLINICAL PRESENTATION



Presenting signs and symptoms may include hematuria, flank or abdominal pain, and a palpable mass. Other symptoms are fever, weight loss, anemia, and a varicocele. Tumors are, however, commonly detected as an incidental finding on a radiograph. Widespread use of radiologic cross-sectional imaging (computed tomography [CT], magnetic resonance imaging [MRI]) contributes to earlier detection of renal masses during evaluation for other medical conditions. The increasing number of incidentally discovered low-stage tumors has contributed to an improved 5-year survival for patients with RCC and increased use of nephron-sparing surgery (partial nephrectomy). A spectrum of paraneoplastic syndromes has been associated with these malignancies, including erythrocytosis, hypercalcemia, nonmetastatic hepatic dysfunction (Stauffer's syndrome), and acquired dysfibrinogenemia. Erythrocytosis is noted at presentation in only about 3% of patients. Anemia, commonly a sign of more advanced disease, is more common. Kidney cancer was called the "internist's tumor" since it was often discovered from the initial presentation of a paraneoplastic syndrome. This was more common before the era of modern imaging, as was initial presentation by the classic triad of hematuria, flank pain, and a palpable abdominal mass.

The standard evaluation of patients with suspected renal tumors includes a CT scan of the abdomen and pelvis, chest radiograph, and urine analysis. If metastatic disease is suspected from the chest radiograph, a CT of the chest is warranted. MRI is useful in evaluating the inferior vena cava in cases of suspected tumor involvement or invasion by thrombus, or when intravenous contrast administration given with CT is prohibited by impaired renal function. In clinical practice, any solid renal masses should be considered malignant until proven otherwise; a definitive diagnosis is required. If no metastases are demonstrated, surgery is indicated, even if the renal vein or inferior vena cava is invaded. In small tumors (particularly those of clear cell variant), the risk of impending metastatic spread is lower and surgery can potentially be delayed. In that setting, a needle biopsy should be performed to confirm the underlying histology, and radiographic surveillance is indicated until the time of surgery. The differential diagnosis of a renal mass includes cysts, benign neoplasms (adenoma, angiomyolipoma, oncocytoma), inflammatory lesions (pyelonephritis or abscesses), and other malignancies originating in the kidney such as transitional cell carcinoma of the renal pelvis, sarcoma, lymphoma, and Wilms' tumor or metastases from cancers originating in other organs. All of these are less common causes of renal masses than is RCC. The most common sites of distant metastases are the lungs, lymph nodes, liver, bone, and brain. These tumors may follow an unpredictable and protracted clinical course.

STAGING AND PROGNOSIS

Staging is based on the American Joint Committee on Cancer (AJCC) staging system **(Fig. 90-1)**. Stage I tumors are ≤7 cm in greatest diameter and confined to the kidney; stage II tumors are >7 cm and confined to the kidney; stage III tumors extend through the renal capsule but are confined to Gerota's fascia, grossly infiltrate the renal vein, or involve regional lymph nodes (N1); and stage IV disease includes tumors that have invaded adjacent organs or involve nonregional lymph nodes or distant metastases. Sixty-five percent of patients present with stage I or II disease, 15–20% with stage III, and 15–20% with stage IV. The 5-year survival rate is currently 77% across all RCCs but varies greatly by stage.

Prognostic risk models are helpful for counseling patients diagnosed with metastatic disease and for anticipating survival rates when designing a clinical trial. A widely used prognostic model for advanced disease, the International Metastatic RCC Database Consortium (IMDC) risk model, incorporates six factors shown to correlate with worse survival: poor performance status, low hemoglobin concentration, high serum calcium, high neutrophil levels, high platelet levels, and <1-year interval from diagnosis to systemic treatment. Patients with zero risk factors achieve significantly longer median survival (≥5 years) than patients with one or two risk factors (~4 years) and those with three to six risk factors (~3 years) when treated with first-line checkpoint inhibitor–containing combination regimens (see below).

TNM	Involvement	Extent of Disease
TX	Primary not involved	
T1	≤7 cm	limited to kidney
T1a	≤4 cm	
T1b	>4 cm	
T2	>7 cm	limited to kidney
T2a	>7 cm to ≤10 cm	
T2b	>10 cm	
T3	into major veins or perinephric tissues	not beyond Gerota's fascia
T3a	in renal vein, renal sinus fat, or pelvicalyceal system	not beyond Gerota's fascia
T3b	into vena cava	below diaphragm
T3c	into vena cava	above diaphragm
T4	invasion beyond Gerota's fascia	including contiguous extensions & into ipsilateral adrenal gland
Regional		
NX	Regional lymph nodes not assessed	
N0	No regional lymph node involvement	
N1	Regional lymph node involvement	
Distant Metastases		
M0	No distant metastases	
M1	Distant metastases, including nonregional lymph nodes	

Anatomic Stage/Prognostic Groups			
I	T1	N0	M0
II	T2	N0	M0
III	T1 or T2,	N1	M0
	T3	N0 or N1	M0
IV	T4	Any N	M0
	Any T	Any N	M1

TREATMENT

Renal Cell Carcinoma

LOCALIZED TUMOR

The standard management for stage I or II tumors and selected cases of stage III disease is radical or partial nephrectomy. A radical nephrectomy involves en bloc removal of Gerota's fascia and its contents, including the kidney, and commonly the ipsilateral adrenal gland and regional lymph nodes that appear abnormal on imaging or intraoperatively. Open, laparoscopic, or robotic surgical techniques may be used. The role of a template lymphadenectomy in patients without apparent lymphadenopathy is controversial. Extension into the renal vein or inferior vena cava (stage III disease) does not preclude resection, which would then include thrombectomy.

Nephron-sparing approaches, i.e., open or laparoscopic partial nephrectomy, may be appropriate depending on the size and location of the tumor. This approach is particularly relevant for patients with solitary kidneys, bilateral tumors, or chronic renal insufficiency but can also be applied electively to resect small masses for patients with normal kidney function. Radical nephrectomy carries a greater risk for chronic kidney disease and cardiovascular morbidity and mortality.

Adjuvant systemic therapies, including cytokines and targeted agents, have been studied in randomized clinical trials, largely with negative results. The checkpoint inhibitor pembrolizumab is approved in patients with increased risk of recurrence following nephrectomy, where 12 months of therapy was shown to improve disease-free survival compared to placebo. For those with low risk of recurrence, the standard of care remains active surveillance after nephrectomy.

METASTATIC DISEASE

Surgery has a limited role for patients with metastatic disease. Long-term survival may occur in patients who relapse with a solitary site that is removed (metastasectomy). Nephrectomy despite presence of metastases (cytoreductive nephrectomy) is considered for carefully selected patients with stage IV disease. One indication for this approach can be to alleviate pain or hemorrhage of a primary tumor.

Radiation therapy is used for palliation of bone or brain metastases. The type of radiotherapy most commonly used is external-beam therapy, including stereotactic radiosurgery and other forms of image-guided radiotherapy.

Systemic therapy is the mainstay of care for metastatic disease. The timing of initiating such treatment should be carefully considered; some patients are asymptomatic at diagnosis, and with indolent behavior, it may be best to document progression before initiating treatment.

Metastatic RCC is refractory to cytotoxic chemotherapy. Patients are treated with molecularly targeted agents, including targeted immunotherapies, i.e., checkpoint inhibitors. Treatments are continued with noncurative intent while tolerated and until disease progression is evident on cross-sectional imaging. Outcomes for patients with metastatic disease improved when increased understanding of underlying biology led to the successful development of several tyrosine kinase inhibitors (TKIs) targeting proangiogenic signaling through the VEGF receptors as well as allosteric inhibitors of mammalian target of rapamycin (mTOR) signaling. Serial large-scale randomized trials demonstrated that such agents, typically orally available, could be administered sequentially and in combination. Pivotal studies, by design, defined a dedicated space for each regimen in treatment-naïve or pretreated patients **(Table 90-3)**.

Targeted immunotherapies were introduced after VEGF- and mTOR-directed agents had established standards of care in the first- and second-line setting. Nivolumab, a checkpoint inhibitor targeting PD-1, demonstrated superior overall survival compared to the mTOR inhibitor everolimus in a randomized trial in patients who had progressed on prior TKI therapy, challenging the standard approach in pretreated patients and positioning nivolumab as the new second-line agent of choice. Subsequently, immunotherapy combination regimens demonstrated efficacy in randomized trials conducted in treatment-naïve patients. In separate studies, four doublets demonstrated survival benefit over standard sunitinib therapy and changed the standard of care for untreated metastatic clear cell RCC toward two-drug, immunotherapy-containing regimens: nivolumab in combination with the CTLA-4–directed checkpoint inhibitor ipilimumab; the TKI axitinib together with the PD-1 inhibitor pembrolizumab; the TKI cabozantinib plus nivolumab; and the TKI lenvatinib paired with pembrolizumab. These combinations demonstrated objective radiographic responses in 40–70% of patients, and complete radiographic disappearance of cancer is achieved in about 10% of patients. The majority of such anticancer effects were reported to be long-lasting.

With an ever-growing number of approved options directed toward different molecular targets, biomarkers are urgently needed to help individualize therapeutic choices and to gain insight as to

TABLE 90-3 Commonly Used Systemic Regimens for Metastatic Renal Cell Carcinoma

CLASS	DRUG	FIRST FDA APPROVAL FOR RCC	CURRENTLY USED FOR
Antiangiogenic: TKIs	Sunitinib	2006	Advanced RCC, first line
	Pazopanib	2009	Advanced RCC, first line
	Axitinib	2012	Advanced RCC, pretreated

whether and why treatments are working. Although a multitude of candidate biomarkers have been investigated for their predictive value in metastatic RCC, none have been validated for clinical use to date.

Projected overall survival in patients starting systemic therapies for newly diagnosed metastatic disease has tripled over the past 15–20 years; this can largely be attributed to the successful drug developments discussed here.

GLOBAL CONSIDERATIONS

Worldwide, >400,000 patients are diagnosed each year with malignant tumors arising from the kidney, resulting in >175,000 deaths annually. Kidney cancer is the sixth most common cancer in men and the 10th most common cancer in women. Higher incidence is observed in developed countries, including the United States, Canada, Europe, Australia, New Zealand, and Uruguay. Lower rates are reported in Southeast Asia and Africa, though it is speculated that these rates may be underreported due to lack of disease-reporting structure and reduced access to diagnostic facilities. The incidence of kidney cancer has been steadily increasing over the past four decades. Mortality trends have stabilized in Europe and the United States, but not in less developed countries. This is likely related to differences in access to optimal therapies. Treatment guidelines for both localized and metastatic renal cancer are similar between U.S. and European documents and contingent on the access to adequate health care and availability of targeted drugs to treat metastases.

91 Cancer of the Bladder and Urinary Tract

Noah M. Hahn

GLOBAL CONSIDERATIONS

Within the United States, urothelial carcinomas of the bladder and urinary tract are most closely related to tobacco smoking history. However, within developing countries, water supplies contaminated with arsenic or schistosomiasis parasites also are major carcinogenic contributors.

INTRODUCTION

Cancers of the urinary tract including the bladder, renal pelvis, ureter, and urethra occur frequently, and they represent the second most common class of genitourinary cancers. Bladder cancer alone represents the sixth most common cancer diagnosis annually in the United States with 82,290 new cases and 16,710 deaths every year. Because cancers of the renal pelvis are often lumped in with all kidney cancers, the true incidence and mortality from nonbladder urinary tract cancers are less precise. While less frequent than bladder cancer, an additional 20,000 new cases and 5000 deaths are estimated every year. An accelerated understanding of the molecular underpinnings of bladder and urinary tract cancer biology has led to a significant increase in urothelial cancer clinical trials resulting in U.S. Food and Drug Administration (FDA) approval of multiple new therapeutic agents since 2016 with more expected to follow. This chapter reviews the established, current, and emerging evidence that serves as the basis for the rapidly evolving standards of care for patients with bladder and urinary tract cancers.

CLINICAL EPIDEMIOLOGY AND RISK FACTORS

Bladder cancer typically affects older patients with a median age at diagnosis of 73 years. Males are four times more frequently affected than females. Similarly, bladder cancer is more common in Caucasians than in Asian patients. Inheritable germline genetic risk factors have been observed in up to one-seventh of patients with bladder or urinary tract cancers. However, a predominant, singular germline genetic alteration has not been identified. Patients with defects in mismatch repair genes leading to microsatellite instability (*MLH1, MSH2, MSH6*, etc.) as part of the familial cancer Lynch syndrome are at particular risk of upper urinary tract cancers of the renal pelvis and ureter. Additionally,

patients with Cowden disease (*PTEN* mutations) or retinoblastoma (*RB1* mutations) are at increased risk for developing bladder cancer.

Historically, associations have existed between environmental toxic exposures and higher rates of developing bladder cancer. The aromatic amines benzidine and β-naphthylamine that can be present in industrial dyes as well as arsenic that can be found in drinking water supplies in underdeveloped countries have been associated with increased bladder cancer risk. Other chemicals in the leather, paint, rubber, textiles, and printing industries have been associated with bladder cancer. Associations with exposures to hair dyes and hair sprays in workers in the hairstyling field have been suggested. Additionally, concern has been raised regarding use of the antidiabetic medication, pioglitazone, and bladder cancer risk. Extensive reviews and meta-analyses have produced differing conclusions. The data suggest a small risk of bladder cancer from long-term pioglitazone use, which has led to inclusion of bladder cancer risk within the pioglitazone prescribing information. An association between chronic inflammatory states and the development of squamous bladder cancer clearly exists in underdeveloped countries in patients chronically infected with the parasitic disease schistosomiasis and in paraplegic patients with chronic indwelling catheters. Above and beyond each of these associations, however, smoking of tobacco products (cigarettes, cigars, pipes, etc.) remains the overwhelming leading risk factor for development of bladder cancer. Among new bladder cancer diagnoses, 90% of cases occur in current or former smokers. Toxicologists have estimated that >70 confirmed carcinogenic toxins are present within tobacco smoke. It is estimated that one-third of bladder cancer cases could be prevented through simple modification of lifestyle choices, in particular cessation of smoking.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Occasionally, patients will present with flank pain in association with an upper tract renal pelvis or ureter cancer or due to hydronephrosis in association with a bladder tumor obstructing the orifice of the ureter within the bladder. Only in rare cases do patients present with significant cachexia and widespread metastatic disease. For most patients, painless hematuria (either gross or microscopic) represents the initial manifestation of an underlying urinary tract cancer. In females, hematuria due to malignancy can often be mistaken for a urinary tract infection or menstrual bleeding. While treatment with antibiotics is warranted if a concurrent urinary tract infection is noted on initial urinalysis, persistent hematuria requires further workup. Painless hematuria in males is almost always abnormal and should be worked up. Initial investigations in patients of either sex should include urine cytology and visual examination of the bladder by cystoscopy. Cytology is successful in identifying cancer in only 50% of individuals with high-grade bladder cancers. In addition to urine cytology, radiographic evaluation of the kidneys and upper urinary tract by CT urogram should be performed. A magnetic resonance (MR) urogram may be substituted in patients with poor renal function. Additional diagnostic testing of the urine to assess for cancer-associated chromosomal changes by fluorescent in situ hybridization, increased levels of nuclear mitotic proteins, increased bladder tumor–associated antigens, or higher levels of staining on cells shed by the bladder may identify some cancers missed by traditional cytology testing. However, they may also produce abnormal results in patients who do not have cancer. For now, these adjunct molecular tests are primarily utilized in detecting recurrent cancer in patients with a prior diagnosis of urinary tract cancer. Small tumors, particularly flat noninvasive tumors of the bladder, may be detected at higher rates with the use of blue light cystoscopy or narrow-band imaging cystoscopy. Both blue light and narrow-band imaging cystoscopies are now used routinely in the monitoring of patients with bladder cancer. For patients with no bladder abnormalities in whom upper tract tumors are suspected, visualization of the upper urinary tracts and renal pelvises should be performed by ureteroscopy or retrograde pyelography.

In all patients with abnormalities noted in the bladder or upper urinary tracts, complete endoscopic resection for histologic diagnosis and staging should be performed when possible via either transurethral resection of bladder tumor (TURBT) or endoscopic resection of upper tract tumors. All metastatic patients should have genomic sequencing performed on their tumor tissue, circulating tumor DNA (ctDNA), or both. The role of genomic sequencing in earlier stages of disease is evolving.

HISTOLOGY

Urothelial carcinoma, often called transitional cell carcinoma in the past, is the most common urinary tract cancer histology and is observed in ~90% of cases. Squamous, glandular, micropapillary, plasmacytoid, sarcomatoid, and other variant features can often be found in portions of urothelial carcinoma tumors; however, pure variant histologies are rare. The presence of some variant histologies including micropapillary and plasmacytoid has been associated with worse surgical outcomes compared to urothelial carcinoma. Nonurothelial variant histologies including squamous cell carcinoma, adenocarcinoma, small-cell carcinoma, and carcinosarcoma collectively account for ≤10% of urinary tract tumors. Examples of traditional urothelial carcinoma and some of the variant histologies are shown in **Fig. 91-1**.

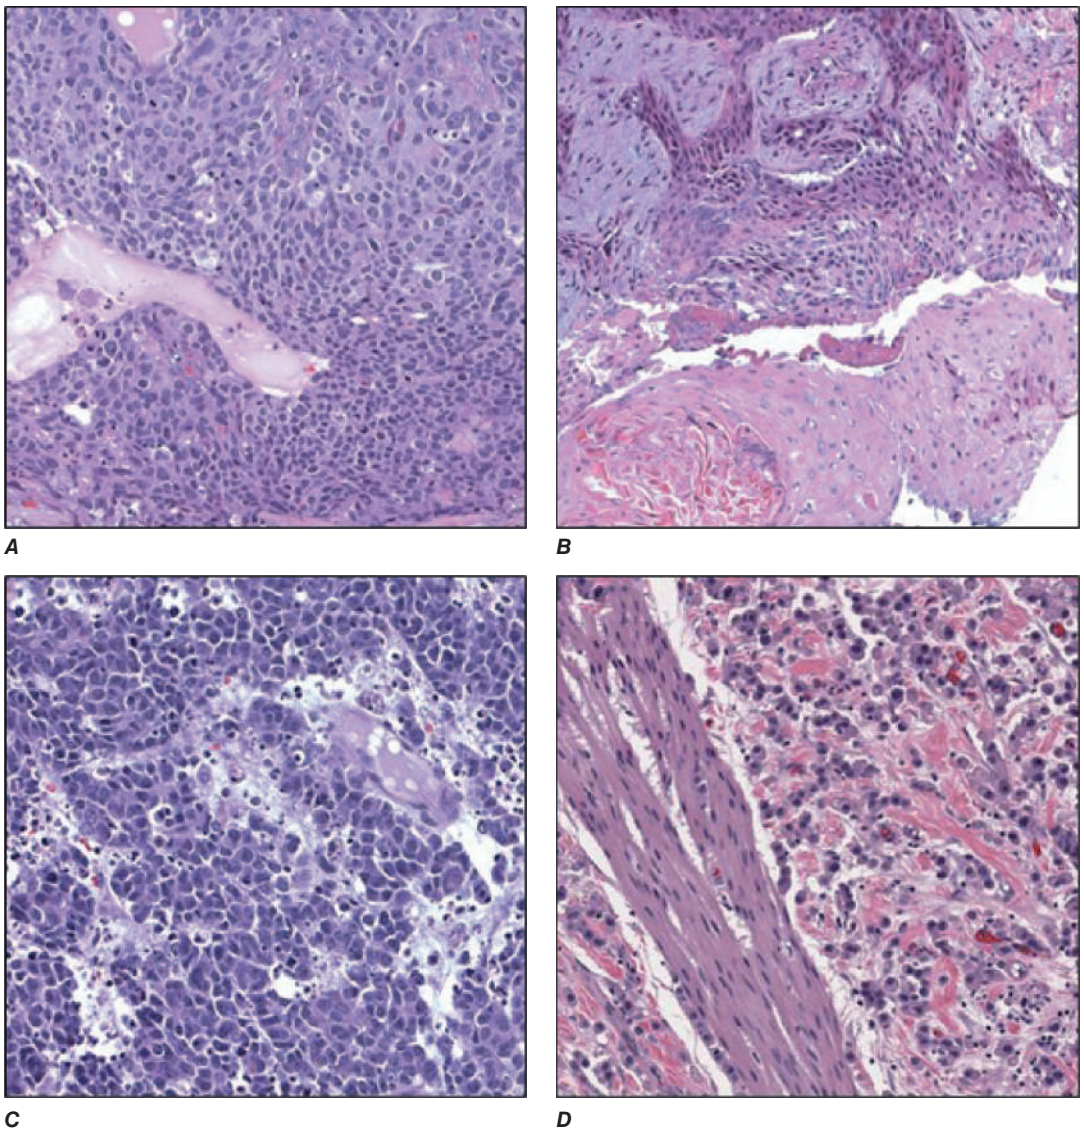
MOLECULAR BIOLOGY

Clinically, urothelial carcinoma of the bladder displays a biphasic phenotype characterized by (1) low-grade papillary tumors that frequently recur but rarely invade or metastasize and (2) high-grade sometimes flat tumors that invade early leading to lethal metastatic disease. In both of these phenotypes, loss of portions of chromosomes 9q and 9p by loss of heterozygosity is an early molecular event, whose exact significance is not clear. Potential candidate regulatory genes in these genomic regions include *CDNK2A,* a cyclin-dependent kinase inhibitor, and *TSC1,* a gene encoding hamartin mutated in tuberous sclerosis. Genomic investigations have demonstrated that low-grade tumors are characterized by alterations in the *RAS/RAF* signaling pathway with activating *FGFR3* mutations or gene fusions present in 60–80% of patients. In contrast, the high-grade invasive phenotype is notable for early deleterious mutations in *TP53* and *RB1*, alterations in *CDH1* (E-cadherin), and increased expression of *VEGFR2*. In urothelial carcinoma of the renal pelvis and ureter, 10–20% of cases may be associated with Lynch syndrome hereditary defects in the *MLH1*, *MSH2*, or *MSH6* mismatch repair genes, leading to microsatellite instability and frequent DNA mutations. Testing for germline mutations in these genes is recommended in patients with upper urinary tract urothelial carcinoma under the age of 60 at diagnosis, with a first-degree relative with a Lynch syndrome–associated cancer diagnosed under the age of 50, or with two first-degree relatives with a Lynch syndrome–associated cancer regardless of the age at diagnosis.

As genomic analysis technologies have improved, so has our understanding of the molecular biology unique to urothelial carcinoma. In 2017, the full bladder cancer results of The Cancer Genome Atlas (TCGA) project were published. This effort comprehensively analyzed gene mutations, fusions, expression, copy number variations, methylation, and microRNA across the genome of patients with bladder urothelial carcinoma treated with surgery. Key findings from this effort include (1) genomic alterations in genes (e.g., *FGFR3*, *EGFR*, *ERBB2*, *ERBB3*, *PIK3CA*, *TSC1*, etc.) targetable by currently approved drugs or drugs in development in 71% of patients; (2) genomic alterations in chromatin-modifying genes (*KMT2D, KDM6A, KMT2C, EP300, CREBBP*, etc.) in the majority of patients; (3) hypermethylation with epigenetic silencing of gene expression in one-fourth of patients; and (4) the identification by RNA sequencing of five distinct intrinsic molecular subtypes (luminal papillary, luminal infiltrated, luminal, basal squamous, and neuronal) closely resembling luminal and basal subclassifications of breast cancers. These bladder TCGA findings have led to clinical trial designs enriching for patients with specific gene mutation profiles as well as interrogation of candidate biomarkers according to intrinsic molecular subtypes.

STAGING AND OUTCOMES BY STAGE

The staging of bladder cancer is dependent on the depth of invasion within the bladder wall, involvement of lymph nodes, and spread to



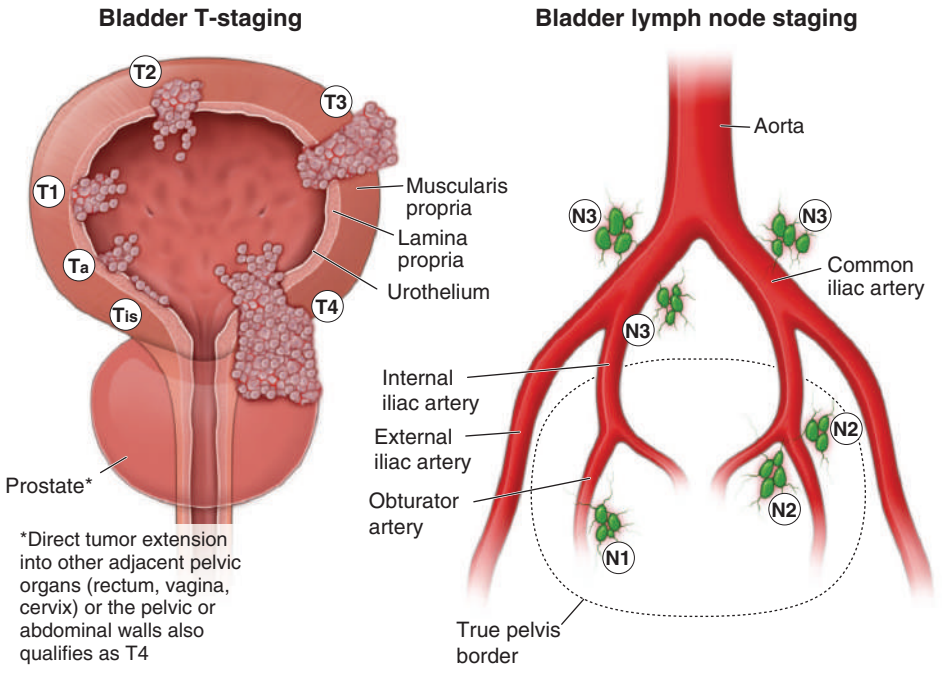


FIGURE 91-1 Bladder and urinary tract cancer histologies. ***A***. Urothelial carcinoma. ***B.*** Squamous cell carcinoma. ***C.*** Small-cell carcinoma. ***D.*** Plasmacytoid variant. *(Courtesy of Alex Baras, MD, PhD, Johns Hopkins University Department of Pathology.)*

surrounding and distant organs as depicted in Fig. 91-2. Approximately 75% of bladder cancer presents with non–muscle-invasive bladder cancer (NMIBC), 18% with disease invading into or through the muscular wall of the bladder, and only 3% with metastatic spread to distant organs. NMIBC is defined by tumors that involve only the immediate epithelial layer of cells (carcinoma in situ [CIS] and Ta) or that only penetrate into the connective tissue below the urothelium (T1) but not into the muscular layer known as the *muscularis propria*. Muscle-invasive bladder cancer (MIBC) is defined by tumors that invade into the muscularis propria (T2), through the muscularis propria to involve the surrounding serosa (T3), or into immediately adjacent pelvic organs such as the rectum, prostate, vagina, or cervix (T4). Lymph node staging is classified according to involvement of a solitary node within the true pelvis (N1), two nodes involved in the true pelvis (N2), or involvement of the common iliac nodes (N3). Any disease that has spread beyond the common iliac nodes is considered metastatic (M1). The staging of bladder cancer is driven primarily by the T stage of the tumor, with stages 0a–II defined entirely by the T stage in the absence of nodal or metastatic disease. Involvement of regional lymph nodes in the true pelvis or along the common iliac artery qualifies as stage III disease, whereas involvement of any distant metastases qualifies as stage IV disease. Clinical outcomes of patients with bladder cancer correlate closely with staging at diagnosis with 5-year overall survival rates of 70–90% for disease confined to the bladder (stage I–II), 39–50% for disease that penetrates through the bladder or has spread to regional lymph nodes (stage III), and only 8% for disease extending to metastatic sites (stage IV).

TREATMENT APPROACHES

Early-Stage Disease For NMIBC, removal of all visible tumors by TURBT in the operating room is considered the mainstay of surgical treatment. Risk of recurrence can be classified as low, intermediate, or high depending on the presence of features summarized in Table 91-1. For patients with low-risk disease, meta-analyses have demonstrated a 12% reduction in early relapses when a single chemotherapy treatment of mitomycin C, epirubicin, or gemcitabine was instilled directly into the bladder (intravesical therapy) within 24 hours of the TURBT. For patients with intermediate- or high-risk tumors, weekly intravesical instillations for 6 consecutive weeks of the attenuated mycobacterium strain known as *Bacille Calmette-Guérin* (BCG) reduce the risk of recurrence from 50 to 29%. In addition, BCG treatment has been shown to decrease the rate of progression to MIBC by 27%. Intravesical BCG is generally well tolerated. Side effects can include dysuria, urinary frequency, bladder spasms, hematuria, and, in rare cases (<5%), a systemic inflammatory response that can mimic disseminated BCG infection. Following a 6-week induction BCG schedule, additional maintenance BCG treatments given according to the Southwest

Bladder cancer prognosis according to stage

T	N	M	Stage	5-yr survival
Tis/Ta	N0	M0	0is/0a	96%
T1	N0	M0	1	90%
T2	N0	M0	2	70%
T3	N0	M0	3	50%
T1-T4	N1-N3	M0	3	36%
Any T	Any N	M1	4	5%

N1 - Cancer spread to 1 lymph node in the true pelvis

N2 - Cancer spread to 2 lymph nodes in the true pelvis

N3 - Cancer spread to lymph nodes along the common iliac artery

FIGURE 91-2 Bladder cancer staging and prognosis. TNM, tumor-node-metastasis.

Oncology Group schedule further reduce the risk of recurrent NMIBC compared to induction BCG alone. In patients with NMIBC that recurs long after initial BCG treatment, a repeat course of BCG can be considered. For patients with recurrence after a second adequate course of BCG or with relapsed NMIBC within 6 months of initial BCG exposure, surgical removal of the entire bladder by cystectomy is recommended due to the high risk of progression to MIBC and potentially metastatic disease. For patients who are not fit enough for or who refuse cystectomy, non-BCG alternative intravesical agents (nadofaragene firadenovec, mitomycin C, gemcitabine, docetaxel, valrubicin) or systemically administered agents that inhibit the PD-1/PD-L1 immune checkpoint pathway (pembrolizumab) can achieve durable tumor responses in a small fraction of patients.

Upper Tract Disease In patients with urothelial carcinoma of the renal pelvis or ureter, endoscopic tissue acquisition and staging are more challenging than primary tumors located in the bladder. Tumors possessing all of the following are considered low risk: solitary tumor, low grade, size <1 cm, and no invasive component on imaging. Low-risk tumors can successfully be treated by laser ureteroscopic ablation or surgical resection and reanastomosis of the remaining ureter ends in tumors that cannot be successfully eradicated endoscopically.

Muscle-Invasive Disease In patients with urothelial carcinoma of the bladder that invades into or through the muscularis propria but with no evidence of metastatic spread, more aggressive therapy options summarized in Table 91-2 are required to achieve cure. In carefully selected patients with no evidence of CIS or hydronephrosis, bladder-sparing combined-modality therapy with concurrent chemotherapy and radiation can achieve cure in ~65% of patients. Various chemotherapy regimens have been utilized in combination with radiation including cisplatin, carboplatin, 5-fluorouracil, mitomycin C, paclitaxel, and gemcitabine. It is important to note that a maximal debulking of all visible tumor by TURBT is required prior to initiation of combined-modality therapy. In patients who achieve a complete response to combined-modality therapy, regular cystoscopic monitoring of the bladder is required with salvage cystectomy offered to patients who develop MIBC in follow-up.

In a similar fashion, bladder-sparing partial cystectomy can be performed in a very small subset of MIBC patients. The ideal patient for partial cystectomy is the patient with a solitary, clinical T2 urothelial carcinoma in the dome of the bladder. In such patients, the tumor and immediate surrounding urothelium can

TABLE 91-1 Non–Muscle-Invasive Bladder Cancer Recurrence Risk Groups

RISK GROUP	CHARACTERISTICS
Low risk	Initial tumor, solitary tumor, low grade, <3 cm, no CIS
Intermediate risk	All tumors not defined in the two adjacent categories (between the category of low and high risk)
High risk	Any of the following: • T1 tumor • High-grade • CIS • Multiple and large (>3 cm) Ta low-grade tumors in patients over age 70 (all conditions must be met for this point on Ta low-grade tumors)

Abbreviation: CIS, carcinoma in situ.

TABLE 91-2 Treatment Approaches to MIBC Patients

TREATMENT	PATIENT SELECTION	CLINICAL OUTCOMES
Bladder-sparing chemoradiation	No CIS, no hydronephrosis, maximal TURBT required	65% cure, 55% bladder intact, highly dependent on patient selection
Bladder-sparing partial cystectomy	Solitary tumors in dome of bladder are ideal	Variable, highly dependent on patient selection
Cystectomy	Any MIBC patient	50% cure with surgery alone, highly dependent on pathologic stage
Neoadjuvant cisplatin-based chemotherapy	Cisplatin-eligible MIBC patients	5–10% improvement in overall survival compared to cystectomy alone
Adjuvant cisplatin-based chemotherapy	Cisplatin-eligible, high-risk, postcystectomy MIBC patients (pT3-4, N+)	Similar improvement as neoadjuvant treatment, data less robust, many patients not suitable for adjuvant treatment
Adjuvant nivolumab anti–PD-1 immunotherapy	Postsurgery, high-risk MIBC and UTUC patients (pT3-4, N+, cisplatin-eligible after neoadjuvant therapy OR pT2-4, N+, cisplatin-ineligible who did not receive neoadjuvant therapy)	30% improvement in disease-free survival compared to surgery alone

Abbreviations: CIS, carcinoma in situ; MIBC, muscle-invasive bladder cancer; TURBT, transurethral resection of bladder tumor; UTUC, upper tract urothelial carcinoma.

be resected with reconstruction of the remaining bladder to maintain near physiologic urinary function.

In the majority of patients, however, resection of the entire bladder is required. In males, a cystoprostatectomy with removal of the bladder, prostate, and pelvic lymph nodes is performed, whereas in females, an anterior exenteration with removal of the bladder, uterus, ovaries, cervix, and pelvic lymph nodes is performed. With the bladder removed, three options exist to reroute the urine outflow. In an ileostomy, the bilateral ureters are connected to a portion of ileum that is brought through an incision in the abdominal wall to create a stoma that drains urine into an affixed bag outside of the body. In a continent urinary reservoir or "Indiana pouch," the ureters are connected to a portion of ileum that has been separated on both ends from the rest of the small-bowel transit to form a urinary reservoir. The remaining small bowel is reanastomosed, and the urinary reservoir is brought up just beneath the abdominal wall muscles with patients catheterizing the urinary reservoir several times per day via a small stoma tract. Last, in a neobladder, the same urinary reservoir described previously is brought down into the pelvis and is anastomosed to the remaining urethra to provide the opportunity to the patient to void urine through the urethra. The choice of which urinary reconstruction to perform is affected not only by patient choice but also by anatomic tumor considerations and urologist experience with each procedure. Regardless of the type of surgery performed, all patients undergo a significant catabolic change in their metabolism following removal of the bladder. While many MIBC patients are affected by weight loss preoperatively, it is not uncommon for postcystectomy patients to lose an additional 10–15 pounds in the first month postoperatively. In addition, patients can experience long-term nutritional changes such as low B_{12} levels due to alterations in small-bowel physiology caused by all of the urinary diversion options.

Despite aggressive surgery, only half of patients undergoing cystectomy are cured by surgery alone. Therefore, many clinical trials have investigated the role of systemic chemotherapy and immunotherapy before (neoadjuvant) or after (adjuvant) surgery. Meta-analyses have shown a 5–10% absolute overall survival advantage when combination chemotherapy regimens utilizing cisplatin have been used before surgery. Importantly, non–cisplatin-containing chemotherapy regimens have proven inferior to cisplatin-containing regimens. Therefore, if patients are not suitable candidates for cisplatin administration due to poor functional status or comorbidities (e.g., poor renal function), patients should proceed directly to surgery and forego neoadjuvant therapy. A similar benefit exists with cisplatin-based combination chemotherapy given after surgery. However, in the postoperative setting, some patients may not recover sufficiently from their surgery within a time frame optimal for chemotherapy administration. In bladder and upper tract urothelial cancer patients with high-risk postsurgery pathology features, adjuvant treatment with the PD-1–targeting immune checkpoint inhibitor, nivolumab, has demonstrated a 30% improvement in disease-free survival compared to observation and is considered a standard treatment option.

For patients with high-risk urothelial carcinoma of the upper urinary tract, resection of the kidney and ureter (including the ureter bladder cuff) by nephroureterectomy is preferred. Segmental ureterectomy may be appropriate in patients with decreased renal function in which nephron-sparing outcomes are critical to prevent the need for dialysis. Similarly, in CIS patients, administration of BCG therapy via a nephrostomy tube can be considered to preserve intact renal function. The use of cisplatin-based neoadjuvant chemotherapy has been associated with a pathologic complete response at surgery of 14% in upper tract urothelial carcinoma patients. Similarly, in the post-nephroureterectomy setting, adjuvant platinum-based chemotherapy (carboplatin or cisplatin) reduced recurrence rates by 55% compared to surgery alone. The use of perioperative chemotherapy (before or after surgery) or PD-1–targeting immunotherapy (after surgery) is now recommended for upper tract urothelial carcinoma patients in national guidelines.

Metastatic Disease For patients with metastatic urothelial carcinoma regardless of primary tumor origin, systemic platinum-based chemotherapy remained the established initial treatment for decades. However, the regimen of a nectin-4–targeting antibody-drug conjugate, enfortumab vedotin, carrying the monomethyl auristatin E (MMAE) cytotoxic payload combined with the PD-1 immune checkpoint inhibitor pembrolizumab (EV+P) supplanted platinum-based chemotherapy in 2023 as the preferred first-line therapy for metastatic urothelial carcinoma patients. In a randomized, phase 3 clinical trial, EV+P treatment resulted in a highly significant improved median overall survival of 31.5 months compared to 16.2 months with platinum-based chemotherapy. These results led to the FDA approval of the EV+P regimen in first-line metastatic urothelial carcinoma patients. The optimal second-line therapy for patients who experience disease progression on front-line EV+P is not defined. Second-line options include platinum-based chemotherapy or fibroblast growth factor receptor (FGFR) inhibitor therapy (erdafitinib) for patients with activating *FGFR* genomic alterations. For patients with progression after receiving both platinum-based chemotherapy and a PD-1/PD-L1 immune checkpoint inhibitor, the Trop-2–targeting antibody-drug conjugate sacituzumab govitecan, containing a topoisomerase-inhibiting cytotoxic payload, SN-38, remains a third-line option. Prior to the approval of EV+P in the metastatic front-line setting, maintenance treatment with the PD-L1 immune checkpoint inhibitor avelumab had demonstrated an improvement in overall survival compared to platinum-based chemotherapy alone in patients demonstrating stable disease or objective response to their front-line treatment. The role of maintenance PD-1/PD-L1 immune checkpoint inhibitor therapy in the second-line and beyond settings is undefined and is being evaluated in ongoing clinical trials. Additional novel urothelial carcinoma therapeutics are under ongoing investigation.

With the increased number of therapeutic agents for metastatic urothelial cancer patients now available, differing toxicity profiles between treatment regimens commonly impact treatment decisions for individual patients. With platinum-based chemotherapy, renal insufficiency, myelosuppression, nausea, and neuropathy are common. With enfortumab vedotin, myelosuppression can occur; however, neuropathy is dose-limiting with rare but serious skin toxicity and new-onset diabetes events. Myelosuppression and significant diarrhea requiring intravenous fluid support are common with sacituzumab govitecan. In contrast, myelosuppression is uncommon with PD-1/PD-L1 immune checkpoint inhibitors. Rare immune-related toxicities can be severe and may include colitis, pneumonitis, hepatitis, nephritis, myocarditis, rash, hypothyroidism, Guillain-Barré syndrome, idiopathic thrombocytopenia purpura, and adrenal insufficiency. Lastly, erdafitinib side effects are notable for hyperphosphatemia, dystrophic nail changes, and rare central serous retinopathy. Thus, ophthalmologic evaluations are recommended for patients receiving FGFR inhibitor therapies.

92 Benign and Malignant Diseases of the Prostate

Oliver Sartor, James A. Eastham

Benign and malignant changes in the prostate increase with age. Autopsies of men in the eighth decade of life show hyperplastic changes in >90% and malignant changes in >70% of individuals. The high prevalence of these diseases among the elderly, who often have competing causes of morbidity and mortality, mandates a risk-adapted approach to diagnosis and treatment. This can be achieved by considering these diseases as a series of states. Each state represents a distinct clinical milestone for which therapy(ies) may be recommended based on disease extent, current symptoms, risk of developing symptoms, and/or the risk of death from prostate cancer in relation to death from other causes. Given the complexities and, at times, the uncertainties of optimal decision-making, patient preferences are an important consideration. For benign proliferative disorders, symptoms of bladder outlet obstruction and potential complications including urinary retention and urinary tract infection are weighed against the side effects and complications of medical or surgical intervention. For prostate malignancies, the likelihood that a clinically significant cancer is present in the gland and the concomitant risk of symptoms or death from cancer are necessarily balanced against the risks and morbidities of the recommended treatments.

ANATOMY AND PATHOLOGY

The prostate is in the pelvis and is adjacent to the rectum, the bladder, the periprostatic and dorsal vein complexes, the neurovascular bundles that are responsible for erectile function, and the urinary sphincter that is responsible for passive urinary control. The prostate is composed of branching tubuloalveolar glands arranged in lobules surrounded by fibromuscular stroma. The acinar unit includes an epithelial compartment made up of epithelial, basal, and neuroendocrine cells separated by a basement membrane and a stromal compartment that includes fibroblasts and smooth-muscle cells. Prostate-specific antigen (PSA) is produced in the epithelial cells. Both prostate epithelial cells and stromal cells express androgen receptors (ARs) and depend on androgens for growth. Testosterone, the major circulating androgen, is converted by prostatic 5α-reductase to dihydrotestosterone, a more potent androgen.

The periurethral portion of the gland increases in size during puberty and after the age of 55 years due to the growth of nonmalignant cells in the transition zone of the prostate that surrounds the urethra. Most cancers develop in the peripheral zone, and cancers in this location may or may not be palpated during a digital rectal examination (DRE).

PROSTATE CANCER

The American Cancer Society's estimates for prostate cancer in the United States for 2024 are 299,010 new prostate cancer cases and 35,250 deaths from prostate cancer. In the United States, prostate cancer is the most common nonskin malignancy in men and the second leading cause of cancer death. The absolute number of prostate cancer deaths has decreased in the past 30 years, attributed by some to the widespread use of PSA-based detection strategies. The incidence/mortality ratio for prostate cancer is extremely high relative to most other malignancies, and most men diagnosed with prostate cancer will not die from their disease.

EPIDEMIOLOGY

Epidemiologic studies show that the risk of being diagnosed with prostate cancer increases 2.5-fold if one first-degree relative is affected and even more if two or more are affected. Risk is greatest for those whose relatives are diagnosed before the age of 65. Current estimates are that 40% of early-onset and 5–10% of all prostate cancers are hereditary. Prostate cancer affects ethnic groups differently. Matched for age, African-American patients have a higher incidence and present at a more advanced stage with higher-grade, more aggressive cancers. The causes for this disparity are debated, but genetic, environmental, and societal factors are implicated. Genome-wide association studies (GWAS) have identified >100 prostate cancer susceptibility loci that are estimated to explain up to 25% of prostate cancer risk. Each prostatic risk loci typically confers only a small incremental risk of cancer, but combinations are more impactful. Some mutated genes such as *BRCA2, HOXB13, ATM*, and *PALB2* clearly confer an increased risk of prostate cancer; however, that risk can be substantially modulated by presence or absence of additional genomic prostatic risk loci. Polygenic risk scores to better ascertain prostate cancer risk are under development but not routinely available for clinical care today.

The prevalence of autopsy-detected cancers is relatively similar around the world, while the incidence of clinical disease varies. In part, this is due to the substantial variations in the use of PSA screening tests. Environmental and dietary factors may play a role in prostate cancer growth and progression. High consumption of dietary fats, such as α-linoleic acid or polycyclic aromatic hydrocarbons that form when red meats are cooked, is believed to increase risk. Like breast cancer in Asians, the risk of prostate cancer in Asians increases when they move to Western environments. Reasons for this are poorly understood but in part likely reflect a greater probability of PSA screening tests in the Western world. Protective factors may include consumption of lycopene found in tomatoes and inhibitors of cholesterol biosynthesis (e.g., statin drugs). Not smoking and avoiding obesity reduce the risk of disease progression.

DIAGNOSIS AND TREATMENT BY CLINICAL STATE

The prostate cancer continuum—from the appearance of a preneoplastic and invasive lesion that is localized to the gland to a metastatic lesion causing symptoms and, ultimately, mortality—can span years to decades. To limit overdiagnosis of clinically insignificant cancers and for disease management in general, competing risks are considered in the context of a series of clinical states **(Fig. 92-1)**. The states are defined operationally based on whether or not a cancer diagnosis has been established and, for those with a diagnosis, the state of the primary tumor (treated vs untreated), the presence of absence of metastases on imaging studies, and the measured level of testosterone in the blood. With this approach, an individual resides in only one state and remains in that state until progression. At each assessment, the decision to offer treatment and the specific form of treatment are based on the presence or absence of cancer-related symptoms and, if absent, the risk posed by the cancer relative to competing causes of morbidity and mortality that may be present in that individual. It follows that the more advanced the disease, the greater is the need for treatment. Individual decision-making and patient preferences are key for prostate cancer throughout the continuum. Considerable heterogeneity can be encountered in patients seeking treatment recommendations given widely varying perceptions of risks and benefits, especially for those with early-stage disease.

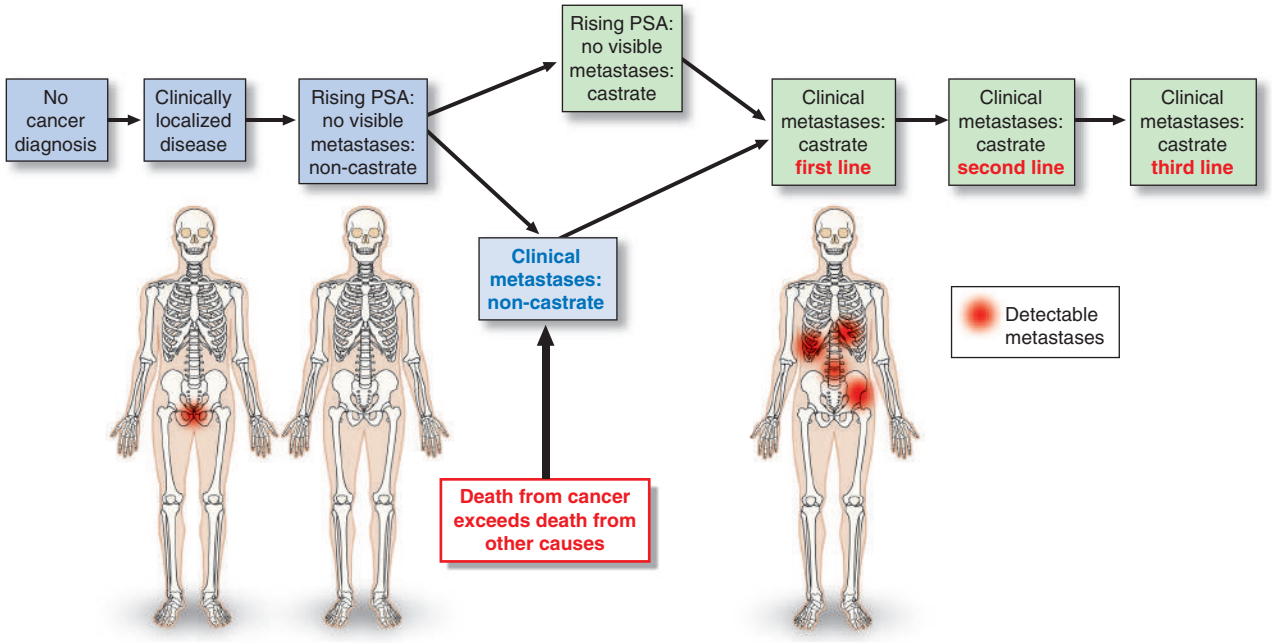

FIGURE 92-1 Clinical states of prostate cancer. PSA, prostate-specific antigen.

For those without a cancer diagnosis, the decision to undergo testing to detect a cancer is based on the individual's estimated life expectancy and, separately, the probability that a clinically significant cancer may be present. For those with a prostate cancer diagnosis, the clinical states model considers the probability of developing symptoms or dying from the disease. Thus, a patient with a localized tumor that has been surgically removed remains in the state of localized disease if the PSA remains undetectable. The time within a state then becomes a measure of the efficacy of an intervention. Because many patients with active cancer are not at risk for developing metastases, symptoms, or death, the clinical states model allows a distinction between cure—the elimination of all cancer cells, the primary therapeutic objective of treatment for most cancers—and cancer control, by which the tempo of the illness is determined to be so slow or has been altered by treatment to the point where it is unlikely to cause symptoms, to metastasize, or to shorten a patient's life expectancy. Importantly, from a patient standpoint, both outcomes can be considered equivalent therapeutically assuming the patient has not experienced symptoms of the disease or the treatment needed to control it. Even when a recurrence is documented, immediate therapy is not always necessary. Rather, as at the time of diagnosis, the need for intervention is based on the tempo of the illness as it unfolds in the individual, relative to the risk-to-benefit ratio of the intervention being considered. Assessment of the future risk and tempo of the cancer, balanced with an understanding of the patient's morbidities and life expectancy, is key to management of prostate cancer.

NO CANCER DIAGNOSIS

Prevention No agent is currently approved for the prevention of prostate cancer. The results from several large double-blind, randomized chemoprevention trials have established 5α-reductase inhibitors (5ARIs) as the predominant therapy to reduce the future risk of a prostate cancer diagnosis; however, most of the prevented cancers were low risk, and those cancers typically require no treatment as their natural history is indolent. No drug is approved for prostate cancer prevention. Various vitamins and supplements have been studied in large-scale prostate cancer prevention trials, but no intervention has been shown to be effective.

Early Detection and Diagnosis The decision to pursue a diagnosis of prostate cancer must balance the benefit from detecting and treating clinically significant cancers that, left untreated, would adversely affect a patient's quality and duration of life, against the morbidity associated with the overtreatment of clinically insignificant cancers highly prevalent in the general population. The balance is best approached through shared decision-making between the patient and physician; however, the complexities of the subject and the limited time available for most primary care physicians often preclude truly informed decisions. Considerations regarding whether to pursue a diagnosis include symptoms, an abnormal DRE, or more typically, a change in or elevated serum PSA. Genetic risk and family history are also relevant in the decision-making process, and those with a family history of lethal cancer represent patients of particular concern.

PHYSICAL EXAMINATION The digital rectal exam (DRE) focuses on prostate size, symmetry, consistency, and abnormalities within and/or beyond the gland. Most cancers occur in the peripheral zone and may be palpated on DRE. Carcinomas are characteristically hard, nodular, irregular, and often result in an asymmetric DRE finding. Induration may also be due to benign prostatic hyperplasia (BPH) or calculi. Overall, 20–25% of patients with an abnormal DRE have prostate cancer. The DRE is a not accepted as a validated prostate cancer screening test given the frequent false positives and false negatives associated with this exam.

PROSTATE-SPECIFIC ANTIGEN PSA (kallikrein-related peptidase 3; KLK3) is a kallikrein-related serine protease that causes liquefaction of seminal coagulum. It is produced by both nonmalignant and malignant epithelial cells and, as such, is prostate specific, not prostate cancer specific. Serum levels of PSA may increase from prostatitis, BPH, or prostate cancer. PSA circulating in the blood is inactive and mainly occurs as a complex with the protease inhibitor α_1-antichymotrypsin and as free (unbound) PSA forms. A lower free PSA is more likely to be associated with cancer at the time of biopsy. PSA levels should be undetectable after about 6 weeks if the prostate has been completely removed (radical prostatectomy). If there is no prostate, there should be no detectable PSA. Persistence of measurable serum PSA after prostate removal is typical of recurrent cancer.

PSA testing was approved by the U.S. Food and Drug Administration (FDA) in 1994 for early detection of prostate cancer, and the widespread use of the test has played a significant role in the proportion of patients diagnosed with early-stage cancers: today, >70–80% of

newly diagnosed cancers are clinically organ confined. The level of PSA in blood is strongly associated with the risk and outcome of prostate cancer. A single PSA measured at age 60 is associated (area under the curve [AUC] of 0.90) with lifetime risk of death from prostate cancer. Most (90%) prostate cancer deaths occur among patients with PSA levels in the top quartile (>2 ng/mL), although only a minority of patients with PSA >2 ng/mL will develop lethal prostate cancer. Despite this and mortality rate reductions reported from large, randomized prostate cancer screening trials, routine use of the test remains controversial given both false positives and false negatives and the fact that PSA testing may lead to the diagnosis and treatment of indolent cancers that pose little risk to the patient's overall health.

The U.S. Preventive Services Task Force (USPSTF) current guideline states, "For men aged 55 to 69 years, the decision to undergo periodic PSA-based screening for prostate cancer should be an individual one. Before deciding whether to be screened, men should have an opportunity to discuss the potential benefits and harms of screening with their clinician and to incorporate their values and preferences in the decision." The USPSTF recommends against screening men aged 70 or older. The USPSTF guideline can be accessed at *https://www.uspreventiveservicestaskforce.org/uspstf/draft-update-summary/prostate-cancer-screening-adults*. The American Urologic Association (AUA) guidelines indicate that "clinicians should engage in shared decision-making with people for whom prostate cancer screening would be appropriate and proceed based on a person's values and preferences." In contrast to the USPSTF, the AUA guidelines state that "clinicians should offer prostate cancer screening beginning at age 40 to 45 years for people at increased risk of developing prostate cancer based on the following factors: Black ancestry, germline mutations, strong family history of prostate cancer." Further, "clinicians should offer regular prostate cancer screening every 2 to 4 years to people aged 50 to 69 years." The current AUA guidelines are available at *https://www.auanet.org/guidelines-and-quality/guidelines/early-detection-of-prostate-cancer-guidelines*.

There is no rationale for recommending PSA screening in asymptomatic patients with a short life expectancy. Hence, patients over the age of 70 should only be tested in selected circumstances, such as a higher than median PSA measured before age 70 or excellent overall health. In addition, because a baseline PSA is a strong predictor of the future risk of lethal prostate cancer, patients with low PSAs, for example <1 ng/mL, can undergo testing less frequently, perhaps every 4 years, with screening possibly ending at age 60 if the PSA remains at ≤1 ng/mL

Though early detection of prostate cancer can potentially reduce the risk of prostate cancer death, high proportions of patients with screen-detected prostate cancer may not need immediate treatment and can be managed by active surveillance. The goal of prostate cancer screening should be to maximize the benefits of early cancer detection among patients who can benefit from treatment and minimize its harms.

The PSA criteria used to recommend additional testing have evolved over time. However, based on the commonly used cut point (a total PSA ≥4 ng/mL), most patients with a PSA elevation do not have histologic evidence of prostate cancer at biopsy. In addition, many patients with PSA levels below this cut point harbor cancer cells in their prostate. Information from the large Prostate Cancer Prevention Trial demonstrates that there is no PSA below which the risk of prostate cancer is zero. Thus, the PSA level helps establish the likelihood that a person will harbor cancer if he undergoes a prostate biopsy. The goal is to increase the sensitivity of the test for younger patients harboring clinically significant cancers that may shorten survival and to reduce the frequency of detecting cancers of low malignant potential in patients more likely to die of other causes. Patients with symptomatic bacterial prostatitis should have a course of antibiotics before biopsy. However, the routine use of antibiotics in an asymptomatic person with an elevated PSA level is discouraged.

SECOND-LINE SCREENING TESTS Several tests have been developed to better stratify patients with an elevated PSA test into those more or less likely to have clinically significant prostate cancer. The 4K Score Test (OPKO Lab, Nashville, TN) measures four prostate-specific kallikreins (total PSA, free PSA, intact PSA, and human kallikrein 2). The results are combined with clinical information in an algorithm that estimates an individual's percent risk of having an aggressive prostate cancer should that individual opt for a prostate biopsy.

The Prostate Health Index (PHI; Innovative Diagnostic Laboratory, Richmond, VA) is a blood test that estimates the risk of having prostate cancer. The PHI test is a combination of free PSA, total PSA, and the [–2]proPSA isoform of free PSA. These three tests are combined in a formula that calculates the PHI score. The PHI score is a better predictor of prostate cancer than the total PSA test alone or the free PSA test alone. Urine-based testing measuring exosomes (ExoDx Prostate Test) or mRNA levels of prostate cancer–related genes (Select-MDx) are also available.

The most important current test to stratify risk after detection of an elevated PSA is multiparametric prostate magnetic resonance imaging (mpMRI). The mpMRI varies from a traditional magnetic resonance imaging (MRI) by including not only the T1/T2-weighted images but also measurement of diffusion-weighted imaging with or without dynamic contrast enhancement. Using a structured reading system termed the Prostate Imaging Reporting and Data System (PI-RADS), patients can be risk stratified to determine the risk of clinically significant cancer. Data indicate that men with a PI-RADS 1–2 lesion can safely avoid biopsy, whereas patients with a PI-RADS 3–5 lesion can have targeted biopsies that are more likely to yield a true sense of the findings within the gland. The addition of an mpMRI in the prebiopsy decision-making unequivocally reduces the number of patients undergoing biopsy and reduces the diagnosis of Gleason 6 (grade group 1) cancers, without compromising the diagnosis of clinically relevant cancers. Today, an mpMRI of the prostate should be obtained in most cases prior to performing a prostate biopsy. Doing so will reduce the number of patients who are recommended to have a biopsy and improve the accuracy of the biopsies that are performed.

PROSTATE BIOPSY A diagnosis of cancer is established by an image-guided needle biopsy. Direct visualization of the gland by transrectal ultrasound (TRUS), MRI, or fusion of the ultrasound and MRI images ensures that all areas of the gland, including suspicious areas, are sampled. Contemporary schemas advise an extended-pattern 12-core biopsy that includes sampling from the peripheral zone as well as a lesion-directed palpable nodule or suspicious image-guided sampling. MRI-guided biopsy is superior to that of ultrasound-guided biopsy in terms of ascertaining an accurate depiction of the prostate pathology. Patients with an elevated PSA and a negative biopsy should continue to be followed as a negative biopsy does not rule out a future diagnosis of cancer.

PATHOLOGY Each core of the biopsy is examined for the presence of cancer, and the amount of cancer should be quantified based on the length of the cancer within the core and the percentage of the core involved. Of the cancers identified, >95% are adenocarcinomas; the rest are squamous or transitional cell tumors or, rarely, carcinosarcomas or small-cell histologies. Metastases to the prostate are rare, but colon cancers or transitional cell tumors of the bladder can invade the gland by direct extension.

When prostate cancer is diagnosed, a measure of histologic aggressiveness is assigned using the Gleason grading system, in which the dominant and secondary glandular histologic patterns are scored from 1 (well differentiated) to 5 (undifferentiated) and summed to give a total score of 6–10 for each tumor. The most poorly differentiated area of tumor (i.e., the area with the highest histologic grade) often determines biologic behavior. The presence or absence of perineural invasion and extracapsular spread should also be recorded.

Over the years, the Gleason grading system has undergone several changes. Currently, Gleason total scores of 2–5 are no longer assigned, and in practice, the lowest total score now assigned is 6. This leads to a logical yet incorrect assumption on the part of patients that a Gleason 6 cancer is in the middle of the scale, triggering the fear that their cancer is serious and the assumption that treatment is necessary despite

TABLE 92-1 TNM Classification

TNM (tumor, node, metastasis) Staging System for Prostate Cancer[a]	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Localized Disease	
T1	Clinically inapparent tumor, neither palpable nor visible by imaging
T1a	Tumor incidental histologic finding in ≤5% of resected tissue; not palpable
T1b	Tumor incidental histologic finding in >5% of resected tissue
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)
T2	Tumor confined within prostate[b]
T2a	Tumor involves half of one lobe or less
T2b	Tumor involves more than one half of one lobe, not both lobes
T2c	Tumor involves both lobes
Local Extension	
T3	Tumor extends through the prostate capsule[c]
T3a	Extracapsular extension (unilateral or bilateral)
T3b	Tumor invades seminal vesicles
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
Metastatic Disease	
N1	Positive regional lymph nodes
M1	Distant metastases

[a]Revised from SB Edge et al (eds): *AJCC Cancer Staging Manual*, 7th ed. New York, Springer, 2010. [b]Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c. [c]Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.

Abbreviation: PSA, prostate-specific antigen.

Gleason score 6 being favorable risk. To address these issues, a new five-grade group system has been developed:

Grade group 1 (Gleason score ≤6)
Grade group 2 (Gleason score 3 + 4 = 7)
Grade group 3 (Gleason score 4 + 3 = 7)
Grade group 4 (Gleason score 4 + 4 = 8)
Grade group 5 (Gleason scores 9 and 10)

The new system simplifies the grading of prostate cancer, appropriately classifying the lowest risk as grade group 1 (rather than Gleason score 6), and accurately predicts prognosis.

PROSTATE CANCER STAGING The TNM (tumor, node, metastasis) staging system includes categories for cancers that are identified solely based on an abnormal PSA (T1c), those that are palpable but clinically confined to the gland (T2), and those that have extended outside the gland (T3 and T4) (Table 92-1 and Fig. 92-2). DRE alone is inaccurate in determining the extent of disease within the gland, the presence or absence of capsular invasion, involvement of seminal vesicles, and extension of disease to lymph nodes. Unfortunately, no single test has been proven to perfectly indicate the stage or the presence of organ-confined disease, seminal vesicle involvement, or lymph node spread in part due to fact that cancer cells can microscopically spread below the limits of sensitivity for any imaging test. That said, mpMRI imaging can often reveal evidence of extracapsular spread or seminal vesicle invasion with a higher degree of accuracy than DRE, and taking MRI findings into account is typically done in staging today.

Prognosis and classification for nonmetastatic prostate cancer are typically done in three broad categories (low, intermediate, and high risk). Low-risk tumors are confined to the prostate with a PSA of <10 ng/mL and grade group 1. Intermediate-risk tumors are confined to the prostate, have a PSA between 10 and 20 ng/mL, or are grade group 2 or 3 (Gleason 7). This category is typically divided into a "favorable" and "unfavorable" intermediate risk depending on grade group 2 (favorable) or 3 (unfavorable) and number of positive biopsies (>50% of cores positive for cancer is unfavorable). High-risk tumors extend outside the prostate, have a PSA >20 ng/mL, or are grade group 4 or 5 (Gleason 8–10). There is also a subset of high-risk tumors termed "very high risk" in which the cancer extends into the seminal vesicles (T3b) or adjacent organs, i.e., rectum or bladder (T4), or there are multiple biopsy samples with high-grade cancer.

Computed tomography (CT) lacks sensitivity and specificity to detect extraprostatic extension and is inferior to MRI in visualization of lymph nodes. In general, mpMRI is superior to CT to detect cancers in the prostate, to assess local disease extent, and fused with ultrasound imaging, to guide sites to biopsy within the gland. Thus, mpMRI can be quite useful for the planning of surgery and radiation therapy.

The use of prostate-specific membrane antigen (PSMA) positron emission tomography (PET) scans has radically altered the assessment of prostate cancer spread beyond the prostate. This scan is now FDA approved for patients with intermediate- and high-risk prostate cancer and is substantially more sensitive and accurate in the detection of metastases as compared to conventional imaging (including MRI). Currently, state-of-the-art staging for Gleason grade group 3 and higher patients involves PSMA PET imaging before treatment. PSMA PET scans significantly improve specificity over conventional imaging while maintaining comparable sensitivity. PSMA PET scans are not capable of detecting low-volume microscopic disease. In studies where surgically removed lymph nodes were assessed for metastatic prostate cancer, sensitivity was consistently <50%. Simply stated, PET scans cannot detect microscopic disease (<2 mm focus), and a negative scan cannot rule out the possibility of cancer spread. We emphasize that no test is capable of microscopic cancer detection and note that a "negative" scan is not equated with the definitive absence of cancer.

Radionuclide bone scans (bone scintigraphy) have been used in the past to evaluate spread to osseous sites. This test is insensitive relative to PSMA PET and nonspecific because it does not detect the cancer itself, only reaction of the bone in the presence of the cancer. Staging

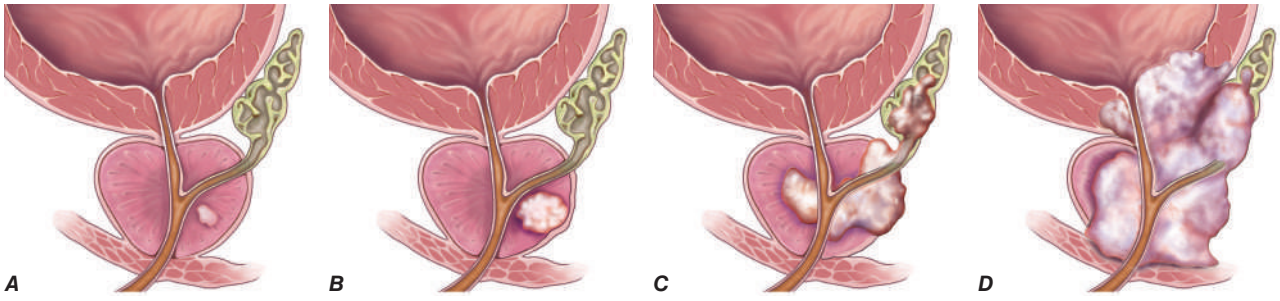

FIGURE 92-2 T stages of prostate cancer. ***A.*** T1—Clinically inapparent tumor, neither palpable nor visible by imaging. ***B.*** T2—Tumor confined within prostate. ***C.*** T3—Tumor extends through prostate capsule and may invade the seminal vesicles. ***D.*** T4—Tumor is fixed or invades adjacent structures. Eighty percent of patients present with local disease (T1 and T2), which is associated with a 5-year survival rate of 100%. An additional 12% of patients present with regional disease (T3 and T4 without metastases), which is also associated with a 100% survival rate after 5 years. Four percent of patients present with distant disease (T4 with metastases), which is associated with a 30% 5-year survival rate. (Three percent of patients are ungraded.) *(© 2010 Memorial Sloan-Kettering Cancer Center, New York, NY. All rights reserved. Republished with permission.)*

early-stage cancers with a bone scan is much less effective than using PSMA PET, and most centers no longer routinely use bone scans for initial staging in patients with suspected localized cancer given its known insensitivity and propensity for false-positive findings.

TREATMENT

Prostate Cancer

CLINICALLY LOCALIZED PROSTATE CANCER

Patients with clinically localized disease are typically managed by radical prostatectomy, radiation therapy, or active surveillance. Choice of therapy requires the consideration of several factors: the presence of symptoms, the probability that the untreated tumor will adversely affect the quality or duration of survival, and the probability that the tumor can be cured by single-modality therapy directed to the prostate versus requiring combinations of both local and systemic therapy.

There is no clear evidence for the superiority of any one form of local therapy relative to another. This is due to the lack of prospective randomized trials, referral bias and physician bias, variation in the experience of the treating teams, and differences in trial end points and the definitions of cancer control. Often, PSA relapse-free survival is used because an effect on metastatic progression or survival may not be apparent for years (if ever). A PSA recurrence does not necessarily mean that the disease will cause symptoms or shorten survival. The rate at which PSA doubles (PSA doubling time [PSADT]) is an important predictor of future clinical impact. Those with a PSADT of 14 months or greater are at low risk of clinical consequences, while those with a more rapid PSADT, especially those with a doubling time of 3 months or less, are at much higher risk for future clinically relevant events. Understanding the PSADT and the age/comorbidities of the patient is essential for decision-making.

After radical surgery to remove all prostate tissue, PSA should become undetectable in the blood within 6 weeks. If PSA remains or becomes detectable after radical prostatectomy, the patient is considered to have persistent or recurrent disease. A patient with no prostate should have no detectable PSA. After radiation therapy, in contrast, PSA does not become undetectable because the remaining nonmalignant elements of the gland continue to produce PSA even if the cancer cells have been eliminated.

Similarly, cancer control is not well defined by PSA for a patient managed by active surveillance. For patients with an intact prostate and a PSA of <10 ng/mL, the fluctuations in PSA are more reflective of the benign rather than malignant cells in the prostate. Other outcomes are time to objective progression (local or systemic), cancer-specific survival, and overall survival; however, these outcomes may take years to ascertain; thus, studies of localized disease are necessarily large, long, and often quite expensive.

The more extensive the local disease, the higher the probability of regional lymph node involvement (even when imaging studies are normal), the lower the probability of local control, and the higher the probability of relapse and the development of metastases. More important is that within the categories of clinical stage T1, T2, and T3 disease are cancers with a range of prognoses. Some T3 tumors are curable with therapy directed solely at the prostate, and some T1 lesions have a high probability of systemic relapse that requires the integration of local and systemic therapy to achieve cure. For T1c cancers, stage alone is inadequate to predict outcome and select treatment; other factors (especially Gleason score) must be considered. Genomic stratification of risk is increasingly viewed as important, and tools such as transcriptomic profiling may one day be routinely used in addition to traditional pathology.

To better assess risk and guide treatment selection, many groups have developed prognostic models or nomograms that use a combination of the initial clinical T stage, biopsy Gleason score, number of biopsy cores in which cancer is detected, and baseline PSA. Not all variables are equally important, and Gleason score is required to make accurate prognostication. Some prognostic models use discrete cut points, as mentioned above (PSA <10 or ≥10 ng/mL; Gleason score of ≤6, 7, or ≥8), while others employ nomograms that use PSA and Gleason score as continuous variables. More than 100 nomograms have been reported to predict (1) the probability that a clinically significant cancer is present, (2) disease extent (organ-confined vs non–organ-confined, node-negative or -positive), or (3) the relative probability of treatment success for specific local therapies using pretreatment variables.

Exactly what probability of success or failure would lead a physician to recommend and a patient to seek alternative approaches is controversial and highly dependent on the age and comorbidities of the patient. As an example, it may be appropriate to recommend radical surgery for a younger patient with intermediate-risk disease, while recommending surveillance for an older patient with a tumor having identical characteristics. Nomograms and various biomarkers are being refined continually to incorporate additional clinical parameters and biologic determinants that can affect outcomes, making treatment decisions a dynamic process. Patient preferences are also critically important in shared decision-making. Side effects of therapy are not the same for various treatment options, and patient preferences for one approach or another may require careful discussions that extend beyond the simple calculations of risk and benefit.

Radical Prostatectomy The goal of radical prostatectomy is to excise the cancer completely with a clear margin, to maintain continence by preserving the external sphincter, and to preserve potency by sparing the autonomic nerves in the neurovascular bundle. The procedure is advised for patients with a life expectancy of 10 years or more with a Gleason score 7 or higher disease. Radical prostatectomy can be performed via a retropubic or perineal approach or via a minimally invasive robotic-assisted or handheld laparoscopic approach. Outcomes can be predicted using postoperative nomograms that consider pretreatment factors and the pathologic findings at surgery. PSA failure is usually defined as a value >0.1 or 0.2 ng/mL, but as stated above, the patient without a prostate should typically have no detectable PSA. Specific criteria to guide the choice of one surgical approach over another are lacking. Minimally invasive approaches offer the advantage of a shorter hospital stay and reduced blood loss. Rates of cancer control, recovery of continence, and recovery of erectile function are comparable for robotic and open surgery. The individual surgeon, rather than the surgical approach used, is most important in determining outcomes after surgery.

Neoadjuvant hormonal treatment with gonadotropin-releasing hormone (GnRH) agonists/antagonists alone has also been explored to improve the outcomes of surgery for high-risk patients using a variety of definitions. The results of several large trials evaluating 3 or 8 months of androgen depletion before surgery have not been shown to improve clinically relevant outcomes. Currently, neoadjuvant hormonal therapies are not considered to be standard of care for surgically treated patients.

Factors associated with incontinence following radical prostatectomy include older age and membranous urethral length, which impacts the ability to preserve the urethra beyond the apex and the distal sphincter. The skill and experience of the surgeon are also critical factors.

The likelihood of recovery of erectile function is associated with younger age, quality of erections before surgery, and the absence of damage to the neurovascular bundles. In general, erectile function begins to return ~6 months after surgery if neurovascular tissue has been preserved. Potency is reduced by half if at least one neurovascular bundle is sacrificed. Overall, with the availability of drugs such as sildenafil, intraurethral inserts of alprostadil, and intracavernosal injections of vasodilators, many patients recover satisfactory sexual function.

Radiation Therapy Radiation therapy is given by external beam, by radioactive sources implanted into the gland, or by a combination of the two techniques.

Contemporary external beam intensity-modulated radiation therapy (IMRT) permits shaping of the dose and allows the delivery of higher doses to the prostate and a dramatic reduction in normal tissue exposure compared to three-dimensional conformal treatment alone. These advances have enabled the safe administration of doses >78 Gy and resulted in higher local control rates and fewer side effects. Proton beam radiation has not been demonstrated to have superior outcomes as compared to conventional radiation with IMRT. Lack of randomized studies prevents the use of routinely adopting proton beam as a standard of care.

Cancer control after radiation therapy has been defined by various criteria, including a decline in PSA to <0.5 or 1 ng/mL, "nonrising" PSA values, and (rarely) a negative biopsy of the prostate 2 years after completion of treatment. The standard definition of biochemical failure is a rise in PSA by ≥2 ng/mL higher than the lowest PSA achieved; however, newer data question whether the cutoff should be lower, particularly in those with higher grade cancers.

Radiation dose is critical to the eradication of prostate cancer. In a representative study, a PSA nadir of <1.0 ng/mL was achieved in 90% of patients receiving 81.0 Gy versus 76% and 56% of those receiving 70.2 and 64.8 Gy, respectively. Positive biopsy rates at 2.5 years were 4% for those treated with 81 Gy versus 27% and 36% for those receiving 75.6 and 70.2 Gy, respectively. Higher doses of radiation, however, may be associated with a higher risk of adverse events.

Hypofractionation schedules, utilizing fewer treatments of higher radiation doses, have been evaluated and shown to provide good cancer control rates based on posttreatment biopsies showing no evidence of cancer, with no apparent increase in treatment-related morbidity. Hypofractionated treatments can range from as few as 5 treatments to upward of 26 treatments, with both regimens representing substantial reductions in treatment length.

Multiple clinical trials have evaluated the use of androgen deprivation therapy (ADT) in combination with radiation. In patients with unfavorable intermediate-risk prostate cancer, short-course ADT (6 months), when combined with external beam radiotherapy, has demonstrated significant improvements in overall survival. Higher doses of radiation cannot substitute for ADT. In patients with high-risk localized disease, longer courses of ADT (18–36 months) have proven superior to shorter courses and represent the current standard of care when combined with radiotherapy. Novel genomic and transcriptomic biomarkers are being explored to assess the responsiveness of tumors to ADT, but as of yet, there are no accepted biomarkers that determine who should or should not receive ADT. Artificial intelligence assessments are promising, and new assays suggest the possibility that prostate cancers treated with radiation can be stratified into those that do and do not benefit from androgen deprivation.

For patients with nonmetastatic cancer by conventional imaging (bone scan, CT, or MRI) and two or more high risk factors (Gleason 8–10, stage T3/T4, or PSA ≥40 ng/mL) or positive pelvic lymph nodes, a large randomized trial demonstrated that the addition of abiraterone/prednisone to 2 years of ADT and radiotherapy is superior to 3 years of ADT and radiotherapy. This study defined a new standard of care for these particularly high-risk patients.

The Prostate Testing for Cancer and Treatment (ProtecT) trial investigated the effects of active monitoring, radical prostatectomy, and radical radiotherapy with hormones on patient-reported outcomes in patients diagnosed with predominantly low-risk prostate cancer (~75% with Gleason score 6 or grade group 1 cancer). Cancer outcomes were essentially the same for these three approaches. Patient-reported outcomes among 1643 patients who completed questionnaires before diagnosis, at 6 and 12 months, and annually thereafter were compared. Of the three treatments, prostatectomy had the greatest negative effect on sexual function and urinary continence, and although there was some recovery, these outcomes remained worse in the prostatectomy group than in the other groups throughout the trial. The negative effect of radiotherapy on sexual function was greatest at 6 months, but sexual function then recovered somewhat and was stable thereafter; radiotherapy had little effect on urinary continence. Sexual and urinary function declined gradually in the active-monitoring group. Bowel function was worse in the radiotherapy group at 6 months than in the other groups but then recovered somewhat, except for the increasing frequency of bloody stools; bowel function was unchanged in the other groups. Urinary voiding and nocturia were worse in the radiotherapy group at 6 months but then mostly recovered and were like the other groups after 12 months. Effects on quality of life mirrored the reported changes in function. No significant differences were observed among the groups in measures of anxiety, depression, or general health-related or cancer-related quality of life. Taken together, both surgery and radiation had clear side effects, but these side effects were distinct.

Brachytherapy Brachytherapy is the direct implantation of radioactive sources into the prostate. It is based on the principle that the deposition of radiation energy in tissues decreases as a function of the square of the distance from the source **(Chap. 78)**. The goal is to deliver intensive irradiation to the prostate, minimizing the exposure of the surrounding tissues. The current standard technique achieves a more homogeneous dose distribution by delivering radiation according to a customized template based on imaging assessment of the cancer and computer-optimized dosimetry. The implantation is typically performed transperineally as an outpatient procedure with real-time imaging.

Improvements in brachytherapy techniques have resulted in fewer complications and a marked reduction in local failure rates. In a series of 197 patients followed for a median of 3 years, 5-year actuarial PSA relapse–free survival for patients with pretherapy PSA levels of 0–4, 4–10, and >10 ng/mL were 98, 90, and 89%, respectively. In a separate report of 201 patients who underwent posttreatment biopsies, 80% were negative, 17% were indeterminate, and 3% were positive. The results did not change with longer follow-up. Brachytherapy is well tolerated, although most patients experience urinary frequency and urgency that can persist for several months. Higher complication rates are observed in patients who have undergone a prior transurethral resection of the prostate (TURP), while those with obstructive symptoms at baseline are at a higher risk for retention and persistent voiding symptoms. Proctitis has been reported in <2% of patients. Like surgery, brachytherapy is best performed by those well-practiced in the technique.

Active Surveillance With the advent of PSA testing, many patients are diagnosed with low-risk prostate cancers that may not pose a threat to either the quantity or quality of a person's life. Active surveillance, described previously as watchful waiting or deferred therapy, initially evolved from (1) studies that evaluated predominantly elderly patients with well-differentiated tumors (Gleason 6 or grade group 1) who remained untreated and demonstrated no clinically significant progression for protracted periods, (2) recognition of the contrast between incidence and disease-specific mortality, (3) the high prevalence of autopsy cancers, and (4) an effort to reduce overtreatment and treatment-related side effects. In practice, active surveillance is the treatment recommended to patients with cancers of low aggressiveness that can be safely monitored at fixed intervals with DREs, PSA measurements, imaging (best done with prostate mpMRI), and repeat prostate biopsies as indicated until histopathologic or serologic changes correlative of progression warrant treatment with curative intent. It is important to recognize that no treatment has proven superior to active surveillance for those with PSA-detected grade group 1 (Gleason score 6) disease. Surveillance remains underutilized today, and needless morbidity can result from overtreatment of those who have little chance to benefit from therapy given the indolent nature of the vast majority of patients with Gleason 6 localized disease.

Case selection is critical, and determining the clinical parameters predictive of cancer aggressiveness that can be used to reliably select patients most likely to benefit from active surveillance is an area of intense study. One set of criteria includes patients with clinical T1c

tumors that are biopsy Gleason grade 6. Nomograms to help predict which patients can safely be managed by active surveillance continue to be refined, and as their predictive accuracy improves, it can be anticipated that more patients will be candidates. Older patients and those with substantial comorbidities can have more permissive criteria for surveillance including those with Gleason 3 + 4 = 7 (grade group 2) localized disease. Treatment decision-making for all localized prostate cancers depends on both the characteristics of the cancer and the age and comorbidities of the patient. Anxiety remains a problem for some patients with untreated cancers, and management of that anxiety can at times be problematic.

RISING PSA AFTER DEFINITIVE LOCAL THERAPY

Patients in this state include those in whom the sole manifestation of disease is a rising PSA after surgery and/or radiation therapy. For most of these patients in the initial phases, there is no evidence of disease on imaging studies. For these patients, the central issue is whether the rise in PSA results from persistent disease in the primary site, systemic disease, or both. Disease in the primary site may still be curable by additional local treatment.

The decision to recommend radiation therapy after prostatectomy is guided by the age and comorbidities of the patient, pathologic findings at surgery, the timing of PSA failure, the PSA doubling time, and the PSA level at the time of failure. Traditional imaging (MRI, CT, and radionucleotide bone scans), especially at low levels of PSA, is typically uninformative, but newer imaging methods may or may not be useful.

New PET tracers such as ^{18}F-fluciclovine and ^{18}F- or ^{68}Ga-PSMA that directly image the cancer are more sensitive and can detect low-volume disease in the prostate bed or other sites to better inform the decisions regarding treatment. Detection rates, both in and outside the prostate bed, correlate with the absolute level of PSA and the rate of PSA rise. Factors that predict for response to salvage radiation therapy after radical prostatectomy are a positive surgical margin, lower Gleason score in the surgical specimen, a long interval from surgery to PSA failure, slower PSA doubling time, a low (<0.5 ng/mL) PSA value at the time of radiation treatment, and the absence of distant disease when using a PSMA or fluciclovine PET scan.

For patients with a rising PSA after radiation therapy, salvage local therapy can be considered if persistent disease has been documented by a biopsy of the prostate and if no disease is detectable outside of the prostate bed or regional lymph nodes by imaging. Unfortunately, case selection is poorly defined in most series. Local treatment options for patients with recurrence after radiation include salvage radical prostatectomy, salvage cryotherapy, salvage radiation therapy, and salvage high-intensity focused ultrasound. Unfortunately, morbidities can be significant in the postradiated patient.

A rise in PSA after surgery or radiation therapy may indicate subclinical or micrometastatic disease with or without local recurrence. The need for treatment depends, in part, on the estimated probability that the patient will develop clinical symptoms and in what time frame. That immediate therapy is not always required was shown in a well-annotated series where patients who developed a rising PSA after radical prostatectomy received no systemic therapy until metastatic disease was documented. Overall, the median time to metastatic progression was 8 years, and 63% of the patients with rising PSA values remained free of metastases at 5 years. Factors associated with progression included the Gleason score of the radical prostatectomy specimen, time to recurrence after surgery, and PSADT. For those with Gleason score ≥8, the probability of metastatic progression was 37, 51, and 71% at 3, 5, and 7 years, respectively. If the time to recurrence was <2 years and PSADT was long (>10 months), the proportions with metastatic disease at the same time intervals were 23, 32, and 53%, versus 47, 69, and 79% if the doubling time was short (<10 months).

PSADTs are also prognostic for survival. Most physicians advise treatment when PSA doubling times are ≤10 months. A difficulty with predicting the risk of metastatic spread, symptoms, or death from disease in the rising PSA state is that many patients receive some form of therapy before the development of metastases as detected by conventional imaging. Nevertheless, predictive models continue to be refined with a consensus that lower risk patients can be watched, whereas higher risk patients may require some intervention. Given that new molecular imaging techniques are now FDA approved, the interplay between imaging and risk continues to be refined.

METASTATIC DISEASE: NONCASTRATE

The state of noncastrate metastatic disease includes patients with metastases visible on an imaging study at the time of diagnosis or after local therapy(ies) who have noncastrate levels of testosterone (>50 ng/dL). The prognosis is distinct for those with metastases detected by conventional imaging versus those detected only with molecular imaging. Symptoms of metastatic disease may include pain from osseous spread, although many patients are asymptomatic despite extensive spread. Less common are symptoms related to weight loss, fatigue, malaise, lymphedema, marrow infiltration by tumor (myelophthisis), coagulopathy, blood clots, or spinal cord compression. Standard treatment is to deplete or lower androgens via ADT by medical or surgical means, the latter being the least acceptable to patients. More than 90% of male hormones originate in the testes; <10% are synthesized in the adrenal gland **(Fig. 92-3)**.

Testosterone-Lowering Agents Medical therapies that lower testosterone levels include the GnRH agonists/antagonists, pure GnRH antagonists, 17,20-lyase inhibitors, CYP17 inhibitors, and estrogens such as oral diethylstilbestrol (DES) (Fig. 92-3). DES is not utilized today due to the excessive risk of vascular complications that include fluid retention, phlebitis, emboli, and stroke. GnRH agonists, such as leuprolide acetate and goserelin acetate, initially produce a very brief rise in luteinizing hormone and follicle-stimulating hormone followed by a downregulation of receptors in the pituitary gland, which causes a chemical castration. Regulatory approval was based on randomized trials showing reduced cardiovascular toxicities relative to DES, with equivalent potency. The initial rise in testosterone may occasionally result in a clinical flare of the disease, and as such, these agents are relatively contraindicated in patients with significant urinary obstructive symptoms, cancer-related pain, or spinal cord compromise. AR antagonists that block testosterone binding to the receptor are commonly used to reduce the risk of flare. Increases in testosterone do not occur with GnRH antagonists such as degarelix, given by injection, or relugolix, given orally, and these agents as well as abiraterone acetate rapidly achieve castrate levels of testosterone.

Agents that lower testosterone are associated with an androgen-deprivation syndrome that includes hot flushes, weakness, fatigue, loss of muscle mass, risk of osteoporosis and fracture, anemia, changes in cognition and personality, and depression. Changes in lipids, obesity, and insulin resistance and an increased risk of diabetes and cardiovascular disease may also be seen, along with a decrease in bone density that worsens over time and may result in an increased risk of clinical fractures. This is a particular concern in patients with preexisting osteopenia that results from hypogonadism that may be worsened with steroid or alcohol use and significantly underappreciated. Baseline fracture risk can be assessed using the FRAX scale, and to minimize fracture risk, patients can be advised to take a bisphosphonate or RANK-ligand inhibitor (denosumab) in combination with calcium and vitamin D supplementation. Hot flushes may be ameliorated by oxybutynin or certain antidepressants such as venlafaxine.

Antiandrogens Nonsteroidal first-generation antiandrogens such bicalutamide and nilutamide have largely been replaced by the more potent next-generation agents (enzalutamide, apalutamide, and darolutamide) that do not lower serum androgen levels and result in fewer hot flushes, less of an effect on libido, less muscle wasting, fewer personality changes, and less bone loss relative to

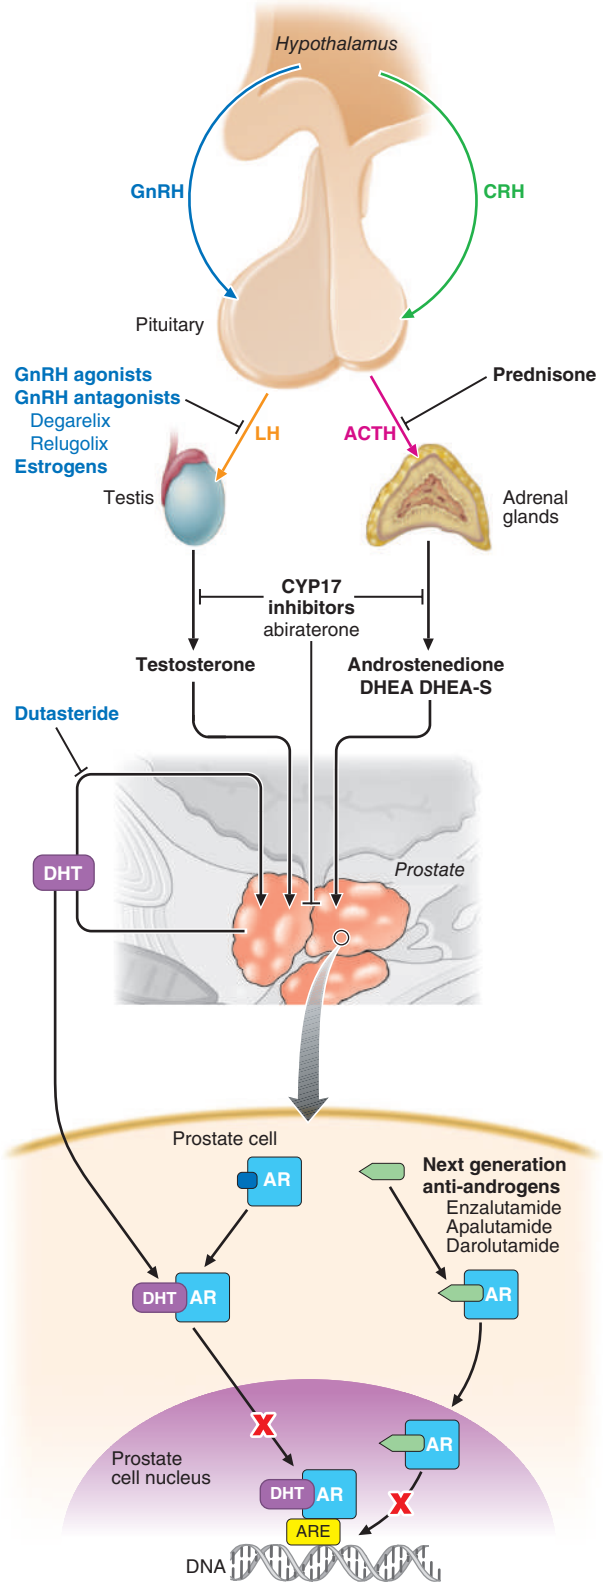

FIGURE 92-3 Sites of action of different hormone therapies.

testosterone-lowering therapies. However, over time, testosterone levels increase and are converted to estrogen, which can result in mastalgia and gynecomastia that limits long-term use. The side effect of antiandrogens as monotherapy can be prevented in part by tamoxifen, aromatase inhibitors, or prophylactic breast irradiation.

Most reported randomized trials in metastatic patients suggest that the cancer-specific outcomes are inferior when antiandrogens are used alone. Bicalutamide, even at a dose of 150 mg (three times the approved dose for use in combination in GnRH agonists), resulted in a shorter time to progression and inferior survival compared to surgical castration for patients with established metastatic disease. Newer studies for those without metastatic disease suggest that enzalutamide is appropriate in selected patients with a PSADT of 10 months or less.

Improving on the outcomes with ADT alone was a focus of the field for decades. Older antiandrogens such as bicalutamide or flutamide did not convincingly achieve these goals. Practice standards changed when an improvement in time to progression and overall survival was shown when ADT was combined with docetaxel relative to ADT alone. The greatest benefit was seen for patients with "high-volume" disease defined as the presence of ≥4 lesions on radionuclide bone scan or visceral disease. Longer progression-free and overall survival times have been noted in separate phase 3 trials comparing ADT with abiraterone, a CYP17 inhibitor that blocks androgen synthesis, and ADT with the AR antagonists such as enzalutamide and apalutamide versus the ADT standard, further changing the standard of care.

Intermittent Androgen Deprivation Therapy One way to reduce the side effects of androgen depletion is to administer hormonal therapy on an intermittent basis; however, the use of this approach in metastatic disease has yet to be proven useful for those being treated with ADT plus a novel hormone such as abiraterone, apalutamide, or enzalutamide. Additional studies in the metastatic setting with intermittent therapy are under consideration.

Chemotherapy Studies with ADT plus docetaxel indicate that patients with high-volume metastatic disease benefit from the addition of docetaxel. However, more recent studies indicate that ADT and docetaxel are not appropriate choices today given that the addition of abiraterone or darolutamide is superior to that of ADT plus docetaxel. Consultation with a clinician practiced in the art of advanced prostate cancer is appropriate given the rapidly changing standards of care.

Outcomes of Androgen Deprivation The anti–prostate cancer effects of the various newer androgen depletion strategies (abiraterone, apalutamide, or enzalutamide in combination with medical or surgical castration) are similar, and the clinical course is predictable: an initial response, a period of stability in which tumor cells are dormant and nonproliferative, followed after a variable period of time by a rise in PSA and regrowth that is visible on a scan as a castration-resistant lesion. Androgen depletion is not curative because cells that survive castration are present when the disease is first diagnosed. Considered by disease manifestation, PSA levels return to normal in 60–70% of patients, and measurable disease regression occurs in >50%. Duration of survival is inversely proportional to disease extent at the time androgen depletion is first started and the nadir level of PSA at 6–8 months. Patients with nadir PSA values >4 ng/mL have markedly inferior survival times and should be considered for alternative approaches.

METASTATIC DISEASE: CASTRATE

Castration-resistant prostate cancer (CRPC), disease that progresses while the measured levels of testosterone in the blood are 50 ng/mL or lower, can produce some of the most feared complications of the disease and is lethal for most patients. The most common manifestation is a rising PSA, frequently co-occurring with progression in bone. Nodal and/or visceral progression is less frequent. Symptoms may or may not be present. Critical for management is that therapeutic objectives be based on the manifestations of the disease in the individual at the time a change in therapy is being considered. As such, for the patient with symptomatic bone disease, relief of pain can be more clinically relevant than lowering the PSA. Naturally, for all patients, the central focus is delaying or preventing disease progression, symptoms, and death from disease.

Through 2010, docetaxel was the only FDA-approved life-prolonging therapy for CRPC. Since then, our understanding of the biology of the disease has increased significantly, which in turn has led to improved therapies. It is now recognized that the majority of

metastatic CRPCs continue to express the AR and remain AR signaling dependent. For those with progression after ADT alone, the next-generation antiandrogen enzalutamide and the CYP17 inhibitor abiraterone acetate (given in combination with prednisone) have been proven to prolong life and are FDA approved for use in CRPC in both the pre- and postchemotherapy setting.

Large-scale molecular profiling efforts have led to a biologically based disease taxonomy that continues to evolve and showed a markedly higher than expected frequency of germline (~6% of patients) and somatic *BRCA* (also ~6% of patients) alterations, along with other genes in the DNA damage repair pathway that have been targeted successfully with poly-ADP ribose polymerase (PARP) inhibitors of which two, olaparib and rucaparib, are FDA approved as monotherapies. Combinations of abiraterone and olaparib are FDA approved for *BRCA1/BRCA2*-mutated CRPC patients, and enzalutamide/talozaparib combinations are approved for *BRCA1/BRCA2*-mutated patients and other DNA repair pathway mutations. Also approved are the checkpoint inhibitors pembrolizumab and dostarlimab for tumors with high microsatellite instability (MSI) scores, mismatch repair gene deficiency, or patients with a high tumor mutational burden. These alterations are found in ~3% of prostate cancers.

Other classes of therapy approved for selected CRPC patients based on demonstrated survival benefits include the biologic agent sipuleucel-T, the second-generation taxane cabazitaxel, the α-emitting bone-targeting radiopharmaceutical radium-223, and the PSMA-directed radionuclide therapy 177-lutetium PSMA-617. The use of 177-lutetium PSMA-617 has garnered intense interest given that this targeted form of radiation was able to extend survival in patients who had exhausted most conventional forms of therapy. Overall, an intense focus of current CRPC research is to understand the optimal sequence in which to utilize these agents to maximize benefit for the individual patient. Most of these agents are also being tested earlier in the course of the disease when tumor burdens are lower and the disease less heterogeneous. The result has been an increase in the frequency of late-state tumors that have undergone a lineage transformation from epithelial to alternative phenotypes (neuroendocrine and more) and are highly resistant to available therapies.

Pain Management Pain secondary to osseous metastases is one of the most feared complications of the disease and a major cause of morbidity, worsened by the narcotics needed to control symptoms.

Management requires accurate diagnoses because noncancer etiologies including degenerative disease, spinal stenosis, and vertebral collapse secondary to bone loss are common. Neurologic symptoms, including those suggestive of base of skull disease or spinal cord compromise, require emergency evaluation because loss of function may be permanent if not addressed quickly. Neurologic symptoms and loss of function are best treated with external beam radiation, as are single sites of pain. Diffuse symptoms in the absence of neurologic deficits can be treated with bone-seeking radioisotopes, such as radium-223 or the β emitter ^{153}Sm–ethylene-diamine-tetramethylene-phosphonic acid (EDTMP); mitoxantrone; or other systemic therapies. Radium-223 is indicated for patients with symptoms and has been shown to prolong survival, whereas ^{153}Sm-EDTMP and mitoxantrone are approved for the palliation of pain but have not been shown to prolong life. Abiraterone, enzalutamide, docetaxel, cabazitaxel, and Lu-177 PSMA-617 do not have a formal indication for pain but were shown to palliate pain in the registration trials that led to their approval by showing a survival benefit.

Other bone-targeting agents, including bisphosphonates such as zoledronic acid and the RANK-ligand inhibitor denosumab, have been shown to reduce the frequency and development of skeletal complications including pain requiring analgesia, neurologic compromise from epidural extension of tumor, and/or the need for surgery or radiation therapy to treat symptomatic osseous disease. It is important to note that, for all of these agents, the direct effects on the tumor are limited and benefits are seen without declines in PSA or improvements on imaging.

BENIGN DISEASE

BENIGN PROSTATIC HYPERPLASIA

BPH is a pathologic process that contributes to the development of lower urinary tract symptoms (LUTS) in patients. LUTS, arising from lower urinary tract dysfunction, are further subdivided into obstructive symptoms (urinary hesitancy, straining, weak stream, terminal dribbling, prolonged voiding, incomplete emptying) and irritative symptoms (urinary frequency, urgency, urge incontinence, small voided volumes). LUTS and other sequelae of BPH are not just due to a mass effect but are also likely due to a combination of the prostatic enlargement and age-related detrusor dysfunction.

Diagnostic Procedures and Treatment LUTS are generally measured using a validated, reproducible index that is designed to determine disease severity and response to therapy—the AUA's Symptom Index (AUASI), also adopted as the International Prostate Symptom Score (IPSS) **(Table 92-2)**. Serial AUASI is particularly useful in

TABLE 92-2 AUA Symptom Index

QUESTIONS TO BE ANSWERED	AUA SYMPTOM SCORE (CIRCLE 1 NUMBER ON EACH LINE)					
	NOT AT ALL	LESS THAN 1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS
Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0+	1	2	3	4	5
Over the past month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	(None)	(1 time)	(2 times)	(3 times)	(4 times)	(5 times)
Sum of 7 circled numbers (AUA Symptom Score): ____

following patients as they are treated with various forms of therapy. Asymptomatic patients do not require treatment regardless of the size of the gland, while those with an inability to urinate, gross hematuria, recurrent infection, or bladder stones require evaluation and treatment. In patients with symptoms, uroflowmetry can identify those with normal flow rates who are unlikely to benefit from treatment, and bladder ultrasound can identify those with high postvoid residuals who may need intervention. Pressure-flow (urodynamic) studies detect primary bladder dysfunction. Cystoscopy is recommended if hematuria is documented and to assess the urinary outflow tract before surgery. Imaging of the upper tracts is advised for patients with hematuria, a history of calculi, or prior urinary tract problems.

Symptomatic relief is the most common reason patients seek treatment for BPH, and therefore, symptomatic relief is usually the goal of therapy for BPH. α-Adrenergic receptor antagonists are thought to treat the dynamic aspect of BPH by reducing sympathetic tone of the bladder outlet, thereby decreasing resistance and improving urinary flow. 5ARIs are thought to treat the static aspect of BPH by reducing prostate volume and having a similar, albeit delayed effect. 5ARIs have also proven beneficial in the prevention of BPH progression, as measured by prostate volume, the risk of developing acute urinary retention, and the risk of having BPH-related surgery. The use of an alpha-adrenergic receptor antagonist and a 5ARI as combination therapy seeks to provide symptomatic relief while preventing progression of BPH.

Another class of medications that has shown improvement in LUTS secondary to BPH is phosphodiesterase-5 (PDE5) inhibitors, used currently in the treatment of erectile dysfunction. All four of the PDE5 inhibitors available in the United States—sildenafil, vardenafil, tadalafil, and avanafil—appear to be effective in the treatment of LUTS secondary to BPH. The use of PDE5 inhibitors is not without controversy, however, given the fact that short-acting phosphodiesterase inhibitors such as sildenafil need to be dosed separately from alpha blockers such as tamsulosin because of potential hypotensive effects.

Symptoms due to BPH often coexist with symptoms due to overactive bladder, and the most common pharmacologic agents for the treatment of overactive bladder symptoms are anticholinergics. This has led to multiple studies evaluating the efficacy of anticholinergics for the treatment of LUTS secondary to BPH.

Surgical therapy is now considered second-line therapy and is usually reserved for patients after a trial of medical therapy. The goal of surgical therapy is to reduce the size of the prostate, effectively reducing resistance to urine flow. Surgical approaches include TURP, transurethral incision, or removal of the gland via a retropubic, suprapubic, or perineal approach. Also used are transurethral ultrasound–guided laser-induced prostatectomy (TULIP), stents, and hyperthermia.

93 Testicular Cancer

David J. Vaughn

Testicular germ cell tumors (GCTs) represent 95% of all testicular neoplasms. Non-GCTs of the testis are much less common. Approximately 5% of GCTs arise in extragonadal locations including the mediastinum, retroperitoneum, and pineal gland. Treatment for testicular GCTs is determined by pathology and stage. The development of effective chemotherapy for this disease represents a landmark achievement in oncology. About 95% of newly diagnosed patients with testicular GCTs will be cured. For this reason, testicular cancer has been called "a model for a curable neoplasm."

INCIDENCE AND GLOBAL CONSIDERATIONS

In 2023, ~9200 cases of testicular GCTs will be diagnosed in the United States, with 470 deaths. The incidence of testicular GCTs appears to be increasing worldwide. The disease has the highest incidence in Scandinavia, Western Europe, and Australia/New Zealand. Africa and Asia have the lowest incidence. The incidence in the United States and the United Kingdom is intermediate. While a distinct biology related to geography is not apparent, several countries have reported a migration to earlier stage disease in part related to public awareness and earlier diagnosis.

EPIDEMIOLOGY

Testicular GCT is the most common malignancy diagnosed in adolescent and young adult males (defined as age 15–39 years). The incidence in patients over 50 is increasing. Testicular GCT is most commonly diagnosed in Caucasians. The disease is much less commonly seen in African Americans. Testicular GCTs have an estimated heritability of almost 50%. Interestingly, the risk of GCT is higher in male siblings than in offspring of the patient. Although epidemiologic studies have been performed attempting to identify a relationship with environmental exposures, no conclusive causal links have been established.

Risk Factors The strongest risk factors for testicular GCT include a prior history of the disease, cryptorchidism, and a history of testicular germ cell neoplasia in situ. Patients with a prior history of testicular GCT have a 1–2% risk of developing a contralateral GCT. These are

more commonly metachronous than synchronous. Men with cryptorchidism have approximately a four- to sixfold increased risk of developing testicular GCT. Orchidopexy before puberty decreases but does not eliminate this risk. Interestingly, the contralateral descended testis is also at risk for this disease. Men undergoing infertility evaluation in which a testicular biopsy demonstrates germ cell neoplasia in situ have a significant risk of developing GCT. Although scrotal ultrasound of patients with testicular GCT may demonstrate testicular microcalcifications that may be related to germ cell neoplasia in situ, the significance of testicular microcalcifications in the general population is unclear.

BIOLOGY

The primordial germ cell is the cell of origin for GCTs. Most malignant GCTs arise from in situ neoplasia. The molecular events that result in the development of germ cell neoplasia in situ and subsequent malignant GCT have not been fully determined. However, genetic analysis of GCTs has demonstrated an excess copy number of isochromosome 12p (i[12p]) in most cases. Several genome-wide association studies have identified multiple independent loci associated with testicular GCT risk. The strongest of these is the *KITLG* (KIT ligand) locus on chromosome 12. These loci contribute significantly to the heritable risk of this disease.

PATHOLOGY

GCTs are either seminomas or nonseminomas. For a tumor to be considered a seminoma, it must be 100% seminoma. Any mixed GCT should be approached as a nonseminomatous GCT. Seminomas represent ~50% of cases. Seminomas arise most commonly in patients in the fourth decade of life. Seminomas may contain syncytiotrophoblastic cells, which may secrete β-human chorionic gonadotropin (hCG). Seminomas do not secrete α-fetoprotein (AFP). Seminomas are exquisitely sensitive to both chemotherapy and radiation therapy. Nonseminomatous GCTs are most commonly diagnosed in the third decade of life. The histologic subtypes include embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma. Embryonal carcinoma is the most undifferentiated nonseminomatous GCT subtype with the potential to differentiate into the other subtypes. Embryonal carcinoma may secrete AFP, hCG, both, or neither. Yolk sac tumor often secretes AFP. Choriocarcinoma is an aggressive subtype, often secreting hCG at very high levels. These nonseminomatous GCT subtypes are all considered chemotherapy sensitive. Teratoma is composed of somatic cell types that are derived from two or more germinal layers (endoderm, mesoderm, and ectoderm). Teratomas are classified as mature, in which cell types resemble normal adult somatic tissue; immature, in which cell types resemble fetal somatic tissue; and malignant, in which the cell types have undergone malignant transformation into the malignant counterpart of the somatic tissue. Teratomas are chemotherapy resistant and must be treated surgically.

INITIAL PRESENTATION

Signs and Symptoms Although a painless testicular mass is pathognomonic of a GCT, most patients present with testicular swelling, firmness, discomfort, or a combination of these. The differential diagnosis may include epididymitis or orchitis, and a trial of antibacterials may be considered. Patients with retroperitoneal metastases may complain of back or flank pain. Patients may have cough, shortness of breath, or hemoptysis because of lung metastases. In patients with elevation of serum hCG, gynecomastia may be present. Diagnostic delay is not uncommon and may be associated with a more advanced stage at diagnosis.

Physical Examination Careful examination of the affected testis and the contralateral normal testis should be performed. Many tumors will have a hard consistency to palpation. Some patients may show testicular atrophy. Evaluation for supraclavicular lymphadenopathy, gynecomastia, and abdominal mass should be performed. Inguinal lymphadenopathy is rare. Most patients with lung metastases will have normal auscultation of the lungs.

Diagnostic Testing If a firm testicular mass is identified, a scrotal ultrasound should be performed. Patients with suspected epididymitis or orchitis who do not respond to antibiotics should also undergo scrotal ultrasound. Scrotal ultrasound should include both testicles. On ultrasound, a testicular GCT is hypoechoic and may be multifocal. A solid mass identified on ultrasound should be considered malignant until otherwise proven. Transscrotal aspiration or biopsy of a testicular mass should never be performed. Such scrotal violation may result in tumor seeding of the scrotum or inguinal lymph nodes.

Serum Tumor Markers Serum AFP, hCG, and lactate dehydrogenase (LDH) should be measured in patients suspected of testicular GCT. AFP is elevated in ~60–70% of patients who present with nonseminomatous GCTs. Seminomas never secrete AFP. A patient with a seminoma with elevation of AFP should be approached as having a nonseminomatous GCT. The half-life of AFP is 5–7 days. A falsely elevated AFP may be seen in patients with hepatic disease or a condition called hereditary persistence of AFP, in which patients may have baseline AFP levels that are mildly elevated. hCG may be elevated in both nonseminomatous GCTs as well as seminomas. Patients with choriocarcinoma may have markedly elevated levels of hCG. The half-life for hCG is 24–36 h. False-positive elevation of hCG may be seen secondary to hypogonadism, marijuana use, or because of interfering substances measured by the assay. LDH is a nonspecific marker for GCT. Its principal use is to help in the assessment of the risk classification of a patient with metastatic disease. Although elevation of serum tumor markers supports the diagnosis of a testicular GCT, most patients with seminoma and up to a third of patients with nonseminomatous GCTs do not have elevated levels. Serum microRNA (miR)-371a-3 has been identified as a promising biomarker for GCT, and validation studies are ongoing.

INITIAL MANAGEMENT

Inguinal Orchiectomy Prompt referral to urology should be performed if a testicular GCT is suspected. The initial treatment for most patients suspected of having a testicular GCT is radical inguinal orchiectomy with removal of the testicle and spermatic cord to the level of the internal inguinal ring. In patients who present with metastatic disease and the diagnosis of GCT is certain, orchiectomy may be deferred until completion of chemotherapy. Although some institutions perform testis-sparing surgery in select patients, the gold standard remains radical inguinal orchiectomy. Pathologic examination of the entire testicle is important, since testicular GCTs may be multifocal. Given the rarity of this cancer, review by an experienced pathologist is essential for accurate tumor classification. Serum tumor markers should be obtained before and after orchiectomy.

Staging The staging of testicular GCT is based on an understanding of the pattern of spread. The initial spread is by the lymphatic route to the retroperitoneal lymph nodes. A left-sided testicular GCT spreads first to the primary landing zone of left paraaortic lymph nodes inferior to the left renal vessels. A right-sided testicular GCT spreads first to the primary landing zone of the aortocaval nodes inferior to the right renal vessels. Nodal metastases may extend into the iliac regions. If scrotal violation occurred, inguinal lymph node metastases may be seen. Subsequent lymphatic spread is to the retrocrural, mediastinal, and supraclavicular lymph nodes. Hematogenous spread to the lung is the next most common site of metastasis. Metastases to the liver, bone, and brain are less common. Patients with newly diagnosed testicular GCTs should undergo computed tomography (CT) scan of the abdomen and pelvis. Chest x-ray should be performed. CT scan of the chest is performed if retroperitoneal metastases are present or if lung nodules are identified on chest x-ray. Bone scan and magnetic resonance imaging (MRI) of the brain are not routinely performed unless clinically indicated. Positron emission tomography (PET) has little role in the initial staging of testicular GCTs.

The American Joint Committee on Cancer tumor-node-metastasis (TNM) staging classification is used. There are three main stages of testicular GCT. Stage I is limited to the testis; stage II involves the retroperitoneal lymph nodes; and stage III includes lymph node involvement beyond the retroperitoneum and/or distant metastatic disease.

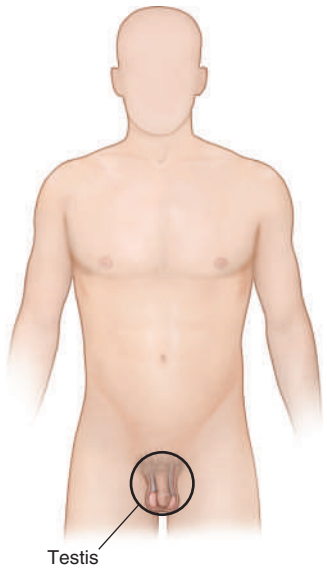
STAGE-BASED MANAGEMENT

Treatment of testicular GCT is based on two factors: (1) whether the tumor is seminoma or nonseminomatous GCT and (2) the stage of the patient. This is summarized in **Fig. 93-1**.

Stage I • **SEMINOMA** About 70% of newly diagnosed patients with seminoma present with stage I disease. This is defined as no evidence of metastatic disease on imaging of the chest, abdomen, and pelvis. Approximately 15% of patients with stage I seminoma have metastatic disease at the microscopic level, usually in the retroperitoneum. Historically, patients with stage I seminoma were treated with a course of adjuvant radiation therapy to the paraaortic lymph nodes. While still an option, this is not usually performed because of concerns for late radiation-induced secondary malignancies. Active surveillance is the most common approach elected by these patients following orchiectomy. With active surveillance, interval physical examination and CT scan of the abdomen are performed. For the 15% of patients who develop metastatic disease during active surveillance, treatment is curative in nearly all. A third option for clinical stage I seminoma is adjuvant chemotherapy with carboplatin monotherapy for one or two cycles. While effective in decreasing the risk of recurrence, most patients are cured by orchiectomy alone, and therefore, the additional treatment is unnecessary. In addition, long-term data on toxicity are not available.

NONSEMINOMATOUS GCTS About 40% of newly diagnosed patients with nonseminomatous GCTs present with stage I disease. Because nonseminomatous GCTs have an increased potential for invasion and metastasis, spread to the retroperitoneum and beyond is more common than with seminoma. If pre-orchiectomy serum tumor markers are elevated, these must normalize after orchiectomy to be considered stage I. Patients with persistently elevated or rising serum tumor markers after orchiectomy have stage IS disease and should be treated with cisplatin-based chemotherapy. If the tumor is limited to testis without lymphovascular invasion, the risk of recurrence is approximately 20%. However, if the tumor has high-risk features including lymphovascular invasion, invasion of the spermatic cord, or invasion of the scrotum, the risk of recurrence is ~50% or higher. Historically, a prophylactic retroperitoneal lymph node dissection (RPLND) was performed. This surgery is not only diagnostic but also therapeutic. In fact, most patients who undergo prophylactic RPLND will never require chemotherapy. While still an option, this approach subjects many patients to unnecessary major abdominal surgery. RPLND is also associated with a small risk of retrograde ejaculation due to nerve injury, and nerve-sparing techniques have been developed. Active surveillance is frequently performed especially for patients without lymphovascular invasion. Most patients who relapse will be treated with cisplatin-based chemotherapy and achieve cure rates approaching 100%. Active surveillance can also be employed for patients with higher risk features, although the risk of progression is significantly higher. For this reason, some advocate adjuvant cisplatin-based chemotherapy with BEP (bleomycin, etoposide, cisplatin) for one cycle for these patients. Other centers favor a prophylactic RPLND. Almost all patients who present with stage I nonseminomatous GCTs will achieve cure.

Stage II • **SEMINOMA** Approximately 15–20% of newly diagnosed patients with seminoma present with stage II disease. Patients are subgrouped into IIA, IIB, or IIC based on the size of the retroperitoneal nodes (≤2 cm, >2 to 5 cm, or >5 cm, respectively). Patients with stage IIA disease are usually treated with "dogleg" radiation therapy (referring to the shape of the radiation field), which includes the paraaortic and ipsilateral iliac nodes. Cisplatin-based chemotherapy may also be considered. Stage IIB disease is treated with cisplatin-based chemotherapy or, in select patients, radiation therapy. Most patients treated with radiation therapy who relapse will subsequently be cured with cisplatin-based chemotherapy. RPLND has been considered in select patients with stage IIA and nonbulky stage IIB seminoma in an effort to avoid chemotherapy and radiation therapy. For patients with stage IIC disease, cisplatin-based chemotherapy should be used.

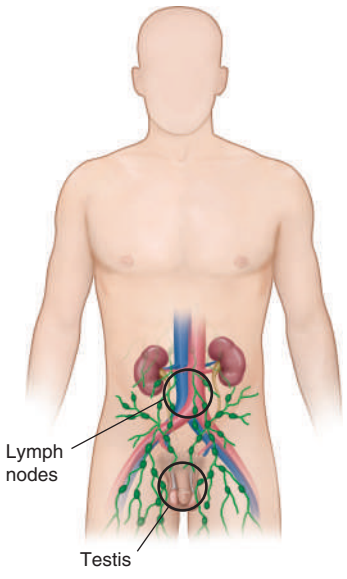


NSGCTS Approximately 15% of newly diagnosed patients with nonseminomatous GCTs present with clinical stage II disease. Patients with stage IIA disease may be treated with primary RPLND. Alternatively, these patients may be treated with cisplatin-based chemotherapy. Patients with stage IIB and IIC disease are best initially managed with cisplatin-based chemotherapy.

Stage III Patients who present with stage III GCT (seminoma or nonseminomatous GCT) are treated with cisplatin-based chemotherapy. These patients are classified into good-, intermediate-, or poor-risk categories using the International Germ Cell Consensus Classification system, which is based on clinical factors including histology, site of primary, the presence of nonpulmonary visceral metastatic disease, and the level of postorchiectomy serum tumor markers **(Table 93-1)**. Most patients with stage III GCT present with good-risk disease and >90% will be cured. The remainder present with intermediate-risk or poor-risk disease associated with 5-year survival rates of ~80% and 50%, respectively. Select patients with rapidly progressive metastatic disease and life-threatening symptoms such as hemoptysis in whom there is a high clinical suspicion of GCT should emergently initiate cisplatin-based chemotherapy, even without a tissue diagnosis.

Chemotherapy The development of cisplatin-based chemotherapy represents an important advance in cancer medicine. Through a series of carefully performed clinical trials with the aim of maximizing cure while minimizing the extent of treatment, the chemotherapy approach to the treatment of these patients has been standardized. Patients with good-risk metastatic GCT are treated with either three cycles of BEP or four cycles of etoposide and cisplatin (EP). Patients with intermediate- and poor-risk metastatic disease are treated with either four cycles of BEP or four cycles of etoposide, ifosfamide, and cisplatin (VIP). Maintaining dose and schedule is important, as dose modifications and delays have been associated with inferior outcomes. Serum tumor markers should be monitored throughout treatment and should normalize during or after treatment. Cisplatin-based chemotherapy is associated with myelosuppression, nausea and vomiting, and alopecia. Cisplatin may result in nephrotoxicity, ototoxicity, and peripheral neuropathy. Bleomycin may result in pulmonary toxicity, and risk factors for this include age >40, renal failure, tobacco use, and the cumulative dose of bleomycin received. For patients at increased risk of bleomycin-induced pneumonitis, non–bleomycin-containing regimens as noted above may be given. Cisplatin-based chemotherapy is also associated with sterility. Approximately 30% of newly diagnosed testicular GCT patients have severe oligospermia or azoospermia. For the remainder with normal baseline spermatogenesis who receive cisplatin-based chemotherapy, all will be azoospermic at the completion of therapy. Approximately 80% of these patients will recover spermatogenesis over a period of several years. For this reason, prechemotherapy sperm banking should be offered to all patients treated with chemotherapy.

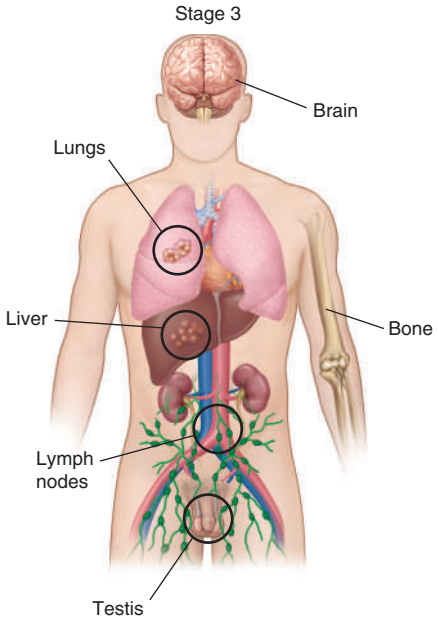
Postchemotherapy Surgery Upon completion of cisplatin-based chemotherapy, many patients with normalized serum tumor markers will have radiographic evidence of residual masses. In approximately half of patients with nonseminomatous GCT, the residual mass is composed of necrosis and/or fibrosis. About 40% will have residual teratoma, and only 10% will have residual viable nonteratomatous GCT. Unfortunately, radiographic imaging cannot accurately differentiate between these entities. For this reason, nonseminomatous GCT patients with residual masses after chemotherapy undergo resection of all sites of disease. This most commonly includes a postchemotherapy RPLND. However, thoracotomy and neck dissection are required in some patients. Given the complexity of this surgery, patients should be referred to highly experienced centers. If the patients are found to have residual necrosis or teratoma, no additional therapy is required.



Stage 1

	Seminoma	NSGCT
Stage IA Testis only, no lymphovascular invasion	Active surveillance; or Adjuvant carboplatin × 1 or 2 cycles; or Adjuvant para-aortic RT	Active surveillance; or Nerve-sparing RPLND; or Adjuvant BEP × 1 cycle
Stage IB Testis only, with lymphovascular invasion or invasion of spermatic cord or scrotum	Active surveillance; or Adjuvant carboplatin × 1 or 2 cycles; or Adjuvant para-aortic RT	Active surveillance; or Adjuvant BEP × 1 cycle; or Nerve-sparing RPLND
Stage IS Elevated serum tumor markers post-orchiectomy	BEP × 3 cycles; or EP × 4 cycles	BEP × 3 cycles; or EP × 4 cycles

A



Stage 2

	Seminoma	NSGCT
Stage IIA N1: nodes ≤ 2 cm	Para-aortic and ipsilateral iliac RT; or BEP × 3 cycles or EP × 4 cycles; Nerve-sparing RPLND in select patients	Nerve-sparing RPLND; or BEP × 3 cycles or EP × 4 cycles
Stage IIB N2: nodes > 2 to 5 cm	BEP × 3 cycles or EP × 4 cycles; or Para-aortic and ipsilateral iliac RT	BEP × 3 cycles or EP × 4 cycles +/– postchemotherapy RPLND
Stage IIC N3: nodes > 5 cm	BEP × 3 cycles or EP × 4 cycles	BEP × 3 cycles or EP × 4 cycles +/– postchemotherapy RPLND

TABLE 93-1 International Germ Cell Consensus Classification System

RISK GROUP	SEMINOMA	NSGCT
Good	Any primary site; and normal AFP, any hCG, any LDH; and nonpulmonary visceral metastases absent	Gonadal or retroperitoneal primary; and nonpulmonary visceral metastases absent; and AFP <1000 ng/mL; and hCG <5000 mIU/mL; and LDH <1.5 × ULN
Intermediate	Any primary site; and normal AFP, any hCG, any LDH; and nonpulmonary visceral metastases present	Gonadal or retroperitoneal primary; and nonpulmonary visceral metastases absent; and one of the following: AFP 1000–10,000 ng/mL HCG 5000–50,000 mIU/mL LDH 1.5–10 × ULN
Poor	N/A	Mediastinal primary; or nonpulmonary visceral metastases present; or one of the following: AFP >10,000 ng/mL HCG >50,000 mIU/mL LDH >10 × ULN

Abbreviations: AFP, α-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; N/A, not applicable; NSGCT, nonseminomatous germ cell tumor; ULN, upper limit normal. Nonpulmonary visceral metastases include liver, bone, and brain.

However, for patients with residual viable nonteratomatous GCT, two additional cycles of chemotherapy may be considered. It should be noted that in most centers, patients with minimal residual tumors defined as retroperitoneal lymph nodes of ≤1 cm forego postchemotherapy RPLND. Patients who experience normalization of serum tumor markers with first-line chemotherapy but have enlarging tumors, most often cystic masses in the retroperitoneum, may have "growing teratoma syndrome." These patients are best approached with surgery.

For patients with metastatic seminoma, most residual masses are necrotic and do not harbor viable tumor. Patients with residual masses of 3 cm or less may be observed without surgery. For patients with residual masses >3 cm, fluorodeoxyglucose (FDG)-PET may be used to distinguish necrosis from viable seminoma and identify patients who should be considered for postchemotherapy surgery or short interval imaging.

RELAPSED DISEASE

Approximately 20–30% of patients with metastatic GCTs treated with cisplatin-based chemotherapy will not achieve durable disease control. Most of these patients will experience disease progression within 2 years following completion of chemotherapy. The International Prognostic Factors Study Group developed a risk stratification classification system for patients in first relapse. Contributors to a worsened prognosis include NSGCT histology, extragonadal primary, incomplete response to first-line chemotherapy, time to relapse of 3 months or less, level of serum tumor markers at relapse, and the presence of nonpulmonary visceral metastatic disease.

Patients in first relapse may be treated with either conventional-dose salvage chemotherapy or high-dose salvage chemotherapy with autologous stem cell rescue. There is controversy concerning which approach is optimal. Some institutions advocate for risk stratification, with more favorable prognosis patients receiving conventional-dose chemotherapy and worse prognosis patients receiving high-dose chemotherapy. The most commonly utilized conventional-dose regimen includes paclitaxel, ifosfamide, and cisplatin (TIP). High-dose chemotherapy consists of initial salvage therapy followed by stem cell harvest and then two or three cycles of high-dose carboplatin and etoposide (CE) with stem cell rescue. A large retrospective analysis has compared conventional-dose salvage chemotherapy to high-dose salvage chemotherapy in patients in first relapse. This study reports a more favorable outcome with high-dose salvage chemotherapy across nearly all risk groups. However, given the retrospective nature of this study and the controversy concerning optimal approaches, an international randomized trial comparing conventional-dose chemotherapy (TIP) to high-dose chemotherapy with autologous stem cell rescue (TI-CE) has completed accrual and results are forthcoming.

Some patients who experience disease progression after conventional-dose salvage chemotherapy may successfully be treated with high-dose salvage chemotherapy with autologous stem cell rescue. Patients with disease progression after high-dose salvage chemotherapy may be treated with subsequent chemotherapy regimens that include gemcitabine/oxaliplatin, gemcitabine/paclitaxel, epirubicin/cisplatin, and oral etoposide. While these patients may benefit from third-line chemotherapy, few will achieve durable disease control. Select patients with relapsed but resectable disease may be candidates for salvage or so-called "desperation" surgery. Studies of molecularly targeted agents and immune checkpoint inhibitors in this population have to date been generally disappointing.

Patients who experience disease progression >2 years after chemotherapy are considered to have "late relapse." Late relapse appears to have a different biology than early relapse. These patients tend to have more chemotherapy-resistant disease. Patients with late relapse usually have nonseminomatous GCT with elevation of serum AFP. Many of these patients experience recurrence in the retroperitoneum many years after first-line chemotherapy, and this likely represents residual retroperitoneal disease that was not controlled after first-line therapy. These patients are best approached with salvage surgery.

EXTRAGONADAL GERM CELL TUMORS

Approximately 5% of patients who present with GCTs have extragonadal primaries. These mainly originate in the mediastinum or retroperitoneum. Patients suspected of extragonadal GCT should undergo scrotal ultrasound to exclude a gonadal primary. Extragonadal seminomas have a similar excellent prognosis as their gonadal counterparts and are approached the same. Mediastinal nonseminomatous GCTs are classified as poor risk and are treated with either four cycles of BEP or four cycles of VIP. These patients frequently require postchemotherapy thoracic surgery for residual disease. For this reason, some advocate avoiding bleomycin in this patient population. Klinefelter's syndrome is associated with an increased risk of mediastinal nonseminomatous GCTs. Rarely, mediastinal nonseminomatous GCTs are associated with hematologic disorders including acute myeloid leukemia. Nonseminomatous GCTs arising in the retroperitoneum do not have a worse prognosis than their gonadal counterparts. Many patients who present with extragonadal GCTs will undergo core needle biopsy for diagnosis. However, select patients with extragonadal tumors and definitive elevation of serum tumor markers may initiate chemotherapy without a tissue diagnosis.

Cancers of unknown primary are defined as histologically proven metastatic malignancy in which the primary site is not obvious. A subgroup of patients with cancer of unknown primary have occult GCTs. Male gender, age <65 years, midline tumors, and nonsmoking status increase the likelihood of this presentation. Pathology may demonstrate a poorly differentiated malignant neoplasm. Immunohistochemical staining is used to exclude lymphoma. Tumor may be analyzed by fluorescence in situ hybridization for i(12p), which confirms the diagnosis. Even if the diagnosis is not certain, patients should be treated with cisplatin-based chemotherapy, which will cure up to 20% of this patient group.

TESTICULAR NON–GERM CELL TUMORS

Rarely, patients may develop testicular non-GCTs. These include non-Hodgkin's lymphoma, most commonly occurring in men over the age of 50; sex cord stromal tumors including Leydig cell tumors and Sertoli cell tumors; mesothelioma of the tunica vaginalis; and paratesticular sarcoma. Metastasis to the testis is rare, most commonly occurring in patients with advanced prostate cancer and melanoma.

SURVIVORSHIP AND LATE EFFECTS

Because most patients with testicular GCT will experience long-term survival, survivorship care is important. Since primary care physicians will follow many of these patients, an understanding of the physical, psychological, and social late effects is important. Late effects are defined as health problems that occur months or years after a disease is diagnosed or after treatment has ended. Late effects may be related to the underlying cancer or to the treatment the patient received. In long-term survivors of testicular GCT, increased cardiovascular risk and increased secondary malignancies have been reported. Patients treated with cisplatin-based chemotherapy have an increased risk of hypertension, hyperlipidemia, metabolic syndrome, and cardiovascular events. Patients treated with high cumulative doses of etoposide (e.g., patients who receive standard chemotherapy, relapse, and then receive salvage high-dose chemotherapy) may experience up to a 1–2% risk of developing acute myeloid leukemia, typically 2–3 years after completing therapy and associated with an 11q23 translocation. Patients treated with radiation therapy, cisplatin-based chemotherapy, or both have an increased risk of developing secondary solid malignancies.

OVARIAN CANCER

INCIDENCE AND PATHOLOGY

Ovarian cancer remains a leading cause of cancer deaths in American women, ranking behind lung, breast, colon, and pancreatic cancers. The ovary is responsible for hormone production and egg production, including maturation and ovulation with the supporting cyclical production of sex steroid hormones. These complex biologic functions are linked to populations of stromal cells, ovarian germ cells, and the enveloping epithelial cells. Malignancies arising from each group include multiple histologic variants, each with unique neoplastic behaviors. Epithelial tumors are, by far, the most common histologic variant of ovarian neoplasms; they may be benign (50%), frankly malignant (33%), or of borderline malignancy (low malignant potential) (16%). In adnexal masses detected by imaging or physical exam,

age influences risk of malignancy; tumors in younger women are more likely benign. In the malignant group, the most common tumors are epithelial. In the group of the ovarian epithelial malignancies are the serous tumors (60–70%), mucinous tumors (10%), endometrioid tumors (10–15%), and clear cell tumors (10–15%) tumors. The distribution of histologic types varies in different parts of the world. The less common stromal tumors arise from the ancillary, supportive cells such as steroid hormone–producing cells and likewise have different phenotypes and clinical presentations. Most stromal tumors do not produce estrogen, but ectopic hormone production can be seen in certain subtypes. Tumors arising in the ovarian germ cell lineage are generally similar in biology and behavior to testicular tumors in males, although their intraperitoneal location alters some metastatic behaviors **(Chap. 93)**. Ovarian tissue may also host metastatic epithelial tumors arising from breast, colon, gastric, and pancreatic primaries. Bilateral ovarian masses from metastatic mucin-secreting gastrointestinal cancers are termed *Krukenberg tumors*. Consideration of other potential malignancies is part of the diagnostic workup of ovarian masses.

OVARIAN CANCER OF EPITHELIAL ORIGIN

Epidemiology An American woman has approximately a 1 in 72 lifetime risk (1.6%) of developing ovarian cancer, with the majority of affected women developing epithelial tumors. In 2024 in the United States, ~19,710 cases of ovarian cancer are expected to be diagnosed, with >13,270 deaths. Sporadic (not familial) epithelial tumors of the ovary have a peak incidence in women in their fifties and sixties, although age at presentation ranges from the third decade to the eighties and nineties. Ovarian cancer risk has been linked to an interactive mixture of epidemiologic, environmental, and genetic factors. Nulliparity, obesity, diet, infertility treatments, talc exposure, and possibly hormone replacement therapy have all been linked to an increase in risk. Protective factors include the use of oral contraceptives, multiparity, tubal ligation, aspirin use, and breast-feeding. Other epidemiologic factors such as the historical use of perineal talc agents remain controversial. The mechanisms underlying the various protective factors are largely unknown, but it is increasingly clear that dysplasia and in situ cancers are seen within the fallopian tube and probably are the original site for a large percentage of cancers.

Genetics and Pathogenesis Ovarian cancers are divided into type 1 cancers and the more aggressive type 2 variant. The type 1 cancers are characterized by low-grade histology and generally indolent behavior. These tumors include the low malignant potential tumors, low-grade endometrial and mucinous histologies, and clear cell cancers (which are more aggressive). Genetic alterations in type 1 cancers include mutations in *KRAS*, *BRAF*, *PTEN*, and *PIK3CA*. In contrast, type 2, high-grade serous epithelial ovarian cancers show serial genetic changes in the fallopian tube with loss of *BRCA1/2* function and *TP53* mutation leading to intraepithelial cancer in the luminal epithelium. Following these early genetic events, additional mutations in these transformed cells lead to tumor cell shedding, metastasis, and invasion. These type 2, poorly differentiated, serous cancer cells can then spread to the ovaries and the peritoneal cavity, aided by the ovarian cancer cell's expression of MUC16 and binding to mesothelin-expressing cells.

Genetically, type 2 serous ovarian cancer is classically a disease characterized by loss of *TP53* (95%) and *BRCA1/2* function in nearly all cases. Widespread amplifications and deletions rather than single-gene point mutations or common gene fusions are also present. Low prevalence but statistically recurrent somatic mutations in seven other genes including *NF1*, *RB1*, and *CDK12* were also seen. The most common heritable abnormality linked to ovarian cancer is a germline mutation in either *BRCA1* (chromosome 17q12–21) or *BRCA2* (chromosome 13q12–13). These genes are essential parts of the homologous DNA repair machinery for double-stranded DNA break repair. Individuals inheriting a single copy of a mutant allele have an increased lifetime risk of breast (46–87% for *BRCA1*; 38–84% for *BRCA2*) and ovarian cancer (39–63% for *BRCA1*; 16.5–27% for *BRCA2*). Many of these women have a family history that includes multiple cases of breast and/or ovarian cancer at an early age. Male breast cancer, pancreatic cancer, and prostate cancer are also linked to familial *BRCA2* mutations. The most common malignancy in women carrying germline *BRCA1/2* mutations is breast carcinoma, although women harboring germline *BRCA1* mutations also have a marked increased risk of developing ovarian malignancies in their forties and fifties. Women harboring a mutation in *BRCA2* have a lower penetrance of ovarian cancer with onset typically in their fifties or sixties. Other uncommon germline mutations of other genes encoding proteins linked to homologous DNA repair (e.g., *PALB2*) can also contribute to cancer risk, although the frequency of mutation and magnitude of risk increment are much lower. Germline *BRCA1/2* testing is recommended for *all* incident epithelial ovarian cancers to detect probands to identify relatives for early therapeutic intervention. Women with these high-risk germline mutations are advised to undergo prophylactic removal of fallopian tubes and ovaries after completing childbearing, ideally before age 40. Early prophylactic salpingo-oophorectomy is highly protective. Salpingo-oophorectomy also appears to protect these women from subsequent breast cancer (risk reduction 50%). Prophylactic salpingectomy is almost certainly the key part of any surgical prophylaxis strategy for ovarian cancer prevention. Although less common, women with type II Lynch syndrome caused by mutations in one of the DNA mismatch repair genes (*MSH2, MLH1, MLH6, PMS1, PMS2*) are at risk for ovarian and endometrial cancer. Like *BRCA1/2*-related cancers, these cancers develop earlier than sporadic ovarian cancer.

Neoplasms of the ovary tend to be painless unless they undergo torsion. Nonspecific gastrointestinal symptoms like bloating and early satiety are common at presentation, probably related to compression of local organs or due to symptoms from metastatic disease. Women with ovarian tumors also may have an increased incidence of symptoms including pelvic discomfort, bloating, and perhaps changes in urinary or bowel pattern. Unfortunately, these same symptoms are common in primary care and are frequently dismissed by either the woman or her health care team until later stages of disease. The pathogenic factors and timing of spread beyond the ovary are still not well understood. The most common symptoms at presentation of advanced disease include a period of progressive complaints of nausea, early satiety, bloating, indigestion, constipation, and abdominal pain. Signs include the rapid increase in abdominal girth due to the accumulation of ascites that typically alerts the patient and her physician that the concurrent gastrointestinal symptoms are likely associated with malignant pathology. Radiologic evaluation typically demonstrates a complex adnexal mass with ascites, carcinomatosis, and pelvic, para-aortic, and mesenteric adenopathy in advanced disease. Positron emission tomography (PET) scans are generally not required. Laboratory evaluation often demonstrates a markedly elevated serum CA-125, the shed mucin component (MUC16) associated with, but not specific for, ovarian cancer. Ovarian cancers are divided into four stages, with stage I tumors confined to the ovary, stage II malignancies confined to the pelvis, and stage III confined to the peritoneal cavity and retroperitoneal nodes **(Table 94-1)**. These three stages are subdivided, with the most common presentation, stage IIIC, defined as tumors with bulky intraperitoneal disease or positive lymph node involvement. About 70% of women present with stage III disease. Stage IV disease includes women with parenchymal metastases (liver, lung, spleen) or, alternatively, abdominal wall or pleural disease. The 30% of patients not presenting with stage III disease are roughly evenly distributed among the other stages.

Screening Advanced ovarian cancer is a highly lethal condition. It is curable in early stages but seldom curable in advanced stages; hence, screening continues to be of considerable interest. Early-stage tumors often secrete excessive amounts of normal proteins that can be measured in the serum such as CA-125, mesothelin, and HE-4. Nevertheless, the incidence of ovarian cancer in the middle-aged female population is very low, with only ~1 in 2000 women between the ages of 50 and 60 carrying an asymptomatic and undetected tumor. Large, well-designed screening studies, even in the mutated *BRCA1/2* families, have thus far failed to decrease ovarian cancer mortality in prospective testing. Circulating DNA approaches have also been unsuccessful so far. Screening for ovarian cancer is currently not recommended outside

TABLE 94-1 Staging and Survival in Gynecologic Malignancies

STAGE	OVARIAN	5-YEAR SURVIVAL, %	ENDOMETRIAL	5-YEAR SURVIVAL, %	CERVIX	5-YEAR SURVIVAL, %
0	—		—		Carcinoma in situ	100
I	Confined to ovary	88–95	Confined to corpus	>90	Confined to uterus	85
II	Confined to pelvic organs	70–80	Involves corpus and cervix	~75	Invades beyond uterus but not to pelvic wall	65
III	Intra-abdominal spread to omentum, diaphragm, or lymph nodes	20–40	Extends outside the uterus but not outside the true pelvis	45–60	Extends to pelvic wall and/or lower third of vagina, or hydronephrosis	35
IV	Spread outside abdominal cavity, parenchymal spread, and pleural effusion cytology	10–20	Extends outside the true pelvis or involves the bladder or rectum	~20	Invades mucosa of bladder or rectum or extends beyond the true pelvis	7

of a clinical trial, but a careful history for familial cancers and directed genetic testing for susceptibility genes are definitely appropriate.

TREATMENT

Ovarian Cancer

Epithelial ovarian cancer can be divided into distinct "disease states" for the purpose of treatment selection, as shown in Fig. 94-1. Detection by ultrasonography generally can identify a complex ovarian mass as "suspicious," but surgery by a skilled gynecologic oncologist remains the preferred initial diagnostic and therapeutic option for an isolated adnexal mass or a more involved picture of peritoneal involvement. The amount of residual visible cancer at the end of a primary operation is strongly predictive of outcome and is paired with histology, grade, and stage to determine prognosis and treatment. Metastatic disease to the ovary can be seen from primary tumors of the colon, appendix, stomach (Krukenberg tumors), and breast. Needle biopsy of adnexal masses is contraindicated to avoid malignant contamination of the peritoneal cavity with malignant cells. Typically, women undergo laparoscopic evaluation and unilateral salpingo-oophorectomy for diagnostic purposes. If pathology reveals a primary ovarian malignancy or the laparoscopy proves disseminated disease is present, then the procedure should be followed by a total hysterectomy, removal of the remaining tube and ovary, omentectomy, and pelvic node sampling along with biopsies of the peritoneal cavity and diaphragms. This extensive surgical procedure is performed because ~30% of tumors that, by visual inspection, appear to be confined to the ovary have already disseminated to the peritoneal cavity and/or surrounding lymph nodes. As with axillary dissections in breast cancer, node sampling is diagnostic, but full lymphadenectomy appears to provide little or no additional therapeutic advantage over nodal sampling. The target outcome of an ovarian cancer surgery is always an R0 resection (no visible residual cancer). The less favorable "optimal resection" (no residual disease >1 cm in size) is still clinically useful, and the prognosis of those patients is much better than that of patients who are left with >1 cm of disease at the end of surgery. These "suboptimally debulked" patients derive very little benefit from their surgery. If large deposits of unresectable residual tumor are anticipated, the surgery should be delayed until after several cycles of neoadjuvant chemotherapy. Such "interval debulking" surgery

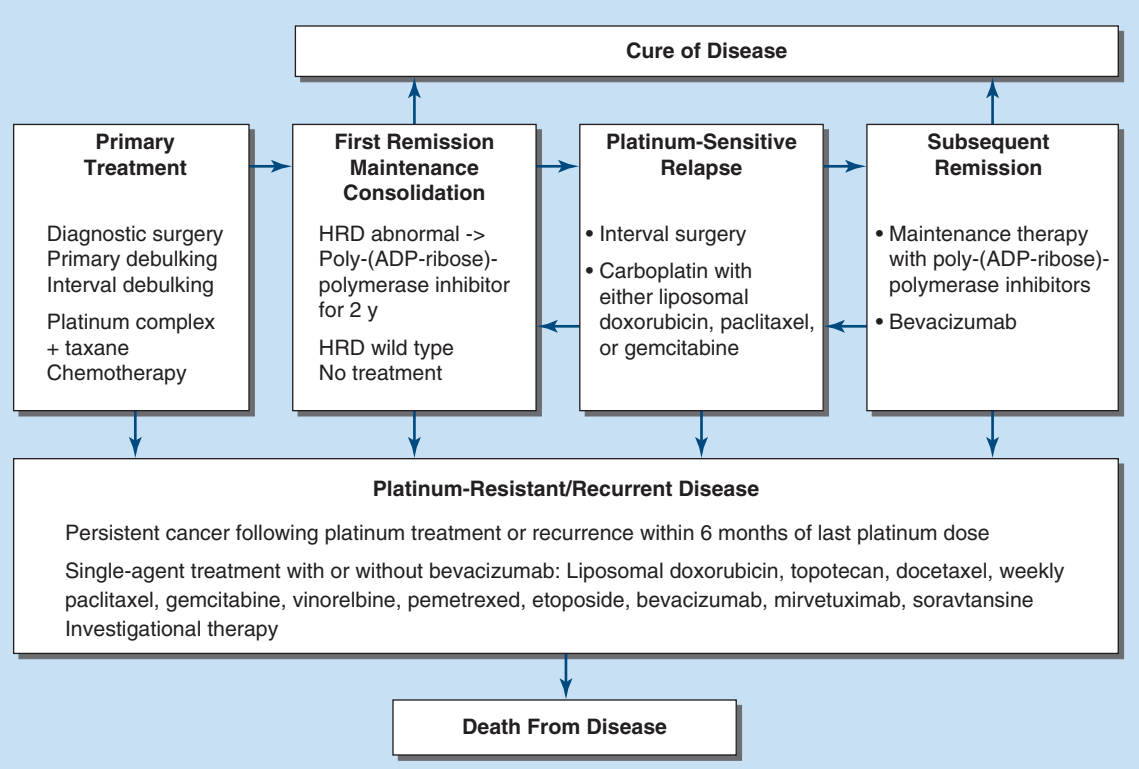

FIGURE 94-1 Disease states model of epithelial ovarian cancer and its treatment. Each box represents a relatively homogenous group of patients who share a palette of potential treatment choices and have a similar prognosis. The *arrows* indicate that a single patient may move from one state to another during the course of her illness, and the choice of treatments will become different in her new disease state. HRD, homologous recombination deficiency.

achieves similar results to primary surgery with diminished surgical morbidity and more timely chemotherapy. Patients without gross residual disease (R0 resection) after resection have a median survival in excess of 60 months, compared to 28–42 months for those left with macroscopic tumor or those undergoing interval debulking, regardless of treatment strategy.

After appropriate surgical treatment, primary chemotherapy will consist of combination treatment with paclitaxel and carboplatin. Primary chemotherapy can be delivered intravenously, or alternatively, some therapy can be directly administered into the peritoneal cavity via an indwelling catheter. The intraperitoneal approach is technically more difficult and is increasingly replaced by carboplatin and paclitaxel, which appears to offer similar results. Although interest in immunotherapy or chemoimmunotherapy has been high, immunotherapeutics have not yet improved primary chemotherapy.

With optimal debulking surgery and platinum-based chemotherapy, 70% of women who present with advanced-stage tumors show tumor reduction, and 40–50% experience a complete remission with normalization of their CA-125, computed tomography (CT) scans, and physical examination. For women with evidence of functional homologous DNA repair defects, administration of oral poly-ADP ribose polymerase inhibitors (PARPi) such as niraparib, olaparib, or rucaparib will improve survival outcomes when administered at the completion of intravenous chemotherapy as consolidation. These drugs substantially delay recurrence and provide survival advantages as well. In the majority of patients, disease still recurs within 1–4 years from the completion of their primary therapy. CA-125 levels often increase as a first sign of relapse, and CT scan findings are eventually confirmatory. Recurrent disease is often successfully managed for years but rarely cured, despite a growing panel of chemotherapeutic agents and antibody-drug conjugates. Additional surgical therapy does not appear to extend survival in randomized trials. Patients with a treatment-free interval are often best treated with additional platinum doublets, combining carboplatin with liposomal doxorubicin, gemcitabine, or a taxane. Eventually all women who experience relapse develop chemotherapy-refractory disease. Refractory ascites, poor bowel motility, and obstruction or tumor-infiltrated aperistaltic bowel are all common premorbid events. Limited surgery to relieve intestinal obstruction, localized radiation therapy to relieve pressure or pain from masses, or palliative chemotherapy may be helpful. Agents with >15% response rates include gemcitabine, topotecan, liposomal doxorubicin, and bevacizumab. Five-year survival correlates with the stage of disease: stage I, 90–95%; stage II, 70–80%; stage III, 25–40%; stage IV, 10–15% (Table 94-1). Prognosis is improved by lower histologic grade and presence of *BRCA1* or *BRCA2* germline mutation.

UNCOMMON OVARIAN TUMORS

Low Malignant Potential Tumors (Borderline Tumors) These type 1 tumors are found in younger women (age 30–50 years) and are indolent in behavior, and few of these patients will succumb to their tumors (10-year survival may approach 98%), although recurrence is not uncommon. Certain features, such as micropapillary histology and microinvasion, are linked to more aggressive behavior. Tumors of low malignant potential have different mutations including mutations *BRAF* or *KRAS* and cyclin-dependent kinase inhibitor (*CDKN*) 2A/2B deletion. Borderline tumor patients are managed primarily by surgery, but targeted therapy for the RAS/RAF pathway and hormonal treatments sometimes have benefit.

Stromal Tumors Approximately 7% of ovarian neoplasms are stromal tumors, with ~1800 cases expected each year in the United States. Ovarian stromal tumors or sex cord tumors are most common in women in their fifties or sixties, but tumors can present at any age. These tumors arise from the mesenchymal components of the ovary, including both steroid-producing cells and fibroblasts. Most of these tumors are indolent tumors with limited metastatic potential and present as unilateral solid masses. These tumors primarily are discovered by the detection of an abdominal mass, sometimes with abdominal pain due to ovarian torsion, intratumoral hemorrhage, or rupture. Rarely, stromal tumors can produce estrogen and present with breast tenderness as well as precocious puberty in children, menstrual disturbances in reproductively active women, or postmenopausal bleeding. In some women, estrogen-associated secondary malignancies, such as endometrial or breast cancer, may present as synchronous malignancies. Sertoli-Leydig tumors often present with hirsutism and virilization due to increased production of androgens. Hormonally inert tumors include fibromas, which present as solitary masses often in association with ascites and occasionally hydrothorax, also known as Meigs's syndrome. A subset of these tumors presents in individuals with a variety of inherited disorders that predispose them to mesenchymal neoplasia including Ollier's disease (juvenile granulosa cell tumors) and Peutz-Jeghers syndrome (ovarian sex cord tumors). The treatment of these tumors is primarily complete surgical resection, without adjuvant chemotherapy. Chemotherapy with carboplatin and paclitaxel is generally reserved for either unresectable or multiply recurrent tumors.

Germ Cell Tumors of the Ovary Germ cell tumors, like their counterparts in the testis, are cancers of germ cells. These totipotent cells contain the programming for differentiation to essentially all tissue types, and hence, the germ cell tumors include a histologic menagerie of bizarre tumors, including benign teratomas (dermoid cysts) and a variety of malignant tumors, such as dysgerminoma, immature teratomas, yolk sac malignancies, and choriocarcinomas. Benign teratoma (or dermoid cyst) is the most common germ cell neoplasm of the ovary and often presents in young women. These tumors include a complex mixture of differentiated tissue including tissues from all three germ layers. In older women, these differentiated tumors can develop malignant transformation, most commonly squamous cell carcinomas. Malignant germ cell tumors include dysgerminomas, yolk sac tumors, immature teratomas, and embryonal and choriocarcinomas. Germ cell tumors can present at all ages, but the peak age of presentation tends to be in adolescents. Typically, these tumors will become large ovarian masses, which eventually present as palpable low abdominal or pelvic masses. Like sex cord tumors, torsion or hemorrhage may present urgently or emergently as acute abdominal pain. Some germ cell tumors produce elevated levels of human chorionic gonadotropin (hCG) or α-fetoprotein (AFP). Unlike epithelial ovarian cancer, these tumors have a higher proclivity for nodal or hematogenous metastases. Germ cell tumors typically present in women who are of childbearing age, and because bilateral tumors are uncommon (except in dysgerminoma, 10–15%), the typical treatment is unilateral oophorectomy or salpingo-oophorectomy with lymph node sampling. Most commonly, women with advanced malignant germ cell tumors typically receive bleomycin, etoposide, and cisplatin (BEP) chemotherapy, in an analogous fashion to the treatment of testicular cancers. In the majority of these women, even those with advanced-stage disease, cure is expected. Dysgerminoma is the ovarian counterpart of testicular seminoma and is highly curable. Although the tumor is highly radiation-sensitive, radiation produces infertility in many patients. BEP chemotherapy is as effective or more so without causing infertility.

FALLOPIAN TUBE CANCER

Transport of the egg to the uterus occurs through the fallopian tube, with the distal ends of these tubes composed of fimbriae that drape about the ovarian surface and capture the egg as it erupts from the ovarian cortex. As described above, the majority of type 2 ovarian cancers are now thought to arise from the tubal epithelium. Fallopian tube malignancies are typically of serous histology and share the same biology and recommended treatment approaches as serous ovarian cancer. These tumors often present as clinically isolated adnexal masses, but like ovarian cancer, these tumors spread relatively early throughout the peritoneal cavity. Fallopian tubal cancers have a natural history and treatment that are essentially identical to ovarian cancer (Table 94-1).

CERVICAL CANCER

ETIOLOGY AND GENETICS

Cervical cancer is the second most common and the most lethal malignancy in women worldwide. Infection with high-risk strains of human papillomavirus (HPV) is the primary neoplastic-initiating event in the vast majority of women with invasive cervical cancer. This double-stranded DNA virus infects epithelium near the transformation zone of the cervix where underlying columnar epithelium becomes squamous epithelium. More than 60 types of HPV are known, with ~20 types having the ability to generate high-grade dysplasia and malignancy. HPV16 and 18 are the types most frequently associated with high-grade dysplasia, but types 31, 33, 35, 52, and 58 are also considered to be high-risk variants. The large majority of sexually active adults are exposed to HPV, and most women clear the infection without specific intervention. The 8-kb HPV genome encodes seven early genes, most notably *E6* and *E7*, which can bind to *RB* and *p53*, respectively. High-risk types of HPV encode *E6* and *E7* molecules that are particularly effective at inhibiting the normal cell cycle checkpoint functions of these regulatory proteins, leading to immortalization but not full transformation of cervical epithelium. A minority of women will fail to clear the infection, with subsequent HPV integration into the host genome. Over as little as a few months to several years, some of these persistently infected women develop worsening dysplasia, a premalignant condition that, untreated, can progress to cervical carcinoma. Complete transformation to cancer occurs over a period of years and almost certainly requires the acquisition of other genetic mutations within the infected and immortalized epithelium.

In 2024, more than half a million new cases of cervical cancer will occur worldwide, with an estimated >300,000 deaths. Cancer incidence is particularly high in women residing in Central and South America, the Caribbean, and southern and eastern Africa. The mortality rate is disproportionately high in Africa. In the United States, an estimated 13,960 women will be diagnosed with cervical cancer in 2024 and ~4300 women will die of the disease.

In the integrated genomic characterization of cervical cancer by The Cancer Genome Atlas (TCGA), integration of HPV sequences was found in all of the HPV18-linked cancers and over three-quarters of the HPV16 cancers. The cervical tumors also showed a characteristic APOBEC (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like; a family of cytidine deaminases that edit DNA and are endogenous mutagenic enzymes) pattern of mutagenesis, with *ERBB3, CASP8*, and *TGFRB2* identified as significantly mutated genes presumably linked to progression from dysplasia to carcinoma. In the much smaller number of HPV-negative cancers, which are more common in older women, mutations in oncogenes *KRAS, ARID1A,* and *PTEN* were frequently seen. The clinical behavior of these cancers is likely to be different.

HPV INFECTION AND PREVENTION

The Pap smear is the primary detection method for asymptomatic preinvasive cervical dysplasia of squamous epithelial lining during a gynecologic exam. Because the progression from dysplasia to cervical cancer takes several years, annual (or longer interval) screening and prevention strategies that detect precancerous dysplasia and carcinoma in situ can be implemented successfully. Annual or biannual cervical scraping for cytology (Pap smear) is highly effective in reducing the incidence of cervical cancer by early detection and subsequent surgical treatment of premalignant disease. The incorporation of HPV testing by polymerase chain reaction (PCR) or other molecular techniques increases the sensitivity of detecting cervical pathology but at the cost of lower sensitivity in that it identifies many women with transient infections who require no specific medical intervention. Unfortunately, both the collection of a Pap smear and its cytologic evaluation require infrastructure beyond the means of many middle- and low-income countries. High-throughput, low-technology prevention strategies and point-of-care testing are needed to identify and treat women bearing high-risk cervical dysplasia to prevent cancer development.

A primary prevention strategy relies on HPV vaccines. In the United States, the Gardasil-9 vaccine protects against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. Vaccination of girls and women between ages 9 and 45 years is recommended with three injections (0, 2, and 6 months). Vaccination before the initiation of sexual activity dramatically reduces the rate of high-risk HPV infection and subsequent dysplasia. Vaccination of both boys and girls is increasingly considered to reduce the risk of HPV-induced cancers of the pharynx. Vaccinated women are still at risk for HPV infection and still benefit from standard Pap smear screening.

CLINICAL PRESENTATIONS

Risk Factors Clinical risk factors include the prevalence of high-risk HPV subtypes in the population and HPV infection–linked features such as a high number of sexual partners, early age of first intercourse, and history of venereal disease. Smoking is a cofactor; heavy smokers have a higher risk of dysplasia with HPV infection. HIV infection, especially when associated with low CD4+ T-cell counts, is associated with a higher rate of high-grade dysplasia and likely a shorter latency period between infection and invasive disease. Histologically, the majority (80%) of cervical malignancies are squamous cell carcinomas associated with HPV, but adenocarcinomas are also HPV related, and both arise in the transitional zone of the endocervical canal; the lesions in the canal or cervical glands may not be seen by visual inspection of the cervix and can be missed by Pap smear screening. Other malignancies, such as vulvar cancer, anal cancer, and, increasingly, pharyngeal cancer, are also linked to HPV infection.

Diagnosis of Cervical Cancer Early cancer of the cervix is asymptomatic, and this biology underlies the recommendations for routine gynecologic care. Larger, invasive carcinomas often have symptoms or signs including postcoital spotting or intermenstrual cycle bleeding or menometrorrhagia. Foul-smelling or persistent yellow discharge may also be present. Symptoms such as pelvic or sacral pain suggest lateral extension into the pelvic nerve plexus by either the primary tumor or a pelvic node metastasis and indicate advanced-stage disease. Likewise, flank pain from hydronephrosis from ureteral compression or deep-venous thrombosis from iliac vessel compression suggests either extensive nodal disease or direct extension of the primary tumor to the pelvic sidewall. The most common finding upon physical exam is a visible tumor on the cervix, but deeper tumors in the cervical os and glands should be considered. Larger tumors may be identified by inspection and biopsied directly. Staging of cervical cancer is performed by expert clinical exam. Stage I cervical tumors are confined to the cervix, whereas stage II tumors extend into the upper vagina or paracervical soft tissue **(Fig. 94-2)**. Stage III tumors extend to the lower vagina or the pelvic sidewalls, whereas stage IV tumors invade the bladder or rectum or have spread to distant sites. While radiographic studies are not part of the formal clinical staging of cervical cancer, treatment planning requires them for appropriate therapy. CT can detect hydronephrosis indicative of pelvic sidewall disease but is not accurate at evaluating other pelvic structures. Magnetic resonance imaging (MRI) is more accurate at estimating uterine extension and paracervical extension of disease into soft tissues typically bordered by broad and cardinal ligaments that support the uterus in the central pelvis. Very small stage I cervical tumors can be treated with a variety of surgical procedures, but minimally invasive surgery has inferior outcome compared to standard open hysterectomy. In young women desiring to maintain fertility, radical trachelectomy removes the cervix with subsequent anastomosis of the upper vagina to the uterine corpus; however, subsequent pregnancies may be more problematic. Patients with large stage I cervical tumors (4 cm) confined to the cervix and all stage II to IV patients are treated with radiation therapy in combination with cisplatin-based immunochemotherapy with concurrent PD-1 blockers. This multimodality treatment can offer the patient with advanced-stage disease a 40–80% chance of cure depending on the clinical circumstances. Immunotherapy with PD-1 blockade, cisplatin, paclitaxel, bevacizumab, and tisotumab vedotin are generally considered as appropriate palliative choices for metastatic

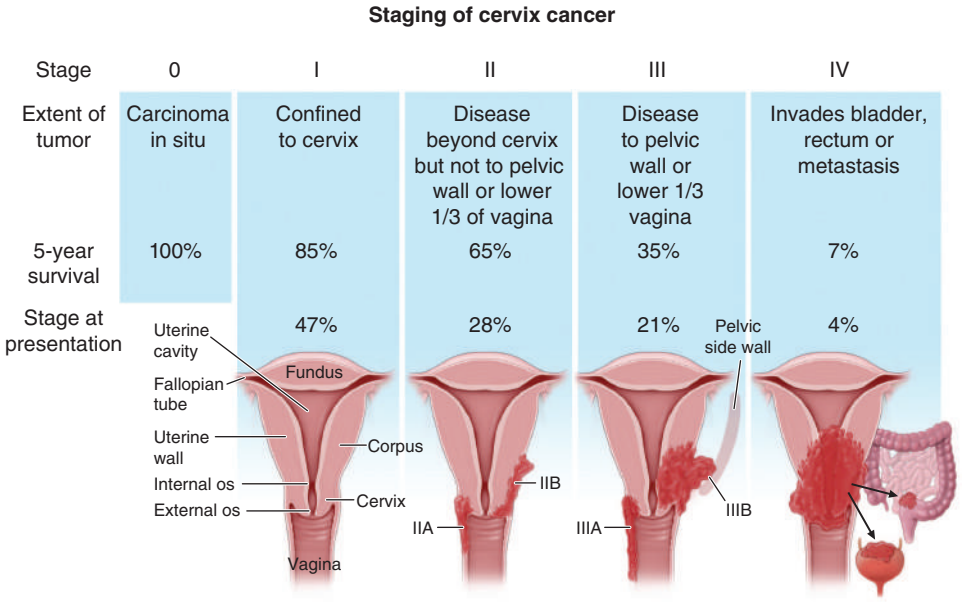

FIGURE 94-2 Anatomic display of the stages of cervix cancer defined by location, extent of tumor, frequency of presentation, and 5-year survival.

cervical cancer patients. Secondary chemotherapy confers minimal improvement in most patients. Additional immunotherapies targeting HPV antigens are potential avenues for improved outcomes in recurrent, unresectable cancers of the cervix.

UTERINE CANCER

EPIDEMIOLOGY

Several different tumor types arise in the uterine corpus. Most tumors arise in the glandular lining and are endometrial adenocarcinomas. Benign (leiomyomas) and malignant smooth muscle tumors (leiomyosarcomas) can also arise in the uterus and have very different clinical features. The endometrioid histologic subtype is the most common gynecologic malignancy in the United States. In 2024, the American Cancer Society predicted that 66,200 new cancers of the uterine corpus are expected in 2024 with 13,030 resulting deaths. Development of these tumors is a multistep process, with estrogen playing an important early role in driving endometrial gland proliferation. Relative overexposure to this class of hormones is the principal risk factor for the subsequent development of endometrioid tumors. In contrast, progestins drive glandular maturation and are protective. Hence, women with high endogenous or pharmacologic exposure to estrogens, especially if unopposed by progesterone, are at higher risk for endometrial cancer. Obese women, women treated with postmenopausal estrogens, or women with estrogen-producing tumors are at higher risk for endometrial cancer. In addition, long-term treatment with tamoxifen, which has antiestrogenic effects in breast tissue but can show weak estrogenic effects in uterine epithelium, is associated with an increased risk of endometrial cancer.

Genetics Women with a germline mutation in one of a series of DNA mismatch repair genes associated with the Lynch syndrome, also known as hereditary nonpolyposis colon cancer (HNPCC) syndrome, are at increased risk for endometrioid endometrial carcinoma. These individuals have germline mutations in *MSH2*, *MLH1*, and, in rare cases, *PMS1* and *PMS2*. Individuals who carry these mutations typically have a family history of cancer and are at markedly increased risk for colon cancer and modestly increased risk for ovarian cancer and a variety of other tumors. Middle-aged women with HNPCC carry a 4% annual risk of endometrial cancer and a relative overall risk of ~200-fold as compared to age-matched women without HNPCC. In sporadic cancers, secondary events such as mutation of the *PI3K* gene or the loss of the *PTEN* tumor-suppressor gene likely serve as secondary genetic "hits" in the carcinogenesis related to estrogenic excess. The molecular events that underlie less common endometrial cancers such as clear cell and papillary serous tumors of the uterine corpus are not well understood.

PATHOLOGY

Approximately 75–80% of endometrial cancers are adenocarcinomas and have been characterized as type 1 (estrogen-linked) endometrial cancers and type 2 cancers that have less clear associations with estrogens (clear cell cancers, serous cancers, and mucinous cancers). Endometrial serous cancers show *TP53* loss of function and behave clinically more like ovarian cancers with high risk for systemic recurrence. Prognosis for endometrial cancer depends on stage, histologic grade, and depth of myometrial invasion.

CLINICAL PRESENTATION

The majority of women with tumors of the uterine corpus present with postmenopausal vaginal bleeding due to shedding of the malignant endometrial lining. Premenopausal women often will present with atypical bleeding between typical menstrual cycles. These signs typically bring a woman to the attention of health care providers, and the majority of women have early-stage disease in which the tumor is confined to the uterine corpus and, consequently, have a high cure rate. Diagnosis is typically established by endometrial biopsy. Type 1 tumors may spread to pelvic or para-aortic lymph nodes and are generally subjected to sentinel lymph node biopsy at the time of primary surgery. Serous tumors tend to have patterns of spread similar to high-grade serous ovarian cancer, and patients may present with omental/peritoneal disease and sometimes ascites. Some women presenting with uterine sarcomas will present with pelvic pain. Uterine sarcomas (carcinosarcomas and leiomyosarcomas) commonly are found by detection of symptomatic large pelvic masses that may not be associated with dysfunctional vaginal bleeding.

TREATMENT

Uterine Cancer

Most women with endometrial cancer have disease that is localized to the uterus (75% are stage I, Table 94-1), and definitive treatment typically involves a hysterectomy with removal of the ovaries and fallopian tubes. The resection of lymph nodes does not improve outcome, but sentinel node resection provides important staging and prognostic information. Node involvement defines stage IIIC disease, which is treated with immunochemotherapy. Tumor grade and depth of invasion are two key prognostic variables in early-stage tumors, and women with low-grade and/or minimally invasive tumors (<50% myometrial penetration) are typically observed after definitive surgical therapy. Patients with high-grade tumors or tumors that are deeply invasive (stage IB) are at higher risk for pelvic recurrence or recurrence at the vaginal cuff, which is typically prevented by intravaginal brachytherapy. It is now routine to test all endometrial cancers for microsatellite instability (MSI) with a larger number of mutations in the tumor. MSI cancers, when recurrent or present at an advanced stage, are likely to respond to immune checkpoint therapy and PD-1–targeted therapy should be part of treatment for those patients. Women with regional metastases or metastatic disease (3% of patients) with low-grade tumors can be treated with progesterone or tamoxifen. In contrast, poorly differentiated tumors lack hormone receptors and are typically unresponsive to hormonal manipulation. The role of adjuvant chemotherapy in stage I–II disease is generally restricted to serous endometrial cancers. For more advanced-stage

cancers (stage III–IV), chemotherapy and/or immune checkpoint blockade are administered because of the higher rates of recurrent systemic disease. Carboplatin and paclitaxel combinations with immune targeting agents are the current standard of care. Chemotherapy for metastatic disease is delivered with palliative intent. Even patients with advanced cancer and known mismatch repair deficits may respond well to immunotherapy with antagonists of the PD-1/PD-L1 axis. Lenvatinib and pembrolizumab (even for microsatellite-stable tumors) have become the most common second-line treatments. Other potentially active treatments include bevacizumab and mammalian target of rapamycin (mTOR) inhibitors (e.g., temsirolimus). Newer antibody-drug conjugates may have good responses in patients with expression of the target antigens. Carcinosarcomas of the uterus (also called Müllerian tumors) contain both mesenchymal and epithelial components but will often respond to paclitaxel and platinum complex therapy. Other uterine sarcomas require an entirely different approach and need histology-specific consideration. The most common are the leiomyosarcomas of the uterus, which are treated with docetaxel/gemcitabine at recurrence but do not appear to benefit from adjuvant therapy. Ifosfamide/doxorubicin and trabectedin can have some benefit in refractory disease.

GESTATIONAL TROPHOBLASTIC TUMORS

Gestational trophoblastic diseases represent a spectrum of neoplasia from benign hydatidiform mole to choriocarcinoma due to persistent trophoblastic disease associated most commonly with molar pregnancy but occasionally seen after normal gestation. The most common presentations of trophoblastic tumors are partial and complete molar pregnancies. These represent approximately 1 in 1500 conceptions in developed Western countries. The incidence widely varies globally, with areas in Southeast Asia having a much higher incidence of molar pregnancy. Regions with high molar pregnancy rates are often associated with diets low in carotene and animal fats.

RISK FACTORS

Trophoblastic tumors result from the outgrowth or persistence of placental tissue. They arise most commonly in the uterus but can also arise in other sites such as the fallopian tubes due to ectopic pregnancy. Risk factors include poorly defined dietary and environmental factors as well as conceptions at the extremes of reproductive age, with the incidence particularly high in females conceiving at younger than age 16 or older than age 50. In older women, the incidence of molar pregnancy might be as high as one in three, likely due to increased risk of abnormal fertilization of the aged ova. Most trophoblastic neoplasms are associated with complete moles, diploid tumors with all genetic material from the paternal donor (known as uniparental disomy). This is thought to occur when a single sperm fertilizes an enucleate egg that subsequently duplicates the paternal DNA. Trophoblastic proliferation occurs with exuberant villous stroma. If pseudopregnancy extends out past the 12th week, fluid progressively accumulates within the stroma, leading to "hydropic changes." Fetal development does not occur in complete moles.

Partial moles arise from the fertilization of an egg with two sperm cells; hence, two-thirds of genetic material is paternal in these triploid tumors. Hydropic changes are less dramatic, and fetal development can often occur through late first trimester or early second trimester, at which point spontaneous abortion is common. Laboratory findings will include excessively high hCG and high AFP. The risk of persistent gestational trophoblastic disease after partial mole is ~5%. Complete and partial moles can be noninvasive or invasive. Myometrial invasion occurs in no more than one in six complete moles and a lower portion of partial moles.

PRESENTATION OF INVASIVE TROPHOBLASTIC DISEASE

The clinical presentation of molar pregnancy is changing in developed countries due to the early detection of pregnancy with home pregnancy kits and the very early use of Doppler and ultrasound to evaluate the early fetus and uterine cavity for evidence of a viable fetus. Thus, in these countries, the majority of women presenting with trophoblastic disease have their moles detected early and have typical symptoms of early pregnancy including nausea, amenorrhea, and breast tenderness. With uterine evacuation of early complete and partial moles, most women experience spontaneous remission of their disease as monitored by serial serum β-hCG levels. These women require no chemotherapy. Patients with persistent elevation of β-hCG or rising β-hCG after uterine evacuation have persistent or actively growing gestational trophoblastic disease and require therapy. Most series suggest that between 15 and 25% of women will have evidence of persistent gestational trophoblastic disease after molar evacuation.

In women who lack access to prenatal care, presenting symptoms can be life-threatening, including the development of preeclampsia or even eclampsia. Hyperthyroidism can also be seen with very high β-hCG values. Evacuation of large moles can be associated with life-threatening complications including uterine perforation, volume loss, high-output cardiac failure, and adult respiratory distress syndrome (ARDS).

For women with evidence of rising β-hCG or radiologic confirmation of metastatic or persistent regional disease, prognosis can be estimated through a variety of scoring algorithms that identify women at low, intermediate, and high risk for requiring multiagent chemotherapy. In general, women with widely metastatic nonpulmonary disease, very elevated β-hCG, and prior normal antecedent term pregnancy are considered at high risk and typically require multiagent chemotherapy at an expert center for cure. Even very advanced gestational trophoblastic disease is almost uniformly curable when managed by an expert in this rare malignancy.

TREATMENT

Invasive Trophoblastic Disease

Management of invasive trophoblastic disease should be 100% curative, and complex patients should only be managed by clinicians experienced in this disease. The management for a persistent and rising β-hCG after evacuation of a molar conception is typically chemotherapy, although surgery can play an important role for chemotherapy-resistant disease that is isolated in the uterus (especially if childbearing is complete) or to control hemorrhage. For women wishing to maintain fertility or with metastatic disease, the preferred treatment is chemotherapy or immunotherapy targeting the PD-1 axis. Trophoblastic disease is exquisitely sensitive to chemotherapy, and guided by serial serum β-hCG testing, successful, curative treatment is the rule. Single-agent treatment with dactinomycin or methotrexate cures 90% of women with low-risk disease. Patients with high-risk disease (very high β-hCG levels, presentation ≥4 months after pregnancy, brain or liver metastases, failure of methotrexate therapy) are typically treated with multiagent chemotherapy (etoposide, methotrexate, and dactinomycin, alternating with cyclophosphamide and vincristine [EMA-CO]), which is typically curative even in women with extensive metastatic disease. A regimen of cisplatin and etoposide alternating with etoposide/methotrexate/dactinomycin is used for the highest-risk patients. In the highest-risk patients with liver, lung, and brain metastases, hemorrhage from the rich tumor vasculature is a major risk during chemotherapy initiation. Cured women may become pregnant again without evidence of increased fetal or maternal complications.

95 Primary and Metastatic Tumors of the Nervous System

Mary Jane Lim-Fat, Patrick Y. Wen

An estimated 95,000 people will be diagnosed with a primary brain tumor annually in the United States. At least 27,000 of these tumors are malignant, and most of these are gliomas. Meningiomas account for 41% of all central nervous system (CNS) tumors, vestibular schwannomas 10%, and CNS lymphomas ~2%. Brain metastases are three times more common than all primary brain tumors combined and are diagnosed in ~150,000 people each year. Metastases to the leptomeninges and epidural space of the spinal cord each occur in ~2–12% of patients with systemic cancer and are also a major cause of neurologic disability.

APPROACH TO THE PATIENT

Primary and Metastatic Tumors of the Nervous System

CLINICAL FEATURES

Brain tumors of any type can present with a variety of symptoms and signs that fall into two categories: general and focal; patients often have a combination of the two (Table 95-1). General symptoms include headache, with or without nausea or vomiting, cognitive difficulties, personality change, and gait disorder. These symptoms arise when the enlarging tumor and its surrounding edema cause an increase in intracranial pressure or compression of cerebrospinal fluid (CSF) circulation, leading to hydrocephalus. The classic brain tumor headache predominates in the morning and improves during the day, but this pattern is seen in a minority of patients. Headaches are often holocephalic but can be ipsilateral to the side of a tumor. Occasionally, headaches have features of a typical migraine with unilateral throbbing pain associated with visual scotoma. Personality changes may include apathy and withdrawal from social situations, mimicking depression. Focal or lateralizing findings include hemiparesis, aphasia, or visual field defect. Lateralizing symptoms are typically subacute and progressive; language difficulties may be mistaken for confusion. Seizures are common, occurring in ~25% of patients with brain metastases or malignant gliomas, and are the presenting symptom in up to 90% of patients with a low-grade glioma. All seizures arising from a brain tumor will have a focal onset whether or not it is apparent clinically.

NEUROIMAGING

Cranial magnetic resonance imaging (MRI) is the preferred diagnostic test for any patient suspected of having a brain tumor and should be performed with gadolinium contrast administration. Computed tomography (CT) scan should be reserved for those patients unable to undergo MRI. Malignant brain tumors—whether primary or metastatic—typically enhance with gadolinium, have central areas of necrosis, and are surrounded by edema of the neighboring white matter. Low-grade gliomas usually do not enhance with gadolinium and are best appreciated on fluid-attenuated inversion recovery (FLAIR) MRI sequences. Meningiomas have a typical appearance on MRI because they are dural-based enhancing tumors with a dural tail and compress but do not invade the brain. Dural metastases or a dural lymphoma can have a similar appearance. Imaging is characteristic for many primary and metastatic tumors and sometimes will suffice to establish a diagnosis when the location precludes surgical intervention (e.g., brainstem glioma). Functional MRI is useful in presurgical planning to define eloquent sensory, motor, or language cortex. Positron emission tomography (PET) is useful in determining the metabolic activity of the lesions seen on MRI; MR perfusion and spectroscopy can provide information on blood flow or tissue composition. These techniques may help distinguish tumor progression from tissue necrosis due to treatment with radiation and chemotherapy. Neuroimaging is the only test necessary to diagnose a brain tumor. Laboratory tests are rarely useful, although patients with metastatic disease may have elevation of a serum tumor marker (e.g., β human chorionic gonadotropin [β-hCG] from testicular cancer). Additional testing such as cerebral angiogram, electroencephalogram (EEG), or lumbar puncture is rarely indicated or helpful.

TREATMENT

Brain Tumors

Therapy of any intracranial malignancy requires both symptomatic and definitive treatments. Definitive treatment is based on the specific tumor type and includes surgery, radiotherapy, and chemotherapy. However, symptomatic treatments apply to brain tumors of any type. Most high-grade malignancies are accompanied by substantial surrounding edema, which contributes to neurologic disability and raised intracranial pressure. Glucocorticoids are highly effective at reducing perilesional edema and improving neurologic function, often within hours of administration. Dexamethasone has been the glucocorticoid of choice because of its relatively low mineralocorticoid activity; initial doses are 4–12 mg/d in one to two daily doses. Glucocorticoids rapidly ameliorate symptoms and signs, but their long-term use causes substantial toxicity including insomnia, weight gain, diabetes mellitus, steroid myopathy, and personality changes. Consequently, a taper is indicated as definitive treatment is administered and the patient improves.

Patients with brain tumors who present with seizures require antiepileptic drug therapy. Prophylactic antiepileptic drugs are occasionally used in the perioperative setting, but there is no role for extended use in patients who have not had a seizure. The agents of choice are drugs that do not induce the hepatic microsomal enzyme system. These include levetiracetam, topiramate,

TABLE 95-1 Symptoms and Signs at Presentation of Brain Tumors

	HIGH-GRADE GLIOMA (%)	LOW-GRADE GLIOMA (%)	MENINGIOMA (%)	METASTASES (%)
Generalized				
Impaired cognitive function	50	10	30	60
Hemiparesis	40	10	36	60
Headache	50	40	37	50

Seizures	20	70+	17	12
Aphasia	20	<5	—	18
Visual field deficit	—	—	—	7

lamotrigine, valproic acid, and lacosamide (Chap. 447). Other drugs, such as phenytoin and carbamazepine, are used less frequently because they are potent enzyme inducers that can interfere with both glucocorticoid and chemotherapy metabolism. Venous thromboembolic disease occurs in 20–30% of patients with HGGs or brain metastases. Prophylactic anticoagulants should be used during hospitalization and in nonambulatory patients. Those who have had either a deep vein thrombosis or a pulmonary embolus can receive therapeutic doses of anticoagulation safely and without increasing the risk of hemorrhage into the tumor. Inferior vena cava filters are reserved for patients with absolute contraindications to anticoagulation such as recent craniotomy.

PRIMARY BRAIN TUMORS

EPIDEMIOLOGY

No etiology has been identified for most primary brain tumors. The only established risk factors are exposure to ionizing radiation (meningiomas, gliomas, and schwannomas) and immunosuppression (primary CNS lymphoma). There is no proven evidence for any association with exposure to electromagnetic fields including cellular telephones, head injury, foods containing *N*-nitroso compounds, or occupational risk factors. A small minority of patients have a family history of brain tumors. Some of these familial cases are associated with genetic syndromes (Table 95-2).

MOLECULAR PATHOGENESIS

As with other neoplasms, brain tumors arise as a result of a multistep process driven by the sequential acquisition of genetic alterations. These include loss of tumor-suppressor genes (e.g., *p53*, cyclin-dependent kinase inhibitor 2A and 2B [*CDKN2A/B*], and phosphatase and tensin homolog on chromosome 10 [*PTEN*]) and amplification and overexpression of protooncogenes such as the epidermal growth factor receptor (*EGFR*) and platelet-derived growth factor receptors (*PDGFR*). The accumulation of these genetic abnormalities results in uncontrolled cell growth and tumor formation. Many brain tumors, including glioblastomas, are characterized by significant molecular heterogeneity, which contributes to the difficulty in developing effective therapies.

Important progress has been made in understanding the molecular pathogenesis of several types of brain tumors, including glioblastoma and medulloblastoma, allowing them to be separated into different subtypes with different prognoses. This has led the World Health Organization (WHO) to issue an update on the classification of CNS tumors in 2016 that for the first time incorporated molecular parameters in addition to traditional histology into the diagnosis of brain tumors. The most recent 2021 WHO Classification of Tumors of the CNS further stressed the use of integrated diagnoses based on both molecular diagnostics and histology. This has improved the classification of brain tumors, allowing for better understanding of the prognosis and optimal therapy for patients.

INTRINSIC "MALIGNANT" TUMORS

DIFFUSE GLIOMA

Gliomas are the most common type of malignant primary brain tumor. The 2021 WHO Classification now differentiates gliomas as "adult type" or "pediatric type" based on molecular genetic differences. Both adult-type and pediatric-type diffuse gliomas can be subclassified into high- or low-grade glioma based on histology and are further characterized by key molecular alterations (Table 95-3). Although uncommon, pediatric-type diffuse gliomas also occur in adults, hence their inclusion here.

TABLE 95-2 Genetic Syndromes Associated with Primary Brain Tumors

SYNDROME	INHERITANCE	GENE/PROTEIN	ASSOCIATED TUMORS
Cowden's syndrome	AD	Mutations of *PTEN* (ch10p23)	Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease), meningioma, astrocytoma Breast, endometrial, thyroid cancer, trichilemmomas
Familial schwannomatosis	Sporadic Hereditary	Mutations in *INI1/SNF5* (ch22q11)	Schwannomas, gliomas
Gardner's syndrome	AD	Mutations in *APC* (ch5q21)	Medulloblastoma, glioblastoma, craniopharyngioma Familial polyposis, multiple osteomas, skin and soft tissue tumors
Gorlin syndrome (basal cell nevus syndrome)	AD	Mutations in *Patched 1* gene (ch9q22.3)	Medulloblastomas Basal cell carcinoma
Li-Fraumeni syndrome	AD	Mutations in *p53* (ch17p13.1)	Gliomas, medulloblastomas Sarcomas, breast cancer, leukemias, others
Lynch syndrome	AD	Mutations in *MSH2, MSH1, MSH6, PMS2*	Glioblastoma and other gliomas Gastrointestinal, endometrial, and other cancers
Multiple endocrine neoplasia 1 (Wermer's syndrome)	AD	Mutations in *Menin* (ch11q13)	Pituitary adenoma, malignant schwannomas Parathyroid and pancreatic islet cell tumors
NF1	AD	Mutations in *NF1*/neurofibromin (ch17q12-22)	Schwannomas, astrocytomas, optic nerve gliomas, meningiomas Neurofibromas, neurofibrosarcomas, others
NF2	AD	Mutations in *NF2*/merlin (ch22q12)	Bilateral vestibular schwannomas, astrocytomas, multiple meningiomas, ependymomas
TSC (Bourneville disease)	AD	Mutations in *TSC1/TSC2* (ch9q34/16)	Subependymal giant cell astrocytoma, ependymomas, glioma, ganglioneuroma, hamartoma
Turcot syndrome	AD AR	Mutations in *APC*[a] (ch5) hMLH1 (ch3p21)	Gliomas, medulloblastomas Adenomatous colon polyps, adenocarcinoma
VHL	AD	Mutations in *VHL* gene (ch3p25)	Hemangioblastomas Retinal angiomas, renal cell carcinoma, pheochromocytoma, pancreatic tumors and cysts, endolymphatic sac tumors of the middle ear

[a]Various DNA mismatch repair gene mutations may cause a similar clinical phenotype, also referred to as Turcot syndrome, in which there is a predisposition to nonpolyposis colon cancer and brain tumors.

Abbreviations: AD, autosomal dominant; APC, adenomatous polyposis coli; AR, autosomal recessive; ch, chromosome; NF, neurofibromatosis; PTEN, phosphatase and tensin homologue; TSC, tuberous sclerosis complex; VHL, von Hippel-Lindau.

TABLE 95-3 Summary of Gliomas and Relevant Molecular Alterations

TUMOR TYPE	CHARACTERISTIC MOLECULAR ALTERATIONS
Adult-Type Diffuse Gliomas	
Astrocytoma, IDH-mutant	*IDH1, IDH2*
Oligodendroglioma, IDH-mutant, 1p/19q-codeleted	*IDH1, IDH2*, 1p/19q
Glioblastoma, IDH wild type	Chromosome 7 gain and 10 loss, *TERT, EGFR*
Pediatric-Type Diffuse High-Grade Gliomas	
Diffuse midline glioma, H3 K27-altered	H3 K27M, H3K27me3, *EGFR, EZHIP*
Diffuse hemispheric glioma, H3 G34-mutant	H3.3 G34R/V
Diffuse pediatric-type high-grade glioma, H3 wild type and IDH wild type	*EGFR, PDGFRA, MYCN*
Pediatric-Type Diffuse Low-Grade Gliomas	
Diffuse low-grade glioma, MAPK pathway-altered	MAPK pathway genes (*BRAF V600E* mutation, *BRAF* fusion, *FGFR* mutation)

Abbreviations: IDH, isocitrate dehydrogenase; *TERT*, telomerase reverse transcriptase; *EGFR*, epidermal growth factor receptor; *FGFR*, fibroblast growth factor receptor; *MAPK*, mitogen-activated protein kinase; *EZHIP*, EZH inhibitor protein; *PDGFRA*, platelet-derived growth factor receptor alpha; *MYCN*, MYCN proto-oncogene.

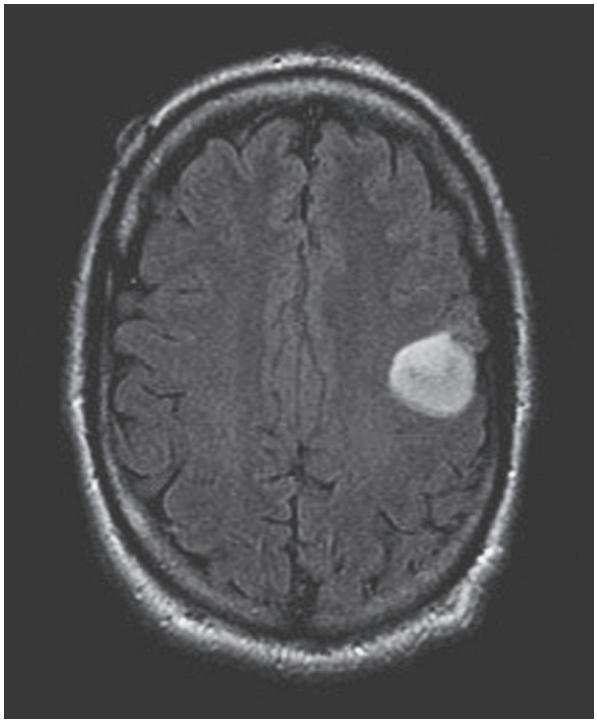

FIGURE 95-1 Fluid-attenuated inversion recovery (FLAIR) MRI of a left frontal low-grade astrocytoma. This lesion did not enhance.

ADULT-TYPE DIFFUSE GLIOMA

Adult-type diffuse gliomas are classified based on the presence of a mutation in a key driver, the isocitrate dehydrogenase (*IDH*) gene, followed by the presence of 1p/19q co-deletion. Both of these molecular alterations have significant prognostic impact and lead to the emergence of three distinct groups: *IDH*-mutant astrocytoma (1p/19q intact), *IDH*-mutant oligodendroglioma (1p/19q co-deleted), and *IDH* wild-type glioblastoma.

Diffuse gliomas can present rarely as widespread infiltration of the brain tissue without a focal mass. Such tumors usually present with cognitive problems, and the MRI demonstrates confluent, typically nonenhancing areas of increased signal on FLAIR sequences without significant mass effect. Formerly known as gliomatosis cerebri, these lesions are now categorized by the pathology identified on biopsy, but they can be diagnostically challenging when the nature of the imaging abnormalities is unclear. Often diagnosis is delayed until the patient develops worsening deficits or there is clear progression on imaging. Treatment is then determined by the pathology.

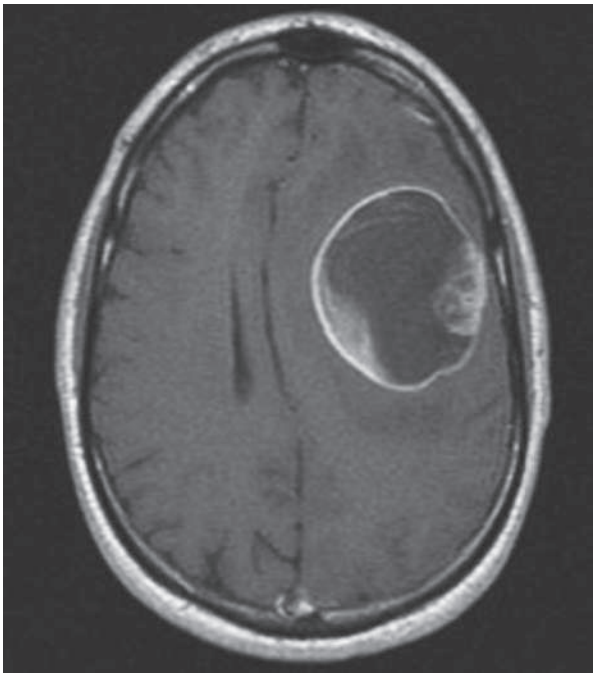
Astrocytoma, IDH-Mutant *IDH*-mutant astrocytoma can be further classified into grade 2, 3, or 4 based on histologic features, with higher grade tumors incorporating additional features of malignancy. *CDKN2A/B* homozygous deletion is associated with poor prognosis, and its presence confers a grade 4 to *IDH*-mutant astrocytomas with lower-grade histologic features. Low-grade (grade 2) *IDH*-mutant astrocytomas are infiltrative tumors that usually present with seizures in young adults or can be detected incidentally. They appear as nonenhancing tumors with increased T2/FLAIR signal **(Fig. 95-1)**. If feasible, patients should undergo maximal surgical resection, although complete resection is rarely possible because of the invasive nature of the tumor. In patients at higher risk for recurrence (subtotal resection or above the age of 40 years), there is evidence that radiation therapy (RT) followed by PCV (procarbazine, lomustine, and vincristine) or temozolomide chemotherapy may be of benefit. The tumor transforms to a higher-grade astrocytoma in most patients, leading to variable survival with a median of ~10 years. The *IDH*-inhibitor vorasidenib has been showed to be effective in delaying the progression-free survival and time to next intervention, and *IDH* inhibitors may become an integral part of the management for both *IDH*-mutant low-grade glioma astrocytoma and oligodendroglioma. High-grade *IDH*-mutant astrocytoma includes grade 3 astrocytoma (formerly termed anaplastic astrocytoma) and grade 4 astrocytoma (previously *IDH*-mutant glioblastoma) and generally presents in the fourth and fifth decades of life as variably enhancing tumors. Treatment is the same as for glioblastoma, consisting of maximal safe surgical resection followed by RT and adjuvant temozolomide alone or RT with concurrent and adjuvant temozolomide. The median survival for high-grade anaplastic astrocytoma can range from 3 to 9 years.

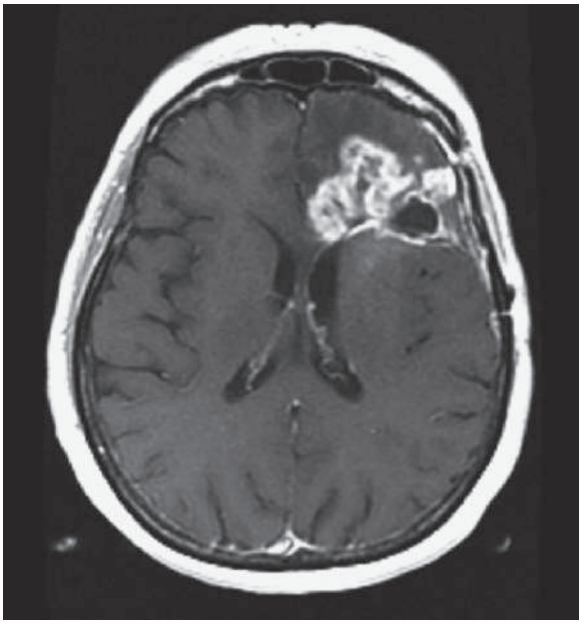
Oligodendroglioma, IDH-Mutant and 1p/19q Co-deleted Oligodendrogliomas account for ~15–20% of gliomas. They are characterized by co-deletion of 1p/19q and have *IDH* mutations. Oligodendrogliomas are classified by the WHO into grade 2 or grade 3 oligodendrogliomas (formerly anaplastic oligodendrogliomas). Oligodendrogliomas have distinctive pathologic features such as perinuclear clearing—giving rise to a "fried egg" appearance—and a reticular pattern of blood vessel growth. Some tumors have both an oligodendroglial as well as an astrocytic component. With molecular testing, it is now clear that almost all of these mixed tumors (oligoastrocytomas) are genetically either astrocytomas or oligodendrogliomas. As a result, the diagnosis of oligoastrocytoma is now rarely made unless molecular testing is not available.

Grade 2 oligodendrogliomas are generally more responsive to therapy and have a better prognosis than pure astrocytic tumors. These tumors present similarly to grade 2 astrocytomas in young adults. The tumors are nonenhancing and often partially calcified. They should be treated with surgery and, in patients with residual disease or aged >40 years, RT and chemotherapy. Targeting mutant *IDH* with inhibitors such as vorasidenib to delay progression and transformation to higher grade may become an effective strategy in low-grade oligodendroglioma. Patients with oligodendrogliomas have a median survival in excess of 10 years.

Grade 3 oligodendrogliomas present in the fourth and fifth decades as variably enhancing tumors. They are more responsive to therapy than grade 3 astrocytomas. Treatment involves maximal safe resection followed by RT and PCV or temozolomide chemotherapy. Median survival of patients is in excess of 10 years.

Glioblastoma Glioblastomas account for the majority of high-grade astrocytomas and are now defined by the absence of *IDH* mutations. With the new WHO classification, grade 2 and 3 astrocytomas without the classic histologic features of glioblastoma (necrosis and endothelial proliferation) but harboring molecular features of glioblastoma





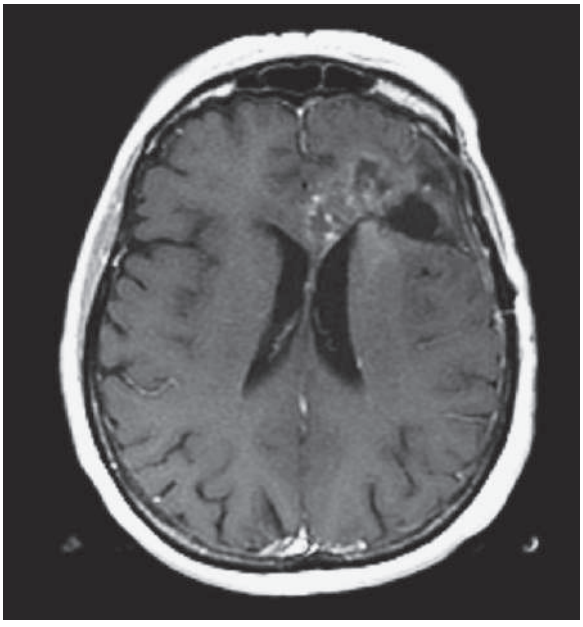


FIGURE 95-2 Postgadolinium T1 MRI of a large cystic left frontal glioblastoma.

(epidermal growth factor amplification, combined with whole chromosome 7 gain and 10 loss, or telomerase reverse transcriptase [*TERT*] promoter mutations) are considered molecular glioblastomas.

Glioblastomas are the most common malignant primary brain tumor, with >12,000 cases diagnosed each year in the United States. Patients usually present in the sixth and seventh decades of life with headache, seizures, or focal neurologic deficits. The tumors appear as ring-enhancing masses with central necrosis and surrounding edema **(Fig. 95-2)**. These are highly infiltrative tumors, and the areas of increased T2/FLAIR signal surrounding the main tumor mass contain invading tumor cells. Treatment involves maximal surgical resection followed by involved-field external-beam RT (6000 cGy in thirty 200-cGy fractions) with concomitant temozolomide, followed by 6 months of adjuvant temozolomide. With this regimen, median survival is increased to 15–18 months compared to only 12 months with RT alone, and 5-year survival is ~10%. Efforts to increase the dose of RT locally using brachytherapy or stereotactic radiosurgery (SRS) have failed to improve the outcome, and these treatments are not recommended. Patients whose tumor contains the DNA repair enzyme O^6-methylguanine-DNA methyltransferase (MGMT) are relatively resistant to temozolomide and have a worse prognosis compared to those whose tumors contain low levels of MGMT as a result of silencing of the *MGMT* gene by promoter hypermethylation. Implantation of biodegradable polymers containing carmustine chemotherapy into the tumor bed after resection of the tumor or addition of tumor treating fields (scalp electrodes delivering low-intensity electric currents) produces a modest improvement in survival.

For elderly patients aged >65–70 years, a hypofractionated RT regimen of 40 Gy over 3 weeks with temozolomide is well tolerated and likely leads to similar outcomes as the 6-week standard RT regimen.

Despite optimal therapy, glioblastomas invariably recur. Treatment options for recurrent disease may include reoperation, reirradiation, and treatment with bevacizumab and standard chemotherapeutic regimens. Bevacizumab, a humanized vascular endothelial growth factor (VEGF) monoclonal antibody, has activity in recurrent glioblastoma, increasing progression-free survival but not overall survival and reducing peritumoral edema and glucocorticoid use **(Fig. 95-3)**. Immune checkpoint inhibitors have been successful in a variety of solid tumors but have failed to demonstrate substantial activity in glioblastoma. A recent phase 3 trial comparing bevacizumab with nivolumab in recurrent glioblastoma demonstrated an identical median overall survival of approximately 10 months in the two arms, with similar toxicities. Treatment decisions for patients with recurrent glioblastoma must be made on an individual basis, taking into consideration such factors as previous therapy, time to relapse, performance status, and quality of life. Whenever feasible, patients should be enrolled in clinical trials. Novel therapies undergoing evaluation in patients with glioblastoma include targeted molecular agents directed at receptor tyrosine kinases and signal transduction pathways; immunotherapy using vaccines, novel checkpoint inhibitors, or chimeric antigen receptor (CAR) T cells; oncolytic viruses; antiangiogenic agents; chemotherapeutic agents that cross the blood-brain barrier more effectively than currently available drugs; and infusion of radiolabeled drugs and targeted toxins into the tumor and surrounding brain by means of convection-enhanced delivery.

The most important adverse prognostic factors in patients with glioblastomas are older age, unmethylated MGMT promoter, poor Karnofsky performance status, and unresectable tumor.

Gliosarcomas are a variant of glioblastoma containing both an astrocytic and a sarcomatous component and are treated in the same way as glioblastomas.

PEDIATRIC-TYPE DIFFUSE HIGH-GRADE GLIOMA

Pediatric-type diffuse high-grade gliomas (HGGs) are clinically and biologically distinct and are further classified based on their location, which also corresponds to specific molecular alterations. These tumors are typical in younger patients, including young adults, and prior to the recognition of these specific molecular drivers, many pediatric-type HGGs, which do not harbor *IDH* mutations, were often diagnosed and treated as glioblastoma.

Diffuse Midline Glioma, H3K27-Altered These tumors arise from midline structures including the pons, thalamus, or spinal cord and have an infiltrative appearance, often without contrast enhancement on MRI. They harbor mutations in the *H3F3A* gene, resulting in lysine-to-methionine substitution in amino acid residue 27 (K27M). H3K27-altered glioma can occur both in children and adults and carries a poor prognosis regardless of grade. As gross total resection is not feasible in these tumors, treatment mostly consists of RT, while systemic therapy options remain limited in efficacy. The median overall survival is about 1 year.

Diffuse Hemispheric Glioma, H3 G34-Mutant Another HGG that preferentially occurs in young adults is the diffuse hemispheric glioma with the histone variant H3.3 glycine to arginine or valine (H3.3-G34R/V) mutation. These tend to occur in a hemispheric location, and the progression remains poor, with median overall survival of 18–22 months. No standard-of-care treatment exists for these tumors, which are often treated similar to GBM with RT and chemotherapy.

PEDIATRIC-TYPE LOW-GRADE GLIOMA

While most common in pediatric patients, pediatric-type low-grade gliomas can also arise in young and older adults. They include avian myeloblastosis viral oncogene (*MYB*)-altered or MYB proto-oncogene like 1 (*MYBL1*)-altered diffuse gliomas and mitogen-activated protein kinase (*MAPK*)-altered diffuse gliomas (commonly v-Raf murine sarcoma viral oncogene homolog B [*BRAF*] or fibroblast growth factor receptor [*FGFR*] alterations). Gross total resection can be curative in many cases, and systemic therapy can provide durable response with oral BRAF or MAPK inhibitors when a targetable mutation or fusion is found.

CIRCUMSCRIBED ASTROCYTOMA AND OTHER GLIONEURONAL TUMORS

These tumors regroup several histologies of more circumscribed tumors, with a typically more indolent natural history. Pilocytic astrocytomas (WHO grade 1) are the most common tumor of childhood. They occur typically in the cerebellum but may also be found elsewhere in the neuraxis, including the optic nerves and brainstem. Frequently they appear as cystic lesions with an enhancing mural nodule. Often, they have *BRAF* fusions or mutations. These are well-demarcated lesions that are potentially curable if they can be resected completely. Subependymal giant cell astrocytomas (SEGAs) are usually found in the ventricular wall of patients with tuberous sclerosis, discussed later.

Gangliogliomas and pleomorphic xanthoastrocytomas occur in young adults. They behave as more indolent forms of grade 1 gliomas and are usually treated with surgery. Frequently they will have *BRAF* V600E mutations, which can be targeted with BRAF inhibitors.

EPENDYMOMAS

Ependymomas are tumors derived from ependymal cells that line the ventricular surface. They arise in three different compartments and are classified according to location as supratentorial, posterior fossa, or spinal ependymomas. Further molecular stratification within each location (supratentorial ependymoma with *ZFTA* or *YAP1* oncogenic fusion; posterior fossa A or posterior fossa B; and spinal with or without *MYCN* amplification) and grading can help guide management. Children typically present with posterior fossa ependymoma followed by supratentorial ependymoma. Although adults can have intracranial ependymomas, they occur more commonly in the spine, especially in the filum terminale of the spinal cord where they have a myxopapillary histology. Ependymomas that can be completely resected are potentially curable. Partially resected ependymomas will recur and require irradiation. The less common anaplastic ependymoma is more aggressive and is treated with resection and RT; chemotherapy has limited efficacy. Subependymomas are slow-growing benign lesions arising in the wall of ventricles that often do not require treatment.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary central nervous system lymphoma (PCNSL) is a rare non-Hodgkin's lymphoma accounting for <3% of primary brain tumors. For unclear reasons, its incidence is increasing, particularly in immunocompetent, older individuals.

PCNSL in immunocompetent patients is usually a diffuse large B-cell lymphoma. Immunocompromised patients, especially those infected with the human immunodeficiency virus (HIV) or organ transplant recipients, are at risk for PCNSL that is typically large cell with immunoblastic and more aggressive features. Epstein-Barr virus (EBV) plays an important role in the pathogenesis of PCNSL in this population. These patients are usually severely immunocompromised, with CD4 counts of <50/mL.

Immunocompetent patients with PCNSL are older (median age, 60 years) than those with HIV-related PCNSL (median age, 31 years). PCNSL usually presents as a mass lesion, with neuropsychiatric symptoms, lateralizing signs, or seizures. Ocular and leptomeningeal involvement each occur in 15–20% of patients, and involvement of these compartments may be asymptomatic. Rarely, it may present as isolated ocular lymphoma or as primary leptomeningeal lymphoma. When restricted to the leptomeninges, it may present as a subacute or chronic meningitis that causes progressive cranial and spinal nerve dysfunction. CSF cytologic examination or flow cytometry is required to establish the diagnosis.

On contrast-enhanced MRI, PCNSL usually appears as a densely enhancing tumor **(Fig. 95-4)**. Immunocompetent patients have solitary lesions more often than immunosuppressed patients. Frequently, there is involvement of the basal ganglia, corpus callosum, or periventricular region. Stereotactic biopsy is necessary to obtain a histologic diagnosis. Whenever possible, glucocorticoids should be withheld until after the biopsy has been obtained because they have a cytolytic effect on

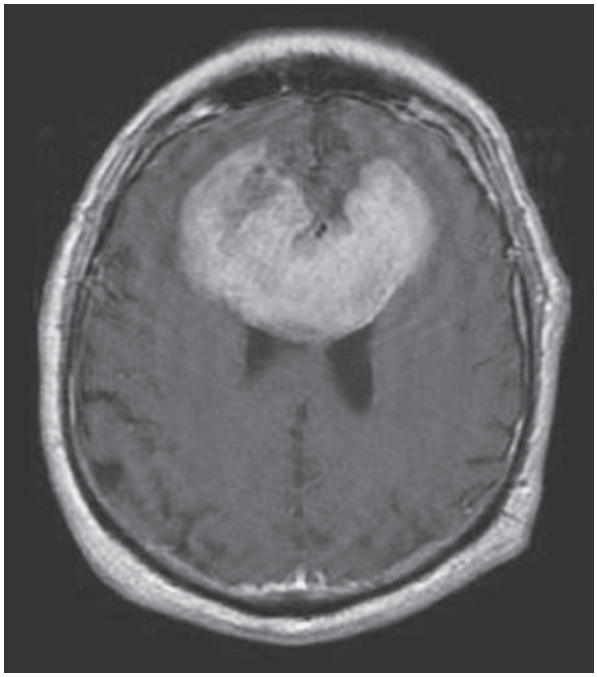

FIGURE 95-4 Postgadolinium T1 MRI demonstrating a large bifrontal primary central nervous system lymphoma (PCNSL). The periventricular location and diffuse enhancement pattern are characteristic of lymphoma.

lymphoma cells and may lead to nondiagnostic tissue. In addition, patients should be tested for HIV, and the extent of disease should be assessed by performing PET or CT of the body, MRI of the spine, CSF analysis, and slit-lamp examination of the eye. Bone marrow biopsy and testicular ultrasound are occasionally performed.

TREATMENT

Primary Central Nervous System Lymphoma

PCNSL is more sensitive to glucocorticoids, chemotherapy, and RT than other primary brain tumors. Durable complete responses and long-term survival are possible with these treatments. High-dose methotrexate, a folate antagonist that interrupts DNA synthesis, produces response rates ranging from 35 to 80% and median survival of up to 50 months. The combination of methotrexate with other chemotherapeutic agents such as cytarabine increases the response rate to 70–100%. The addition of whole-brain RT (WBRT) to methotrexate-based chemotherapy prolongs progression-free survival but not overall survival, but it is associated with delayed neurotoxicity, especially in patients aged >60 years. As a result, full-dose RT is frequently omitted, but there may be a role for reduced-dose RT. The anti-CD20 monoclonal antibody rituximab is often incorporated into the chemotherapy regimen, although there are studies questioning its benefit. For some patients, high-dose chemotherapy with autologous stem cell rescue may offer the best chance of preventing relapse. At least 50% of patients will eventually develop recurrent disease. Treatment options include RT for patients who have not had prior irradiation, retreatment with methotrexate, and other chemotherapeutic agents such as temozolomide and pemetrexed. High-dose chemotherapy with autologous stem cell rescue may be appropriate in selected patients with relapsed disease. Bruton's tyrosine kinase (BTK) inhibitors such as ibrutinib, immunomodulatory drugs such as pomalidomide and lenalidomide, and immune checkpoint inhibitors have shown promising preliminary activity and are being evaluated in clinical trials, as are CAR-T cells.

PCNSL IN IMMUNOCOMPROMISED PATIENTS

PCNSL in immunocompromised patients often produces multiple ring-enhancing lesions that can be difficult to differentiate from metastases or infections such as toxoplasmosis. The diagnosis is usually established by examination of the CSF for cytology and EBV DNA; toxoplasmosis serologic testing; brain PET imaging for hypermetabolism of the lesions, which, although nonspecific, can be consistent with tumor; and, if necessary, brain biopsy. Since the advent of highly active antiretroviral drugs, the incidence of HIV-related PCNSL has declined. These patients are preferably treated with high-dose methotrexate-based regimens and initiation of highly active antiretroviral therapy; WBRT is reserved for those who cannot tolerate systemic chemotherapy. In organ transplant recipients, reduction of immunosuppression may improve outcome.

MEDULLOBLASTOMA

Medulloblastomas are the most common malignant brain tumor of childhood, accounting for ~20% of all primary CNS tumors among children. They arise from granule cell progenitors or from multipotent progenitors from the ventricular zone. Approximately 5% of children with medulloblastoma have an inherited syndrome, such as Gorlin, Turcot, or Li-Fraumeni, which predisposes to the development of medulloblastoma. Histologically, medulloblastomas are highly cellular tumors with abundant dark staining, round nuclei, and rosette formation (Homer-Wright rosettes). In the 2016 WHO pathologic classification, they have been divided into four molecular subgroups: (1) WNT-activated (primarily affects children and has the best outcome); (2) SHH-activated (affects adults, infants, and children, with the younger patients having the better outcome and adults doing poorly); (3) non-WNT/non-SHH, group 3 (frequently has disseminated CNS disease at diagnosis and has the worst outcome); and (4) non-WNT/non-SHH, group 4 (30% have metastases at diagnosis, but 5-year progression-free survival is 95%). Regardless of subtype, patients present with headache, ataxia, and signs of brainstem involvement. On MRI, they appear as densely enhancing tumors in the posterior fossa, sometimes associated with hydrocephalus. Treatment involves maximal surgical resection, craniospinal irradiation, and chemotherapy with agents such as cisplatin, lomustine, cyclophosphamide, and vincristine. Approximately 70% of patients overall have long-term survival but usually at the cost of significant neurocognitive impairment. A major goal of current research is to improve survival while minimizing long-term complications, and clinical trials are now being designed for specific molecular subgroups.

PINEAL REGION TUMORS

A large variety of tumors can arise in the region of the pineal gland. These typically present with headache, visual symptoms, and hydrocephalus. Patients may have Parinaud's syndrome characterized by impaired upgaze and accommodation. Some pineal tumors such as pineocytomas and benign teratomas can be treated by surgical resection. Germinomas respond to irradiation, whereas pineoblastomas and nongerminomatous germ cell tumors require craniospinal RT and chemotherapy.

EXTRINSIC "BENIGN" TUMORS

MENINGIOMA

Meningiomas are diagnosed with increasing frequency as more people undergo neuroimaging for various indications. They are now the most common primary brain tumor, accounting for ~35% of the total. Their incidence increases with age. They tend to be more common in women and in patients with neurofibromatosis type 2 (NF2). They also occur more commonly in patients with a history of cranial irradiation.

Meningiomas arise from the dura mater and are composed of neoplastic meningothelial (arachnoidal cap) cells. They are most commonly located over the cerebral convexities, especially adjacent to the sagittal sinus, but they can also occur in the skull base and along the dorsum of the spinal cord. Meningiomas are classified by the WHO into three histologic grades of increasing aggressiveness: grade I (benign), grade II (atypical), and grade III (malignant).

Many meningiomas are found incidentally following neuroimaging for unrelated reasons. They can also present with headaches, seizures, or focal neurologic deficits. On imaging studies, they have a characteristic appearance usually of a densely enhancing extra-axial tumor arising from the dura **(Fig. 95-5)**. Typically they have a dural tail, consisting of thickened, enhanced dura extending like a tail from the mass. The main differential diagnosis of meningioma is a dural metastasis.

If the meningioma is small and asymptomatic, no intervention is necessary and the lesion can be observed with serial MRI studies. Larger, symptomatic lesions should be resected. If complete resection is achieved, the patient is cured. Incompletely resected tumors tend to recur, although the rate of recurrence can be very slow with grade I tumors. Tumors that cannot be resected or can only be partially removed may benefit from external-beam RT or SRS. These treatments may also be helpful in patients whose tumor has recurred after surgery. Hormonal therapy and chemotherapy are currently unproven.

Rarer tumors that resemble meningiomas include hemangiopericytomas and solitary fibrous tumors. Since they share similar molecular alterations (*NAB2-STAT6* fusion), the 2016 WHO classification introduced the combined term *solitary fibrous tumor/hemangiopericytoma* for this entity. These tumors are treated with surgery and RT but have a higher propensity to recur locally or metastasize systemically.

SCHWANNOMA

These are generally benign tumors arising from the Schwann cells of cranial and spinal nerve roots. The most common schwannomas, termed *vestibular schwannomas* or *acoustic neuromas*, arise from the vestibular portion of the eighth cranial nerve and account for ~9% of primary brain tumors. Patients with NF2 have a high incidence of vestibular schwannomas that are frequently bilateral. Schwannomas arising from other cranial nerves, such as the trigeminal nerve (cranial nerve V), occur with much lower frequency. Neurofibromatosis type 1

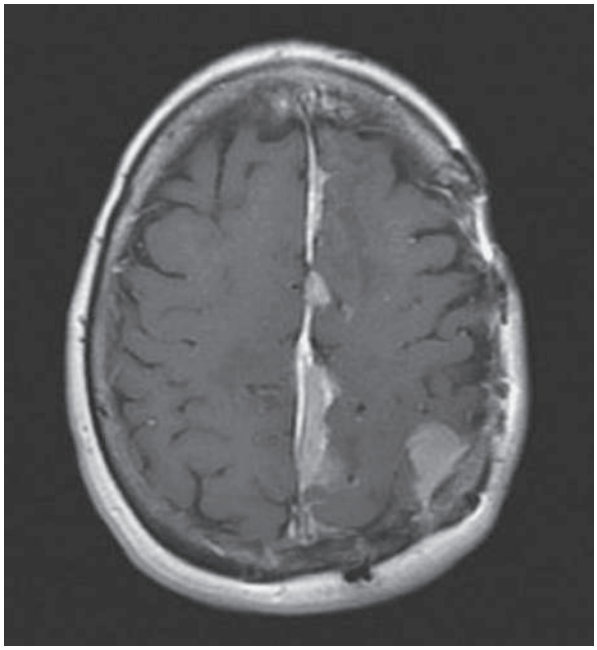

FIGURE 95-5 Postgadolinium T1 MRI demonstrating multiple meningiomas along the falx and left parietal cortex.

(NF1) is associated with an increased incidence of schwannomas of the spinal nerve roots.

Vestibular schwannomas may be found incidentally on neuroimaging or present with progressive unilateral hearing loss, dizziness, tinnitus, or, less commonly, symptoms resulting from compression of the brainstem and cerebellum. On MRI, they appear as densely enhancing lesions, enlarging the internal auditory canal and often extending into the cerebellopontine angle **(Fig. 95-6)**. The differential diagnosis includes meningioma. Very small, asymptomatic lesions can be observed with serial MRIs. Larger lesions should be treated with surgery or SRS. The optimal treatment will depend on the size of the tumor, symptoms, and the patient's preference. In patients with small vestibular schwannomas and relatively intact hearing, early surgical intervention increases the chance of preserving hearing.

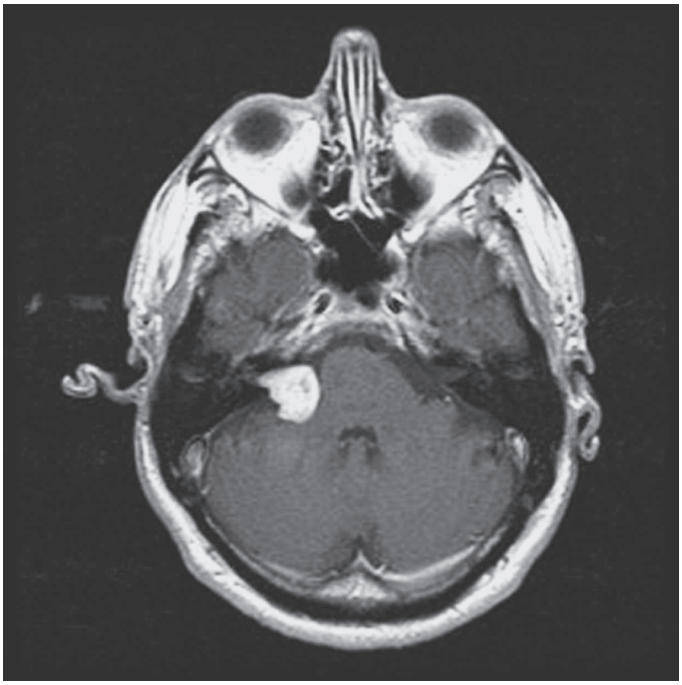

FIGURE 95-6 Postgadolinium MRI of a right vestibular schwannoma. The tumor can be seen to involve the internal auditory canal.

PITUITARY TUMORS

These are discussed in detail in **Chap. 392**.

CRANIOPHARYNGIOMAS

Craniopharyngiomas are rare, usually suprasellar, partially calcified, solid, or mixed solid-cystic benign tumors that arise from remnants of Rathke's pouch. They have a bimodal distribution, occurring predominantly in children but also between the ages of 55 and 65 years. They present with headaches, visual impairment, and impaired growth in children and hypopituitarism in adults. Treatment involves surgery, RT, or a combination of the two. The papillary subtype of craniopharyngiomas often has *BRAF* V600E mutations and can be treated with RAF/MEK inhibitors.

OTHER BENIGN TUMORS

Epidermoid Cysts These consist of squamous epithelium surrounding a keratin-filled cyst. They are usually found in the cerebellopontine angle and the intrasellar and suprasellar regions. They may present with headaches, cranial nerve abnormalities, seizures, or hydrocephalus. MRI demonstrates an extra-axial lesion with characteristics that are similar to CSF but have restricted diffusion. Treatment involves surgical resection.

Dermoid Cysts Like epidermoid cysts, dermoid cysts arise from epithelial cells that are retained during closure of the neural tube. They contain both epidermal and dermal structures such as hair follicles, sweat glands, and sebaceous glands. Unlike epidermoid cysts, these tumors usually have a midline location. They occur most frequently in the posterior fossa, especially the vermis, fourth ventricle, and suprasellar cistern. On MRI, dermoid cysts resemble lipomas, demonstrating T1 hyperintensity and variable signal on T2. Symptomatic dermoid cysts can be treated with surgery.

Colloid Cysts These usually arise in the anterior third ventricle and may present with headaches, hydrocephalus, and, very rarely, sudden death. Surgical resection is curative, or a third ventriculostomy may relieve the obstructive hydrocephalus and be sufficient therapy.

NEUROCUTANEOUS SYNDROMES (PHAKOMATOSES)

A number of genetic disorders are characterized by cutaneous lesions and an increased risk of brain tumors. Most of these disorders have an autosomal dominant inheritance with variable penetrance.

NEUROFIBROMATOSIS TYPE 1 (von RECKLINGHAUSEN'S DISEASE)

NF1 is an autosomal dominant disorder with variable penetrance and an incidence of ~1 in 2600–3000. Approximately one-half of cases are familial; the remainder are caused by new mutations arising in patients with unaffected parents. The *NF1* gene is located on chromosome 17q11.2 and encodes neurofibromin, a guanosine triphosphatase (GTPase) activating protein (GAP) that is a negative regulator of the RAS–mitogen-activated protein (MAP) kinase signaling pathway, which includes the downstream kinase MEK. It is a classic tumor suppressor, and biallelic loss can result in a variety of nervous system tumors including neurofibromas, plexiform neurofibromas, optic nerve gliomas, astrocytomas, and meningiomas. In addition to neurofibromas, which appear as multiple, soft, rubbery cutaneous tumors, other cutaneous manifestations of NF1 include café-au-lait spots and axillary freckling. NF1 is also associated with hamartomas of the iris termed Lisch nodules, pheochromocytomas, pseudoarthrosis of the tibia, scoliosis, epilepsy, and intellectual disability. The MEK inhibitor selumetinib has activity against inoperable plexiform neurofibromas and is the only treatment that targets the dysregulated signaling pathway.

NEUROFIBROMATOSIS TYPE 2

NF2 is less common than NF1, with an incidence of 1 in 25,000–40,000. It is an autosomal dominant disorder with full penetrance. As with NF1, approximately one-half of cases arise from new mutations.

The *NF2* gene on 22q encodes a cytoskeletal protein, merlin (moesin, ezrin, radixin-like protein), that functions as a tumor suppressor. NF2 is characterized by bilateral vestibular schwannomas in >90% of patients, multiple meningiomas, and spinal ependymomas and astrocytomas. Treatment of bilateral vestibular schwannomas can be challenging because the goal is to preserve hearing for as long as possible. These patients may also have diffuse schwannomatosis that may affect the cranial, spinal, or peripheral nerves; posterior subcapsular lens opacities; and retinal hamartomas.

TUBEROUS SCLEROSIS (BOURNEVILLE DISEASE)

This is an autosomal dominant disorder with an incidence of ~1 in 5000–10,000 live births. It is caused by mutations in either the *TSC1* gene, which encodes a protein termed hamartin, or the *TSC2* gene, which encodes the protein tuberin. Hamartin forms a complex with tuberin, which inhibits cellular signaling through the mammalian target of rapamycin (mTOR), and acts as a negative regulator of the cell cycle. Patients with tuberous sclerosis may have seizures, intellectual disability, adenoma sebaceum (facial angiofibromas), shagreen patch, hypomelanotic macules, periungual fibromas, renal angiomyolipomas, and cardiac rhabdomyomas. These patients have an increased incidence of subependymal nodules, cortical tubers, and SEGAs. Patients frequently require anticonvulsants for seizures. SEGAs do not always require therapeutic intervention, but the most effective therapy is with the mTOR inhibitors sirolimus or everolimus, which often decrease seizures as well as SEGA size.

TUMORS METASTATIC TO THE BRAIN

Brain metastases arise from hematogenous spread and frequently originate from a lung primary or are associated with pulmonary metastases. Most metastases develop at the gray matter–white matter junction in the watershed distribution of the brain where intravascular tumor cells lodge in terminal arterioles. The distribution of metastases in the brain approximates the proportion of blood flow such that ~85% of all metastases are supratentorial and 15% occur in the posterior fossa. The most common sources of brain metastases are lung and breast carcinomas; melanoma has the greatest propensity to metastasize to the brain, being found in 80% of patients at autopsy (Table 95-4). Other tumor types such as ovarian and esophageal carcinoma rarely metastasize to the brain. Prostate and breast cancers also have a propensity to metastasize to the dura and can mimic meningioma. Leptomeningeal metastases are common from hematologic malignancies and also breast and lung cancers. Spinal cord compression primarily arises in patients with prostate and breast cancer, tumors with a strong propensity to metastasize to the axial skeleton.

DIAGNOSIS OF METASTASES

Brain metastases are best visualized on MRI, where they usually appear as well-circumscribed lesions (Fig. 95-7). The amount of perilesional edema can be highly variable, with large lesions causing minimal edema and sometimes very small lesions causing extensive edema. Enhancement may be in a ring pattern or diffuse. Occasionally, intracranial metastases will hemorrhage; melanoma, thyroid, and kidney cancer have the greatest propensity to hemorrhage, but the most common cause of a hemorrhagic metastasis is lung cancer because it accounts for the majority of brain metastases. The radiographic appearance of brain metastasis is nonspecific, and similar-appearing lesions can occur with infection including brain abscesses, demyelinating lesions, sarcoidosis, radiation necrosis in a previously treated patient, or a primary brain tumor that may be a second malignancy in a patient with systemic cancer. Biopsy is rarely necessary for diagnosis because imaging alone in the appropriate clinical situation usually suffices. However, in ~10% of patients, a systemic cancer may present with a brain metastasis, and if there is not an easily accessible systemic site to biopsy, a brain lesion must be removed for diagnostic purposes.

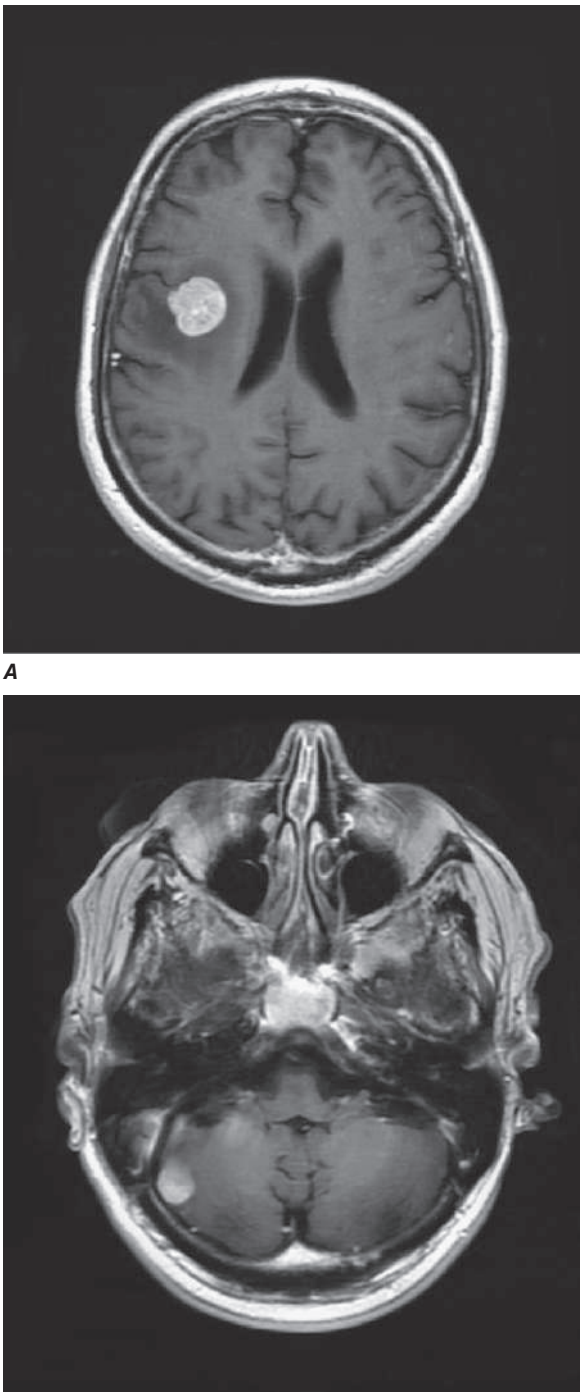

FIGURE 95-7 Postgadolinium T1 MRI of multiple brain metastases from non-small-cell lung cancer involving the right frontal (***A***) and right cerebellar (***B***) hemispheres. Note the diffuse enhancement pattern and absence of central necrosis.

TABLE 95-4 Frequency of Nervous System Metastases for Common Primary Tumors

	BRAIN (%)	LM (%)	ESCC (%)
Lung	41	17	15
Breast	19	57	22
Melanoma	10	12	4
Prostate	1	1	10
GIT	7	—	5
Renal	3	2	7
Lymphoma	<1	10	10
Sarcoma	7	1	9
Other	11	—	18

Abbreviations: ESCC, epidural spinal cord compression; GIT, gastrointestinal tract; LM, leptomeningeal metastases.

TREATMENT

Tumors Metastatic to the Brain

DEFINITIVE TREATMENT

The number and location of brain metastases often determine the therapeutic options. The patient's overall condition and current or potential control of systemic disease are also major determinants. Brain metastases are single in approximately one-half of patients and multiple in the other half.

RADIATION THERAPY

The standard treatment for brain metastases has previously been WBRT usually administered to a total dose of 3000 cGy in 10 fractions. This affords rapid palliation, and ~80% of patients improve with glucocorticoids and RT. However, it is not curative, is associated with neurocognitive toxicity, and produces median survival of only 4–6 months. Hippocampal avoidance during WBRT can preserve cognitive function without increasing the risk of an intracranial relapse. The use of WBRT has declined with the development of more effective systemic options and access to SRS. If feasible, SRS has become the primary radiation oncology approach to brain metastases. It can be delivered through a variety of equally effective techniques including the gamma knife, linear accelerator, proton beam, or CyberKnife, all of which can deliver highly focused doses of RT, usually in a single fraction. SRS can effectively sterilize the visible lesions and afford local disease control in 80–90% of patients. Some patients have been cured of their brain metastases using SRS, whereas this is distinctly rare with WBRT. Traditionally SRS was used only for patients with 1–3 metastases, but recent data suggest that SRS can effectively treat 10 or more lesions. It is, however, confined to lesions of ≤3 cm and is most effective in metastases of ≤1 cm. The addition of WBRT to SRS improves disease control in the nervous system but does not prolong survival and thus is rarely employed.

SURGERY

Randomized controlled trials have demonstrated that surgical extirpation of a single brain metastasis followed by WBRT is superior to WBRT alone. Removal of two lesions or a single symptomatic mass, particularly if compressing the ventricular system, can also be useful. This is particularly important in patients who have highly radioresistant lesions such as renal carcinoma. Surgical resection can produce rapid amelioration of symptoms, improve control of edema, and result in prolonged survival. WBRT administered after complete resection of a brain metastasis improves disease control but does not prolong survival. There is increasing use of focal RT or even SRS to a resected cavity, especially if there is concern that tumor has been left behind, but most avoid postoperative WBRT because of its cognitive effects.

CHEMOTHERAPY

Chemotherapy and targeted therapy are becoming increasingly useful for brain metastases. Metastases from tumor types that are highly chemosensitive, such as germ cell tumors or small-cell lung cancer, may respond to chemotherapeutic regimens chosen according to the underlying malignancy. Increasingly, data demonstrate responsiveness of brain metastases to targeted therapeutics, such as for patients with lung cancer harboring *EGFR* mutations that sensitize them to EGFR inhibitors. Immunotherapy is also effective against those primary tumors that are sensitive to this approach, such as melanoma. Antiangiogenic agents such as bevacizumab are effective in the treatment of CNS metastases in those primary tumors for which it is approved.

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases are also described as carcinomatous meningitis, meningeal carcinomatosis, or, in the case of specific tumors, leukemic or lymphomatous meningitis. Among the hematologic malignancies, acute leukemias most commonly metastasize to the subarachnoid space, followed in frequency by aggressive diffuse lymphomas. Among solid tumors, breast and lung carcinomas and melanoma most frequently spread in this fashion. Tumor cells reach the subarachnoid space via the arterial circulation or occasionally through retrograde flow in venous systems that drain metastases along the bony spine or cranium. In addition, leptomeningeal metastases may develop as a direct consequence of prior brain metastases and occur in almost 40% of patients who have a metastasis resected from the cerebellum.

CLINICAL FEATURES

Leptomeningeal metastases are characterized by multilevel symptoms and signs along the neuraxis. Combinations of lumbar and cervical radiculopathies, cranial neuropathies, seizures, confusion, and encephalopathy from hydrocephalus or raised intracranial pressure can be present. Focal deficits such as hemiparesis or aphasia are rarely due to leptomeningeal metastases unless there is direct brain infiltration. New-onset limb pain in patients with breast cancer, lung cancer, or melanoma should prompt consideration of leptomeningeal spread.

LABORATORY AND IMAGING DIAGNOSIS

Leptomeningeal metastases are particularly challenging to diagnose because identification of tumor cells in the subarachnoid compartment may be elusive. MRI can be definitive when there are clear tumor nodules adherent to the cauda equina or spinal cord, enhancing cranial nerves, or subarachnoid enhancement on brain imaging **(Fig. 95-8)**. Imaging is diagnostic in ~75% of patients and is more often positive in patients with solid tumors. Demonstration of tumor cells in the CSF is definitive and often considered the gold standard. However, CSF cytologic examination is positive in only 50% of patients on the first lumbar puncture and still misses 10% after three CSF samples. New technologies, such as rare cell capture, enhance identification of tumor cells in the CSF; molecular profiling of the CSF can also identify tumor-specific mutations, indicating malignancy in the leptomeninges. CSF cytologic examination is most useful in hematologic malignancies, especially when combined with flow cytometry to identify a clonal population. Accompanying CSF abnormalities include an elevated protein concentration and an elevated white blood cell count; hypoglycorrhachia is noted in <25% of patients but is useful when present. Identification of tumor markers may be helpful in some solid tumors.

TREATMENT

Leptomeningeal Metastases

The treatment of leptomeningeal metastasis is palliative because there is no curative therapy. RT to the symptomatically involved areas, such as skull base for cranial neuropathy, can relieve pain and sometimes improve function. Craniospinal irradiation (CSI) was previously avoided because it has significant toxicity with myelosuppression and gastrointestinal irritation as well as limited effectiveness. However, recent data on proton beam CSI suggest better disease control with fewer systemic toxicities. Systemic chemotherapy, targeted therapeutics, and immunotherapy have all demonstrated limited efficacy in the appropriate setting. Alternatively, intrathecal chemotherapy can be effective, particularly in hematologic malignancies. This is optimally delivered through an intraventricular cannula (Ommaya reservoir) rather than by lumbar puncture. Few drugs can be delivered safely into the subarachnoid space, and they have a limited spectrum of antitumor activity, perhaps accounting for the relatively poor response to this approach, particularly in solid tumors. In addition, impaired CSF flow dynamics can compromise intrathecal drug delivery. Surgery has a limited role in leptomeningeal metastasis. A ventriculoperitoneal shunt can relieve raised intracranial pressure but complicates the use of intrathecal drugs.

EPIDURAL METASTASIS

Epidural metastasis occurs in 3–5% of patients with a systemic malignancy and causes neurologic compromise by compressing the spinal cord or cauda equina. The most common cancers that metastasize to

A

B

FIGURE 95-8 Postgadolinium MRI images of extensive leptomeningeal metastases from breast cancer. Nodules along the dorsal surface of the spinal cord (***A***) and cauda equina (***B***) are seen.

the epidural space are those malignancies that spread to bone, such as breast and prostate. Lymphoma can cause bone involvement and compression, but it can also invade an intervertebral foramen and cause spinal cord compression without bone destruction. The thoracic spine is affected most commonly, followed by the lumbar and then cervical spine.

CLINICAL FEATURES

Back pain is the presenting symptom of epidural metastasis in virtually all patients; the pain may precede neurologic findings by weeks or months. The pain is usually exacerbated by lying down; by contrast, arthritic pain is often relieved by recumbency. Leg weakness is seen in ~50% of patients, as is sensory dysfunction. Sphincter problems are present in ~25% of patients at diagnosis.

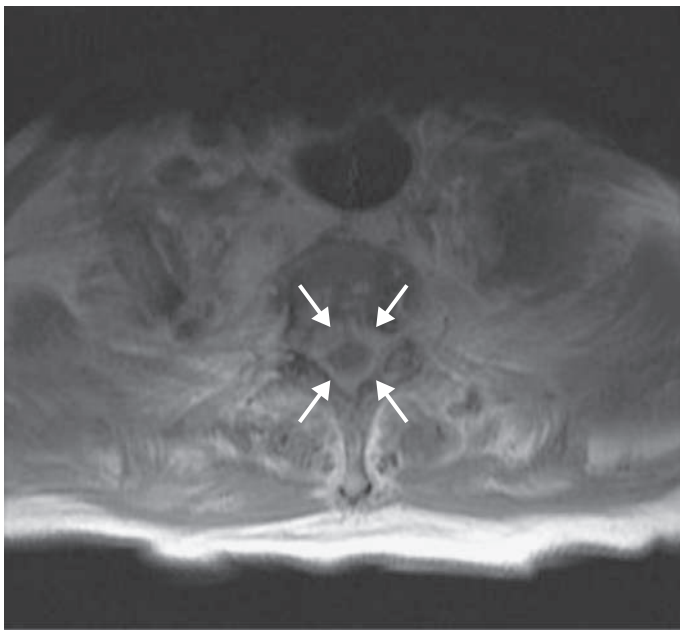

FIGURE 95-9 Postgadolinium T1 MRI showing circumferential epidural tumor around the thoracic spinal cord from esophageal cancer.

DIAGNOSIS

Diagnosis is established by imaging, preferably with an MRI of the entire spine (Fig. 95-9). Any patient with cancer who has severe back pain should undergo an MRI. Plain films, bone scans, or even CT scans may show bone metastases, but only MRI can reliably delineate epidural tumor. For patients unable to have an MRI, CT myelography should be performed to outline the epidural space. The differential diagnosis of epidural tumor includes epidural abscess, acute or chronic hematomas, epidural lipomatosis, and, rarely, extramedullary hematopoiesis.

TREATMENT

Epidural Metastasis

Epidural metastasis requires immediate treatment. A randomized controlled trial demonstrated the superiority of surgical resection followed by RT compared to RT alone. However, patients must be able to tolerate surgery, and the surgical procedure of choice is a complete removal of the mass, which is typically anterior to the spinal canal, necessitating an extensive approach and resection. Otherwise, RT is the mainstay of treatment and can be used for patients with radiosensitive tumors, such as lymphoma, or for those unable to undergo surgery. SRS or stereotactic body radiotherapy is increasingly being used, especially for radioresistant tumor types or for reirradiation. Chemotherapy is rarely used for epidural metastasis unless the patient has minimal to no neurologic deficit and a highly chemosensitive tumor such as lymphoma or germinoma. Patients generally fare well if treated before there is a severe neurologic deficit. Recovery from paraparesis is better after surgery than with RT alone, but survival is often short due to widespread metastatic tumor.

NEUROLOGIC TOXICITY OF THERAPY

TOXICITY FROM RADIOTHERAPY

RT can cause a variety of toxicities in the CNS. These are usually described based on their relationship in time to the administration of RT: acute (occurring within days of RT), early delayed (months), or late delayed (years). In general, the acute and early delayed syndromes resolve and do not result in persistent deficits, whereas the late delayed toxicities are usually permanent and sometimes progressive.

Acute Toxicity Acute cerebral toxicity may occur during RT to the brain. RT can cause a transient disruption of the blood-brain barrier, resulting in edema and elevated intracranial pressure. This is usually manifest as headache, lethargy, nausea, and vomiting and can be both prevented and treated with the administration of glucocorticoids.

Early Delayed Toxicity Early delayed toxicity is usually apparent weeks to months after completion of cranial irradiation and is likely due to focal demyelination. Clinically it may be asymptomatic or take the form of worsening or reappearance of a preexisting neurologic deficit. At times, a contrast-enhancing lesion can be seen on MRI/CT that can mimic the tumor for which the patient received the RT. For patients with a malignant glioma, this has been described as "pseudoprogression" because it mimics tumor recurrence on MRI, but it represents inflammation and necrotic debris engendered by effective therapy. This is seen with increased frequency when chemotherapy, particularly temozolomide, is given concurrently with RT. Pseudoprogression can resolve on its own or, if very symptomatic, may require glucocorticoids, resection, or bevacizumab.

In the spinal cord, early delayed RT toxicity is manifest as a Lhermitte symptom with paresthesias of the limbs or along the spine when the patient flexes the neck. Although frightening, it is benign, resolves on its own, and does not portend more serious problems.

Late Delayed Toxicity Late delayed toxicities are the most serious because they are often irreversible and cause severe neurologic deficits. In the brain, late toxicities can take several forms, the most common of which include radiation necrosis and leukoencephalopathy. Radiation necrosis is a focal mass of necrotic tissue that is contrast enhancing on CT/MRI and may be associated with significant edema. This may appear identical to pseudoprogression but is seen months to years after RT and is always symptomatic. Clinical symptoms and signs include seizures and findings referable to the location of the necrotic mass. The necrosis is caused by the effect of RT on cerebral vasculature with fibrinoid necrosis and occlusion of blood vessels. It can mimic tumor radiographically, but unlike tumor, it is typically hypometabolic on a PET scan and has reduced cerebral blood volume on perfusion MR sequences. It may require resection for diagnosis and treatment unless it can be managed with glucocorticoids. There are reports of improvement with bevacizumab and laser interstitial thermal therapy.

Leukoencephalopathy is seen most commonly after WBRT as opposed to focal RT. On T2 or FLAIR MR sequences, there is diffusely increased signal seen throughout the hemispheric white matter, often bilaterally and symmetrically. There tends to be a periventricular predominance that may be associated with atrophy and ventricular enlargement. Clinically, patients develop cognitive impairment, a gait disorder, and later urinary incontinence, all of which can progress over time. These symptoms mimic those of normal pressure hydrocephalus, and placement of a ventriculoperitoneal shunt can improve function in some patients but does not reverse the deficits completely. Increased age is a risk factor for leukoencephalopathy but not for radiation necrosis. Necrosis appears to depend on an unidentified predisposition.

Other late neurologic toxicities include endocrine dysfunction if the pituitary or hypothalamus was included in the RT port. An RT-induced neoplasm can occur many years after therapeutic RT for either a prior CNS or a head and neck tumor; accurate diagnosis requires surgical resection or biopsy. In addition, RT causes accelerated atherosclerosis, which can cause stroke either from intracranial vascular disease or carotid plaque from neck irradiation.

The peripheral nervous system is relatively resistant to RT toxicities. Peripheral nerves are rarely affected by RT, but the plexus is more vulnerable. Plexopathy develops more commonly in the brachial than in the lumbosacral distribution. It must be differentiated from tumor progression in the plexus, which is usually visualized by CT/MRI or PET scan demonstrating tumor infiltrating the region. Clinically, tumor progression is usually painful, whereas RT-induced plexopathy is painless. Radiation plexopathy is also more commonly associated with lymphedema and myokymia of the affected limb. Sensory loss and weakness are seen in both.

TABLE 95-5 Neurologic Toxicities Caused by Agents Commonly Used in Patients with Cancer

Acute encephalopathy (delirium)	Seizures
Methotrexate (high-dose IV, IT)	Methotrexate
Cisplatin	Etoposide (high-dose)
Vincristine	Cisplatin
Asparaginase	Vincristine
Procarbazine	Asparaginase
5-Fluorouracil (± levamisole)	Nitrogen mustard
Cytarabine (high-dose)	Carmustine
Nitrosoureas (high-dose or arterial)	Dacarbazine (intraarterial or high-dose)
Ifosfamide	Busulfan (high-dose)
Etoposide (high-dose)	Myelopathy (IT drugs)
Bevacizumab (PRES)	Methotrexate
CAR-T cells	Cytarabine
Chronic encephalopathy (dementia)	Thiotepa
Methotrexate	Peripheral neuropathy
Carmustine	Vinca alkaloids
Cytarabine	Cisplatin
Fludarabine	Procarbazine
Visual loss	Etoposide
Tamoxifen	Teniposide
Gallium nitrate	Cytarabine
Cisplatin	Taxanes
Fludarabine	Suramin
Cerebellar dysfunction/ataxia	Bortezomib
5-Fluorouracil (± levamisole)	
Cytarabine	
Procarbazine	

Abbreviations: CAR, chimeric antigen receptor; IT, intrathecal; IV, intravenous; PRES, posterior reversible encephalopathy syndrome.

TOXICITY FROM CHEMOTHERAPY

Neurotoxicity is second to myelosuppression as the dose-limiting toxicity of chemotherapeutic agents (Table 95-5). Chemotherapy causes peripheral neuropathy from many commonly used agents, and the type of neuropathy can vary depending on the drug. Vincristine causes paresthesias but little sensory loss and is associated with motor dysfunction, autonomic impairment (frequently ileus), and, rarely, cranial nerve compromise. Cisplatin causes large-fiber sensory loss resulting in sensory ataxia but little cutaneous sensory loss and no weakness. The taxanes also cause a predominately sensory neuropathy. Agents such as bortezomib and thalidomide also cause neuropathy. Sometimes a severe neuropathy emerges after multiple neurotoxic agents have been used together or in sequence.

Encephalopathy and seizures are common toxicities from chemotherapeutic drugs. Ifosfamide can cause a severe encephalopathy, which is reversible with discontinuation of the drug. Fludarabine also causes a severe global encephalopathy that may be permanent. Bevacizumab and other anti-VEGF agents can cause posterior reversible encephalopathy syndrome. Cisplatin can cause hearing loss and less frequently vestibular dysfunction. Immunotherapy with monoclonal antibodies such as ipilimumab or nivolumab can cause an autoimmune hypophysitis, Guillain-Barré syndrome, or an autoimmune encephalitis. CAR-T cells frequently cause a reversible encephalopathy due to an immune effector cell–associated neurotoxicity syndrome (Chap. 318).

96 Soft Tissue and Bone Sarcomas and Bone Metastases

Shreyaskumar R. Patel

Sarcomas are rare (<1% of all malignancies) mesenchymal neoplasms that arise in bone and soft tissues. These tumors are usually of mesodermal origin, although a few are derived from neuroectoderm, and they are biologically distinct from the more common epithelial malignancies. Sarcomas affect all age groups; 15% are found in children <15 years of age, and 40% occur after age 55 years. Sarcomas are one of the most common solid tumors of childhood and are the fifth most common cause of cancer deaths in children. Sarcomas may be divided into two groups, those derived from bone and those derived from soft tissues.

SOFT TISSUE SARCOMAS

Soft tissues include muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Approximately 60% of soft tissue sarcomas arise in the extremities, with the lower extremities involved three times as often as the upper extremities. Thirty percent arise in the trunk, with the retroperitoneum accounting for 40% of all trunk lesions. The remaining 10% arise in the head and neck.

INCIDENCE

Approximately 13,400 new cases of soft tissue sarcomas occurred in the United States in 2023. The annual age-adjusted incidence is 3 per 100,000 population, but the incidence varies with age. Soft tissue sarcomas constitute 0.7% of all cancers in the general population and 6.5% of all cancers in children.

EPIDEMIOLOGY

Malignant transformation of a benign soft tissue tumor is extremely rare, with the exception that malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannoma) can arise from neurofibromas in patients with neurofibromatosis. Several etiologic factors have been implicated in soft tissue sarcomas.

Environmental Factors Trauma or previous injury is rarely involved, but sarcomas can arise in scar tissue resulting from a prior operation, burn, fracture, or foreign body implantation. Chemical carcinogens such as polycyclic hydrocarbons, asbestos, and dioxin may be involved in the pathogenesis.

Iatrogenic Factors Sarcomas in bone or soft tissues occur in patients who are treated with radiation therapy. The tumor nearly always arises in the irradiated field. The risk increases with time.

Viruses Kaposi's sarcoma (KS) in patients with HIV type 1, classic KS, and KS in HIV-negative homosexual men is caused by human herpesvirus (HHV) 8 **(Chap. 200)**. No other sarcomas are associated with viruses.

Immunologic Factors Congenital or acquired immunodeficiency, including therapeutic immunosuppression, increases the risk of sarcoma.

GENETIC CONSIDERATIONS

Li-Fraumeni syndrome is a familial cancer syndrome in which affected individuals have germline abnormalities of the tumor-suppressor gene *p53* and an increased incidence of soft tissue sarcomas and other malignancies, including breast cancer, osteosarcoma, brain tumor, leukemia, and adrenal carcinoma **(Chap. 76)**. Neurofibromatosis 1 (NF-1; peripheral form, von Recklinghausen's disease) is characterized by multiple neurofibromas and café-au-lait spots. Neurofibromas occasionally undergo malignant degeneration to become malignant peripheral nerve sheath tumors. The gene for *NF1* is located in the pericentromeric region of chromosome 17 and encodes neurofibromin, a tumor-suppressor protein with guanosine 5′-triphosphate (GTP)ase-activating activity that inhibits ras function **(Chap. 95)**. Germline mutation of the *RB1* locus (chromosome 13q14) in patients with inherited retinoblastoma is associated with the development of osteosarcoma in those who survive the retinoblastoma and of soft tissue sarcomas unrelated to radiation therapy. Other soft tissue tumors, including desmoid tumors, lipomas, leiomyomas, neuroblastomas, and paragangliomas, occasionally show a familial predisposition.

Insulin-like growth factor (IGF) type II is produced by some sarcomas and may act as an autocrine growth factor and as a motility factor that promotes metastatic spread. IGF-II stimulates growth through IGF-I receptors, but its effects on motility are through different receptors. If secreted in large amounts, IGF-II may produce hypoglycemia **(Chaps. 98 and 418)**. A large international sarcoma kindred study including 1162 patients and 6545 Caucasian controls revealed that about half the patients with sarcoma have putatively pathogenic monogenic and polygenic variation in previously reported and new cancer genes, some of them representing therapeutically actionable targets. These patients were diagnosed with sarcoma at an earlier age compared to controls.

CLASSIFICATION

Approximately 20 different groups of sarcomas are recognized on the basis of the pattern of differentiation toward normal tissue. For example, rhabdomyosarcoma shows evidence of skeletal muscle fibers with cross-striations; leiomyosarcomas contain interlacing fascicles of spindle cells resembling smooth muscle; and liposarcomas contain adipocytes. When precise characterization of the group is not possible, the tumors are called *unclassified sarcomas*. All of the primary bone sarcomas can also arise from soft tissues (e.g., extraskeletal osteosarcoma). The entity *malignant fibrous histiocytoma* (MFH) includes many tumors previously classified as fibrosarcomas or as pleomorphic variants of other sarcomas and is characterized by a mixture of spindle (fibrous) cells and round (histiocytic) cells arranged in a storiform pattern with frequent giant cells and areas of pleomorphism. As immunohistochemical suggestion of differentiation, particularly myogenic differentiation, may be found in a significant fraction of these patients, many are now characterized as poorly differentiated leiomyosarcomas, and the terms *undifferentiated pleomorphic sarcoma* (UPS) and *myxofibrosarcoma* are replacing MFH and myxoid MFH.

For purposes of treatment, most soft tissue sarcomas can be considered together. However, some specific tumors have distinct features. For example, *liposarcoma* can have a spectrum of behaviors. Pleomorphic liposarcomas and dedifferentiated liposarcomas behave like other high-grade sarcomas; in contrast, well-differentiated liposarcomas (better termed *atypical lipomatous tumors*) lack metastatic potential,

and myxoid liposarcomas metastasize infrequently, but, when they do, they have a predilection for unusual metastatic sites containing fat, such as the retroperitoneum, mediastinum, and subcutaneous tissue. Rhabdomyosarcomas, Ewing's sarcoma, and other small-cell sarcomas tend to be more aggressive and are more responsive to chemotherapy than other soft tissue sarcomas.

Approximately a third of all soft tissue sarcomas have a translocation that may have diagnostic and prognostic relevance; for example, 90% of synovial sarcomas contain a characteristic chromosomal translocation t(X;18)(p11;q11) involving a nuclear transcription factor on chromosome 18 called *SYT* and two breakpoints on X. Patients with translocations to the second X breakpoint (*SSX2*) may have longer survival than those with translocations involving *SSX1*. Targeting these translocations for therapy is an area of ongoing investigation.

Gastrointestinal stromal tumors (GISTs), previously classified as gastrointestinal leiomyosarcomas, are now recognized as a distinct entity within soft tissue sarcomas. Its cell of origin resembles the interstitial cell of Cajal, which controls peristalsis. The majority of malignant GISTs have activating mutations of the c-*kit* gene that result in ligand-independent phosphorylation and activation of the KIT receptor tyrosine kinase, leading to tumorigenesis. Approximately 5–10% of tumors will have a mutation in the platelet-derived growth factor receptor α (*PDGFRA*). GISTs that are wild type for both *KIT* and *PDGFRA* mutations may show mutations in *SDH* B, C, or D and may be driven by the IGF-I pathway.

DIAGNOSIS

The most common presentation is an asymptomatic mass. Mechanical symptoms referable to pressure, traction, or entrapment of nerves or muscles may be present. All new and persistent or growing masses should be biopsied, either by a small incision or by a cutting needle (core-needle biopsy) placed so that it can be encompassed in the subsequent excision without compromising a definitive resection. Lymph node metastases occur in 5%, except in synovial and epithelioid sarcomas, clear cell sarcoma (melanoma of the soft parts), angiosarcoma, and rhabdomyosarcoma, where nodal spread may be seen in 17%. The pulmonary parenchyma is the most common site of metastases. Exceptions are GISTs, which metastasize to the liver; myxoid liposarcomas, which seek fatty tissue; and clear cell sarcomas, which may metastasize to bones. Central nervous system metastases are rare, except in alveolar soft part sarcoma.

Radiographic Evaluation Imaging of the primary tumor is best with plain radiographs and magnetic resonance imaging (MRI) for tumors of the extremities or head and neck and by computed tomography (CT) for tumors of the chest, abdomen, or retroperitoneal cavity. A radiograph and CT scan of the chest are important for the detection of lung metastases. Other imaging studies may be indicated, depending on the symptoms, signs, or histology.

STAGING AND PROGNOSIS

The histologic grade and size of the primary tumor are the most important prognostic factors. The current American Joint Committee on Cancer (AJCC) staging system is shown in **Table 96-1**. Prognosis is related to the stage. Cure is common in the absence of metastatic disease, but a small number of patients with metastases can also be cured. Historically, most patients with stage IV disease used to die within 12 months, but with availability of multiple lines of treatments, median survival in second-line and beyond ranges from 13 to 18 months, and some patients may live with stable or slowly progressive disease for many years.

TABLE 96-1 American Joint Commission on Cancer Staging System for Sarcomas, Eighth Edition

T1	Tumor ≤5 cm in greatest dimension
T2	Tumor >5 cm and ≤10 cm in greatest dimension
T3	Tumor >10 cm and ≤15 cm in greatest dimension
T4	Tumor >15 cm in greatest dimension
N0	No regional lymph node metastasis or unknown lymph node status
N1	Regional lymph node metastasis
M0	No distant metastasis
M1	Distant metastasis

Stage IA	T1; N0; M0; G1
Stage IB	T2, T3, T4; N0; M0; G1
Stage II	T1; N0; M0; G2/3
Stage IIIA	T1A, T2; N0; M0; G2/3
Stage IIIB	T3, T4; N0; M0; G2/3
Stage IV	Any T; N1; M0; any G Any T; any N; M1; any G

TREATMENT

Soft Tissue Sarcomas

AJCC stage I patients are adequately treated with surgery alone. Stage II patients are considered for adjuvant radiation therapy. Stage III patients may benefit from neoadjuvant or adjuvant chemotherapy. Stage IV patients are managed primarily with systemic therapy, with or without other modalities.

SURGERY

Soft tissue sarcomas tend to grow along fascial planes, with the surrounding soft tissues compressed to form a pseudocapsule that gives the sarcoma the appearance of a well-encapsulated lesion. This is invariably deceptive because "shelling out," or marginal excision, of such lesions results in a 50–90% probability of local recurrence. Wide excision with a negative margin, incorporating the biopsy site, is the standard surgical procedure for local disease. The adjuvant use of radiation therapy and/or chemotherapy improves the local control rate and permits the use of limb-sparing surgery with a local control rate (85–90%) comparable to that achieved by radical excisions and amputations. Limb-sparing approaches are indicated except when negative margins are not obtainable, when the risks of radiation are prohibitive, or when neurovascular structures are involved so that resection will result in serious functional consequences to the limb.

RADIATION THERAPY

External-beam radiation therapy is an adjuvant to limb-sparing surgery for improved local control. Preoperative radiation therapy allows the use of smaller fields and smaller doses but results in a higher rate of wound complications. Postoperative radiation therapy must be given to larger fields, because the entire surgical bed must be encompassed, and in higher doses to compensate for hypoxia in the operated field. This results in a higher rate of late complications. Brachytherapy or interstitial therapy, in which the radiation source is inserted into the tumor bed, is comparable in efficacy (except in low-grade lesions), less time consuming, and less expensive.

With the advent of stereotactic body radiotherapy (SBRT), the role of radiation therapy in oligometastatic disease in various visceral sites is evolving.

ADJUVANT CHEMOTHERAPY

Chemotherapy is the mainstay of treatment for Ewing's sarcomas/primitive neuroectodermal tumors (PNETs) and rhabdomyosarcomas. Meta-analysis of 14 randomized trials in non-small-cell sarcomas revealed a significant improvement in local control and disease-free survival in favor of doxorubicin-based chemotherapy. Overall survival improvement was 4% for all sites and 7% for the extremity site. An updated meta-analysis including four additional trials with doxorubicin and ifosfamide combination reported a statistically significant 6% survival advantage in favor of chemotherapy. A chemotherapy regimen including an anthracycline and ifosfamide with growth factor support improved overall survival by 19% for high-risk (high-grade, ≥5 cm primary, or locally recurrent)

extremity soft tissue sarcomas. Long-term follow-up of a trial evaluating neoadjuvant use of the same combination confirms survival advantage and reports a 10-year survival of 61%. A more contemporary randomized trial compared the standard anthracycline and ifosfamide combination to specific histology-tailored chemotherapy as an active control and confirmed superiority of the standard regimen.

ADVANCED DISEASE

Metastatic soft tissue sarcomas are largely incurable, but up to 20% of patients who achieve a complete response become long-term survivors. The therapeutic intent, therefore, is to produce a complete remission with chemotherapy (<10%) and/or surgery (30–40%). Surgical resection of metastases, whenever possible, is an integral part of the management. Some patients benefit from repeated surgical excision of metastases. The two most active chemotherapeutic agents are doxorubicin and ifosfamide. These drugs show a steep dose-response relationship in sarcomas. Gemcitabine with or without docetaxel has become an established second-line regimen and is particularly active in patients with UPS and leiomyosarcomas. Dacarbazine also has some modest activity. Taxanes have selective activity in angiosarcomas, and vincristine, etoposide, and irinotecan are effective in rhabdomyosarcomas and Ewing's sarcomas. Pazopanib, an inhibitor of the vascular endothelial growth factor, platelet-derived growth factor (PDGF), and c-kit, is approved for patients with advanced soft tissue sarcomas excluding liposarcomas after failure of chemotherapy. Two additional chemotherapy drugs have gained approval from the U.S. Food and Drug Administration (FDA). Trabectedin was compared to dacarbazine in a large phase 3 randomized study in advanced leiomyosarcomas and liposarcomas after failure of an anthracycline and resulted in significant improvement in progression-free survival. Eribulin was also tested in a similar trial and showed improvement in survival, predominantly in the liposarcoma subgroup, and is therefore now approved for that subset. Tazemetostat, an EZH2 inhibitor, is now approved for use in metastatic epithelioid sarcomas characterized by loss of tumor-suppressor gene *INI1*, resulting in activation of the EZH2 pathway. Nab-sirolimus, an inhibitor of the mammalian target of rapamycin (mTOR) pathway, is now approved for treatment of metastatic perivascular epithelioid cell tumors (PEComas). The FDA granted approval for nirogacestat, a γ-secretase inhibitor, for the treatment of desmoid tumors. Imatinib targets KIT and PDGF tyrosine kinase activity and is standard therapy for advanced/metastatic GISTs and dermatofibrosarcoma protuberans. Imatinib is also indicated as adjuvant therapy for completely resected primary GISTs. Three years of adjuvant imatinib appear to be superior to 1 year of therapy for high-risk GISTs, although the optimal treatment duration remains unknown. Sunitinib and regorafenib are approved for second- and third-line use, respectively, in metastatic GIST after failure of or intolerance to imatinib. Ripretinib, an inhibitor of c-kit and PDGFRA, was approved for fourth-line use in metastatic GIST based on a placebo-controlled randomized trial reporting an improved median progression-free and overall survival. Avapritinib also received approval for use in the specific molecular subset of *PDGFRA* D842V–mutant metastatic GIST.

Immune checkpoint inhibitors have generally been ineffective in most forms of sarcoma, but atezolizumab, an anti-PD-L1 antibody, has produced responses in about one-third of patients with alveolar soft part sarcoma.

BONE SARCOMAS

INCIDENCE AND EPIDEMIOLOGY

Bone sarcomas are rarer than soft tissue sarcomas; they accounted for only 0.2% of all new malignancies and 3970 new cases in the United States in 2023. Several benign bone lesions have the potential for malignant transformation. Enchondromas and osteochondromas can transform into chondrosarcoma; fibrous dysplasia, bone infarcts, and Paget's disease of bone can transform into either UPS or osteosarcoma.

CLASSIFICATION

Benign Tumors The common benign bone tumors include enchondroma, osteochondroma, chondroblastoma, and chondromyxoid fibroma, of cartilage origin; osteoid osteoma and osteoblastoma, of bone origin; fibroma and desmoplastic fibroma, of fibrous tissue origin; hemangioma, of vascular origin; and giant cell tumor, of unknown origin.

Malignant Tumors The most common malignant tumors of bone are plasma cell tumors (Chap. 116). The four most common malignant nonhematopoietic bone tumors are osteosarcoma, chondrosarcoma, Ewing's sarcoma, and UPS. Rare malignant tumors include chordoma (of notochordal origin), malignant giant cell tumor, adamantinoma (of unknown origin), and hemangioendothelioma (of vascular origin).

Musculoskeletal Tumor Society Staging System Sarcomas of bone are staged according to the Musculoskeletal Tumor Society staging system based on grade and compartmental localization. A Roman numeral reflects the tumor grade: stage I is low grade, stage II is high grade, and stage III includes tumors of any grade that have lymph node or distant metastases. In addition, the tumor is given a letter reflecting its compartmental localization. Tumors designated A are intracompartmental (i.e., confined to the same soft tissue compartment as the initial tumor), and tumors designated B are extracompartmental (i.e., extending into the adjacent soft tissue compartment or into bone). The tumor-node-metastasis (TNM) staging system is shown in Table 96-2.

OSTEOSARCOMA

Osteosarcoma, accounting for almost 45% of all bone sarcomas, is a spindle cell neoplasm that produces osteoid (unmineralized bone) or bone. Approximately 60% of all osteosarcomas occur in children and

TABLE 96-2 Staging System for Bone Sarcomas

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Tumor ≤8 cm in greatest dimension
	T2	Tumor >8 cm in greatest dimension
	T3	Discontinuous tumors in the primary bone site
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Lung
	M1b	Other distant sites
Histologic grade (G)	GX	Grade cannot be assessed
	G1	Well differentiated—low grade
	G2	Moderately differentiated—low grade
	G3	Poorly differentiated—high grade
	G4	Undifferentiated—high grade (Ewing's is always classed G4)

Stage Grouping				
Stage IA	T1	N0	M0	G1,2 low grade
Stage IB	T2	N0	M0	G1,2 low grade

adolescents in the second decade of life, and ~10% occur in the third decade of life. Osteosarcomas in the fifth and sixth decades of life are frequently secondary to either radiation therapy or transformation in a preexisting benign condition, such as Paget's disease. Males are affected 1.5–2 times as often as females. Osteosarcoma has a predilection for metaphyses of long bones; the most common sites of involvement are the distal femur, proximal tibia, and proximal humerus. The classification of osteosarcoma is complex, but 75% of osteosarcomas fall into the "classic" category, which includes osteoblastic, chondroblastic, and fibroblastic osteosarcomas. The remaining 25% are classified as "variants" on the basis of (1) clinical characteristics, as in the case of osteosarcoma of the jaw, postradiation osteosarcoma, or Paget's osteosarcoma; (2) morphologic characteristics, as in the case of telangiectatic osteosarcoma, small-cell osteosarcoma, or epithelioid osteosarcoma; or (3) location, as in parosteal or periosteal osteosarcoma. Diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction (sunburst appearance), and a cuff of periosteal new bone formation at the margin of the soft tissue mass (Codman's triangle). A CT scan of the primary tumor is best for defining bone destruction and the pattern of calcification, whereas MRI is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. Metastases to the bony skeleton should be imaged by a bone scan or by fluorodeoxyglucose positron emission tomography (FDG-PET). Almost all osteosarcomas are hypervascular and PET-avid. Pathologic diagnosis is established either with a core-needle biopsy, where feasible, or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcomas are high grade. The most important predictive factor for long-term survival is response to chemotherapy. Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in >80% of patients) followed by postoperative chemotherapy is standard management. The effective drugs are doxorubicin, ifosfamide, cisplatin, and high-dose methotrexate with leucovorin rescue. The various combinations of these agents that have been used have all been about equally successful. Long-term survival rates in extremity osteosarcoma range from 60 to 80%. Osteosarcoma is radioresistant; radiation therapy has no role in the routine management. UPS is considered a part of the spectrum of osteosarcoma and is managed similarly. A randomized trial has shown improved progression-free survival with regorafenib compared to placebo.

CHONDROSARCOMA

Chondrosarcoma, which constitutes ~20–25% of all bone sarcomas, is a tumor of adulthood and old age, with a peak incidence in the fourth to sixth decades of life. It has a predilection for the flat bones, especially the shoulder and pelvic girdles, but can also affect the diaphyseal portions of long bones. Chondrosarcomas can arise de novo or as a malignant transformation of an enchondroma or, rarely, of the cartilaginous cap of an osteochondroma. Chondrosarcomas have an indolent natural history and typically present as pain and swelling. Radiographically, the lesion may have a lobular appearance with mottled or punctate or annular calcification of the cartilaginous matrix. It is difficult to distinguish low-grade chondrosarcoma from benign lesions by x-ray or histologic examination. The diagnosis is therefore influenced by clinical history and physical examination. A new onset of pain, signs of inflammation, and progressive increase in the size of the mass suggest malignancy. The histologic classification is complex, but most tumors fall within the classic category. Like other bone sarcomas, high-grade chondrosarcomas spread to the lungs. Most chondrosarcomas are resistant to chemotherapy, and surgical resection of primary or recurrent tumors, including pulmonary metastases, is the mainstay of therapy with the exception of two histologic variants. Dedifferentiated chondrosarcoma has a high-grade osteosarcoma or a UPS component that responds to chemotherapy. Mesenchymal chondrosarcoma, a rare variant composed of a small-cell element, also is responsive to systemic chemotherapy and is treated like Ewing's sarcoma.

EWING'S SARCOMA

Ewing's sarcoma, which constitutes ~10–15% of all bone sarcomas, is common in adolescence and has a peak incidence in the second decade of life. It typically involves the diaphyseal region of long bones and also has an affinity for flat bones. The plain radiograph may show a characteristic "onion peel" periosteal reaction with a generous soft tissue mass, which is better demonstrated by CT or MRI. This mass is composed of sheets of monotonous, small, round, blue cells and can be confused with lymphoma, embryonal rhabdomyosarcoma, and small-cell carcinoma. The presence of p30/32, the product of the *mic-2* gene (which maps to the pseudoautosomal region of the X and Y chromosomes), is a cell-surface marker for Ewing's sarcoma (and other members of the Ewing family of tumors, previously also called PNETs). Most PNETs arise in soft tissues; they include peripheral neuroepithelioma, Askin's tumor (chest wall), and esthesioneuroblastoma. The classic cytogenetic abnormality associated with this disease is a reciprocal translocation of the long arms of chromosomes 11 and 22, t(11;22), which creates a chimeric gene product of unknown function with components from the *fli-1* gene on chromosome 11 and *ews* on chromosome 22. This disease is very aggressive, and it is therefore considered a systemic disease. Common sites of metastases are lung, bones, and bone marrow. Systemic chemotherapy is the mainstay of therapy, often being used before surgery. Doxorubicin, cyclophosphamide or ifosfamide, etoposide, and vincristine are active drugs. Topotecan or irinotecan in combination with an alkylating agent is often used in relapsed patients. Local treatment for the primary tumor includes surgical resection, usually with limb salvage or radiation therapy. Overall cure rates approach 60–70% for localized tumors.

TUMORS METASTATIC TO BONE

Bone is a common site of metastasis for carcinomas of the prostate, breast, lung, kidney, bladder, and thyroid and for lymphomas and sarcomas. Prostate, breast, and lung primaries account for 80% of all bone metastases. Metastatic tumors of bone are more common than primary bone tumors. Tumors usually spread to bone hematogenously, but local invasion from soft tissue masses also occurs. In descending order of frequency, the sites most often involved are the vertebrae, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Bone metastases may be asymptomatic or may produce pain, swelling, nerve root or spinal cord compression, pathologic fracture, or myelophthisis (replacement of the marrow). Symptoms of hypercalcemia may be noted in cases of bony destruction.

Pain is the most frequent symptom. It usually develops gradually over weeks, is usually localized, and often is more severe at night. When patients with back pain develop neurologic signs or symptoms, emergency evaluation for spinal cord compression is indicated (Chap. 80). Bone metastases exert a major adverse effect on quality of life in cancer patients.

Cancer in the bone may produce osteolysis, osteogenesis, or both. Osteolytic lesions result when the tumor produces substances that can directly elicit bone resorption (vitamin D–like steroids, prostaglandins, or parathyroid hormone–related peptide) or cytokines that can induce the formation of osteoclasts (interleukin 1 and tumor necrosis factor). Osteoblastic lesions result when the tumor produces cytokines that activate osteoblasts. In general, purely osteolytic lesions are best detected by plain radiography, but they may not be apparent until they are >1 cm. These lesions are more commonly associated with hypercalcemia and with the excretion of hydroxyproline-containing peptides indicative of matrix destruction. When osteoblastic activity is prominent, the lesions may be readily detected using radionuclide bone scanning (which is sensitive to new bone formation), and the radiographic appearance may show increased bone density or sclerosis. Osteoblastic lesions are associated with higher serum levels of alkaline phosphatase and, if extensive, may produce hypocalcemia. Although some tumors may produce mainly osteolytic lesions (e.g., kidney cancer) and others mainly osteoblastic lesions (e.g., prostate cancer), most metastatic lesions produce both types of lesion and may go through stages where one or the other predominates.

In older patients, particularly women, it may be necessary to distinguish metastatic disease of the spine from osteoporosis. In

osteoporosis, the cortical bone may be preserved, whereas cortical bone destruction is usually noted with metastatic cancer.

TREATMENT

Metastatic Bone Disease

Treatment of metastatic bone disease depends on the underlying malignancy and the symptoms. Some metastatic bone tumors are curable (lymphoma, Hodgkin's lymphoma), and others are treated with palliative intent. Pain may be relieved by local radiation therapy. Hormonally responsive tumors are responsive to hormone inhibition (antiandrogens for prostate cancer, antiestrogens for breast cancer). Strontium-89, samarium-153, and radium-223 are bone-seeking radionuclides that can exert antitumor effects and relieve symptoms. Denosumab, a monoclonal antibody that binds to RANK ligand, inhibits osteoclastic activity and increases bone mineral density. Bisphosphonates such as pamidronate may relieve pain and inhibit bone resorption, thereby maintaining bone mineral density and reducing risk of fractures in patients with osteolytic metastases from breast cancer and multiple myeloma. Careful monitoring of serum electrolytes and creatinine is recommended. Monthly administration prevents bone-related clinical events and may reduce the incidence of bone metastases in women with breast cancer. When the integrity of a weight-bearing bone is threatened by an expanding metastatic lesion that is refractory to radiation therapy, prophylactic internal fixation is indicated. Overall survival is related to the prognosis of the underlying tumor. Bone pain at the end of life is particularly common; an adequate pain relief regimen including sufficient amounts of narcotic analgesics is required. **The management of hypercalcemia is discussed in Chap. 422.**

97 Carcinoma of Unknown Primary

Kanwal Raghav, James L. Abbruzzese

Carcinoma (or cancer) of unknown primary (CUP) is a biopsy-proven malignancy for which the anatomic site of origin remains unidentified after a standardized detailed diagnostic evaluation. CUP is one of the 10 most frequently diagnosed cancers globally, accounting for 3–5% of all malignancies. Most investigators limit CUP to epithelial or undifferentiated cancers and do not include lymphomas, metastatic melanomas, and metastatic sarcomas because these cancers have specific histology and stage-based management guidelines, even in the absence of a primary site. CUP can occur in patients of all age groups including adolescents and young adults.

The emergence of sophisticated imaging, robust immunohistochemistry (IHC), and genomic and proteomic tools has challenged the "unknown" designation. Additionally, effective targeted therapies in several cancers and tissue-agnostic biomarker-driven therapies have endorsed a change in paradigm from empiricism to a personalized approach to CUP management. The reasons cancers present as CUP remain unclear. One hypothesis is that the primary tumor either regresses after seeding the metastasis or remains so small that it is not detected. It is possible that CUP falls on the continuum of cancer presentation where the primary has been contained or eliminated by the natural body defenses, including the immune system. Alternatively, CUP may represent a specific malignant event that results in an increase in metastatic spread or survival relative to the primary. Whether the CUP metastases truly define a clone that is genetically and phenotypically unique to this diagnosis remains to be determined.

Since liver is a common site of CUP presentation, intrahepatic cholangiocarcinoma (ICC) can be often misdiagnosed as CUP. Of note, the incidence of ICC is increasing, whereas at the same time, that of CUP is declining. Improvements in diagnostic technologies including next-generation sequencing and other molecular techniques and awareness among clinicians to differentiate the two are possibly contributing to an increased recognition and incidence of ICC.

CUP BIOLOGY

Studies looking for unique signature abnormalities in CUP tumors have not been positive. Abnormalities in chromosomes 1 and 12 and other complex cytogenetic abnormalities have been reported. Aneuploidy has been described in 70% of CUP patients with metastatic adenocarcinoma or undifferentiated carcinoma. The overexpression of various genes, including *RAS*, *BCL2* (40%), *HER2* (11%), and *P53* (26–53%), has been identified in CUP samples, but they are found in many other malignancies. The extent of angiogenesis in CUP relative to that in metastases from known primaries has also been evaluated, but no consistent findings have emerged. Although current comprehensive genomic profiling efforts may help identify targeted therapeutic approaches to improve outcomes for this disease as discussed below, they have failed thus far to reveal a distinct molecular signature. More comprehensive and integrated multiomic efforts are needed to provide insights into CUP biology through recognition of molecular aberrations that specifically drive metastatic growth.

APPROACH TO THE PATIENT

Carcinoma (or Cancer) of Unknown Primary

Initial CUP evaluation has two goals: search for the primary or "putative primary" tumor based on clinicopathologic evaluation of the metastases and determine the extent of disease. Focused evaluation directed by clinicopathologic cues allows for judicious and efficient use of diagnostic tests. Obtaining a thorough medical history from CUP patients is essential, including paying particular attention to risk factors, prior surgeries, and family medical history to assess potential hereditary cancers. Adequate physical examination, including a digital rectal examination in men and breast and pelvic examinations in women, should be performed based on clinical presentation. Finally, all patients with CUP, in the absence of contraindication, must undergo a computed tomography (CT) scan of chest, abdomen, and pelvis as a part of their standard workup.

ROLE OF SERUM TUMOR MARKERS AND CYTOGENETICS

Most tumor markers, including carcinoembryonic antigen (CEA), CA-125, CA 19-9, and CA 15-3, are nonspecific and not helpful in determining the primary site. Men who present with adenocarcinoma

and predominant osteoblastic metastasis should undergo a prostate-specific antigen (PSA) test. In patients with undifferentiated or poorly differentiated carcinoma (especially with a midline tumor), elevated β-human chorionic gonadotropin (β-hCG) and α fetoprotein (AFP) levels suggest the possibility of an extragonadal germ cell (testicular) tumor. With the availability of advanced IHC, cytogenetic studies are rarely needed.

ROLE OF IMAGING STUDIES

In the absence of contraindications, a baseline intravenous (IV) contrast CT scan of the chest, abdomen, and pelvis is the standard of care. This helps to search for the primary tumor, evaluate the extent of disease, and select the most accessible biopsy site. With precise imaging and reporting, latent primary cancers, defined as appearance of a new primary cancer after a latent period of several months to years, is uncommon and seen in ≤5% of CUP patients, usually in patients with very indolent presentations and/or highly responsive metastatic cancers that allows a latent primary to emerge (grow) over time.

Mammography should be performed in women who present with metastatic adenocarcinoma, especially in those with isolated axillary lymphadenopathy. Magnetic resonance imaging (MRI) of the breast can be considered in patients with axillary adenopathy and suspected occult primary breast carcinoma following a negative mammography and ultrasound. The results of these imaging modalities can influence surgical management; a negative MRI of the breast predicts a low tumor yield at mastectomy.

A conventional workup for a squamous cell carcinoma and cervical CUP (neck lymphadenopathy with no known primary tumor) includes a CT scan or MRI and invasive studies, including indirect and direct laryngoscopy, bronchoscopy, and upper endoscopy. Ipsilateral (or bilateral) staging tonsillectomy has been recommended for these patients. 18-Fluorodeoxyglucose positron emission tomography (18-FDG-PET) scans are useful in this patient population and may help guide the biopsy; determine the extent of disease; facilitate the appropriate treatment, including planning radiation fields; and help with disease surveillance. Several studies have evaluated the utility of PET in patients with squamous cervical CUP, and head and neck primary tumors were identified in ~21–30%.

The diagnostic contribution of PET to the evaluation of other CUP presentations (outside of the neck adenopathy indication) remains controversial and is not routinely recommended. PET-CT can be helpful for patients with bone metastases and those deemed candidates for aggressive multimodality therapy (surgical intervention/radiation) such as patients with solitary metastatic disease because the identification of disease in addition to the solitary metastatic site may affect treatment planning.

Invasive studies, including upper endoscopy, colonoscopy, and bronchoscopy, should be limited to symptomatic patients or those with laboratory, imaging, or pathologic abnormalities that suggest that these techniques will result in a high yield in finding a primary cancer.

TABLE 97-1 Major Histologies in Carcinoma (Cancer) of Unknown Primary

HISTOLOGY	PROPORTION, %
Well to moderately differentiated adenocarcinoma	60
Squamous cell cancer	5
Poorly differentiated adenocarcinoma, poorly differentiated carcinoma	30
Neuroendocrine	2
Undifferentiated malignancy	3

ROLE OF PATHOLOGIC STUDIES

A detailed pathologic examination of the most accessible biopsied tissue specimen is mandatory in CUP patients. Pathologic evaluation typically consists of hematoxylin and eosin stains and IHC tests. The importance of adequate tissue acquisition cannot be overemphasized in CUP. In addition to pathologic evaluation, tissue is also needed for molecular profiling, which can aid in identifying biomarkers suggesting the primary site for effective therapeutics including targeted agents, immunotherapy, and clinical trials.

Light Microscopy Evaluation Adequate tissue obtained preferably by excisional biopsy or core needle biopsy (instead of only a fine-needle aspiration) is stained with hematoxylin and eosin and subjected to light microscopic examination. On light microscopy, 60–65% of CUP is adenocarcinoma, and 5% is squamous cell carcinoma. The remaining 30–35% is poorly differentiated adenocarcinoma, poorly differentiated carcinoma, or poorly differentiated neoplasm. A small percentage of lesions are diagnosed as neuroendocrine cancers (2%), mixed tumors (adenosquamous or sarcomatoid carcinomas), or undifferentiated neoplasms (Table 97-1).

Role of IHC Analysis IHC stains are peroxidase-labeled antibodies against specific tumor antigens that are used to define tumor lineage. The number of available IHC stains is ever-increasing. However, a tiered and uniform approach to tissue evaluation in the CUP setting is lacking. For CUP cases, more is not necessarily better, and IHC stains should be used in conjunction with the patient's clinical presentation and imaging studies to select the best therapy. Communication between the clinician and pathologist is essential. No stain is 100% sensitive or specific, and under-/overinterpretation should be avoided. Poor differentiation, even in known primary tumors, decreases sensitivity of hallmark IHC markers. PSA and thyroglobulin tissue markers, which are positive in prostate and thyroid cancer, respectively, are two of the most specific markers. However, these cancers rarely present as CUP, so the yield of these tests may be low. Figure 97-1 delineates a simple algorithm for immunohistochemical staining in CUP cases. Table 97-2 lists additional tests that may be useful to further define the tumor lineage. A more comprehensive algorithm may improve the diagnostic accuracy but can make the process complex and increase

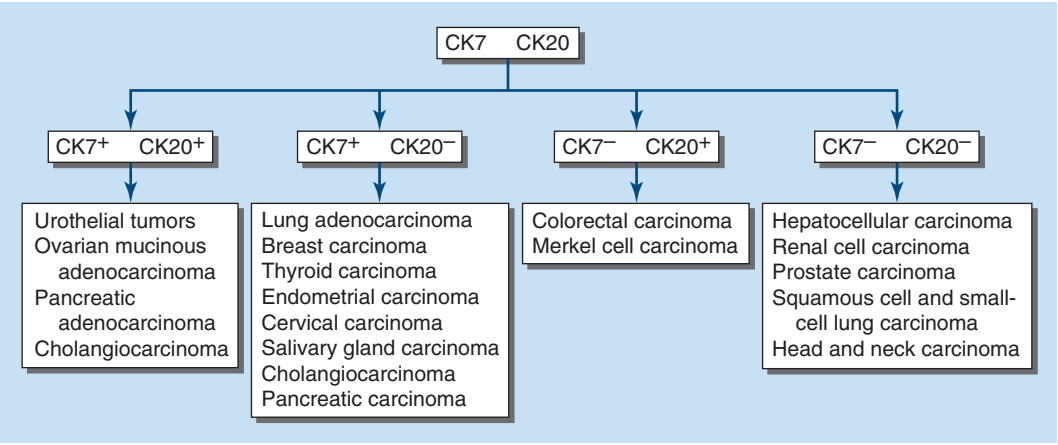

FIGURE 97-1 Approach to cytokeratin (CK7 and CK20) markers used in adenocarcinoma of unknown primary.

TABLE 97-2 Select Immunohistochemical Stains Useful in the Diagnosis of CUP

LIKELY PRIMARY PROFILE	COMMONLY CONSIDERED IHC TO ASSIST IN DIFFERENTIAL DIAGNOSIS OF CUP[a]
Breast	ER, GCDFP-15, mammaglobin, HER2/neu, GATA3
Ovarian/müllerian	ER, WT1, CK7, PAX8, PAX2
Lung adenocarcinoma	TTF-1; nuclear staining, napsin A, SP-A1
Germ cell	β-hCG, AFP, OCT3/4, CKIT, CD30 (embryonal), SALL4
Prostate	PSA, α-methylacyl CoA racemase/P504S (AMACR/P504S), P501S (prostein), PSMA, NKX3-1
Intestinal	CK7, CK20, CDX-2, CEA
Neuroendocrine	Chromogranin, synaptophysin, CD56
Sarcoma	Desmin (desmoid tumors), factor VIII (angiosarcomas), CD31, smooth muscle actin (leiomyosarcoma), MyoD1 (rhabdomyosarcoma)
Renal	RCC, CD10, PAX8, CD10
Hepatocellular carcinoma	Hep Par-1, Arg-1, glypican-3
Melanoma	S100, SOX-10, vimentin, HMB-45, tyrosinase, melan-A
Urothelial	CK7, CK20, thrombomodulin, uroplakin III
Mesothelioma	Calretinin, WT1, D2-40, mesothelin
Lymphoma	LCA, CD3, CD4, CD5, CD20, CD45
SCC	p63, p40 (lung SCC), CK5/6

[a]Patterns emerging from coexpression of stains are better than individual stains to suggest putative primary site. Even with optimization, no IHC panel is 100% sensitive or specific (e.g., ovarian mucinous carcinoma can exhibit positivity with intestinal markers).

Abbreviations: AFP, α fetoprotein; Arg-1, arginase-1; β-hCG, β-human chorionic gonadotropin; CEA, carcinoembryonic antigen; CUP, carcinoma of unknown primary; ER, estrogen receptor; GCDFP-15, gross cystic disease fibrous protein-15; IHC, immunohistochemistry; LCA, leukocyte common antigen; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; SCC, squamous cell carcinoma; SP-A1, surfactant protein A precursor; TTF, thyroid transcription factor; WT, Wilms' tumor.

cost. With the use of IHC markers, electron microscopic analysis, which is time-consuming and expensive, is rarely performed today.

There are >20 subtypes of cytokeratin (CK) intermediate filaments with different molecular weights and differential expression in various cell types and cancers. Monoclonal antibodies to specific CK subtypes have been used to help classify tumors according to their site of origin; commonly used CK stains in adenocarcinoma CUP are CK7 and CK20. CK7 is found in tumors of the lung, ovary, endometrium, breast, and upper gastrointestinal tract including pancreaticobiliary cancers, whereas CK20 is normally expressed in the gastrointestinal epithelium, urothelium, and Merkel cells. The nuclear CDX-2 transcription factor, which is the product of a homeobox gene necessary for intestinal organogenesis, is often used to aid in the diagnosis of gastrointestinal adenocarcinomas. However, CDX-2 positivity can be seen with enteric or mucinous differentiation in tumors from diverse primary sites (e.g., mucinous ovarian cancers).

Thyroid transcription factor 1 (TTF-1) nuclear staining is frequently positive in lung and thyroid cancers. Approximately 68% of adenocarcinomas and 25% of squamous cell lung cancers stain positive for TTF-1, which helps differentiate a lung primary tumor from metastatic adenocarcinoma in a pleural effusion, the mediastinum, or the lung parenchyma.

Gross cystic disease fibrous protein-15 (GCDFP-15), a 15-kDa monomer protein, is a marker of apocrine differentiation that is detected in 62–72% of breast carcinomas. GATA3 is being increasingly used in the CUP setting when there is concern for a breast primary and can be particularly useful as a marker for metastatic breast carcinoma, especially triple-negative and metaplastic carcinomas, which lack specific endocrine markers of mammary origin. UROIII, high-molecular-weight cytokeratin, thrombomodulin, and CK20 are the markers used to diagnose lesions of urothelial origin.

IHC performs the best when used in groups that give rise to patterns that are strongly indicative of certain profiles. For example, the TTF-1/CK7+ and CK20+/CDX-2+/CK7− phenotypes have been reported as very suggestive of lung and lower gastrointestinal cancer profiles, respectively. Despite their practical utility, these patterns have not been validated prospectively in CUP patients. IHC is not without its limitations; several factors affect tissue antigenicity (antigen retrieval, specimen processing, and fixation), interpretation of stains in tumor (nuclear, cytoplasmic, membrane) versus normal tissue, inter- and intraobserver variability, variable performance of different antibodies said to recognize the same antigen, and tissue heterogeneity and inadequacy (given small biopsy sizes). Communication with the pathologist is critical to determine if acquisition of additional tissue will be beneficial in the pathologic evaluation. Pathologic features should not always supersede clinical or radiologic findings when considering testing for biomarkers of therapeutic response (e.g., epidermal growth factor receptor [EGFR], *ALK* mutations, human epidermal growth factor receptor 2 [HER2]).

Role of Cancer Classifier Molecular Profiling In the absence of a known primary, developing therapeutic strategies for CUP is challenging. The current diagnostic yield with imaging and immunochemistry is ~20–30% for CUP patients. To reduce diagnostic uncertainty, sophisticated molecular analytics have been applied to CUP samples. These include gene expression profiling, messenger RNA (mRNA), microRNA, and genetic and epigenetic profiling to classify CUP.

Gene expression profiles are most commonly generated using quantitative reverse transcriptase polymerase chain reaction (RT-PCR) or DNA microarray. Neural network programs are then used to develop predictive algorithms from the gene expression profiles. Typically, a training set of gene profiles from known cancers (preferably from metastatic sites) is used to train the software. Comprehensive gene expression databases that have become available for common malignancies are then applied to CUP samples, and the program can then be used to predict the putative origin of a CUP sample.

mRNA- or microRNA-based tissue of origin cancer classifier assays have also been studied in prospective and retrospective CUP trials. Other assays such as DNA methylation profiling predicted a primary cancer in 87% of 216 CUP patients. Incorporation of machine learning and next-generation sequencing has furthered prediction of these classifiers.

Despite the sophistication of the cancer classifier molecular assays, most of the CUP studies have evaluated assay *performance*, although the challenge with validating the accuracy of an assay for CUP is that, by definition, the primary cancer diagnosis cannot be verified. Thus, current estimates of tissue of origin test accuracy have relied on indirect metrics, including comparison with pathology/IHC, clinical presentation, appearance of latent primaries, and autopsies. Using these measures, the assays suggest a plausible primary in ~70–80% of patients studied. Three outcomes-based studies have been performed. First, a single-arm study reported a median survival of 12.5 months for patients who received assay-directed site-specific therapy. Second, a phase 2 trial of site-specific therapy, including molecularly targeted therapy, based on predicted tumor site from an algorithm using gene expression and alteration profile showed a 1-year survival of 53.1%. However, two randomized clinical trials evaluating site-specific therapy directed by gene expression profiling versus empirical chemotherapy with either paclitaxel plus carboplatin or gemcitabine plus cisplatin failed to show a significant improvement in survival with this approach. Firm conclusions of therapeutic impact cannot be drawn from these studies given the sample size, design, statistical biases, confounding variables including use of subsequent lines of (empiric) therapy, and heterogeneity of the CUP cancers. Additional studies are needed to better understand the clinical impact of tissue of origin profiling tools and how these assays complement IHC and help guide therapy.

Role of Next-Generation Sequencing A significant push is being made toward personalized medicine across all cancer types with the goal of identifying driver mutation(s) in a patient who can be treated with targeted agents independent of the site of origin. A retrospective study of 200 CUP tumor specimens reported on genomic

alterations using the hybrid capture–based FoundationOne assay. The authors reported that a large number of CUP samples (85%) harbored at least one clinically relevant genomic alteration with the potential to influence and personalize therapy. The mean number of genomic alterations was 4.2 per tumor, and the most common genetic alterations included *TP53* (55%), *KRAS* (20%), *CDKN2A* (19%), and *ARID1A* (11%). The adenocarcinoma CUP tumors were more frequently driven by genetic alterations in the receptor tyrosine kinase (RTK)/Ras/mitogen-activated protein kinase (MAPK) signaling pathway than nonadenocarcinoma CUP tumors. Although druggable genetic lesions seen in CUP are comparable to those in known primary cancer databases, whether molecularly stratified approaches for CUP will successfully improve outcomes remains to be seen and clinical trials are needed. In a single-arm phase 2 study of 97 patients with molecularly targeted therapy, five patients were found to have targetable *EGFR* mutations. Of these, four patients were treated with afatinib, an anti-EGFR drug, and two patients achieved a progression-free survival of >6 months. It is anticipated that second- and third-generation drugs targeting *EGFR* mutations are likely to be even more effective. The emerging use of assays looking for circulating tumor DNA (ctDNA), so-called liquid biopsies, has been increasingly useful within known tumor types and has stirred interest in their potential utility in CUP **(Chap. 503)**.

Ongoing histology and cellular-context agnostic prospective clinical trials are studying the presence of actionable mutations and matching patients to the right targeted drug. As this strategy gains traction, CUP would be a natural fit for genomic alteration–based targeted therapy independent of tumor site. Established tumor-agnostic therapies such as immune checkpoint inhibitors (pembrolizumab) for microsatellite instability high (MSI-H) or deficient mismatch repair (dMMR) tumors or tumors with high tumor mutation burden (TMB) and NTRK inhibitors for *NTRK* fusion–positive tumors can help a small minority of CUP patients.

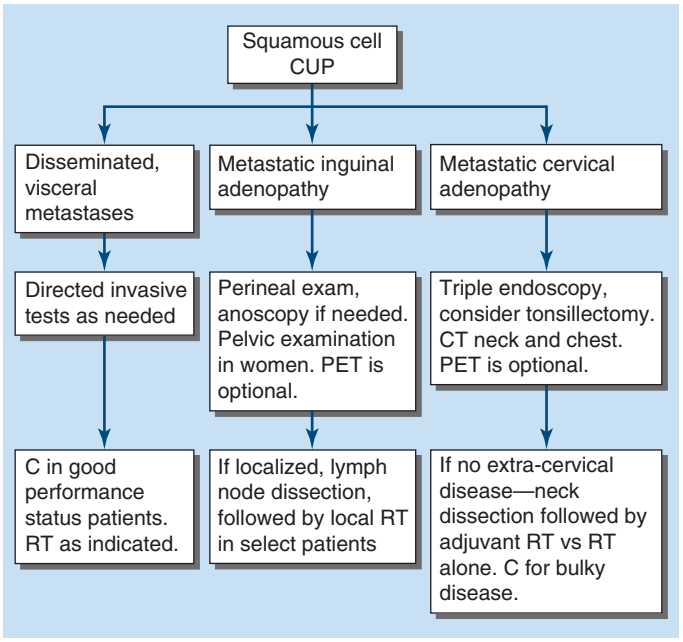

FIGURE 97-3 Treatment algorithm for squamous cell carcinoma of unknown primary (CUP). C, chemotherapy; CT, computed tomography; PET, positron emission tomography; RT, radiation.

TREATMENT

Carcinoma (or Cancer) of Unknown Primary

GENERAL CONSIDERATIONS

The treatment of CUP continues to evolve, albeit slowly. The median survival of most patients with disseminated CUP is ~6–10 months.

Systemic chemotherapy is the primary treatment modality in most patients with disseminated disease, but the careful integration of surgery, radiation therapy, and even periods of observation is important in the overall management of this condition **(Figs. 97-2 and 97-3)**. Prognostic factors include performance status, site and number of metastases, response to chemotherapy, and serum lactate dehydrogenase (LDH) levels. Culine and colleagues developed a prognostic model using performance status and serum LDH levels, which allowed the assignment of patients into two subgroups with divergent outcomes. Raghav and colleagues developed a prognostic nomogram to provide individualized survival estimates for patients with CUP based on baseline gender, Eastern Cooperative Oncology

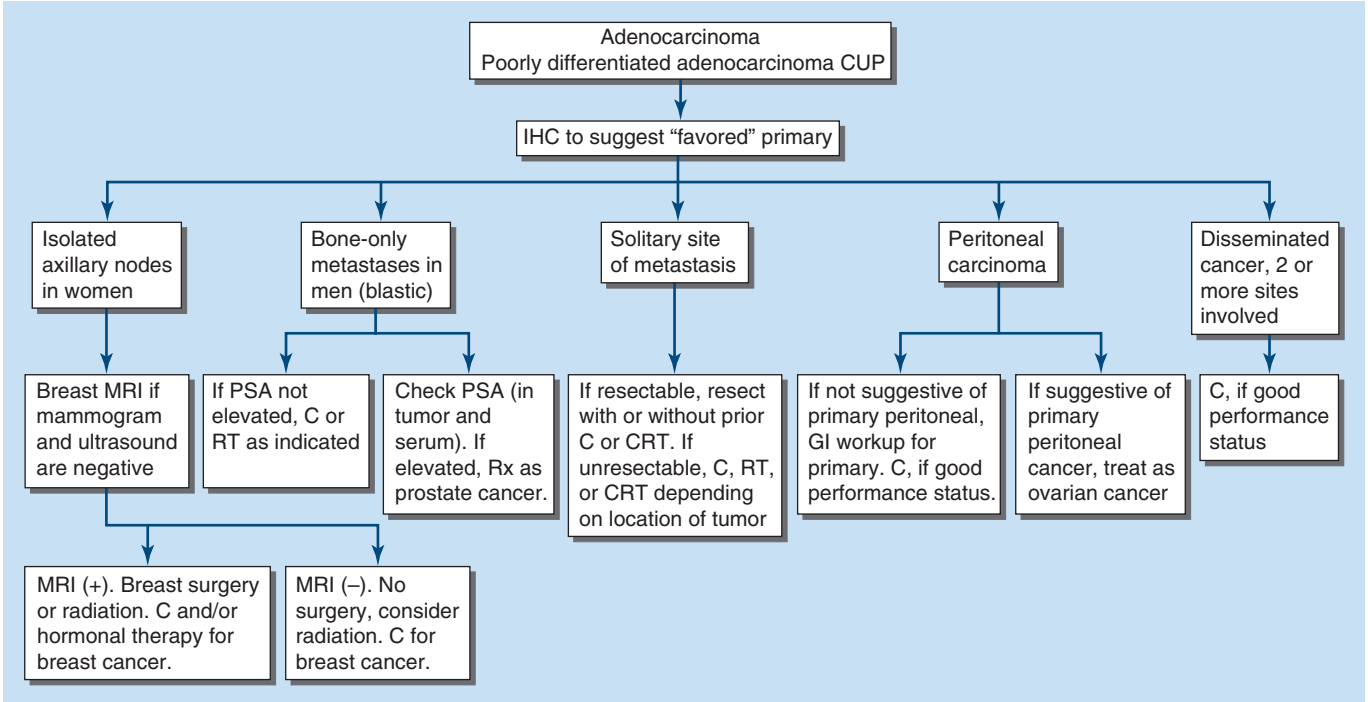

FIGURE 97-2 Treatment algorithm for adenocarcinoma and poorly differentiated adenocarcinoma of unknown primary (CUP). C, chemotherapy; CRT, chemoradiation; GI, gastrointestinal; IHC, immunohistochemistry; MRI, magnetic resonance imaging; PSA, prostate-specific antigen; RT, radiation.

Group performance status, histology, number of metastatic sites, and neutrophil-lymphocyte ratio. Future prospective trials using this prognostic model are warranted. Clinically, some CUP diagnoses fall into a favorable prognostic subset. Others, including those with disseminated CUP, have a more unfavorable prognosis.

TREATMENT OF FAVORABLE CUP SUBSETS

Women with Isolated Axillary Adenopathy Women with isolated axillary adenopathy with adenocarcinoma or carcinoma are usually treated for stage II or III breast cancer based on pathologic findings. These patients should undergo a breast MRI if mammogram and ultrasound are negative. Radiation therapy to the ipsilateral breast is indicated if the MRI of the breast is positive. Chemotherapy and/or hormonal therapy are indicated based on patient's age (premenopausal or postmenopausal), nodal disease bulk, and hormone receptor and HER2 status **(Chap. 84)**. It is important to verify that the pathology suggests a breast cancer profile (morphology, IHC breast markers including estrogen receptor, mammaglobin, GCDFP-15, GATA3, HER2 gene expression) before embarking on a breast cancer therapeutic program.

Women with Peritoneal Carcinomatosis The term *primary peritoneal papillary serous carcinoma* (PPSC) has been used to describe CUP with carcinomatosis with the pathologic and laboratory (elevated CA-125 antigen) characteristics of ovarian cancer but no ovarian primary tumor identified on transvaginal sonography or laparotomy. Studies suggest that ovarian cancer and PPSC, which are both of müllerian origin, have similar gene expression profiles. Like patients with ovarian cancer, patients with PPSC are candidates for cytoreductive surgery, followed by adjuvant taxane- and platinum-based chemotherapy. In one retrospective study of 258 women with peritoneal carcinomatosis who had undergone cytoreductive surgery and chemotherapy, 22% of patients had a complete response to chemotherapy; the median survival duration was 18 months (range 11–24 months). However, not all peritoneal carcinomatosis in women is PPSC. Careful pathologic evaluation can help diagnose a colon cancer profile (CDX-2+, CK20+, CK7−) or a pancreaticobiliary cancer or even a mislabeled peritoneal mesothelioma (calretinin, D2-40 positive; BerEp4, MOC-31 negative).

Poorly Differentiated Carcinoma with Midline Adenopathy (Chap. 93) Men with poorly differentiated or undifferentiated carcinoma who present with midline adenopathy should be evaluated for extragonadal germ cell malignancy. If diagnosed and treated as such, they often experience a good response to treatment with platinum-based combination chemotherapy. Response rates of >50% have been noted, and long-term survival rates of 10–15% have been reported. Older patients, especially smokers, who present with mediastinal adenopathy are more likely to have a lung or head and neck cancer profile.

Neuroendocrine Cancer (Chap. 89) Low-grade neuroendocrine tumor (NET) often has an indolent course, and treatment decisions are based on symptoms and tumor bulk. Urine 5-HIAA and serum chromogranin may be elevated and can be followed as markers. Often the patient is treated with somatostatin analogues alone for hormone-related symptoms (diarrhea, flushing, nausea). Specific local therapies or systemic therapy would only be indicated if the patient is symptomatic with local pain secondary to significant growth of the metastasis or the hormone-related symptoms are not controlled with endocrine therapy. Novel therapy options have demonstrated benefit in patients with low-grade NET, including sunitinib (which targets the vascular endothelial growth factor pathway), everolimus (which inhibits the mammalian target of rapamycin), and lutetium-177 dotatate (a somatostatin peptide receptor radioligand). Patients with high-grade NET are treated with platinum-based doublet therapy; 20–25% show a complete response, and up to 10% patients with limited/oligo presentations survive for >5 years. Some degree of neuroendocrine differentiation can be seen in diverse poorly differentiated carcinomas.

Squamous Cell Carcinoma Presenting as Neck Adenopathy Patients with early-stage squamous cell carcinoma involving the cervical lymph nodes are candidates for node dissection and radiation therapy, which can result in long-term survival. The role of chemotherapy in these patients is undefined, although chemoradiation therapy or induction chemotherapy is often used and is beneficial in bulky N2/N3 lymph node disease.

Solitary Metastatic Sites Patients with solitary metastases can also experience good treatment outcomes. Some patients who present with locoregional disease are candidates for aggressive trimodality (chemotherapy, radiation, and surgery) management—both prolonged disease-free survival and, occasionally, cure are possible.

Men with Blastic Skeletal Metastases and Elevated PSA (Chap. 92) Blastic bone-only metastasis is a rare presentation, and elevated serum PSA or tumor staining with PSA may provide confirmatory evidence of prostate cancer in these patients. Those with elevated levels are candidates for hormonal or other therapy for prostate cancer, although it is important to rule out other primary tumors (lung most common).

MANAGEMENT OF DISSEMINATED CUP

Patients who present with liver, brain, and adrenal metastatic disease usually have a poor prognosis. Patients with peritoneal carcinomatosis secondary to metastatic adenocarcinoma have a broad differential diagnosis, which includes mainly gastrointestinal cancers including gastric, appendiceal, colon, and pancreaticobiliary cancers.

Traditionally, platinum-based combination chemotherapy regimens have been used to treat CUP. Several broadly used regimens have been studied in the past two decades; these include paclitaxel-carboplatin, gemcitabine-cisplatin, gemcitabine-oxaliplatin, and irinotecan and fluoropyrimidine-based therapies. These chemotherapeutic agents used as empiric regimens have shown response rates of 25–40%, and their use obtains median survival times of 6–13 months.

Outside of favorable subsets, there is a small group of patients with a "definitive" IHC profile. These patients usually have a single diagnosis based on their clinicopathologic presentation and are often treated for the putative primary tumor. This does not guarantee a response, although it increases the probability of response when select drugs are chosen from a class of drugs known to be effective in that cancer type. Efforts should be made to search for biomarkers of response to tumor-agnostic effective therapies such as immunotherapy for MSI-H/dMMR tumors. Patients who do not fall into those categories are candidates for broad-spectrum platinum-based regimens, clinical trials, and additional trial-based genomic and proteomic tests. Today, we do not have many effective drugs for several CUP cancer profiles, and treatments overlap for some cancers. Immunotherapy has been an area of active interest due to robust and durable responses in cancers with known primaries and has shown some activity in CUP. However, biomarkers of response and immune-sensitive subsets need to be defined within CUP.

SUMMARY

Patients with CUP should undergo a directed diagnostic search for the primary tumor based on clinical and pathologic data. Subsets of patients have prognostically favorable disease, as defined by clinical or histologic criteria, and may substantially benefit from aggressive treatment; in these patients, prolonged survival can be expected. However, for most patients who present with advanced CUP, the prognosis remains poor with early resistance to available cytotoxic therapy. The current focus has shifted away from empirical chemotherapeutic trials to understanding the metastatic phenotype, tissue of origin profiling in select patients, and next-generation sequencing to identify actionable mutations in CUP patients. As novel therapies evolve in cancers with known primaries, investigations to assess their value in CUP will likely have a positive impact on management of CUP patients.

98 Paraneoplastic Syndromes: Endocrinologic/Hematologic

J. Larry Jameson, Dan L. Longo

Neoplastic cells can produce a variety of substances that can alter the physiology of hormonal, hematologic, dermatologic, rheumatologic, renal, and neurologic systems. *Paraneoplastic syndromes* refer to the disorders that accompany benign or malignant tumors but are not directly related to mass effects or invasion. Tumors of neuroendocrine origin, such as small-cell lung carcinoma (SCLC) and carcinoids, are common causes of paraneoplastic syndromes, but these syndromes are associated with many types of tumors that produce peptide hormones, cytokines, and growth factors and induce the production of antibodies. Studies of the prevalence of paraneoplastic syndromes indicate that they are more common than is generally appreciated. The signs, symptoms, and metabolic alterations associated with paraneoplastic disorders are easily overlooked in the context of a malignancy and its treatment. Consequently, atypical clinical manifestations in a patient with cancer should prompt consideration of a paraneoplastic syndrome. The most common hormonal and hematologic syndromes associated with underlying neoplasia will be discussed here.

ENDOCRINE PARANEOPLASTIC SYNDROMES

Etiology Hormones can be produced from eutopic or ectopic sources. *Eutopic* refers to the expression of a hormone from its normal tissue of origin, whereas *ectopic* refers to hormone production from an atypical tissue source. For example, adrenocorticotropic hormone (ACTH) is expressed eutopically by the corticotrope cells of the anterior pituitary, but it can be expressed ectopically in SCLC. Many hormones are produced at low levels from tissues other than the classic endocrine source. Thus, ectopic expression is often a quantitative change rather than an absolute change in tissue expression. Nevertheless, the term *ectopic expression* is firmly entrenched and conveys the abnormal physiology associated with hormone production by neoplastic cells. In addition to high levels of hormones, ectopic expression is often characterized by abnormal regulation of hormone production (e.g., defective feedback control in ectopic ACTH) and peptide processing (resulting in large, unprocessed precursor peptide such as proopiomelanocortin [POMC]).

Many different molecular mechanisms can cause ectopic hormone production. In rare instances, genetic rearrangements account for aberrant hormone expression. For example, translocation of the parathyroid hormone (*PTH*) gene can result in high levels of PTH expression in tissues other than the parathyroid gland because the genetic rearrangement brings the *PTH* gene under the control of atypical regulatory elements. A related phenomenon is well documented in many forms of leukemia and lymphoma, in which somatic genetic rearrangements confer a growth advantage and alter cellular differentiation and function. Although genetic rearrangements cause selected cases of ectopic hormone production, this mechanism is rare, as many tumors are associated with excessive production of numerous peptides. Cellular dedifferentiation probably underlies most cases of ectopic hormone production. Many cancers are poorly differentiated, and certain tumor products, such as human chorionic gonadotropin (hCG), PTH–related protein (PTHrP), and α-fetoprotein, are characteristic of gene expression at earlier developmental stages. In contrast, the propensity of certain cancers to produce particular hormones (e.g., squamous cell carcinomas produce PTHrP) suggests that dedifferentiation is partial or that selective pathways are derepressed. These expression profiles probably reflect epigenetic modifications that alter transcriptional repression, microRNA expression, and other pathways that govern cell differentiation.

Ectopic hormone production might be considered merely epiphenomenon associated with cancer if it did not cause clinical manifestations. Excessive and unregulated production of hormones such as ACTH, PTHrP, and vasopressin can lead to substantial morbidity and complicate the cancer treatment plan. Moreover, the paraneoplastic endocrinopathies may be a presenting clinical feature of underlying malignancy and prompt the search for an unrecognized tumor.

General features that confirm cancer-associated ectopic hormone syndromes include: (1) excess hormone production from an atypical tissue source; (2) documentation of tumor hormone production based on immunostaining, mRNA production, or hormone secretion in vitro; (3) hormone gradient across the tumor vascular supply; and (4) resolution or decline of hormone levels after reduction of tumor mass. Imaging studies, including computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and octreotide scintigraphy also play an important role in the detection and characterization of tumors associated with paraneoplastic syndromes, particularly when endocrine clinical manifestations precede a cancer diagnosis (i.e., ectopic ACTH in lung cancer). Treatment of the underlying tumor is the mainstay of all paraneoplastic endocrine syndromes. Depending on the hormone produced, specific therapies can be used (see below) to ameliorate symptoms but rarely influence overall survival or cancer progression.

A large number of paraneoplastic endocrine syndromes have been described, linking overproduction of particular hormones with specific types of tumors. However, certain recurring syndromes emerge from this group **(Table 98-1)**. The most common paraneoplastic endocrine

TABLE 98-1 Paraneoplastic Syndromes Caused by Ectopic Hormone Production

PARANEOPLASTIC SYNDROME	ECTOPIC HORMONE	TYPICAL TUMOR TYPES[a]
Common		
Hypercalcemia of malignancy	Parathyroid hormone–related protein (PTHrP)	Squamous cell (head and neck, lung, skin), breast, genitourinary, gastrointestinal; osteolytic metastases
	1,25-Dihydroxyvitamin D	Lymphomas
	Parathyroid hormone (PTH) (rare)	Lung, ovary
	Prostaglandin E_2 (PGE_2) (rare)	Renal, lung
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Vasopressin	Lung (squamous, small cell), gastrointestinal, genitourinary, breast, ovary
Cushing's syndrome	Adrenocorticotropic hormone (ACTH)	Lung (small cell, bronchial carcinoid, adenocarcinoma, squamous), thymus, pancreatic islet, medullary thyroid carcinoma, pheochromocytoma
	Corticotropin-releasing hormone (CRH) (rare)	Pancreatic islet, carcinoid, lung, prostate
	Ectopic expression of gastric inhibitory peptide (GIP), luteinizing hormone (LH)/human chorionic gonadotropin (hCG), other G protein–coupled receptors (rare)	Macronodular adrenal hyperplasia
Less Common		
Non–islet cell hypoglycemia	Insulin-like growth factor type II (IGF-II)	Mesenchymal tumors, sarcomas, adrenal, hepatic, gastrointestinal, kidney, prostate
	Insulin (rare)	Cervix (small-cell carcinoma)
Male feminization	hCG[b]	Testis (embryonal, seminomas), germinomas, choriocarcinoma, lung, hepatic, pancreatic islet
Diarrhea or intestinal hypermotility	Calcitonin[c]	Lung, colon, breast, medullary thyroid carcinoma
	Vasoactive intestinal peptide (VIP)	Pancreas, pheochromocytoma, esophagus
Rare		
Oncogenic osteomalacia	Fibroblast growth factor 23 (FGF23) or phosphatonin	Hemangiopericytomas, osteoblastomas, fibromas, sarcomas, giant cell tumors, prostate, lung
Acromegaly	Growth hormone–releasing hormone (GHRH)	Pancreatic islet, bronchial, and other carcinoids
	Growth hormone (GH)	Lung, pancreatic islet
Hyperthyroidism	Thyroid-stimulating hormone (TSH)	Hydatidiform mole, embryonal tumors, struma ovarii
Hypertension	Renin	Juxtaglomerular tumors, kidney, lung, pancreas, ovary
Consumptive hypothyroidism	Type 3 deiodinase	Hepatic and other hemangiomas
Cancer immunotherapy associated autoimmune diseases	Autoimmune hormone deficiencies Thyroiditis, Graves' disease	Cancers treated with immunotherapy, particularly anti–CTLA-4, PD-1, PD-L1

[a]Only the most common tumor types are listed. For most ectopic hormone syndromes, an extensive list of tumors has been reported to produce one or more hormones. [b]hCG is produced eutopically by trophoblastic tumors. Certain tumors produce disproportionate amounts of the hCG α or hCG β subunit. High levels of hCG rarely cause hyperthyroidism because of weak binding to the TSH receptor. [c]Calcitonin is produced eutopically by medullary thyroid carcinoma and is used as a tumor marker.
Abbreviations: CTLA-4, cytotoxic T lymphocyte-associated protein-4; PD-1, programmed cell death protein 1; PD-L1, programmed death ligand 1.

syndromes include hypercalcemia from overproduction of PTHrP and other factors, hyponatremia from excess vasopressin, and Cushing's syndrome from ectopic ACTH.

HYPERCALCEMIA CAUSED BY ECTOPIC PRODUCTION OF PTHRP

(See also **Chap. 422**).

Etiology Humoral hypercalcemia of malignancy (HHM) occurs in up to 20% of patients with cancer. HHM is most common in cancers of the lung, head and neck, skin, esophagus, breast, and genitourinary tract and in multiple myeloma and lymphomas, as well as metastases associated with these, and other cancers. There are several distinct humoral causes of HHM, but it is caused most commonly by overproduction of PTHrP. In addition to acting as a circulating humoral factor, bone metastases (e.g., breast, multiple myeloma) may produce PTHrP and other chemokines, leading to local osteolysis and hypercalcemia. PTHrP may also affect the initiation and progression of tumors by acting through pro-survival and chemokine pathways.

PTHrP is structurally related to PTH and binds to the PTH receptor, explaining the similar biochemical features of HHM and hyperparathyroidism. PTHrP plays a key physiologic role in skeletal development and regulates cellular proliferation and differentiation in other tissues, including skin, bone marrow, breast, and hair follicles. The mechanism of PTHrP induction in malignancy is incompletely understood; however, tumor-bearing tissues commonly associated with HHM normally produce PTHrP during development or cell renewal. Hypomethylation of the *PTHLH* locus, which encodes PTHrP, suggests a role for epigenetic factors in upregulating PTHrP production. PTHrP expression is stimulated by hedgehog pathways and Gli transcription factors that are active in many malignancies. Transforming growth factor β (TGF-β), which is produced by many tumors, also stimulates PTHrP. Mutations in certain oncogenes, such as *Ras*, also can activate PTHrP expression, as does loss of the tumor suppressor, p53. In addition to its role in HHM, the PTHrP pathway may also provide a potential target for therapeutic intervention to impede cancer growth.

Another relatively common cause of HHM is excess production of 1,25-dihydroxyvitamin D. Like granulomatous disorders associated with hypercalcemia, lymphomas can produce an enzyme that converts 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D, leading to enhanced gastrointestinal calcium absorption. Other causes of HHM include tumor-mediated production of osteolytic cytokines and inflammatory mediators.

Clinical Manifestations The typical presentation of HHM is a patient with a known malignancy who is found to be hypercalcemic on routine laboratory tests. Less often, hypercalcemia is the initial presenting feature of malignancy. Particularly when calcium levels are markedly increased (>3.5 mmol/L [>14 mg/dL]), patients may experience fatigue, mental status changes, polyuria, dehydration, or symptoms of

nephrolithiasis. Hypercalcemia can shorten ST segments and QT intervals, as well as bundle branch blocks and bradyarrhythmias.

Diagnosis Features that favor HHM, as opposed to primary hyperparathyroidism, include known malignancy, recent onset of hypercalcemia, and very high serum calcium levels. Like hyperparathyroidism, hypercalcemia caused by PTHrP is accompanied by hypercalciuria and hypophosphatemia. Patients with HHM typically have metabolic alkalosis rather than hyperchloremic acidosis, as is seen in hyperparathyroidism. In contrast to PTH, PTHrP does not appear to stimulate 1-α-hydroxylase and 1,25-dihydroxyvitamin D levels. Measurement of PTH is useful to exclude primary hyperparathyroidism; the PTH level should be suppressed in HHM. An elevated PTHrP level confirms the diagnosis, and it is increased in ~80% of hypercalcemic patients with cancer. 1,25-Dihydroxyvitamin D levels may be increased in patients with lymphoma.

TREATMENT

Humoral Hypercalcemia of Malignancy

The management of HHM begins with removal of excess calcium in the diet, medications, or intravenous (IV) solutions. Saline rehydration (typically 200–500 mL/h) is used to dilute serum calcium and promote calciuresis; exercise caution in patients with cardiac, hepatic, or renal insufficiency. Forced diuresis with furosemide (20–80 mg IV in escalating doses) or other loop diuretics can enhance calcium excretion but provides relatively little value except in life-threatening hypercalcemia. When used, loop diuretics should be administered only after complete rehydration and with careful monitoring of fluid balance. Oral phosphorus (e.g., 250 mg Neutra-Phos 3–4 times daily) should be given until serum phosphorus is >1 mmol/L (>3 mg/dL). Bisphosphonates such as zoledronate (4–8 mg IV), pamidronate (60–90 mg IV), and etidronate (7.5 mg/kg per day orally [PO] for 3–7 consecutive days) can reduce serum calcium within 1–2 days and suppress calcium release for several weeks. Bisphosphonate infusions can be repeated, or oral bisphosphonates can be used for chronic treatment. Denosumab (120 mg subcutaneously [SC] weekly for 4 weeks and then monthly) can be used in patients who do not respond adequately to bisphosphonates. It acts as a decoy receptor for RANK ligand to mitigate stimulation of osteoclasts. Cinacalcet (30 mg PO bid to 90 mg PO qid) stimulates calcium-sensing receptors to suppress PTH secretion and is therefore applicable in parathyroid carcinoma and rare cases of ectopic PTH-producing tumors. Hypercalcemia associated with lymphomas, multiple myeloma, or leukemia may respond to glucocorticoid treatment (e.g., prednisone 40–100 mg PO in four divided doses). Dialysis should be considered in severe hypercalcemia when saline hydration and bisphosphonate treatments are not possible or are too slow in onset. Previously used agents such as calcitonin and mithramycin have little utility now that bisphosphonates and other agents are available.

ECTOPIC VASOPRESSIN: TUMOR-ASSOCIATED SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

(See also Chap. 56).

Etiology Vasopressin is an antidiuretic hormone normally produced by the posterior pituitary gland. Ectopic vasopressin production by tumors is a common cause of the syndrome of inappropriate antidiuretic hormone (SIADH), occurring in at least half of patients with SCLC. SIADH also can be caused by a number of nonneoplastic conditions, including central nervous system (CNS) trauma, infections, and medications (Chap. 398). Compensatory responses to SIADH, such as decreased thirst, may mitigate the development of hyponatremia. However, with prolonged production of excessive vasopressin, the osmostat controlling thirst and hypothalamic vasopressin secretion may become reset. In addition, intake of free water, orally or intravenously, can quickly worsen hyponatremia because of reduced renal diuresis.

Tumors with neuroendocrine features, such as SCLC and carcinoids, are the most common sources of ectopic vasopressin production, but it also occurs in other forms of lung cancer and with CNS lesions, head and neck cancer, and genitourinary, gastrointestinal, and ovarian cancers. The mechanism of activation of the vasopressin gene in these tumors is unknown, but the frequent concomitant expression of the adjacent oxytocin gene suggests derepression of this locus.

Clinical Manifestations Most patients with ectopic vasopressin secretion are asymptomatic and are identified because of the presence of hyponatremia on routine chemistry testing. Symptoms may include weakness, lethargy, nausea, confusion, depressed mental status, and seizures. The severity of symptoms reflects the rapidity of onset as well as the severity of hyponatremia. Hyponatremia usually develops slowly but may be exacerbated by the administration of IV fluids or the institution of new medications.

Diagnosis The diagnostic features of ectopic vasopressin production are the same as those of other causes of SIADH (Chaps. 56 and 398). Hyponatremia and reduced serum osmolality occur in the setting of an inappropriately normal or increased urine osmolality. Urine sodium excretion is normal or increased unless volume depletion is present. Other causes of hyponatremia should be excluded, including renal, adrenal, or thyroid insufficiency. Physiologic sources of vasopressin stimulation (CNS lesions, pulmonary disease, nausea), adaptive circulatory mechanisms (hypotension, heart failure, hepatic cirrhosis), and medications, including many chemotherapeutic agents, also should be considered as possible causes of hyponatremia. Vasopressin measurements are not usually necessary to make the diagnosis.

TREATMENT

Ectopic Vasopressin: Tumor-Associated SIADH

Most patients with ectopic vasopressin production develop hyponatremia over several weeks or months. The disorder should be corrected gradually unless mental status is altered or there is risk of seizures. Rapid correction can cause brain dehydration and central pontine myelinolysis. Treatment of the underlying malignancy may reduce ectopic vasopressin production, but this response is slow if it occurs at all. Fluid restriction to less than urine output, plus insensible losses, is often sufficient to correct hyponatremia partially. However, strict monitoring of the amount and types of liquids consumed or administered intravenously is required for fluid restriction to be effective. Salt tablets and saline are not helpful unless volume depletion is also present. Demeclocycline (150–300 mg orally 3–4 times daily) can be used to inhibit vasopressin action on the renal distal tubule, but its onset of action is relatively slow (1–2 weeks), and it has largely been supplanted by newer vasopressin receptor antagonists. The vaptan class of drugs acts by inhibiting vasopressin receptors (V_{1A}, V_{1B}, V_2) in the renal collecting ducts. Nonpeptide V_2-receptor antagonists, tolvaptan (15 mg PO daily) or conivaptan (20–120 mg PO bid or 10–40 mg IV), are particularly effective when used in combination with fluid restriction in euvolemic hyponatremia. Severe hyponatremia (Na <115 meq/L) or mental status changes may require treatment with hypertonic (3%) or normal saline infusion together with furosemide to enhance free water clearance. The rate of sodium correction should be slow (0.5–1 meq/L per hour) to prevent rapid fluid shifts and the possible development of central pontine myelinolysis.

CUSHING'S SYNDROME CAUSED BY ECTOPIC ACTH PRODUCTION

(See also Chap. 398).

Etiology Ectopic ACTH production accounts for 10–20% of cases of Cushing's syndrome. The syndrome is particularly common in neuroendocrine tumors. SCLC is the most common cause of ectopic ACTH, followed by bronchial and thymic carcinoids, islet cell tumors, other carcinoids, and pheochromocytomas. Ectopic ACTH production

is caused by increased expression of the proopiomelanocortin (*POMC*) gene, which encodes ACTH, along with melanocyte-stimulating hormone (MSH), β-lipotropin, and several other peptides. In many tumors, there is abundant but aberrant expression of the *POMC* gene from an internal promoter, proximal to the third exon, which encodes ACTH. However, because this product lacks the signal sequence necessary for protein processing, it is not secreted. Increased production of ACTH arises instead from less abundant, but unregulated, *POMC* expression from the same promoter site used in the pituitary. Because tumors lack many of the enzymes needed to process the POMC polypeptide, it is typically released as multiple large, biologically inactive fragments along with relatively small amounts of fully processed, active ACTH.

Rarely, corticotropin-releasing hormone (CRH) is produced by pancreatic islet cell tumors, SCLC, medullary thyroid cancer, carcinoids, or prostate cancer. When levels are high enough, CRH can cause pituitary corticotrope hyperplasia and Cushing's syndrome. Tumors that produce CRH sometimes also produce ACTH, raising the possibility of a paracrine mechanism for ACTH production.

A distinct mechanism for ACTH-independent Cushing's syndrome involves ectopic expression of various G protein–coupled receptors in adrenal nodules. Ectopic expression of the gastric inhibitory peptide (GIP) receptor is the best-characterized example of this mechanism. In this case, meals induce GIP secretion, which inappropriately stimulates adrenal growth and glucocorticoid production.

Clinical Manifestations The clinical features of hypercortisolemia are detected in only a fraction of patients with documented ectopic ACTH production. Patients with ectopic ACTH syndrome generally exhibit less marked weight gain and centripetal fat redistribution, probably because the exposure to excess glucocorticoids is relatively brief and because cachexia reduces the propensity for weight gain and fat deposition. The ectopic ACTH syndrome is associated with several clinical features that distinguish it from other causes of Cushing's syndrome (e.g., pituitary adenomas, adrenal adenomas, iatrogenic glucocorticoid excess). The metabolic manifestations of ectopic ACTH syndrome are dominated by fluid retention and hypertension, hypokalemia, metabolic alkalosis, glucose intolerance, and occasionally steroid psychosis. The very high ACTH levels often cause increased pigmentation, reflecting increased activity of MSH derived from the POMC precursor peptide. The extraordinarily high glucocorticoid levels in patients with ectopic sources of ACTH can lead to marked skin fragility and easy bruising. In addition, the high cortisol levels often overwhelm the renal 11β-hydroxysteroid dehydrogenase type II enzyme, which normally inactivates cortisol and prevents it from binding to renal mineralocorticoid receptors. Consequently, in addition to the excess mineralocorticoids produced by ACTH stimulation of the adrenal gland, high levels of cortisol exert activity through the mineralocorticoid receptor, leading to severe hypokalemia.

Diagnosis The diagnosis of ectopic ACTH syndrome is usually not difficult in the setting of a known malignancy. Urine-free cortisol levels fluctuate but are typically greater than two to four times normal, and the plasma ACTH level is usually >22 pmol/L (>100 pg/mL). A suppressed ACTH level excludes this diagnosis and indicates an ACTH-independent cause of Cushing's syndrome (e.g., adrenal or exogenous glucocorticoid). In contrast to pituitary sources of ACTH, most ectopic sources of ACTH do not respond to glucocorticoid suppression. Therefore, high-dose dexamethasone (8 mg PO) suppresses 8:00 A.M. serum cortisol (50% decrease from baseline) in ~80% of pituitary ACTH-producing adenomas but fails to suppress ectopic ACTH in ~90% of cases. Bronchial and other carcinoids are well-documented exceptions to these general guidelines, as these ectopic sources of ACTH may exhibit feedback regulation indistinguishable from pituitary adenomas, including suppression by high-dose dexamethasone, and ACTH responsiveness to adrenal blockade with metyrapone. If necessary, petrosal sinus catheterization can be used to evaluate a patient with ACTH-dependent Cushing's syndrome when the source of ACTH is unclear. After CRH stimulation, a 3:1 petrosal sinus:peripheral ACTH ratio strongly suggests a pituitary ACTH source. Imaging studies (CT or MRI) are also useful in the evaluation of suspected carcinoid lesions, allowing biopsy and characterization of hormone production using special stains. If available, PET scans or octreotide scintigraphy may identify some sources of ACTH production.

TREATMENT

Cushing's Syndrome Caused by Ectopic ACTH Production

The morbidity associated with the ectopic ACTH syndrome can be substantial. Patients may experience depression or personality changes because of extreme cortisol excess. Metabolic derangements, including diabetes mellitus and hypokalemia, can worsen fatigue. Poor wound healing and predisposition to infections can complicate the surgical management of tumors, and opportunistic infections caused by organisms such as *Pneumocystis carinii* and mycoses are often the cause of death in patients with ectopic ACTH production. These patients have increased risk of venous thromboembolism, reflecting the combination of malignancy and altered coagulation factor profiles. Depending on prognosis and treatment plans for the underlying malignancy, measures to reduce cortisol levels are often indicated. Treatment of the underlying malignancy may reduce ACTH levels but is rarely sufficient to reduce cortisol levels to normal. Adrenalectomy is not practical for most of these patients but should be considered during surgery for the malignancy or if the underlying tumor is not resectable and the prognosis is otherwise favorable (e.g., carcinoid). Medical therapy with ketoconazole (300–600 mg PO bid), metyrapone (250–500 mg PO every 6 h), mitotane (3–6 g PO in four divided doses, tapered to maintain low cortisol production), etomidate (0.1–0.3 mg/kg/h IV), or other agents that block steroid synthesis or action is often the most practical strategy for managing the hypercortisolism associated with ectopic ACTH production. Glucocorticoid replacement should be provided to prevent adrenal insufficiency (Chap. 398). Unfortunately, many patients eventually progress despite medical blockade. Mifepristone (200–1000 mg PO qd) inhibits both glucocorticoid and progesterone receptors, has rapid onset of action, and improves glucose intolerance and hypertension in a subset of patients. ACTH-neutralizing antibodies and ACTH receptor blockers are under investigation, as are selective inhibitors of the glucocorticoid receptor.

TUMOR-INDUCED HYPOGLYCEMIA CAUSED BY EXCESS PRODUCTION OF INSULIN-LIKE GROWTH FACTOR TYPE II

(See also Chap. 418) Mesenchymal tumors, hemangiopericytomas, hepatocellular tumors, adrenal carcinomas, and a variety of other large tumors have been reported to produce excessive amounts of insulin-like growth factor type II (IGF-II) precursor, which binds weakly to insulin receptors and more strongly to IGF-I receptors, leading to insulin-like actions. The gene encoding IGF-II resides on chromosome 11p15, a locus that is normally imprinted (that is, expression is exclusively from a single parental allele). Biallelic expression of the IGF-II gene occurs in a subset of tumors, suggesting loss of methylation and loss of imprinting as a mechanism for gene induction. In addition to increased IGF-II production, IGF-II bioavailability is increased due to complex alterations in circulating binding proteins. Increased IGF-II suppresses growth hormone (GH) and insulin, resulting in reduced IGF binding protein 3 (IGFBP-3), IGF-I, and acid-labile subunit (ALS). The reduction in ALS and IGFBP-3, which normally sequester IGF-II, causes it to be displaced to a small circulating complex that has greater access to insulin target tissues. For this reason, circulating IGF-II levels may not be markedly increased despite causing hypoglycemia. In addition to IGF-II–mediated hypoglycemia, tumors may occupy enough of the liver to impair gluconeogenesis.

In most cases, a tumor causing hypoglycemia is clinically apparent (usually >10 cm in size), and hypoglycemia develops in association with fasting. As with other causes of hypoglycemia, patients may

present with sweating, tremors, palpitations, confusion, seizures, or coma. The diagnosis is made by documenting low serum glucose and suppressed insulin levels in association with symptoms of hypoglycemia. Serum IGF-II levels may not be increased (IGF-II assays may not detect IGF-II precursors), but an elevated IGF-II/IGF-I ratio greater than 10:1 is suggestive. Increased IGF-II mRNA expression is found in most of these tumors. Any medications associated with hypoglycemia should be eliminated. Treatment of the underlying malignancy, if possible, may reduce the predisposition to hypoglycemia. Frequent meals and IV glucose, especially during sleep or fasting, are often necessary to prevent hypoglycemia. Glucagon, recombinant GH, and glucocorticoids have also been used to enhance glucose production. Antibodies that inhibit IGF-II action are under development.

HUMAN CHORIONIC GONADOTROPIN

hCG is composed of α and β subunits and can be produced as intact hormone, which is biologically active, or as uncombined biologically inert subunits. Ectopic production of intact hCG occurs most often in association with testicular embryonal tumors, germ cell tumors, extragonadal germinomas, lung cancer, hepatoma, and pancreatic islet tumors. Eutopic production of hCG occurs with trophoblastic malignancies. hCG α subunit production is particularly common in lung cancer and pancreatic islet cancer. In men, high hCG levels stimulate steroidogenesis and aromatase activity in testicular Leydig cells, resulting in increased estrogen production and the development of gynecomastia. Precocious puberty in boys or gynecomastia in men should prompt measurement of hCG and consideration of a testicular tumor or another source of ectopic hCG production. Most women are asymptomatic. hCG is easily measured. Treatment should be directed at the underlying malignancy.

ONCOGENIC OSTEOMALACIA

Hypophosphatemic oncogenic osteomalacia, also called tumor-induced osteomalacia (TIO), is caused by excessive production of fibroblast growth factor 23 (FGF23), previously referred to as phosphotonin. Oncogenic osteomalacia is characterized by markedly reduced serum phosphorus and renal phosphate wasting, leading to muscle weakness, bone pain, and osteomalacia. Serum calcium and PTH levels are normal. FGF23 inhibits the renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, resulting in low levels of 1,25-dihydroxyvitamin D. Oncogenic osteomalacia is usually caused by benign mesenchymal tumors, such as hemangiopericytomas, fibromas, and giant cell tumors, often of the skeletal extremities or head. It has also been described in sarcomas and in patients with prostate or lung cancer. Resection of the tumor reverses the disorder, confirming its humoral basis. FGF23 levels are increased in some, but not all, patients with osteogenic osteomalacia. FGF23 forms a ternary complex with the klotho protein and renal FGF receptors to reduce renal phosphate reabsorption. Treatment involves removal of the tumor, if possible, and supplementation with phosphate and vitamin D. Octreotide treatment reduces phosphate wasting in some patients with tumors that express somatostatin receptor subtype 2. Octreotide scans may also be useful in detecting these tumors. A human monoclonal antibody against FGF23, burosumab (0.5 mg/kg every 4 weeks) has been approved for the treatment of osteogenic osteomalacia. If needed, it can be increased to 2 mg/kg every 2 weeks. Burosumab improves metabolic features of the disease and may improve bone structure and fracture risk, but these outcomes are still being evaluated. The calcium-sensing receptor agonist cinacalcet has been effective in some patients, apparently by reducing PTH-mediated phosphaturia. FGF receptor inhibitors hold promise as future therapies targeted either to pathways that stimulate FGR23 production (e.g., FGFR1) or inhibit its action (e.g., FGF23 receptor).

CONSUMPTIVE HYPOTHYROIDISM

Newborns with hepatic hemangiomas can develop a rare form of hypothyroidism caused by overexpression of type 3 deiodinase (D3), an enzyme that degrades and inactivates thyroxine (T_4) and triiodothyronine (T_3). The very high expression of D3 and consumption of thyroid hormones apparently outstrip the thyroid gland's rate of hormone production. The disorder is characterized by low T_4, low T_3, high TSH, and markedly elevated reverse T_3 (rT_3), reflecting the degradation of T_4 to rT_3. In addition to treating the underlying hemangioma (rarely other tumor types), patients are treated with L-thyroxine replacement, titrated to normalize TSH. Steroids and propranolol may provide benefit, perhaps by inhibiting growth factor pathways thought to stimulate D3 production.

CANCER IMMUNOTHERAPY-ASSOCIATED ENDOCRINOPATHIES (SEE ALSO CHAPS. 78, 401)

Although not strictly a paraneoplastic endocrine syndrome, the introduction of cancer immunotherapies, particularly immune checkpoint inhibitors (i.e., anti–CTLA-4, PD-1, PD-L1), is associated with a high incidence (~10%) of autoimmune endocrine disease. Hypophysitis and autoimmune thyroid diseases are most common, but autoimmune diabetes mellitus, adrenal insufficiency, hypoparathyroidism, and diabetes insipidus also occur. The mechanism of these autoimmune side effects remains unclear. CTLA-4 is expressed in the pituitary gland, likely explaining predisposition to anti–CTLA-4–associated hypophysitis. Genetic predisposition and underlying endocrine autoimmunity likely play a role in thyroid and other endocrinopathies, becoming exacerbated following checkpoint inhibitor–induced immune activation. Autoimmune endocrine disease can emerge in the early weeks of immunotherapy but can also present after several months. At present, screening and prophylactic treatment are not routinely recommended. However, clinicians should be attuned to clinical or laboratory features of these disorders as they can be challenging to identify during cancer management. Treatment is similar to that of individual hormone deficiencies (Chaps. 391, 395, and 398). These endocrinopathies are generally irreversible and require lifelong hormone replacement.

HEMATOLOGIC SYNDROMES

The elevation of granulocyte, platelet, and eosinophil counts in most patients with myeloproliferative disorders is caused by the proliferation of the myeloid elements due to the underlying disease rather than to a paraneoplastic syndrome. The paraneoplastic hematologic syndromes in patients with solid tumors are less well characterized than are the endocrine syndromes because the ectopic hormone(s) or cytokines responsible have not been identified in most of these tumors (Table 98-2). The extent of the paraneoplastic syndromes parallels the course of the cancer. With very rare exception, red cell, white cell, or platelet numbers are self-limited and not associated with symptomatic abnormalities. In some circumstances, elevations in platelet counts can be a marker that influences prognosis. By far, the most consequential hematologic abnormality in cancer patients is hypercoagulability.

ERYTHROCYTOSIS

Ectopic production of erythropoietin by cancer cells causes most paraneoplastic erythrocytosis. The ectopically produced erythropoietin

TABLE 98-2 Paraneoplastic Hematologic Syndromes

SYNDROME	PROTEINS	CANCERS TYPICALLY ASSOCIATED WITH SYNDROME
Erythrocytosis	Erythropoietin	Renal cancers, hepatocarcinoma, cerebellar hemangioblastomas
Granulocytosis	G-CSF, GM-CSF, IL-6	Lung cancer, gastrointestinal cancer, ovarian cancer, genitourinary cancer, Hodgkin's disease
Thrombocytosis	IL-6	Lung cancer, gastrointestinal cancer, breast cancer, ovarian cancer, lymphoma
Eosinophilia	IL-5	Lymphoma, leukemia, lung cancer
Thrombophlebitis	Unknown	Lung cancer, pancreatic cancer, gastrointestinal cancer, breast cancer, genitourinary cancer, ovarian cancer, prostate cancer, lymphoma

Abbreviations: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.

stimulates the production of red blood cells (RBCs) in the bone marrow and raises the hematocrit. Other lymphokines and hormones produced by cancer cells may stimulate erythropoietin release but have not been proved to cause erythrocytosis.

Most patients with erythrocytosis have an elevated hematocrit (>52% in men, >48% in women) that is detected on a routine blood count. Approximately 3% of patients with renal cell cancer, 10% of patients with hepatoma, and 15% of patients with cerebellar hemangioblastomas have erythrocytosis. In most cases, the erythrocytosis is asymptomatic.

Patients with erythrocytosis due to a renal cell cancer, hepatoma, or CNS cancer should have measurement of red cell mass. If the red cell mass is elevated, the serum erythropoietin level should be measured. Patients with a cancer that has been associated with erythrocytosis, elevated erythropoietin levels, and no other explanation for erythrocytosis (e.g., hemoglobinopathy that causes increased O_2 affinity; **Chaps. 66 and 103**) have the paraneoplastic syndrome.

TREATMENT

Erythrocytosis

Successful resection of the cancer usually resolves the erythrocytosis. If the tumor cannot be resected or treated effectively with radiation therapy or chemotherapy, phlebotomy may control any symptoms or risk related to erythrocytosis.

GRANULOCYTOSIS

Approximately 30% of patients with solid tumors have granulocytosis (granulocyte count >8000/μL). In about half of patients with granulocytosis and cancer, the granulocytosis has an identifiable nonparaneoplastic etiology (e.g., infection, tumor necrosis, glucocorticoid administration). The other patients have proteins in urine and serum that stimulate the growth of bone marrow cells. Tumors and tumor cell lines from patients with lung, ovarian, and bladder cancers have been documented to produce granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and/or interleukin 6 (IL-6). However, the etiology of granulocytosis has not been characterized in most patients.

Patients with granulocytosis are nearly all asymptomatic, and the differential white blood cell count does not have a shift to immature forms of neutrophils. Granulocytosis occurs in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast cancer, 30% of patients with brain tumors and ovarian cancers, 20% of patients with Hodgkin's disease, and 10% of patients with renal cell carcinoma. Patients with advanced-stage disease are more likely to have granulocytosis than are those with early-stage disease.

Paraneoplastic granulocytosis does not require treatment. The granulocytosis resolves when the underlying cancer is treated.

THROMBOCYTOSIS

Some 35% of patients with thrombocytosis (platelet count >400,000/μL) have an underlying diagnosis of cancer. IL-6, a candidate molecule for the etiology of paraneoplastic thrombocytosis, stimulates the production of platelets in vitro and in vivo. Some patients with cancer and thrombocytosis have elevated levels of IL-6 in plasma. Another candidate molecule is thrombopoietin, a peptide hormone that stimulates megakaryocyte proliferation and platelet production. The etiology of thrombocytosis has not been established in most cases.

Patients with thrombocytosis are nearly all asymptomatic. Thrombocytosis is not clearly linked to thrombosis in patients with cancer. Thrombocytosis is present in 40% of patients with lung and gastrointestinal cancers; 20% of patients with breast, endometrial, and ovarian cancers; and 10% of patients with lymphoma. Patients with thrombocytosis are more likely to have advanced-stage disease and have a poorer prognosis than do patients without thrombocytosis. In ovarian cancer, IL-6 has been shown to directly promote tumor growth. Paraneoplastic thrombocytosis does not require treatment other than treatment of the underlying tumor.

EOSINOPHILIA

Eosinophilia is present in ~1% of patients with cancer. Tumors and tumor cell lines from patients with lymphomas or leukemia may produce IL-5, which stimulates eosinophil growth. Activation of IL-5 transcription in lymphomas and leukemias may involve translocation of the long arm of chromosome 5, to which the genes for IL-5 and other cytokines map.

Patients with eosinophilia are typically asymptomatic. Eosinophilia is present in 10% of patients with lymphoma, 3% of patients with lung cancer, and occasional patients with cervical, gastrointestinal, renal, and breast cancer. Patients with markedly elevated eosinophil counts (>5000/μL) can develop shortness of breath and wheezing. A chest radiograph may reveal diffuse pulmonary infiltrates from eosinophil infiltration and activation in the lungs.

TREATMENT

Eosinophilia

Definitive treatment is directed at the underlying malignancy. Tumors should be resected or treated with radiation or chemotherapy. In most patients who develop shortness of breath related to eosinophilia, symptoms resolve with the use of oral or inhaled glucocorticoids. IL-5 antagonists exist but have not been evaluated in this clinical setting.

THROMBOPHLEBITIS AND DEEP VENOUS THROMBOSIS

Deep venous thrombosis and pulmonary embolism are the most common thrombotic conditions in patients with cancer. Migratory or recurrent thrombophlebitis may be the initial manifestation of cancer. Nearly 15% of patients who develop deep venous thrombosis or pulmonary embolism have a diagnosis of cancer **(Chap. 122)**. The coexistence of peripheral venous thrombosis with visceral carcinoma, particularly pancreatic cancer, is called *Trousseau's syndrome*.

Pathogenesis Patients with cancer are predisposed to thromboembolism because they are often at bed rest or immobilized, and tumors may obstruct or slow blood flow. Postoperative deep venous thrombosis is twice as common in cancer patients who undergo surgery. Chronic IV catheters also predispose to clotting. In addition, clotting may be promoted by release of procoagulants or cytokines from tumor cells or associated inflammatory cells or by platelet adhesion or aggregation. The specific molecules that promote thromboembolism have not been identified.

Chemotherapeutic agents, particularly those associated with endothelial damage, can induce venous thrombosis. The annual risk of venous thrombosis in patients with cancer receiving chemotherapy is about 11%, sixfold higher than the risk in the general population. Bleomycin, L-asparaginase, nitrogen mustard, thalidomide analogues, cisplatin-based regimens, and high doses of busulfan and carmustine are all associated with an increased risk.

In addition to cancer and its treatment causing secondary thrombosis, primary thrombophilic diseases may be associated with cancer. For example, the antiphospholipid antibody syndrome is associated with a wide range of pathologic manifestations **(Chap. 369)**. About 20% of patients with this syndrome have cancers. Among patients with cancer and antiphospholipid antibodies, 35–45% develop thrombosis.

Clinical Manifestations Patients with cancer who develop deep venous thrombosis usually develop swelling or pain in the leg, and physical examination reveals tenderness, warmth, and redness. Patients who present with pulmonary embolism develop dyspnea, chest pain, and syncope, and physical examination shows tachycardia, cyanosis, and hypotension. Some 5% of patients with no history of cancer who have a diagnosis of deep venous thrombosis or pulmonary embolism will have a diagnosis of cancer within 1 year. The most common cancers associated with thromboembolic episodes include lung, pancreatic, gastrointestinal, breast, ovarian, and genitourinary cancers; lymphomas; and brain tumors. Patients with cancer who undergo

surgical procedures requiring general anesthesia have a 20–30% risk of deep venous thrombosis.

Diagnosis The diagnosis of deep venous thrombosis in patients with cancer is made by impedance plethysmography or bilateral compression ultrasonography of the leg veins. Patients with a noncompressible venous segment have deep venous thrombosis. If compression ultrasonography is normal and there is a high clinical suspicion for deep venous thrombosis, venography should be done to look for a luminal filling defect. Elevation of D-dimer is not as predictive of deep venous thrombosis in patients with cancer as it is in patients without cancer; elevations are seen in people over age 65 years without concomitant evidence of thrombosis, probably as a consequence of increased thrombin deposition and turnover in aging.

Patients with symptoms and signs suggesting a pulmonary embolism should be evaluated with a chest radiograph, electrocardiogram, arterial blood gas analysis, and ventilation-perfusion scan. Patients with mismatched segmental perfusion defects have a pulmonary embolus. Patients with equivocal ventilation-perfusion findings should be evaluated as described above for deep venous thrombosis in their legs. If deep venous thrombosis is detected, they should be anticoagulated. If deep venous thrombosis is not detected, they should be considered for a pulmonary angiogram.

Patients without a diagnosis of cancer who present with an initial episode of thrombophlebitis or pulmonary embolus need no additional tests for cancer other than a careful history and physical examination. In light of the many possible primary sites, diagnostic testing in asymptomatic patients is wasteful. However, if the clot is refractory to standard treatment or is in an unusual site, or if the thrombophlebitis is migratory or recurrent, efforts to find an underlying cancer are indicated.

TREATMENT

Thrombophlebitis and Deep Venous Thrombosis

Patients with cancer and a diagnosis of deep venous thrombosis or pulmonary embolism should be treated initially with IV unfractionated heparin or low-molecular-weight heparin for at least 5 days, and warfarin should be started within 1 or 2 days. The warfarin dose should be adjusted so that the international normalized ratio (INR) is 2–3. Patients with proximal deep venous thrombosis and a relative contraindication to heparin anticoagulation (hemorrhagic brain metastases or pericardial effusion) should be considered for placement of a filter in the inferior vena cava (Greenfield filter) to prevent pulmonary embolism. Warfarin should be administered for 3–6 months. An alternative approach is to use low-molecular-weight heparin for 6 months. The new oral anticoagulants (factor Xa and thrombin inhibitors) are attractive because they do not require close monitoring of the prothrombin time and are not affected by dietary factors. Oral apixaban (10 mg bid for 7 days followed by 5 mg bid for 6 months) is noninferior to dalteparin in the treatment of cancer patients who develop deep vein thrombosis or pulmonary embolism. Patients with cancer who undergo a major surgical procedure should be considered for heparin prophylaxis or pneumatic boots. Breast cancer patients undergoing chemotherapy and patients with implanted catheters should be considered for prophylaxis. Guidelines recommend that hospitalized patients with cancer and patients receiving a thalidomide analogue receive prophylaxis with low-molecular-weight heparin or low-dose aspirin. Use of prophylaxis routinely during chemotherapy is controversial. Risk is affected by type of cancer, type of therapy, blood counts, and body mass index (all taken into account in the Khorana risk score; Table 98-3). Studies of Khorana high-risk patients with cancer using rivaroxaban and apixaban as clot prophylaxis have resulted in a 50% reduction in risk with a level of bleeding of about 5%. However, prophylaxis is not routinely recommended by the American Society of Clinical Oncology.

TABLE 98-3 Khorana Risk Score for Venous Thromboembolism in Cancer Patients

PATIENT CHARACTERISTICS	RISK SCORE POINTS
Site of cancer	
Very high risk (stomach, pancreas)	2
High risk (lung, lymphoma, gynecologic, genitourinary excluding prostate)	1
Prechemotherapy platelet count ≥350,000/μL	1
Hemoglobin level <10 g/dL or use of red cell growth factors	1
Prechemotherapy leukocyte count >11,000/μL	1
BMI ≥35 kg/m^2	1

RISK SCORE (POINTS)	RISK CATEGORY	RATES OF sVTE ACCORDING TO SCORES (%)
0	Low	0.3–0.8
1–2	Intermediate	1.8–2.0
≥3	High	6.7–7.1

Abbreviations: BMI, body mass index; sVTE, symptomatic venous thromboembolism.

MISCELLANEOUS REMOTE EFFECTS OF CANCER

Patients with cancer can develop paraneoplastic autoimmune disorders (e.g., thrombocytopenia) and dysfunction of organs not directly invaded or involved with the cancer (rheumatologic and renal abnormalities are among the most frequent). The pathogenesis of these disorders is undefined, but often, the conditions reverse if the tumor is removed or successfully treated.

Cutaneous paraneoplastic syndromes are discussed in Chap. 61. Neurologic paraneoplastic syndromes are discussed in Chap. 99.

99 Paraneoplastic Neurologic Syndromes and Autoimmune Encephalitis

Josep Dalmau, Francesc Graus

Paraneoplastic neurologic disorders (PNDs) are cancer-related syndromes that can affect any part of the nervous system (Table 99-1). Initially defined as syndromes of unknown cause, currently most PNDs are considered to have an autoimmune pathogenesis triggered by the underlying cancer. In 60% of patients, the neurologic symptoms precede the cancer diagnosis. Clinically disabling PNDs occur in 0.5–1% of all cancer patients, but they affect 2–3% of patients with neuroblastoma or small-cell lung cancer (SCLC) and 30–50% of patients with thymoma.

PATHOGENESIS

Most PNDs are mediated by immune responses triggered by neuronal proteins ectopically expressed by tumors (e.g., SCLC and other cancers) or as a result of altered immunologic responses caused by some types of tumors such as thymomas or lymphomas. In PNDs of the central nervous system (CNS), many antibody-associated immune responses have been identified. These antibodies react with neurons and the patient's tumor, and their detection in serum or cerebrospinal fluid (CSF) variably predicts the presence of cancer. According to the frequency of an underlying tumor, these antibodies are classified as high risk (>70% probability of an underlying tumor; Table 99-2); intermediate risk (30–70% probability of an underlying tumor; Table 99-3), and low risk (<30% probability of an underlying tumor; Table 99-4). All the target antigens of high-risk antibodies are intracellular proteins except for Tr (DNER [delta/notch-like epidermal growth factor-related receptor]), which is expressed on the cell surface. By contrast, all target antigens of intermediate- and low-risk antibodies are cell-surface proteins or receptors except for GAD65 and glial fibrillary acidic protein (GFAP), which are intracellular. When the antigens are intracellular, most neurologic syndromes are associated with extensive infiltrates of CD4+ and CD8+ T cells, microglial activation, gliosis, and variable neuronal loss. The infiltrating T cells are often in close contact with neurons undergoing degeneration, suggesting a primary pathogenic role. T-cell–mediated cytotoxicity may contribute directly to cell death in these PNDs and probably underlies the resistance of many of these conditions to therapy.

In contrast to the predominant role of cytotoxic T-cell mechanisms in PNDs associated with antibodies against intracellular antigens, those associated with antibodies to antigens expressed on the neuronal cell surface of the CNS or at the neuromuscular junction are mediated by direct antibody effects on the target antigens and are more responsive to immunotherapy (Tables 99-3 and 99-4, Fig. 99-1). These disorders occur with and without a cancer association and may affect children and young adults. Some disorders are triggered by viral encephalitis such as herpes simplex virus encephalitis or Japanese encephalitis leading to autoimmune encephalitis.

TABLE 99-1 Paraneoplastic Syndromes of the Nervous System

CLASSIC SYNDROMES: HIGH RISK OF ASSOCIATED CANCER[a]	NONCLASSIC SYNDROMES: MODERATE OR LOW RISK OF ASSOCIATED CANCER
Encephalomyelitis	Brainstem encephalitis
Limbic encephalitis	Stiff-person syndrome
Cerebellar degeneration (adults)	Progressive encephalomyelitis with rigidity and myoclonus
Opsoclonus-myoclonus	Necrotizing myelopathy
Sensory neuronopathy	Motor neuron disease
Gastrointestinal pseudo-obstruction (enteric neuropathy)	Subacute axonal sensory-motor neuropathies
Dermatomyositis (adults)	Paraproteinemic neuropathies
Lambert-Eaton myasthenic syndrome	Pure autonomic neuropathy
Cancer- or melanoma-associated retinopathy	Acute necrotizing myopathy
	Polymyositis
	Optic neuropathy
	BDUMP
	Peripheral nerve hyperexcitability (neuromyotonia)
	Myasthenia gravis

[a]These syndromes frequently associate with cancer.

Abbreviation: BDUMP, bilateral diffuse uveal melanocytic proliferation.

TABLE 99-2 High-Risk Antibodies (>70% Probability of an Underlying Cancer), Syndromes, and Associated Tumors

ANTIBODY[a]	ASSOCIATED NEUROLOGIC SYNDROME(S)	TUMORS
Anti-Hu (ANNA1)	Encephalomyelitis, sensory neuronopathy	SCLC
Anti-Yo (PCA1)	Rapidly progressive cerebellar syndrome	Ovary, breast
Anti-Ri (ANNA2)	Cerebellar degeneration, opsoclonus, brainstem encephalitis	Breast, gynecologic, SCLC
Anti-CRMP5 (CV2)	Encephalomyelitis, chorea, optic neuritis, uveitis, peripheral neuropathy	SCLC, thymoma, other
Anti-Tr (DNER)	Rapidly progressive cerebellar syndrome	Hodgkin's lymphoma
Anti-Ma proteins	Limbic, hypothalamic, brainstem encephalitis	Testicular (Ma2), other (Ma)
Anti-PCA2 (MAP1B)	Sensorimotor neuropathy, rapidly progressive cerebellar syndrome, and encephalomyelitis	SCLC, non-SCLC, breast cancer
Anti-Kelch-like protein 11	Brainstem encephalitis, ataxia, sensorineural hearing loss	Seminoma, germ cell tumor, teratoma,
Anti-amphiphysin[b]	Stiff-person syndrome, encephalomyelitis	Breast, SCLC
Anti-SOX1	LEMS, rapidly progressive cerebellar syndrome with and without LEMS	SCLC

[a]All the antibodies of this table are against intracellular antigens, except for Tr (DNER), which is a cell-surface protein. [b]Amphiphysin is likely exposed to the cell surface during synaptic vesicle endocytosis.

Abbreviations: CRMP, collapsin response-mediator protein; DNER, delta/notch-like epidermal growth factor-related receptor; LEMS, Lambert-Eaton myasthenic syndrome; MAP1B, microtubule associated protein 1B; PCA, Purkinje cell antigen; SCLC, small-cell lung cancer.

TABLE 99-3 Intermediate-Risk Antibodies (30–70% Probability of an Underlying Cancer), Syndromes, and Associated Tumors

ANTIBODY[a]	NEUROLOGIC SYNDROME	TUMOR TYPE WHEN ASSOCIATED
Anti-NMDAR[b]	Anti-NMDAR encephalitis	Teratoma in young women (children and men rarely have tumors)
Anti-AMPAR[b]	Limbic encephalitis with relapses	SCLC, thymoma, breast
Anti-$GABA_BR$[c]	Limbic encephalitis with early and prominent seizures	SCLC
Anti-Caspr2[b]	Morvan syndrome	Thymoma
Anti-mGluR5[b]	Autoimmune encephalitis without distinctive features	Hodgkin lymphoma
Anti-VGCC[b]	LEMS, cerebellar degeneration	SCLC

[a]All the antibodies of this table are against neuronal cell-surface proteins. [b]A direct pathogenic role of these antibodies has been demonstrated in cultured neurons or animal models. [c]These antibodies are strongly suspected to be pathogenic.

Abbreviations: AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; Caspr2, contactin-associated protein-like 2; $GABA_BR$, γ-aminobutyric acid B receptor; LEMS, Lambert-Eaton myasthenic syndrome; mGluR, metabotropic glutamate receptor; NMDAR, *N*-methyl-D-aspartate receptor; SCLC, small-cell lung cancer; VGCC, voltage-gated calcium channel.

TABLE 99-4 Low-Risk Antibodies (<30% Probability of an Underlying Cancer), Syndromes, and Associated Tumors

ANTIBODY[a]	NEUROLOGIC SYNDROME	TUMOR TYPE WHEN ASSOCIATED
Anti-LGI1[b]	Limbic encephalitis, hyponatremia, faciobrachial dystonic seizures	Rarely thymoma
Anti-$GABA_AR$[b]	Encephalitis with prominent seizures and status epilepticus	Thymoma in ~20% of the patients
Anti-DPPX[b]	Agitation, myoclonus, tremor, seizures, hyperekplexia, encephalomyelitis with rigidity	No cancer, but frequent diarrhea or cachexia suggesting paraneoplasia
Anti-glycine receptor[b]	PERM, stiff-person syndrome	Rarely, thymoma, lung, Hodgkin's lymphoma
Anti-IgLON5[b]	NREM and REM sleep disorder, brainstem dysfunction, movement disorder, obstructive sleep apnea, stridor	No tumor association
Anti-GAD65	Stiff-person, cerebellar syndrome, encephalitis with seizures, limbic encephalitis	Infrequent tumor association (thymoma, lung, and breast cancer)
Anti-mGluR1[b]	Cerebellar syndrome	Hodgkin's lymphoma in <10% of patients
Anti-GFAP	Meningoencephalitis and myelitis	No cancer association
Anti-aquaporin 4[b]	Neuromyelitis optica spectrum disorders	Lung and breast adenocarcinomas in a few patients
Anti-MOG	ADEM, optic neuritis, myelitis, cortical encephalitis	No cancer association
Anti-AChR (muscle)[b]	Myasthenia gravis	Thymoma
Anti-AChR (neuronal)[b]	Autonomic ganglionopathy	SCLC

[a]All the antibodies of this table are against cell-surface proteins except for GAD65 and GFAP which are intracellular proteins. Rare antibodies reported in <30 patients are not included. [b]A direct pathogenic role of these antibodies has been demonstrated in cultured neurons or animal models.

Abbreviations: AChR, acetylcholine receptor; ADEM, acute disseminated encephalomyelitis; DPPX, dipeptidyl-peptidase-like protein-6; $GABA_AR$, γ-aminobutyric acid A receptor; GAD, glutamic acid decarboxylase; GFAP, glial fibrillary acidic protein; LGI1, leucine-rich glioma-inactivated 1; mGluR, metabotropic glutamate receptor; MOG, myelin oligodendrocyte glycoprotein; NREM, non–rapid eye movement; PERM, progressive encephalomyelitis with rigidity and myoclonus; REM, rapid eye movement; SCLC, small-cell lung cancer.

In patients with cancer, the use of immune checkpoint inhibitors is associated in <3% of cases with neurologic immune-related adverse events that may be accompanied by neuronal antibodies, in which case the associated syndromes are indistinguishable from PNDs.

Other PNDs are likely immune-mediated, although their antigens are unknown. The best example is opsoclonus-myoclonus syndrome associated with neuroblastoma or SCLC. For still other PNDs, the cause remains quite obscure. These include, among others, several neuropathies that occur in the terminal stages of cancer and a number of neuropathies associated with plasma cell dyscrasias or lymphoma without evidence of tumor infiltration or deposits of immunoglobulin, cryoglobulin, or amyloid.

APPROACH TO THE PATIENT

Paraneoplastic Neurologic Disorders

Three key concepts are important for the diagnosis and management of PNDs. First, it is common for symptoms to appear before the presence of a tumor is known; second, the neurologic syndrome usually develops rapidly, producing severe deficits in a short period of time; and third, there is evidence that prompt tumor control improves the neurologic outcome. Therefore, the major concern of the physician is to recognize a disorder as paraneoplastic as early as possible and to identify and treat the tumor.

PND OF THE CENTRAL NERVOUS SYSTEM AND DORSAL ROOT GANGLIA

When symptoms involve brain, spinal cord, or dorsal root ganglia, the suspicion of PND is usually based on a combination of clinical, radiologic, and CSF findings. Presence of antineuronal antibodies (Tables 99-2, 99-3, and 99-4) may help in the diagnosis, but only 60–70% of PNDs of the CNS and <20% of those involving the peripheral nervous system have neuronal or neuromuscular junction antibodies that can be used as diagnostic tests.

Magnetic resonance imaging (MRI) and CSF studies are important to rule out neurologic complications due to the direct spread of cancer, particularly metastatic and leptomeningeal disease. In most PNDs, the MRI findings are nonspecific. Paraneoplastic limbic encephalitis is usually associated with characteristic MRI abnormalities in the mesial temporal lobes (see below), but similar findings can occur with other disorders (e.g., nonparaneoplastic autoimmune limbic encephalitis and human herpesvirus type 6 [HHV-6] encephalitis) **(Fig. 99-2*A*)**. The CSF profile of patients with PND of the CNS or dorsal root ganglia typically consists of mild to moderate pleocytosis (<200 mononuclear cells, predominantly lymphocytes), an increase in the protein concentration, and a variable presence of oligoclonal bands. There are no specific electrophysiologic tests that are diagnostic of PND of the CNS. Moreover, a biopsy of the affected tissue is often difficult to obtain, and although useful to rule out other disorders (e.g., metastasis), the pathologic findings are not specific for PND.

PND OF NERVE AND MUSCLE

If symptoms involve peripheral nerve, neuromuscular junction, or muscle, the diagnosis of a specific PND is usually established on clinical, electrophysiologic, and pathologic grounds. The clinical history, accompanying symptoms (e.g., anorexia, weight loss), and type of syndrome dictate the studies and degree of effort needed to demonstrate a neoplasm. For example, the frequent association of Lambert-Eaton myasthenic syndrome (LEMS) with SCLC should lead to a chest and abdomen computed tomography (CT) or body positron emission tomography (PET) scan and, if negative, periodic tumor screening for at least 3 years after the neurologic diagnosis. In contrast, the weak association of polymyositis with cancer calls into question the need for repeated cancer screenings in this situation. Serum and urine immunofixation studies should be considered in patients with peripheral neuropathy of unknown cause; detection of a monoclonal gammopathy suggests the need for additional studies to uncover a B-cell or plasma-cell malignancy. In paraneoplastic neuropathies, diagnostically useful neuronal antibodies are limited to CRMP5 (CV2) and Hu (ANNA1).

For any type of PND, if neuronal antibodies are negative, the diagnosis relies on the demonstration of cancer and the exclusion of other cancer-related or independent neurologic disorders. Combined CT and PET scans often uncover tumors undetected by other tests. For germ cell tumors of the testis and teratomas of the ovary, ultrasound (testicular, transvaginal, or pelvic) and MRI or CT of the abdomen and pelvis may reveal tumors undetectable by PET.

SPECIFIC PARANEOPLASTIC NEUROLOGIC SYNDROMES

■ PARANEOPLASTIC ENCEPHALOMYELITIS AND FOCAL ENCEPHALITIS WITH HIGH-RISK ANTIBODIES FOR AN UNDERLYING CANCER

The term *encephalomyelitis* describes an inflammatory process with multifocal involvement of the nervous system, including brain, brainstem, cerebellum, and spinal cord. It is often associated with dorsal root ganglia and autonomic dysfunction. For any given patient, the clinical

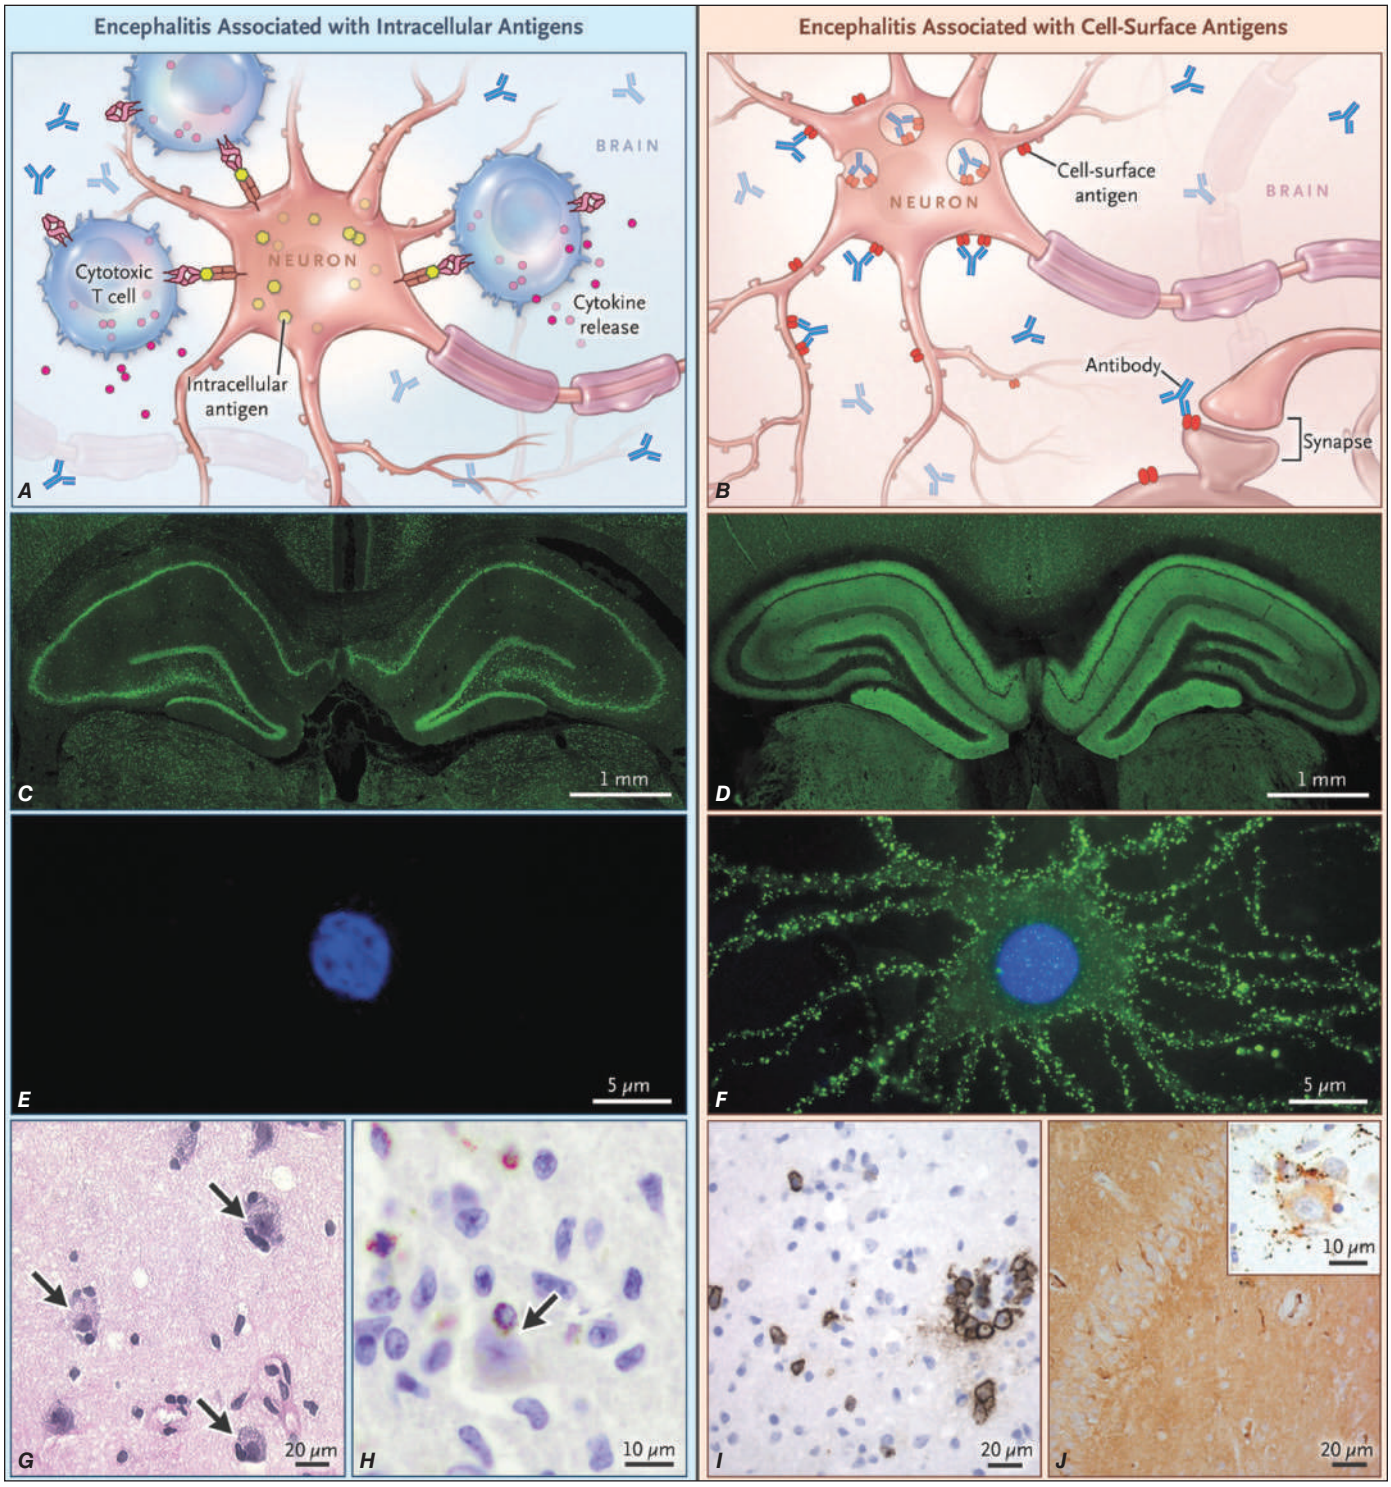

FIGURE 99-1 Antibody reactivity and pathologic findings in patients with antibodies against intracellular antigens compared with those of patients with antibodies against neuronal surface antigens. In encephalitis associated with antibodies against intracellular antigens, the antibodies cannot reach the intracellular epitopes and cytotoxic T-cell mechanisms are predominantly involved (***A***), whereas in encephalitis with antibodies against surface antigens, the antibodies have access to the epitopes and can potentially alter the structure and function of the antigen (***B***). The Hu antibodies (***C, E***) are shown here to exemplify the group of antibodies against intracellular antigens, and the NMDAR antibodies (***D, F***) are shown to exemplify the group of antibodies against cell-surface antigens. In rodent brain immunofluorescence with tissue permeabilized to allow entry of antibodies, the Hu antibodies produce a discrete pattern of cellular immunolabeling (***C***), whereas the NMDAR antibodies produce a pattern of neuropil-like immunolabeling (***D***). In contrast, with live cultured neurons, only the NMDAR antibodies have access to the target antigen showing intense immunolabeling (***F***), whereas the Hu antibodies cannot reach the intracellular antigen showing no immunolabeling (***E***). In autopsy studies, patients with encephalitis associated with antibodies to intracellular antigens (Hu or other) have extensive neuronal loss and inflammatory infiltrates (not shown); the T cells show direct contact with neurons (*arrows* in ***G***) likely contributing to neuronal degeneration via perforin and granzyme mechanisms (*arrow* in ***H***). In contrast, patients with antibodies against cell-surface antigens (NMDAR shown here, and probably applicable to other antigens) have moderate brain inflammatory infiltrates along with plasma cells (brown cells in ***I***), deposits of IgG (diffuse brown staining in ***J***), and microglial proliferation (inset in ***J***), without evidence of predominant T-cell–mediated neuronal loss (not shown). All human tissue sections (***G-J***) were obtained from hippocampus. *(From J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission.)*

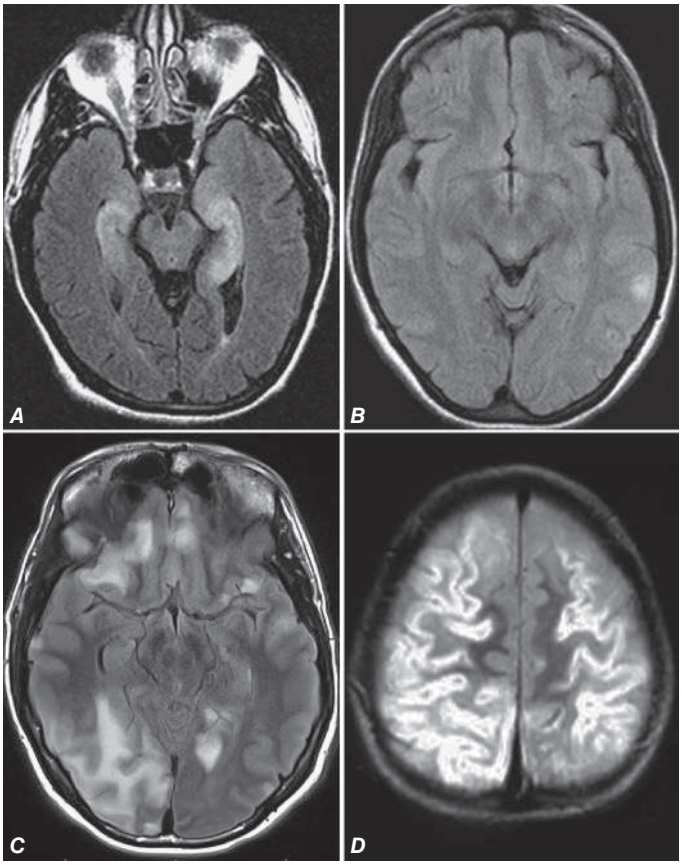

FIGURE 99-2 Brain MRI findings in paraneoplastic and autoimmune encephalitis. Representative MRI studies of patients with several types of autoimmune encephalitides. ***A.*** Limbic encephalitis (LE) may result from several different immune responses (Hu, Ma2, AMPAR, $GABA_BR$, LGI1, Caspr2) and typically manifests with unilateral or bilateral medial temporal lobe increased FLAIR signal. ***B.*** Anti-NMDAR encephalitis often occurs with normal MRI findings or mild FLAIR signal abnormalities. ***C.*** In contrast, anti-$GABA_AR$ encephalitis usually occurs with multiple cortical-subcortical increased FLAIR signal changes. ***D.*** Cortical encephalitis can occur in patients with myelin oligodendrocyte glycoprotein (MOG) antibodies, as shown in this T2-weighted MRI image from a 3-year-old boy who presented with extensive cortical abnormalities with mild enhancement (not shown here) suggesting cortical necrosis. *(Panels A-C from J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission. Panel D from T Armangue: Associations of paediatric demyelinating and encephalitic syndromes with myelin oligodendrocyte glycoprotein antibodies: A multicentre observational study. Lancet Neurol 19:234, 2020.)*

manifestations are determined by the areas predominantly involved, but pathologic studies almost always reveal abnormalities beyond the symptomatic regions. Several clinicopathologic syndromes may occur alone or in combination: (1) *cortical encephalitis*, which may present as "epilepsia partialis continua"; (2) *limbic encephalitis*, characterized by confusion, depression, agitation, anxiety, severe deficit forming new memories ("short-term memory deficit"), and temporal lobe or generalized seizures (the MRI usually shows unilateral or bilateral medial temporal lobe abnormalities, best seen with T2 and fluid-attenuated inversion recovery [FLAIR] sequences); (3) *brainstem encephalitis,* resulting in eye movement disorders (nystagmus, opsoclonus, supranuclear or nuclear paresis), cranial nerve paresis, dysarthria, dysphagia, unsteady gait, and central autonomic dysfunction; (4) *cerebellar gait and limb ataxia*; (5) *myelitis*, which may cause lower or upper motor neuron symptoms, myoclonus, muscle rigidity, spasms, fasciculations, sensory deficits, and sphincter dysfunction; and (6) *autonomic dysfunction* as a result of involvement of the neuraxis at multiple levels, including hypothalamus, brainstem, and autonomic nerves (see "Paraneoplastic Peripheral Neuropathies," below). Cardiac arrhythmias, postural hypotension, and central hypoventilation can be the cause of death in patients with encephalomyelitis.

Paraneoplastic encephalomyelitis and focal encephalitis are usually associated with SCLC, but many other cancers have been implicated. Patients with SCLC and these syndromes usually have Hu antibodies in serum and CSF. CRMP5 antibodies occur less frequently; some of these patients may develop chorea, uveitis, or optic neuritis. Antibodies to Ma proteins are associated with limbic, hypothalamic, and brainstem encephalitis and occasionally with cerebellar symptoms; some patients develop hypersomnia, cataplexy, and severe hypokinesia. MRI abnormalities are frequent, including those described with limbic encephalitis and variable involvement of the hypothalamus, basal ganglia, or upper brainstem. Kelch-like protein 11 antibodies are predominantly associated with brainstem encephalitis, vertigo, sensorineural hearing loss, and seminomas, germ cell tumors, and teratomas. Amphiphysin antibodies usually are associated with paraneoplastic stiff-person syndrome, but in some patients, they can occur with paraneoplastic encephalomyelitis or isolated myelitis. The oncologic associations of these antibodies are shown in Table 99-2.

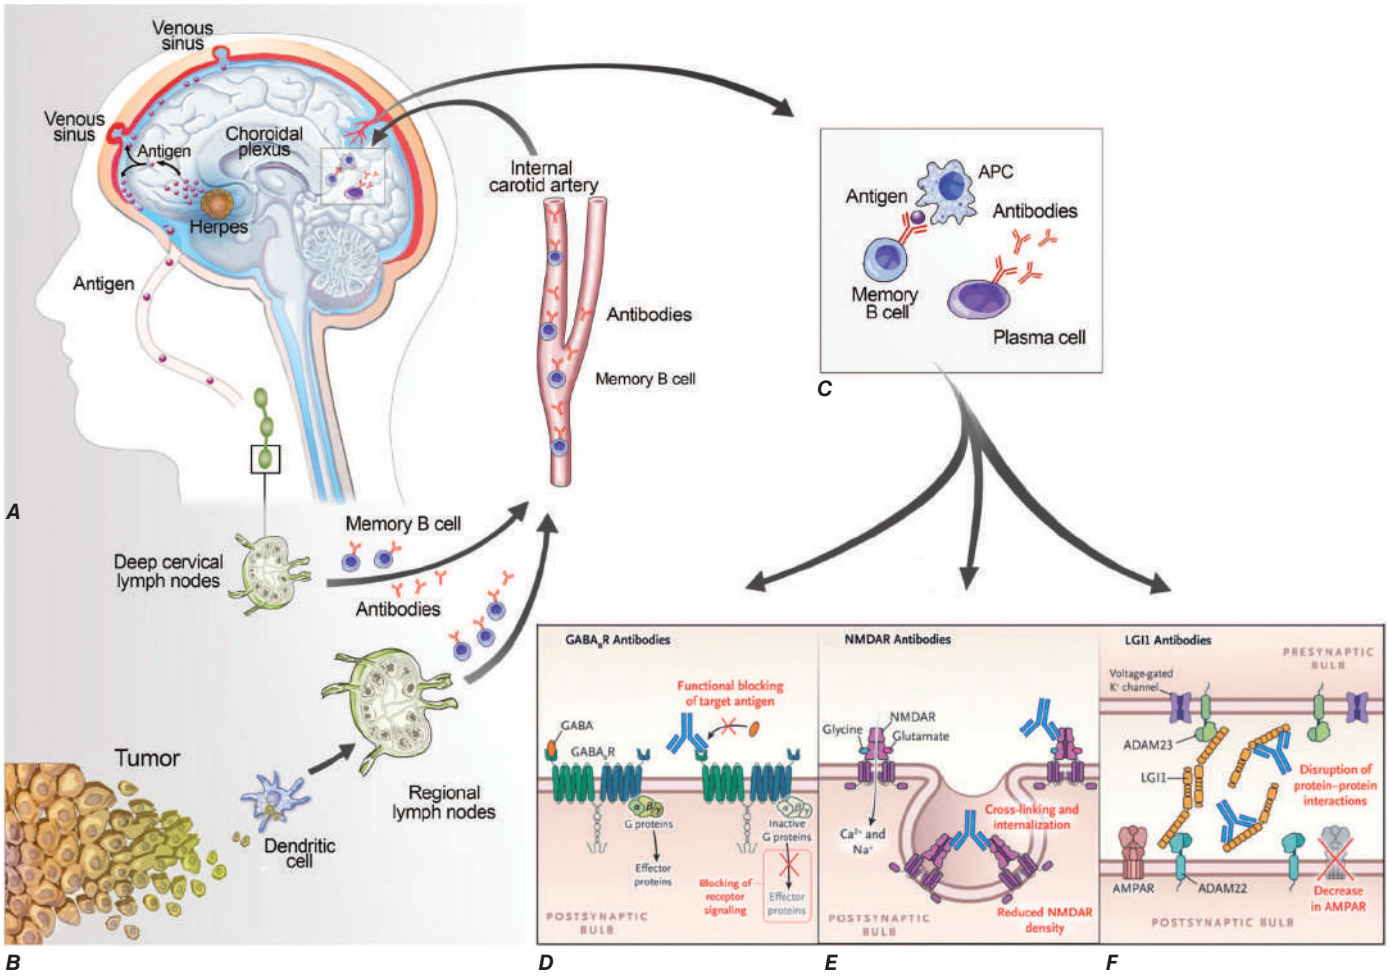
Most types of paraneoplastic encephalitis and encephalomyelitis in which the antigens are intracellular respond poorly to treatment. Stabilization of symptoms or partial neurologic improvement may occur, particularly if there is a satisfactory response of the tumor to treatment. Controlled trials of therapy are lacking, but many reports and the opinion of experts suggest that therapies aimed to remove the antibodies against intracellular antigens, such as intravenous immunoglobulin (IVIg) or plasma exchange, usually fail. The main concern should be to treat the tumor and consider immunotherapies aimed at cytotoxic T-cell responses. Approximately 30% of patients with anti-Ma2-associated encephalitis respond to treatment of the tumor (usually a germ cell neoplasm of the testis) and immunotherapy.

Cortical encephalitis can occur with antibodies against myelin oligodendrocyte glycoprotein (MOG) **(Chap. 456)**, and encephalomyelitis can occur with antibodies against GFAP **(Chap. 456)**. These two disorders rarely associate with cancer and respond better to immunotherapy than the indicated paraneoplastic syndromes. Encephalitis with seizures, limbic encephalitis, stiff-person syndrome, or cerebellar ataxia can occur with GAD65 antibodies; this type of autoimmunity rarely associates with cancer but responds less frequently to immunotherapy than similar syndromes associated with antibodies against neuronal surface proteins.

ENCEPHALITIDES WITH INTERMEDIATE- OR LOW-RISK ANTIBODIES FOR AN UNDERLYING CANCER

These disorders are important for four reasons: (1) they can occur with and without tumor association; less frequently, they develop after a viral encephalitis (herpes simplex or Japanese encephalitis); (2) some syndromes predominate in young individuals and children; (3) despite the severity of the symptoms, patients usually respond to treatment of the tumor, if found, and immunotherapy (e.g., glucocorticoids, IVIg, plasma exchange, rituximab, or cyclophosphamide); and (4) for many of these disorders, the antibody pathogenicity has been demonstrated in models using cultures of neurons or passive transfer of patients' antibodies to animals **(Fig. 99-3)**.

Encephalitis with N*-methyl-*D*-aspartate receptor (NMDAR) antibodies* usually occurs in young women and children, but men and older patients of both sexes can be affected. The disorder has a characteristic pattern of symptom progression that often includes a prodrome resembling a viral process, followed in a few days by the onset of severe psychiatric symptoms, sleep dysfunction (usually insomnia), reduced verbal output, memory loss, seizures, decreased level of consciousness, abnormal movements (orofacial, limb, and trunk dyskinesias, dystonic postures), autonomic instability, and frequent hypoventilation. Monosymptomatic episodes, such as pure psychosis, occur in about 5% of patients. Clinical relapses occur in 12–24% of patients (12% during the first 2 years after initial presentation). Most patients have intrathecal synthesis of antibodies, likely by infiltrating plasma cells in brain and meninges **(Fig. 99-1*I*)**. In about 65% of patients, the brain MRI is normal; in the other 35%, it shows FLAIR abnormalities that can affect cortical and subcortical regions, usually mild and transient, and rarely



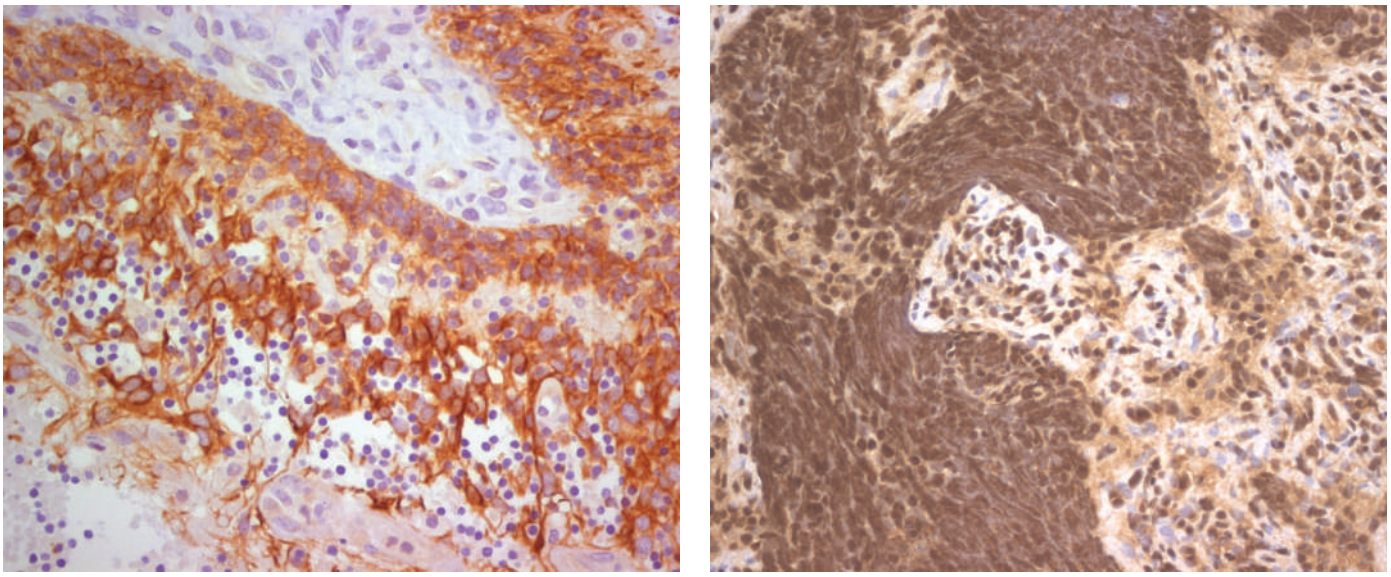


FIGURE 99-3 Proposed mechanisms of disease and functional interactions of autoantibodies with neuronal surface proteins. The graph shows a multistep process that results in antibody-mediated neuronal dysfunction; some of the steps have been demonstrated in reported studies, whereas others are based on proposed hypotheses. Two well-known triggers of autoimmune encephalitides are represented: herpes simplex encephalitis (***A***) and systemic tumors (***B***); the genetic susceptibility of some autoimmune encephalitides and unknown immunologic triggers are not depicted. It is postulated that antigens released by viral-induced neuronal destruction or apoptotic tumor cells are loaded into antigen-presenting cells (APCs; dendritic cells) and transported to regional lymph nodes. In the lymph nodes, naïve B cells exposed to the processed antigens, with cooperation of CD4+ T cells, become antigen-experienced and differentiate into antibody-producing plasma cells. After entering the brain, memory B cells undergo restimulation, antigen-driven affinity maturation, clonal expansion, and differentiation into antibody-producing plasma cells (***C***). The contribution of systemically produced antibodies to the pool of antibodies present in the brain is unclear and may depend on systemic antibody titers and integrity of the blood-brain barrier. Based on experimental models with cultured neurons, the presence of antibodies in the brain may lead to neuronal dysfunction by different mechanisms, including functional blocking of the target antigen (GABA$_B$R antibodies; ***D***), receptor crosslinking and internalization (NMDAR antibodies; ***E***), and disruption of protein-protein interaction, leading to downstream effects on receptors (LGI1 leading to a decrease of Kv1 potassium channels and AMPAR; ***F***). These mechanisms are influenced by the type of antibodies; for example, whereas IgG1 antibodies frequently crosslink and internalize the target antigen, IgG4 antibodies are less effective at crosslinking the target and more often alter protein-protein interactions. *(Panels D-F from J Dalmau: Antibody mediated encephalitis. N Engl J Med 378:840, 2018. Copyright © 2018 Massachusetts Medical Society. Reprinted with permission.)*

the presence of contrast enhancement (Fig. 99-2*B*). The syndrome may be misdiagnosed as a viral or idiopathic encephalitis, neuroleptic malignant syndrome, or encephalitis lethargica, and some patients are initially evaluated by psychiatrists with the suspicion of acute psychosis as the presentation of a primary psychiatric disease. The detection of an associated teratoma is dependent on age and gender: 46% of female patients 12 years or older have uni- or bilateral ovarian teratomas, whereas <7% of girls younger than 12 have a teratoma (Fig. 99-4*A*). In young male patients, the detection of a tumor is rare. Patients older than 45 years are more frequently male; about 20% of these patients have tumors (e.g., cancer of the breast, ovary, or lung). Prompt diagnosis and treatment with immunotherapy (and tumor removal when it applies) improve outcome. Treatment usually includes first-line immunotherapy (steroids, IVIg, or plasma exchange), and if there is no response, second-line immunotherapy (rituximab and cyclophosphamide). Rituximab is highly effective and is increasingly used as part of first-line treatments. The response to treatment can take several weeks, and the improvement is usually slow. Overall, about 85–90% of patients have substantial neurologic improvement or full recovery. Deficits of attention, memory, and executive functions may recover slowly over many months. During the process of recovery, patients often develop transient hypersomnia and, less frequently, hyperphagia, hypersexuality, apathy, and irritability, resembling a Kleine-Levin syndrome.

Approximately 25% of patients with herpes simplex encephalitis develop a form of autoimmune encephalitis that usually is associated with abnormal movements (choreoathetosis after herpes simplex encephalitis) in children and with cognitive and psychiatric symptoms in adults. This disorder develops a few weeks after the viral infection has resolved, is associated with new synthesis of antibodies against the NMDAR and other neuronal cell surface proteins, and is usually less responsive to immunotherapy than anti-NMDAR encephalitis (idiopathic or teratoma-associated).

Encephalitis with α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor antibodies affects middle-aged women, who develop acute limbic dysfunction or, less frequently, prominent psychiatric symptoms; 70% of patients have an underlying tumor in the lung, breast, or thymus (Fig. 99-4*B*). In about 50% of cases, the brain MRI shows typical features of limbic encephalitis (similar to Fig. 99-2*A*).

A **B**

FIGURE 99-4 Immunopathological studies in tumors of patients with autoimmune encephalitis. ***A.*** Neurons and neuronal processes (brown cells; stained with MAP2) in the teratoma of a patient with anti-NMDA receptor encephalitis; these neurons express NMDAR (not shown). ***B.*** Lung cancer from a patient with anti–α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor encephalitis showing expression of AMPA receptors by the neoplastic cells (brown cells). *(Panel B from M Lai et al: AMPA receptor antibodies in limbic encephalitis alter synaptic receptor location. Ann Neurol 65:424, 2009.)*

Neurologic relapses may occur; these also respond to immunotherapy and are not necessarily associated with tumor recurrence.

Encephalitis with GluK2 antibodies can affect children and adults and is associated with rapidly progressive encephalopathy with cerebellar ataxia or cerebellitis. Symptoms of encephalopathy may include impairment of memory and level of consciousness and motor alterations such as dyskinesias, choreoathetosis, bradykinesia, and spastic paraparesis. Some patients develop intracranial hypertension. In one patient, the symptoms were associated with teratoma.

Encephalitis with γ-aminobutyric acid type A ($GABA_A$) receptor antibodies may affect children and adults and is associated with prominent seizures and status epilepticus often requiring a pharmacologically induced coma. In approximately 80% of patients, the brain MRI shows multifocal, asynchronous, cortical-subcortical T2/FLAIR abnormalities predominantly involving temporal and frontal lobes, but also basal ganglia and other regions **(Fig. 99-2*C*)**. Most patients do not have an underlying tumor, but some may have thymoma.

Encephalitis with $GABA_B$ receptor antibodies is usually associated with limbic encephalitis and seizures. In >50% of cases, the MRI shows increased medial temporal lobe FLAIR changes characteristic of limbic encephalitis (similar to Fig. 99-2*A*). In rare instances, patients develop cerebellar symptoms and opsoclonus. Fifty percent of patients have SCLC or a neuroendocrine tumor of the lung. The outcome is substantially better in patients without cancer.

Encephalitis with glycine receptor (GlyR) antibodies usually manifests with a syndrome characterized by progressive encephalomyelitis with rigidity and myoclonus (PERM) or stiff-person spectrum of symptoms. The disease usually occurs in adults and rarely in children. About 20% of adult patients have a concurrent underlying tumor (thymoma, B-cell lymphoma, or breast or lung cancer) or past history of cancer (thymoma, breast cancer, Hodgkin's lymphoma, or melanoma).

Encephalitis with metabotropic glutamate receptor 5 (mGluR5) antibodies is characterized by nonspecific clinical features of encephalitis (confusion, agitation, memory loss, delusions, paranoid ideation, hallucinations, psychosis, or seizures) without distinctive MRI changes and frequent association with Hodgkin's lymphoma. The encephalitis is highly responsive to immunotherapy and treatment of the tumor.

Encephalitis with antibodies against dopamine-2 receptor has been reported in children with basal ganglia encephalitis manifesting with abnormal movements (coarse tremor, parkinsonism, chorea, oculogyric crises) along with psychiatric features, lethargy, drowsiness, brainstem dysfunction, or ataxia. The disorder is extremely rare and is not associated with cancer.

Encephalitis with leucine-rich glioma-inactivated 1 (LGI1) antibodies predominates in patients older than 50 years (65% male) and frequently presents with short-term memory loss and seizures (limbic encephalopathy), along with hyponatremia and sleep dysfunction. The MRI often shows increased FLAIR signal in one or both medial temporal lobes. In about 40% of patients, these symptoms are preceded by faciobrachial dystonic seizures, which consist of sudden, short-lasting, mainly distal muscle contractions involving the arm, face, or leg. These are unilateral but can independently affect both sides and occur multiple times during the day or night. About 15% of patients present with rapidly progressive cognitive decline, resembling a rapidly progressive dementia. Less than 5% of patients have thymoma. An association with the human leukocyte antigen (HLA) haplotypes DRB1*07:01, DQB1*02:02, DQA1*02:01, and DRB4 has been identified. All symptoms, including faciobrachial dystonic seizures, respond to immunotherapy, although about two-thirds of patients are left with memory or cognitive deficits. Despite the improvement with initial immunotherapy, video-polysomnography or prolonged electroencephalogram studies frequently uncover persistent alterations (faciobrachial dystonic seizures, other seizures, rapid eye movement [REM] sleep behavior disorder) only detectable during sleep. These alterations, which might contribute to residual memory or cognitive deficits, respond to additional or prolonged immunotherapy.

Encephalitis with contactin-associated protein-like 2 (Caspr2) antibodies predominates in patients older than 50 years and is associated with a form of encephalitis with three or more of the following core symptoms: encephalopathy (which can be similar to limbic encephalitis), cerebellar symptoms, peripheral nervous system hyperexcitability, dysautonomia, insomnia, neuropathic pain, and weight loss. Patients with Morvan syndrome, which includes clinical features of encephalitis (confusion, hallucinations, prominent sleep dysfunction, or "agrypnia excitata"), autonomic alterations, and peripheral nerve hyperexcitability or neuromyotonia, usually have Caspr2 antibodies. About 20% of patients with Caspr2 antibody–associated syndromes have thymoma; this percentage is higher (~50%) in patients with Morvan syndrome. An association of Caspr2 antibody–associated syndromes with HLA DRB1*11.01 has been reported.

Encephalitis with dipeptidyl-peptidase-like protein-6 (DPPX) antibodies is usually preceded or develops concurrently with diarrhea, other gastrointestinal symptoms, and substantial loss of weight that

often suggest the presence of a gastrointestinal disease. Neurologic symptoms include agitation, hallucinations, paranoid delusions, and features of CNS hyperexcitability such as hyperekplexia, tremor, myoclonus, nystagmus, or seizures. Some patients develop a clinical picture similar to progressive encephalomyelitis with rigidity and myoclonus. The few patients reported with an associated tumor usually had B-cell neoplasms.

Encephalitis with antibodies against neurexin 3 alpha does not have distinctive clinical features; the experience is limited, and the disorder does not appear to be associated with cancer.

Anti-IgLON5 disease is a chronic or subacute encephalopathy that characteristically is associated with REM and non-REM (NREM) parasomnia along with obstructive sleep apnea that may be preceded or accompanied by bulbar symptoms (mainly dysphagia and stridor due to vocal cord palsy), unsteadiness, movement disorders (chorea, craniofacial dyskinesias), oculomotor dysfunction, and, in less than half of cases, cognitive decline. The median age of the patients is in the early 60s, and men and women are equally affected. The sleep disorder is characterized by abnormal sleep initiation with undifferentiated NREM sleep associated with frequent vocalizations and quasi-purposeful movements. Brain MRI is unrevealing or demonstrates minor changes of unclear clinical relevance; the CSF is usually normal or may show transient lymphocytic pleocytosis. It is not associated with cancer but shows a strong association with the HLA-DRB1*10:01 and HLA-DQB1*05 haplotypes, which are present in 60% of patients. The response to immunotherapy is poor. In some patients, neuropathologic studies show a neuronal tauopathy predominantly involving the hypothalamus and tegmentum of the brainstem; however, not all autopsy studies show deposits of hyperphosphorylated tau, and in some patients, mild inflammatory infiltrates have been identified.

With the exception of patients with anti-IgLON5 disease, who rarely respond to treatment, most patients with autoimmune or paraneoplastic encephalopathies associated with antibodies against cell-surface or synaptic proteins respond to immunotherapy and treatment of the tumor (if appropriate). Although there are no specific standardized treatment protocols, the most frequent approach is similar to that indicated for anti-NMDAR encephalitis and consists of progressive escalation of immunotherapy using first a combination of glucocorticoids, IVIg, and plasma exchange, and then, if there is no response, rituximab or cyclophosphamide.

Encephalitis with MOG antibodies can present with a clinical picture suggestive of autoimmune encephalitis related to neuronal antibodies. Most patients with MOG antibody–associated syndromes are children and young adults who present with optic neuritis, myelitis, brainstem (mainly pons) and cerebellar symptoms, or acute disseminated encephalomyelitis (ADEM). About 85% of patients with these syndromes respond to immunotherapy, although relapses occur in about 30% of cases. Besides these syndromes, there is a small group of adults and children who present with unilateral or bilateral cortical encephalitis, and their response to treatment is variable. In children, two phenotypes of poor prognosis include ADEM-like relapses progressing to leukodystrophy-like features and extensive cortical encephalitis evolving to atrophy **(Fig. 99-2*D*)**. In general, MOG antibody syndromes are not associated with tumors.

PARANEOPLASTIC CEREBELLAR DEGENERATION

This disorder is often preceded by a prodrome that may include dizziness, oscillopsia, blurry or double vision, nausea, and vomiting. A few days or weeks later, patients develop dysarthria, gait and limb ataxia, and variable dysphagia. The examination usually shows downbeating nystagmus and, rarely, opsoclonus. Brainstem dysfunction or upgoing toes may occur. Early in the course, MRI studies are usually normal; later, the MRI reveals cerebellar atrophy. The disorder results from extensive degeneration of Purkinje cells, with variable involvement of other cerebellar cortical neurons, deep cerebellar nuclei, and spinocerebellar tracts. The tumors more frequently involved are SCLC, cancer of the breast and ovary, and Hodgkin's lymphoma.

Anti-Yo (PCA1) antibodies in patients with breast or gynecologic cancers typically are associated with prominent or pure cerebellar degeneration. A variable degree of cerebellar dysfunction can be associated with virtually any of the antibodies and PND of the CNS shown in Table 99-2. A number of single case reports have described neurologic improvement after tumor removal, plasma exchange, IVIg, cyclophosphamide, rituximab, or glucocorticoids. However, most patients with paraneoplastic cerebellar degeneration and any of the antibodies shown in Table 99-2 do not improve with treatment; an exception are the cerebellar syndromes associated with antibodies against surface antigens (e.g., Tr antibodies and Hodgkin's lymphoma, VGCC antibodies and SCLC), which are more responsive to immunotherapy.

Antibody-associated cerebellar symptoms can also occur without cancer association. The most common is cerebellar ataxia with antibodies against GAD65 (an intracellular synaptic protein). The median age at diagnosis is 60 years and 75% of cases are women. Concurrent organ-specific autoimmune diseases, mainly type 1 diabetes, are present in 80% of patients. The clinical course is chronic, but in 40% of patients, the presentation is subacute (<6 months). Response to immunotherapy is poor. Subacute onset of symptoms and prompt initiation of immunotherapy are associated with a better chance for improvement. By contrast, the cerebellar syndrome associated with mGluR1 antibodies is more responsive to immunotherapy, and a substantial improvement occurs in almost half of the patients. Immunotherapy is also effective in patients with GluK2 antibodies, who can present with cerebellitis and posterior fossa edema with compression of the fourth ventricle, and in those with septin-5 antibodies. Although septin-5 is an intracellular antigen, it is likely exposed to the cell surface during the process of endo- and exocytosis at synaptic terminals.

PARANEOPLASTIC OPSOCLONUS-MYOCLONUS SYNDROME

Opsoclonus is a disorder of eye movement characterized by involuntary, chaotic saccades that occur in all directions of gaze; it is frequently associated with myoclonus and ataxia. Opsoclonus-myoclonus may be cancer-related or idiopathic. When the cause is paraneoplastic, the tumors involved are usually cancer of the lung and breast in adults and neuroblastoma in children. The pathologic substrate of opsoclonus-myoclonus is unclear, but studies suggest that disinhibition of the fastigial nucleus of the cerebellum is involved. Most patients do not have neuronal antibodies. A small subset of patients with ataxia, opsoclonus, and other eye-movement disorders have Ri antibodies; these patients may also develop muscle rigidity, laryngeal spasms, and autonomic dysfunction. The tumors most frequently involved in anti-Ri-associated syndromes are breast, ovarian, and lung cancers. If the tumor is not successfully treated, the syndrome in adults often progresses to encephalopathy, coma, and death. In addition to treating the tumor, symptoms may respond to immunotherapy (glucocorticoids, plasma exchange, and/or IVIg).

At least 50% of children with opsoclonus-myoclonus have an underlying neuroblastoma. Hypotonia, ataxia, behavioral changes, and irritability are frequent accompanying symptoms. Neurologic symptoms often improve with treatment of the tumor and glucocorticoids, adrenocorticotropic hormone (ACTH), plasma exchange, IVIg, rituximab, or cyclophosphamide. Many patients are left with psychomotor retardation and behavioral and sleep problems.

PARANEOPLASTIC SYNDROMES OF THE SPINAL CORD

The number of reports of paraneoplastic spinal cord syndromes, such as *subacute motor neuronopathy* and *acute necrotizing myelopathy*, has decreased over the years. This may represent a true decrease in incidence, due to improved and prompt oncologic interventions, or the identification of nonparaneoplastic etiologies. Some patients with cancer or lymphoma develop *upper* or *lower motor neuron dysfunction* or both, resembling amyotrophic lateral sclerosis. It is unclear whether these disorders have a paraneoplastic etiology or simply coincide with the presence of cancer.

Paraneoplastic myelitis may present with upper or lower motor neuron symptoms, segmental myoclonus, sensory deficits, sphincter dysfunction, and neurogenic pruritus and can be the first manifestation of

encephalomyelitis. The spine MRI usually shows longitudinally extensive, symmetric tract or gray matter abnormalities in the spinal cord. It is mainly associated with breast and lung carcinomas and with CRMP5 or amphiphysin antibodies. The prognosis is poor. *Neuromyelitis optica (NMO) with aquaporin 4 antibodies* may occur in rare instances as a paraneoplastic manifestation of a cancer. NMO is discussed in detail in **Chap. 456**.

PARANEOPLASTIC STIFF-PERSON SYNDROME

This disorder is characterized by progressive muscle rigidity, stiffness, and painful spasms triggered by auditory, sensory, or emotional stimuli. Rigidity mainly involves the lower trunk and legs, but it can affect the upper extremities and neck. Sometimes, only one extremity is affected (*stiff-limb syndrome*). Symptoms improve with sleep and general anesthetics. Electrophysiologic studies demonstrate continuous motor unit activity. The associated antibodies target proteins (GAD65, amphiphysin) involved in the function of inhibitory synapses that use γ-aminobutyric acid (GABA) or glycine as neurotransmitters. The presence of amphiphysin antibodies usually indicates a paraneoplastic etiology related to SCLC and breast cancer. By contrast, GAD antibodies may occur in some cancer patients but are much more frequently present in the nonparaneoplastic disorder. GlyR antibodies may occur in some patients with stiff-person syndrome; these antibodies are more frequently detectable in patients with PERM **(Fig. 99-5)**.

Optimal treatment of stiff-person syndrome requires therapy of the underlying tumor, glucocorticoids, and symptomatic use of drugs that enhance GABA-ergic transmission (diazepam, baclofen, sodium valproate, tiagabine, vigabatrin). IVIg and plasma exchange are transiently effective in some patients, and there are reports of responses to rituximab and CD19 CAR T-cell therapy in patients who did not respond to other treatments.

PARANEOPLASTIC SENSORY NEURONOPATHY OR DORSAL ROOT GANGLIONOPATHY

This syndrome is characterized by sensory deficits that may be symmetric or asymmetric, painful dysesthesias, radicular pain, and decreased or absent reflexes. All modalities of sensation and any part of the body including face and trunk can be involved. Special senses such as taste and hearing can also be affected. Electrophysiologic studies show decreased or absent sensory nerve potentials with normal or near-normal motor conduction velocities. Symptoms result from an immune-mediated process that targets the dorsal root ganglia, causing neuronal loss and secondary degeneration of the posterior columns of the spinal cord. The dorsal and, less frequently, the anterior nerve roots and peripheral nerves may also be involved. This disorder often precedes or is associated with encephalomyelitis and autonomic dysfunction and has the same immunologic and oncologic associations (Hu antibodies, SCLC).

As with anti-Hu-associated encephalomyelitis, the therapeutic approach focuses on prompt treatment of the tumor and cytotoxic T-cell–mediated mechanisms. Glucocorticoids occasionally produce clinical stabilization or improvement. The benefit of IVIg and plasma exchange is not proven.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES

These disorders may develop any time during the course of the neoplastic disease. Neuropathies occurring at late stages of cancer or lymphoma usually cause mild to moderate sensorimotor deficits due

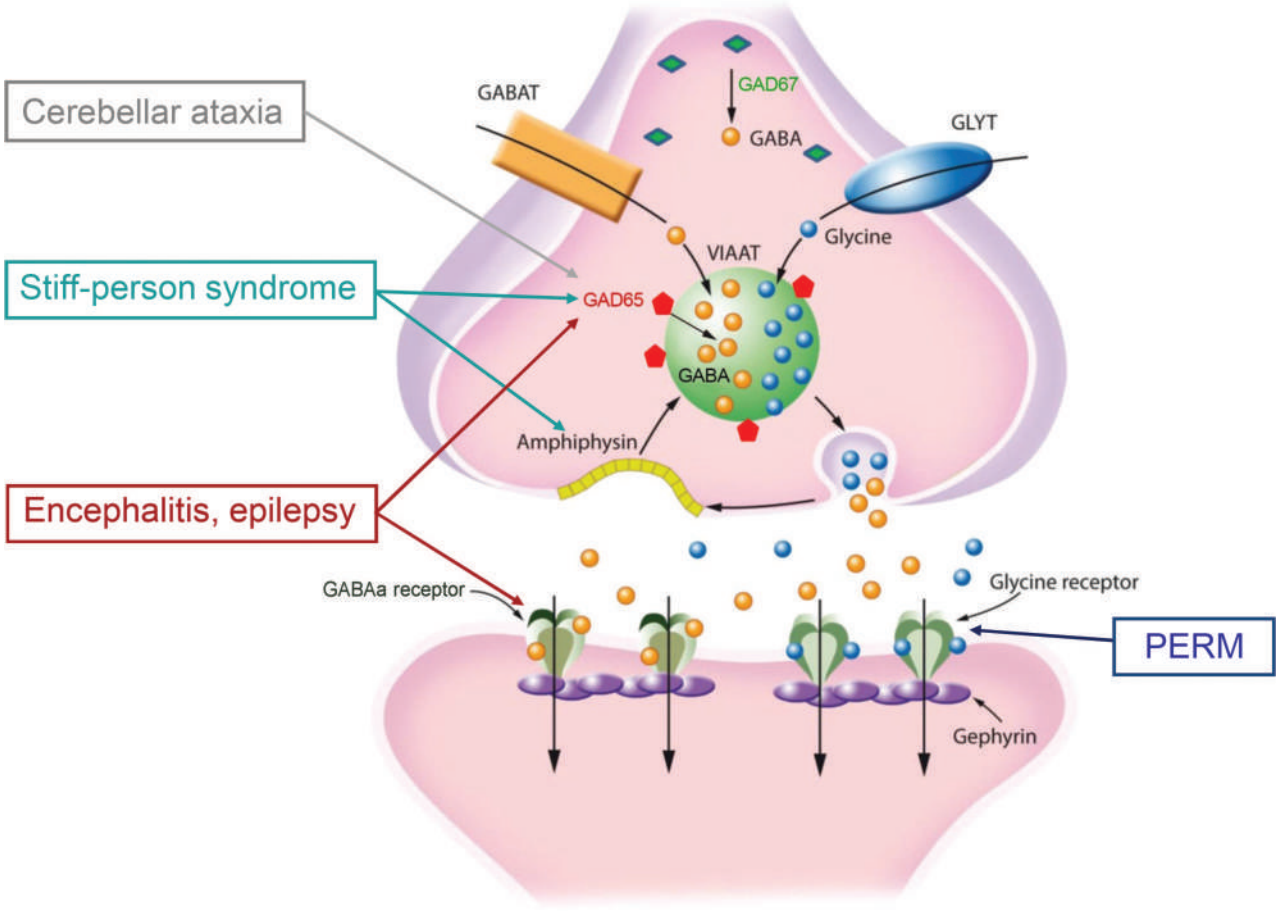

FIGURE 99-5 Schematic representation of an inhibitory synapse showing the main autoimmune targets (GAD, amphiphysin, GABA receptor, and glycine receptor) and the corresponding neurologic disorders. GAD antibodies predominantly occur in stiff-person syndrome (SPS), cerebellar ataxia, and epilepsy, sometimes in the setting of encephalitis. Amphiphysin antibodies are markers of paraneoplastic SPS and breast cancer, GlyR antibodies often associate with progressive encephalomyelitis with rigidity and myoclonus (PERM), and $GABA_A$ receptor antibodies occur in a form of autoimmune encephalitis that is frequently associated with refractory seizures and status epilepticus. *(Modified from F Graus et al: Nat Rev Neurol 16:353, 2020.)*

to axonal degeneration of unclear etiology. These neuropathies are often masked by concurrent neurotoxicity from chemotherapy and other cancer therapies. In contrast, the neuropathies that develop in the early stages of cancer frequently show a rapid progression, sometimes with a relapsing and remitting course, and evidence of inflammatory infiltrates and axonal loss or demyelination. Besides the subacute onset, an asymmetric distribution of symptoms, presence of neuropathic pain and dysautonomia, clinical or neuroimaging evidence of involvement of the spinal cord or nerve roots, and detection of an axonal pattern in the electrophysiological studies are features that suggest the possibility of a paraneoplastic etiology. The response to treatment is usually poor, but if demyelinating features predominate **(Chaps. 457 and 458)**, IVIg, plasma exchange, or glucocorticoids may improve symptoms. Occasionally, CRMP5 antibodies are present; detection of Hu antibodies suggests concurrent dorsal root ganglionitis.

Guillain-Barré syndrome **(Chap. 458)** and *brachial plexitis* **(Chap. 457)** have occasionally been reported in patients with Hodgkin's lymphoma, but there is no clear evidence of a paraneoplastic association.

Diseases associated with paraproteinemia such as multiple myeloma, osteosclerotic myeloma, cryoglobulinemia, amyloidosis, Waldenström's macroglobulinemia, or POEMS (polyneuropathy, organomegaly, endocrinopathy, M-protein spike, and skin manifestations) syndrome, among others, may cause neuropathy by a variety of mechanisms, including compression of roots and plexuses by metastasis to vertebral bodies and pelvis, by deposits of amyloid in peripheral nerves, or through a direct interaction of the abnormal immunoglobulin with peripheral nerve antigens. In other patients, the mechanisms underlying the neuropathy remain unknown and paraneoplastic immune-mediated mechanisms have not been ruled out. Neuropathies more often occur with IgM paraproteinemia followed by IgG and IgA. The phenotype of the neuropathy and likelihood of improvement with successful treatment of the paraproteinemia are dependent on the underlying hematologic disorder **(Chap. 458)**.

Vasculitis of the nerve and muscle causes a painful symmetric or asymmetric distal axonal sensorimotor neuropathy with variable proximal weakness. It predominantly affects elderly men and is associated with an elevated erythrocyte sedimentation rate and increased CSF protein concentration. SCLC and lymphoma are the primary tumors involved. Glucocorticoids and cyclophosphamide often result in neurologic improvement.

Peripheral nerve hyperexcitability (*neuromyotonia,* or *Isaacs' syndrome*) is characterized by spontaneous and continuous muscle fiber activity of peripheral nerve origin. Clinical features include cramps, muscle twitching (fasciculations or myokymia), stiffness, delayed muscle relaxation (pseudomyotonia), and spontaneous or evoked carpal or pedal spasms. The involved muscles may be hypertrophic, and some patients develop paresthesias and hyperhidrosis. The electromyogram (EMG) shows fibrillations; fasciculations; and doublet, triplet, or multiplet single-unit (myokymic) discharges that have a high intraburst frequency. Some patients have Caspr2 antibodies usually in the context of Morvan syndrome, but most patients with isolated neuromyotonia are antibody negative. The disorder often occurs without cancer; if paraneoplastic, benign and malignant thymomas and SCLC are the usual tumors. Phenytoin, carbamazepine, and plasma exchange improve symptoms.

Paraneoplastic autonomic neuropathy usually develops as a component of other disorders, such as LEMS and encephalomyelitis. It may rarely occur as a pure or predominantly autonomic neuropathy with cholinergic or adrenergic dysfunction at the pre- or postganglionic levels. Patients can develop several life-threatening complications, such as gastrointestinal paresis with pseudo-obstruction, cardiac dysrhythmias, and postural hypotension. Other clinical features include abnormal pupillary responses, dry mouth, anhidrosis, erectile dysfunction, and problems with sphincter control. The disorder occurs in association with several tumors, including SCLC, cancer of the pancreas or testis, carcinoid tumors, and lymphoma. Because autonomic symptoms can be the presenting feature of encephalomyelitis, serum Hu and CRMP5 antibodies should be sought. Antibodies to ganglionic (α3-type) neuronal acetylcholine receptors are the cause of autoimmune autonomic ganglionopathy, a disorder that frequently occurs without cancer association **(Chap. 451)**.

LAMBERT-EATON MYASTHENIC SYNDROME

LEMS is discussed in **Chap. 459**.

MYASTHENIA GRAVIS

Myasthenia gravis is discussed in **Chap. 459**.

POLYMYOSITIS-DERMATOMYOSITIS

Polymyositis and dermatomyositis are discussed in detail in **Chap. 377**.

IMMUNE-MEDIATED NECROTIZING MYOPATHY

Patients with this syndrome develop myalgias and rapid progression of weakness involving the extremities, neck, pharyngeal, respiratory, and sometimes cardiac muscles. Serum muscle enzymes are elevated, and muscle biopsy shows extensive necrosis with minimal or absent inflammation and sometimes deposits of complement. The disorder may occur without cancer association (sometimes as a result of statin exposure, connective tissue disease, or HIV) or with cancer association. Patients with antibodies against 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) and seronegative patients are more likely to have an underlying cancer than those with antibodies against signal recognition particle. No specific type of cancer has been found to be predominant. Successful treatment of the tumor and aggressive immunotherapy (steroids, IVIg, and steroid-sparing immunosuppressants) may lead to complete or substantial recovery. Immune-mediated necrotizing myopathy is discussed in **Chap. 377**.

PARANEOPLASTIC VISUAL SYNDROMES

This group of disorders involves the retina and, less frequently, the uvea and optic nerves. The term *cancer-associated retinopathy* is used to describe paraneoplastic cone and rod dysfunction characterized by photosensitivity, progressive loss of vision and color perception, central or ring scotomas, night blindness, and attenuation of photopic and scotopic responses in the electroretinogram (ERG). The most commonly associated tumor is SCLC. Melanoma-associated retinopathy affects patients with metastatic cutaneous melanoma. Patients develop acute onset of night blindness and shimmering, flickering, or pulsating photopsias that often progress to visual loss. The ERG shows reduced b-waves with normal dark adapted a-waves. Paraneoplastic optic neuritis and uveitis can develop in association with encephalomyelitis. Patients with paraneoplastic uveitis and optic neuritis may harbor CRMP5 antibodies.

Some paraneoplastic retinopathies are associated with serum antibodies that specifically react with the subset of retinal cells undergoing degeneration, supporting an immune-mediated pathogenesis. The best-characterized retinal antibodies are against recoverin and have been described in patients with SCLC and cancer-associated retinopathy. However, the specificity of this and other retinal antibodies is low as they have also been reported in nonparaneoplastic autoimmune and nonautoimmune retinopathies. Paraneoplastic retinopathies rarely show substantial improvement after treatment of the tumor and immunotherapy; however, stabilization of symptoms and partial responses to a variety of immunotherapies (glucocorticoids, plasma exchange, IVIg, rituximab, or alemtuzumab) have been reported.

100 Cancer Survivorship and the Long-Term Impact of Cancer and Its Treatment

Mark Roschewski, Dan L. Longo

A cancer diagnosis affects patients well beyond the initial treatment period with health implications that last throughout life. Long-term effects are toxicities that emerge during therapy and may persist after treatment is complete, while late effects are sequelae that may not emerge for months or years after treatment. Both long-term and late effects impact the health-related quality of life of cancer survivors and can affect the safe delivery of future therapy in the event of relapse. The risk of long-term effects varies across patients and depends on both patient-related and treatment-related factors. Older patients are more susceptible to acute treatment-related toxicities that emerge during therapy but can result in permanent disability. Adult survivors of childhood, adolescent, and young adult cancer face perpetual health consequences of cancer treatment related to premature physiologic aging and frailty and remain vulnerable to late effects, including premature death, for decades. (**Table 100-1** lists potential long-term and late effects of cancer therapy by organ system). The emergence of novel targeted therapies and immunotherapy with unique mechanisms of action has introduced new considerations regarding the long-term impact of cancer therapy. Long-term risks are not immediately evident, and lifelong pharmacovigilance remains a critical cornerstone of caring for the cancer patient.

Cancer therapy has substantially improved, and the price of that success is that a greater number of cancer survivors are now at risk for the long-term impact of treatment. It is estimated that the United States currently has >18 million cancer survivors, representing approximately 5% of the total population. The prevalence is sharply increasing and is projected to reach 22 million by 2032 and 26 million by 2040. Almost 70% of patients have lived for at least 5 years since their diagnosis, and nearly half of survivors have lived longer than 10 years. Despite the magnitude of the growing problem, the core issues related to cancer survivorship remain understudied and continue to evolve with emerging therapies. Most studies are descriptive with fewer studies focused on the prevention and treatment of complications. Cancer survivorship remains an area that is ripe for further discovery, including improved risk-assessment tools, a deeper understanding of the pathophysiology and influence of genetics on host susceptibility, emerging biomarkers, and evidence-based clinical practice management guidelines.

TABLE 100-1 Toxicities by Organ System

ORGAN SYSTEM	LONG-TERM EFFECTS	LATE EFFECTS
Cardiovascular	Congestive heart failure Arrhythmias Myocarditis Pericardial disease Hypertension	Coronary artery disease Peripheral vascular disease Cardiac valvular disease
Pulmonary	Interstitial pneumonitis	Pulmonary fibrosis Radiation recall pneumonitis
Immunologic	Recurrent infections Autoimmune disease	Second malignancies Myelodysplasia Opportunistic infections
Endocrine	Gonadal dysfunction Premature ovarian failure Hypothyroidism Diabetes insipidus Hypopituitarism	Infertility Fractures Diabetes mellitus Osteoporosis
Neurologic	Peripheral neuropathy Autonomic dysfunction Hearing loss	Cognitive impairment
Gastrointestinal	Chronic diarrhea Malabsorption	Small-bowel obstruction Intestinal stricture
Genitourinary	Chronic renal failure Bladder dysfunction	Ureteral stricture Hemorrhagic cystitis Hydronephrosis Nephrotic syndrome
Psychological	Anxiety Depression Substance abuse disorders Cancer-related fatigue	Fear of cancer recurrence Posttraumatic stress disorder Sexual dysfunction Psychosocial dysfunction Financial hardship

Our primary understanding of the long-term impact of cancer treatment originated from survivors of childhood malignancies who are often cured after treatment with a combination of chemotherapy, radiation, and surgery. Modern 5-year survival rates for children and adolescents are >80%, with a goal of maintaining high cure rates while minimizing late effects. The cause-specific mortality following initial treatment of Hodgkin's lymphoma includes nearly 40% of deaths attributed to nonlymphoma causes. Indeed, more patients diagnosed with Hodgkin's lymphoma die from treatment-related late toxicity than from Hodgkin's lymphoma. More recently, improvements in the tolerability of cancer therapy and in supportive care have allowed a greater number of patients with comorbid conditions and advanced age to receive treatment, which has increased the rate of treatment-related morbidity. Approximately 67% of current cancer survivors are older than age 65, which carries a higher risk of treatment-related deaths from heart or lung complications, immunologic dysfunction, or adverse effects of drugs. Treatment paradigms for cancer continuously evolve, however, and newer treatments including targeted agents and immunotherapy have introduced unique long-term effects, particularly when these agents are administered indefinitely (**Table 100-2** lists the potential long-term effects of specific cancer treatments). The complexities of cancer survivorship and the importance of longitudinal care of cancer patients are recognized as vital components to comprehensive cancer care. Still, the primary goal of cancer therapy remains long-term disease control, and the treating physician must maintain

TABLE 100-2 Toxicities by Type of Therapy

THERAPY TYPE	LONG-TERM EFFECT
Radiation	Second malignancies, coronary artery disease, pericardial disease, cardiac valvular disease, peripheral vascular disease, hypopituitarism, infertility, hypothyroidism, reduced bone density, intestinal or ureteral strictures
Chemotherapy and Hormonal Agents	
Anthracyclines (doxorubicin, daunorubicin)	Congestive heart failure, acute leukemia, cognitive impairment
Alkylating agents (cyclophosphamide, ifosfamide, melphalan)	Myelodysplasia, acute leukemia, impaired T-cell function, infertility, congestive heart failure, pulmonary fibrosis
Antimetabolites (5-flurouracil, fludarabine, gemcitabine)	Coronary artery disease, myelodysplasia, interstitial pneumonitis, cognitive impairment
Glycopeptide antibiotics (bleomycin)	Pulmonary fibrosis
Platinum agents (cisplatin, carboplatin, oxaliplatin)	Peripheral neuropathy, hearing loss, renal tubular dysfunction, interstitial pneumonitis, second malignancies
Vinca alkaloids (vincristine, vinblastine)	Peripheral neuropathy
Taxanes (paclitaxel, docetaxel)	Peripheral neuropathy, interstitial pneumonitis, cognitive impairment
Aromatase inhibitors (anastrozole, letrozole, fulvestrant)	Vasomotor symptoms, fractures
Antiandrogens (apalutamide, bicalutamide, darolutamide, enzalutamide, flutamide, nilutamide)	Sexual dysfunction
Immunotherapy Agents	
Immune checkpoint inhibitors (nivolumab, pembrolizumab, cemiplimab, avelumab, durvalumab, atezolizumab, dostarlimab, ipilimumab)	Autoimmune conditions, myocarditis, pericarditis, peripheral neuropathy
Bispecific T-cell engagers (mosunetuzumab, glofitamab, epcoritamab)	Recurrent infections
CAR-T therapy	Acute leukemia, myelodysplasia, T-cell lymphoma, peripheral neuropathy, recurrent infections
Targeted Agents	
Antibody-drug conjugates (brentuximab, polatuzumab, gemtuzumab)	Interstitial pneumonitis, peripheral neuropathy, sinusoidal obstruction syndrome
Immunomodulatory agents (thalidomide, lenalidomide, pomalidomide)	Second malignancies, prolonged neutropenia, peripheral neuropathy
Proteasome inhibitors (bortezomib, carfilzomib, ixazomib)	Peripheral neuropathy, congestive heart failure
HER2 inhibitors (trastuzumab, neratinib, capivasertib)	Congestive heart failure, interstitial pneumonitis
BTK inhibitors (ibrutinib, acalabrutinib, zanubrutinib)	Opportunistic infections, atrial and ventricular arrhythmias, hypertension
ALK inhibitors (alectinib, brigatinib, ceritinib, lorlatinib, crizotinib)	Atrial and ventricular arrhythmias, interstitial pneumonitis
CDK inhibitors (palbociclib, ribociclib, abemaciclib)	Hepatitis, colitis
Bcr-Abl inhibitors (imatinib, dasatinib, nilotinib, bosutinib)	Coronary artery disease, pleural effusions, pulmonary hypertension, peripheral vascular disease, nephrotic syndrome
FLT3 inhibitors (quizartinib)	Hypertension
Anti-VEGF agents (bevacizumab, pazopanib, sunitinib, sorafenib, axitinib)	Hypertension, myocardial ischemia, QTc prolongation, pulmonary hypertension, thrombosis
MEK inhibitors (selumetinib, trametinib, cobimetinib)	Retinopathy, hypertension, congestive heart failure
BRAF inhibitors (dabrafenib)	Hyperglycemia, secondary skin cancers, hypertension, congestive heart failure

proper perspective when considering these relative risks. The fear of long-term complications should not prevent the application of effective cancer treatment, particularly when delivered with curative intent. In a sense, managing long-term effects is a privilege only afforded those fortunate enough to overcome the initial threat to life represented by the cancer diagnosis.

CARDIOVASCULAR DYSFUNCTION

The long-term risks of cardiovascular disease after anthracycline chemotherapy and radiation that involves the mediastinum are well characterized and include arrhythmias, myocarditis, hypertension, congestive heart failure (CHF), and pericardial disease along with late effects of premature coronary artery disease, peripheral vascular disease, and cardiac valvular complications. It is estimated that one in eight childhood cancer survivors will experience a life-threatening cardiovascular event within 30 years after initial exposure, and cardiovascular disease is the most common cause of noncancer death in this population. Newer targeted agents and immunotherapy have introduced additional cardiovascular risks. A new discipline of cardio-oncology has emerged to address the increased risk of cardiovascular complications of cancer treatment in a multidisciplinary fashion and to better characterize individuals at high risk for treatment-related cardiac toxicities, develop surveillance strategies, and improve the management of long-term effects.

Radiation therapy, particularly mediastinal radiation that encompasses the heart, causes interstitial myocardial fibrosis, pericarditis, valvular disease, and premature coronary artery disease. Repeated or high (>6000 cGy) radiation doses are associated with greater risk, as is concurrent cardiotoxic chemotherapy exposure. Symptoms of acute pericarditis peak about 9 months after treatment and include dyspnea, chest pain, and fever. Chronic constrictive pericarditis and cardiac valvular diseases including aortic insufficiency and mitral regurgitation may develop 5–10 years following radiation therapy. Radiation is associated with premature coronary artery disease and peripheral vascular disease and a markedly increased risk of late effects such as myocardial infarction and thromboembolic stroke. Three-dimensional conformal techniques and newer particles including proton beams may more precisely spare normal tissue, but these are not widely available and the degree to which they will decrease long-term cardiovascular effects is unknown.

The myocardial toxicity of anthracyclines is dose-dependent and is associated with the pathognomonic finding of myofibrillar dropout on endomyocardial biopsy. Anthracycline cardiotoxicity occurs through a root mechanism of chemical free radical damage. Fe^{3+}-doxorubicin

complexes damage DNA, nuclear and cytoplasmic membranes, and mitochondria. Approximately 5% of patients receiving >450–550 mg/m^2 total dose of doxorubicin will develop CHF, but it can also develop at substantially lower doses in some patients. Regimens that use continuous infusion of doxorubicin or liposomally encapsulated doxorubicin are associated with less cardiotoxicity. Genome-wide association studies have identified multiple genetic polymorphisms associated with a higher risk of cardiotoxicity, but the ability to risk-stratify is limited. Additional risk factors include age >60 years, smoking, hypertension, diabetes, chronic renal failure, and previous cardiovascular disease. Anthracycline-related CHF is often irreversible and carries a high rate of morbidity and mortality, making prevention crucial. Baseline screening with straining imaging echocardiography in patients who are at high risk of cardiac complications is recommended. A patient who develops symptoms suggestive of CHF should have therapy held and undergo additional testing. High-sensitivity troponins are emerging biomarkers that may predict cardiotoxicity, but further validation is needed. Prophylactic use of cardioprotective medications such as beta blockers, angiotensin-converting enzyme inhibitors, or statins is not yet routine.

Inhibitors of the human epidermal growth factor receptor 2 (HER2) (e.g., trastuzumab, lapatinib, neratinib, capivasertib) are also associated with CHF. These targeted agents are used in combination with chemotherapy as both adjuvant therapy and as treatment of metastatic breast cancer. In contrast to anthracyclines, cardiotoxicity is not dose related, is usually reversible, is not associated with pathologic changes on cardiac myofibrils, and has a different biochemical mechanism inhibiting intrinsic cardiac repair mechanisms. Monitoring for cardiac toxicity is typically performed every three or four doses using echocardiograms, and treatment is interrupted when ejection fractions significantly decline from baseline. Other potentially cardiotoxic chemotherapy agents include alkylating agents (cyclophosphamide, ifosfamide) at high doses and 5-flurouracil.

Tyrosine kinase inhibitors (TKIs) are novel classes of molecularly targeted anticancer agents that have become routinely applicable across a variety of malignancies. Although the overall tolerability of these drugs is often better than chemotherapy, they are frequently administered indefinitely and to older patients, which introduces new notions of cumulative long-term effects. These agents also carry risks of cardiovascular toxicities including CHF, atrial and ventricular arrhythmias, prolongation of the QT interval, and pulmonary and systemic hypertension. Other small-molecule inhibitors that have been associated with CHF include Bcr-Abl inhibitors (bosutinib, dasatinib, ponatinib, nilotinib), anti–vascular endothelial growth factor (VEGF) agents (pazopanib, sunitinib, sorafenib, axitinib, lenvatinib, nintedanib), MEK inhibitors (trametinib), and proteasome inhibitors (carfilzomib). Systemic hypertension is commonly associated with anti-VEGF agents, ponatinib, and trametinib, whereas dasatinib has a well-documented association with pulmonary hypertension. Bruton tyrosine kinase (BTK) inhibitors, including ibrutinib, acalabrutinib, and zanubrutinib, have all been associated with atrial fibrillation as well as ventricular arrythmias. As more of these small-molecule inhibitors become widely used, additional monitoring for long-term and late effects should be incorporated into the routine surveillance of oncologists, cardiologists, cardio-oncologists, and primary care providers.

Immunotherapy agents have emerged as anticancer therapies used in a variety of cancers. Immune checkpoint inhibitors (ICI) have been associated with a number of important cardiovascular toxicities including pericardial disease, vasculitis, and fulminant myocarditis. The mechanism of these toxicities is T cell mediated, and the toxicities often respond to rapid initiation of high-dose glucocorticoids, but they can be severe or fatal if not recognized promptly. Patients with definite myocarditis on endomyocardial biopsy may have normal findings on cardiac magnetic resonance imaging (MRI) and only a rise in troponin levels, highlighting the need for a high index of suspicion for this potential complication. Patients who develop ICI-mediated myocarditis should have the drug halted immediately, and it should not be restarted after recovery. Combinations of multiple ICIs increase the risk of these immune-related toxicities, and no clear pattern of which patients are most susceptible has emerged.

Chimeric antigen receptor T-cell (CAR-T) therapies are associated with cytokine release syndromes (CRS), which can be severe and associated with arrhythmias or CHF. Multiple cytokines including interleukin (IL) 1, IL-2, tumor necrosis factor (TNF) α, and IL-6 activate prostaglandins, and levels of IL-6 are associated with more severe CRS, possibly due to the recruitment of additional T cells. Inhibitors of IL-6 such as tocilizumab are commonly used to treat CRS and prevent complications.

PULMONARY DYSFUNCTION

Radiation-induced lung injury presents in early phases as acute pneumonitis at 4 weeks following treatment, but it can evolve into pulmonary fibrosis. Risk factors include advanced age, smoking, poor performance status, preexisting compromised pulmonary function, and radiation volume and dose. It occurs most commonly in patients with lung cancer, mediastinal lymphoma, and breast cancer, and the incidence is decreasing due to advances in radiation delivery techniques. Fever, cough, pleuritic chest pain, and dyspnea on exertion are characteristic symptoms, and the severity may be out of proportion to the lung volume irradiated. Fine, high-pitched "Velcro rales" may be an accompanying physical finding. The diffusion capacity of the lungs for carbon dioxide (D_{LCO}) is the most sensitive measure of pulmonary functional impairment, and ground-glass infiltrates often correspond with relatively sharp edges to the irradiated volume, although the pneumonitis may progress beyond the field. The mechanism of lung injury is a direct effect of radiation that leads to increased capillary permeability and pulmonary edema. Damage to type I and II pneumocytes leads to surfactant loss and the transudation of serum proteins into the alveoli. Cytokines including TNF-α are released from the damaged lung cells and attract inflammatory cells to the alveoli and interstitial space. The late phases of injury are caused by reactive oxygen species that stimulate collagen production and may lead to fibrosis. Transforming growth factor β (TGF-β) is particularly important in stimulating collagen synthesis and may represent a therapeutic target.

Up to 10% of patients will develop chemotherapy-induced pulmonary toxicity that can manifest as both long-term and delayed effects in cancer survivors. Bleomycin generates activated free radical oxygen species and causes pneumonitis associated with a radiographic or interstitial ground-glass appearance diffusely throughout both lungs, often worse in the lower lobes. A nonproductive cough may be an early sign. This toxicity is dose-related and dose-limiting. The D_{LCO} is a sensitive measure of toxicity and recovery, and a baseline value is generally obtained before administering bleomycin therapy. Doses are stopped if the baseline D_{LCO} falls 25% or more. Additive or synergistic risk factors include age, prior lung disease, and concomitant use of other chemotherapy, lung irradiation, and high concentrations of inspired oxygen. Other commonly used chemotherapeutic agents notable for pulmonary toxicity include gemcitabine, irinotecan, methotrexate, fludarabine, and the antibody-drug conjugates brentuximab and fam-trastuzumab deruxtecan, which can cause interstitial lung disease. Most of these toxicities are idiosyncratic and not dose-related. The pathogenesis for pulmonary toxicity is related to direct injury to pneumocytes, oxidative stress, and the release of cytokines that recruit additional inflammatory cells. High-dose alkylating agents, cyclophosphamide, ifosfamide, and melphalan are frequently used in the hematopoietic stem cell transplant setting, which may result in severe pulmonary fibrosis and/or pulmonary venoocclusive disease.

Radiation-induced lung injury and chemotherapy-induced pneumonitis are generally glucocorticoid responsive. Prednisone 1 mg/kg is often used to control acute symptoms and prevent pulmonary dysfunction with a slow taper over months. Antibiotics, bronchodilators, oxygen, and diuretics may all play an important role in management of pneumonitis, and consultation with a pulmonologist should be undertaken. Relapses can occur after an initial response to glucocorticoids, and refractory cases may respond to alternative immunosuppressive agents such as azathioprine or cyclosporine. No effective therapy exists

for pulmonary fibrosis, and the treatment is primarily supportive with supplemental oxygen.

Pulmonary toxicity resulting from targeted anticancer agents including small-molecule inhibitors and immunotherapy agents can be potentially life-threatening and often leads to drug discontinuation. Noninfectious pneumonitis is associated with cough, dyspnea, and infiltrates on chest imaging and has been reported to be associated with anti-VEGF agents (sunitinib, sorafenib), epidermal growth factor receptor (EGFR) inhibitors (cetuximab, afatinib), and the ALK inhibitor crizotinib. The antibody-drug conjugate brentuximab vedotin may also cause severe pulmonary toxicity. The onset of drug-induced pneumonitis can be rapid, and prompt use of glucocorticoids is important once infectious causes are excluded. Severe pneumonitis is a reason to discontinue the offending drug permanently.

IMMUNE SYSTEM DYSFUNCTION

A significant risk of most anticancer treatment is cumulative effects on the host immune system leading to a higher risk of second malignancies and impaired long-term immune health. Second malignancies in cancer survivors are a major cause of death, and up to 20% of all cancer diagnoses now occur in cancer survivors. The risk of second malignancies is related to genetic susceptibility, environmental exposures, and specific cancer treatments. Often, the risk factors that led to the primary cancer remain, and a risk of a second malignancy persists. Genetic cancer syndromes (e.g., multiple endocrine neoplasia or Li-Fraumeni, Lynch's, Cowden's, and Gardner's syndromes) are examples of genetically based second malignancies of specific types, and specific cancer treatments do not increase the risk of secondary malignancies. Genetic disorders that result in DNA repair deficiencies including ataxia-telangiectasia, Bloom's syndrome, and Fanconi's anemia greatly increase the lifetime risk of cancers as well as the risks associated with DNA-damaging agents. Importantly, the risk of treatment-related second malignancies is greatly increased when radiation is combined with chemotherapy, and for such combined-therapy treatment approaches, it is important to establish the necessity of each component in the treatment program.

Patients receiving radiation have a lifelong risk of second malignancies that is 1–2% in the second decade following treatment but increases to >25% after 25 years and does not appear to plateau. The risk of second malignancies from radiation is dose-dependent and often occurs within the treatment field. Common radiation-related solid tumors include central nervous system (CNS), breast, bladder, colon, stomach, liver, lung, and thyroid cancers and sarcomas, which are often aggressive and have a poor prognosis. The age of the patient when they receive radiation affects their risk, and younger patients are more vulnerable to second malignancies. An example of an organ-, age-, and sex-dependent radiation-induced secondary malignancy is breast cancer, in which the risk is small with radiation in women aged older than 30 years but increases about 20-fold over baseline in women aged younger than 30 years. Females with Hodgkin's lymphoma who receive radiation have a cumulative risk of 25% for developing breast cancer at 30 years after treatment.

Chemotherapy is significantly associated with two second malignancies: acute leukemia and myelodysplastic syndromes. Two types of secondary leukemia have been described; in patients treated with alkylating agents, acute myeloid leukemia is associated with deletions in chromosome 5 or 7 and complex karyotypes and often is preceded by myelodysplasia. The lifetime risk is about 1–5%, is increased by radiation therapy, and increases with age. The incidence of these leukemias peaks at 5–8 years after therapy, with risk returning close to baseline at 10 years. The other type of acute myeloid leukemia is related to therapy with topoisomerase inhibitors, is associated with chromosome 11q23 translocations, has an incidence of <1%, generally occurs 2–3 years after treatment, and is rarely preceded by myelodysplasia. Both of these acute myeloid leukemias have a high mortality. A fraction of the population has underlying clonal hematopoiesis not related to prior cancer treatment, and the percentage increases with age. In such patients, the hematopoietic stem cells carry mutations that are associated with myeloid malignancy despite normal blood counts. The presence of these genetic lesions may predispose patients to develop myeloid malignancies, but currently, these are not assessed prior to starting therapy.

Other cytotoxic agents are associated with long-term alterations in immunity beyond the initial treatment period. Bendamustine has significant effects on both B-cell and T-cell subpopulations that can persist for years, and long-term studies of lymphoma patients treated with bendamustine-based regimens show higher rates of death from second malignancies compared to other chemotherapy regimens. Purine analogues like fludarabine also produce long-term T-cell suppression. The risk of solid tumors is also increased after chemotherapy, and alkylating agents such as cyclophosphamide increase the risk of sarcoma, gastrointestinal cancers, and breast cancer in a dose-dependent manner. Other chemotherapy agents, including platinum agents, which are commonly used to treat germ cell tumors, have been associated with second malignancies. Treatment of multiple myeloma with the immunomodulatory agent lenalidomide is associated with a significantly increased risk of second hematologic malignancies including lymphomas and leukemias.

Given the indefinite risk of second malignancies in cancer survivors, patients need lifelong surveillance. Guidelines for breast cancer surveillance in survivors exposed to chest radiation recommend that patients be screened with mammograms and/or breast MRI beginning at age 25 years or 8 years after treatment. Any organ in the treatment field is susceptible to developing a cancer (e.g., radiation to the chest may increase the risk of gastric or esophageal cancer). Patients exposed to abdominal or pelvic radiation should have annual colonoscopies starting at age 35 years or 10 years after exposure. For patients treated with neck radiation, fine-needle aspiration should be performed on any palpable thyroid nodules, and thyroid-stimulating hormone (TSH) levels should be monitored periodically.

Combination chemotherapy is also associated with impaired immune health and increases the long-term risk of recurrent sinopulmonary infections, autoimmune complications, and late-onset opportunistic infections. Survivors of lymphoma have elevated risks of developing autoimmune hemolytic anemia, viral or fungal pneumonias, meningitis, or other infections, and these risks remain decades after treatment. Agents or treatment regimens that result in significant T-cell depletion increase the risk of Epstein-Barr virus–associated B-cell lymphoproliferative disorders. Discontinuing immunosuppressive therapy, if possible, is often associated with complete disease regression. Anti-CD20 monoclonal antibodies, CAR-T therapy, bispecific T-cell engagers (monoclonal antibodies targeting both B cells and T cells), and ICIs have all been associated with long-term B-cell aplasia that often requires intravenous immunoglobulin replacement and persistent vigilance for recurrent sinopulmonary infections. The genetically modified CAR-T cells may also carry a small risk of insertional mutagenesis as T-cell lymphomas have been rarely reported. Rituximab and immunomodulatory agents have both been associated with late-onset neutropenia that can occur months after exposure to the drug and often requires growth factor support. Given these risks of impaired immune system function, all cancer survivors should undergo annual influenza and other seasonal vaccinations and should be considered for pneumococcal vaccination depending on age and immune health status.

REPRODUCTIVE AND ENDOCRINE DYSFUNCTION

Endocrine complications are prevalent in childhood cancer survivors. Nearly half of all survivors will have at least one hormonal disorder in their lifetime, and these most commonly present as late effects. Radiation to the head, neck, or pelvis is associated with the greatest risk of endocrine dysfunction. Testicles and ovaries in prepubertal patients are sensitive to radiation damage in a dose-related fashion; spermatogenesis is affected by low doses of radiation, and complete azoospermia occurs at 600–700 cGy. Leydig cell dysfunction, in contrast, occurs at <2000 cGy, and hence, endocrine function is lost at much higher

radiation doses than spermatogenesis. Erectile dysfunction occurs in up to 80% of men treated with external-beam radiation therapy for prostate cancer. Ovarian function damage with radiation is age-related and occurs at doses of 150–500 cGy. Hormone replacement therapy is often contraindicated (as in estrogen receptor–positive breast cancer). Attention must be paid to maintenance of bone mass with calcium and vitamin D supplements and oral bisphosphonates, and bone mass should be monitored using bone density determinations. Long-term survivors of childhood cancer who have received cranial radiation may have altered leptin biology and growth hormone deficiency, leading to obesity and reduced strength, exercise tolerance, and bone density. Radiation therapy to the neck may lead to hypothyroidism, Graves' disease, and thyroiditis. Cranial radiation may also be associated with an array of endocrine abnormalities with disruption of normal pituitary-hypothalamic axis function, and a high index of suspicion needs to be maintained to identify and treat this toxicity. Patients who have received abdominal radiation should receive annual screens for obesity and diabetes mellitus with height and weight measurements along with a hemoglobin A_{1C} at least every 2 years.

Alkylating agents are associated with the highest rates of male and female infertility, which is directly dependent on dose and duration of treatment. The age at treatment is an important determinant of fertility outcome, with prepubertal patients having the highest tolerance. Chemotherapy reduces the number of primordial follicles in women, and the risk of infertility is age related. Females who resume menses after treatment are still at increased risk for premature ovarian failure. Males generally have reversible reductions in sperm counts and motility during alkylator chemotherapy, and long-term infertility is associated with doses of cyclophosphamide >9 g/m^2 and with high-intensity therapy, such as that used in hematopoietic stem cell transplantation. All patients should be counseled on the potential impact on fertility, and sperm, oocyte, and embryo cryopreservation are now routinely performed prior to therapy in patients of child-bearing age. Some evidence suggests that gonadotropin-releasing hormone agonists given concurrently with chemotherapy may improve the resumption of menses, but long-term data on fertility preservation are lacking and this should not replace oocyte harvesting. In vitro fertilization can be helpful to couples with chemotherapy-induced infertility.

Combination chemotherapy and aromatase inhibitors can impair bone health, and older patients may be more susceptible to these effects. Due to the combined risk of age-related osteoporosis and the effect of therapy, the risk of fractures in patients over the age of 70 years may be as high as 5–10% within a few years of finishing therapy. The risk of low bone mineral density is highest in certain high-risk groups including childhood cancer survivors, breast cancer patients, and those who have undergone hematopoietic stem cell transplant.

ICIs that target CTLA-4 and PD-1 have led to serious chronic toxicities including the breaking of self-tolerance and the autoimmune destruction of certain endocrine organs, particularly the thyroid and adenohypophysis (anterior pituitary). Hypophysitis is more commonly reported in association with CTLA-4 inhibitors, whereas thyroid dysfunction is more common with PD-1 inhibitors. Most immune-related toxicities occur within 8–12 weeks of starting treatment, but they can occur at any time during treatment or even after therapy has stopped. Patients with autoimmune thyroiditis or hypophysitis require lifelong hormone replacement, and early recognition is important.

TKIs have been associated with various endocrine-related toxicities, with hypothyroidism being the most common. Virtually all glands can be affected by TKIs, however, and adrenal insufficiency, growth retardation, increased bone turnover, and hypogonadism have all been reported. Growth deceleration is problematic in children, particularly when treatment is initiated before puberty. The mechanism is postulated to be related to disruptions in growth hormone signaling or inhibition of the insulin-like growth factor 1 (IGFR-1) receptor. Endocrine effects that have been reported to be associated with other small-molecule inhibitors include alterations in bone remodeling, reduced calcium and vitamin D levels, thyroid dysfunction, gonadal dysfunction, adrenal dysfunction, and altered glucose metabolism. Thyroid function tests should be monitored periodically while patients are on these targeted agents, and replacement hormones and/or vitamins should be prescribed as necessary. Careful consideration should be made to keep patients on therapy with limited dose reduction or interruption while managing the symptoms of glandular dysfunction.

NEUROLOGIC DYSFUNCTION

Delayed radiation CNS toxicity occurs weeks to months following therapy; is associated with nausea, drowsiness, hypersomnia, and ataxia; and is pathologically associated with reversible demyelination. Chronic, late radiation injury occurs 9 months to up to 10 years following therapy, and dysfunction increases over time. Diffuse radiation injury is associated with global CNS neurologic dysfunction and diffuse white matter changes on computed tomography (CT) or MRI. Pathologically, small vessel changes are prominent and focal necrosis is common. Prophylactic cranial irradiation in both childhood and adult leukemias/lymphomas has largely been abandoned due to the acute and long-term effects of therapy. Glucocorticoids may be symptomatically useful for acute toxicities but do not alter the course. Psychostimulants such as methylphenidate may improve attention and executive functioning in childhood survivors.

In children and adolescent cancers, younger age, higher cranial irradiation dose, larger brain volumes irradiated, and longer treatment times are associated with worse neurocognitive outcomes. In adult cancers, patients over the age of 60 who receive whole-brain radiation therapy are at high risk for neurocognitive impairment after therapy. Genetic polymorphisms may be associated with an increased risk of neurocognitive problems, and emerging evidence suggests polymorphisms in the folate pathway, oxidative stress genes, and enzymes that regulate both catecholamines and deamination of amines are associated with individual risk.

The most common chemotherapy-related neurologic toxicities that manifest in cancer survivors are peripheral neuropathy and cognitive impairment. Vinca alkaloids produce a characteristic "stocking-glove" neuropathy with pain, numbness, and tingling and increased sensitivity to temperature advancing to loss of motor function, which is highly dose related. Distal sensorimotor polyneuropathy prominently involves loss of deep tendon reflexes with initially loss of pain and temperature sensation, followed by proprioceptive and vibratory loss. The mechanism is axonal degeneration leading to myelin loss with some contribution of alterations in neurotransmitter signaling. Risk factors for peripheral neuropathy include preexisting neuropathies, diabetes mellitus, and older age. Genetic predictors and biomarkers to identify patients at the highest risk are the subject of ongoing research. The most effective management is prevention of acute toxicities resulting in permanent damage. This requires careful patient history and physical examination by experienced oncologists to decide when the drug must be stopped or reduced to prevent permanent damage, which can have a profound effect on the ability to deliver further therapy. Milder toxicity often slowly completely resolves after treatment discontinuation. Cisplatin is associated with sensorimotor neuropathy and hearing loss, especially at doses >400 mg/m^2, requiring audiometry in patients with preexisting hearing compromise. Carboplatin is often substituted in such cases given its lesser effect on hearing.

Chemotherapy-related cognitive impairment, or "chemo brain," occurs in nearly 35% of all cancer survivors and has a profound impact on functional ability and the health-related quality of life after therapy. It is clinically associated with impaired memory, learning, attention, executive functioning, and speed of information processing. The mechanisms are postulated to involve alterations in neurodegeneration, immune dysregulation, and cytokine production. No effective therapy has been identified, although regular exercise and cognitive rehabilitation are associated with improved symptoms. Most symptoms improve within a year of therapy, but symptoms can persist in 10–20% of patients for extended periods of time.

Antibody-drug conjugates (ADCs) are novel therapies in which a monoclonal antibody targeted to a tumor antigen is attached to a potent anticancer agent via a chemical linker. Often, these agents are associated with significant central and peripheral neurotoxicity, as has been described with agents such as brentuximab vedotin and pertuzumab.

These neuropathies often emerge during treatment similar to those seen with chemotherapy and are dose dependent. Early recognition of treatment-emergent neuropathy induced by ADCs mandates dose interruption or modification to less frequent dosing schedules in order for patients to remain on therapy. ICIs have been associated with autoimmune complications and unique neurologic manifestations such as optic neuritis that may be reversible after glucocorticoids.

Newer molecularly targeted agents and immunotherapy have also been associated with neurologic dysfunction and may exacerbate persistent neuropathy from prior therapy. Proteasome inhibitors are associated with neuropathic pain and motor neuropathy that can occur immediately or be delayed in onset. The proposed mechanism is through enhanced oxidative stress on neural cells. Subcutaneous administration of these agents is associated with less peripheral neuropathy than intravenous infusions. Immunotherapy agents such as CAR-T therapies and bispecific monoclonal antibodies targeting both T cells and B cells are associated with significant acute neurotoxicity known as immune effector cell–associated neurotoxicity syndrome (ICANS). Symptoms of ICANS include confusion, encephalopathy, seizures, and cerebellar symptoms. These symptoms are hypothesized to be related to the CRS associated with these therapies and often are time limited. However, a minority of patients treated with these agents will have persistent central and neurologic dysfunction for which management is mainly supportive. Management guidelines to prevent and treat ICANS have been developed and include rapid delivery of glucocorticoids during the acute onset of symptoms along with supportive care. Notably, treatment with IL-6 receptor antagonists such as tocilizumab, which are effective for decreasing the severity of CRS, is largely ineffective at preventing neurologic toxicities. Progressive multifocal leukoencephalopathy (PML) is a rare but serious brain infection that is caused by the JC virus and has been reported as a rare complication of treatment with rituximab, ibrutinib, and PI3K inhibitors. The inflammatory response to the virus presents as unifocal or multifocal hyperintense lesions involving the subcortical white matter that are best seen on T2/fluid-attenuated inversion recovery (FLAIR) images on MRI. Treatment is supportive and includes removal of the offending agent.

HEPATIC AND GASTROINTESTINAL DYSFUNCTION

Long-term hepatic damage from standard chemotherapy regimens is rare. High-dose chemotherapy alone or with radiation therapy in preparative regimens for bone marrow transplantation may result in venoocclusive disease of the liver. This potentially lethal complication classically presents with anicteric ascites, elevated alkaline phosphatase, and hepatosplenomegaly. Pathologically, there is venous congestion, epithelial cell proliferation, and hepatocyte atrophy progressing to frank fibrosis. Frequent monitoring of liver function tests during any chemotherapy is necessary to avoid both idiosyncratic and expected toxicities. Hepatic radiation damage depends on dose, volume, fractionation, preexisting liver disease, and synchronous or metachronous chemotherapy. In general, radiation doses to the liver >1500 cGy can produce hepatic dysfunction with a steep dose-injury curve. Radiation-induced liver disease closely mimics hepatic venoocclusive disease.

Novel targeted agents including immunotherapy agents have introduced a number of hepatic and gastrointestinal toxicities that occur during the course of treatment and persist as long-term toxicities including hepatitis, colitis, malabsorption, and chronic diarrhea. Early signs of serious liver injury should lead to discontinuation of the offending agent as dose reductions do not reliably reduce further liver injury. The mechanisms for colitis or hepatitis associated with these targeted agents are not completely understood but are hypothesized to be T cell mediated, and prompt initiation of glucocorticoids is often effective. Diarrhea with or without severe colitis can be associated with virtually all targeted agents through a variety of mechanisms including BCR-ABL inhibitors, BTK inhibitors, EGFR inhibitors, MEK inhibitors, CDK inhibitors, and immunomodulatory agents. Even if the diarrhea is not severe, the impact associated with indefinite treatment greatly interferes with the quality of life and often leads to discontinuation of targeted therapy. Immunomodulatory agents including lenalidomide are associated with late onset of diarrhea that is caused by bile acid malabsorption and often responds to bile acid sequestrants. ICIs are associated with colitis and hepatitis that may be responsive to prompt initiation of glucocorticoids that may require a long taper over many months.

RENAL AND BLADDER DYSFUNCTION

Cisplatin produces reversible decrements in renal function but may also produce severe irreversible toxicity in the presence of preexisting renal disease and may predispose to additional damage with subsequent therapy. Cyclophosphamide and ifosfamide are prodrugs primarily activated in the liver with cleavage products (acrolein) that can produce hemorrhagic cystitis. This can be prevented with the free radical scavenger MESNA (mercaptoethane sulfonate), which is required for ifosfamide administration. Hemorrhagic cystitis is most commonly an acute toxicity but may become a chronic and recurrent problem as long as 20 years after therapy.

A number of targeted agents, including anti-VEGF agents, FLT3 inhibitors, and BTK inhibitors, are associated with systemic hypertension, which can lead to late effects or a progressive decline in renal function. Pharmacovigilance studies have recently identified a link between the chronic use of BCR-ABL inhibitors and the late effects of chronic renal failure and the nephrotic syndrome. Renal dysfunction following ICIs is uncommon, but acute interstitial nephritis can occur. Similar to other immune-related toxicities, this acute toxicity requires prompt use of glucocorticoids to avoid long-term effects on renal function.

PSYCHOLOGICAL DYSFUNCTION AND SOCIOECONOMIC IMPACT OF SURVIVORSHIP

The diagnosis and treatment of cancer can introduce psychological effects that continue throughout life. Cancer survivors are at increased risk for anxiety, depression, attention problems, and posttraumatic stress syndromes. Many cancer patients experience intrusive or debilitating concerns about cancer recurrence following therapy. In addition, these patients may experience socioeconomic stressors that affect employment, insurance, and relationships and lead to financial and/or sexual difficulties. Survivors of childhood cancers are less likely to graduate from college or gain full-time employment than their peers and are more likely to engage in risky health behaviors such as substance abuse and excessive alcohol use. The long-term psychosocial effects of treatment are greatest in patients who undergo CNS-directed therapies and intensive combination chemotherapy regimens. One of the most challenging long-term effects of cancer therapy is cancer-related fatigue (CRF) that occurs in up to 60% of patients during treatment and may persist as physical, cognitive, or emotional exhaustion for years after therapy. The precise etiology of CRF is unclear, but it has a strong association with impaired sleep and lower physical activity. Patients with CRF have higher levels of proinflammatory cytokines such as IL-1, IL-6, and C-reactive protein, which may be therapeutic targets. Oncologists should ask about physical, emotional, and cognitive issues explicitly with patients and provide appropriate counseling or support systems. The overall risk of suicidal ideation and suicide is low but is greater in cancer patients and survivors than age-matched controls. Tailored cognitive-behavioral therapy may improve the anxiety and posttraumatic stress associated with cancer survivorship. Psychostimulants including methylphenidate and modafinil are modestly effective at treating the symptoms associated with CRF, but further studies are needed.

CANCER SURVIVORSHIP CARE PLANS

Survivorship starts at the time of diagnosis and continues indefinitely. Prevention of late effects may be improved with the implementation of risk-stratification tools prior to therapy. After therapy is initiated, focused surveillance plans for late effects are critical for early detection and implementation of interventions but also must include risk stratification to avoid unnecessary surveillance testing that leads to overdiagnosis and/or psychological distress. Survivorship care has

traditionally been performed by oncologists, but the magnitude of the problem mandates that primary care providers and preventive medicine specialists be trained in the follow-up of treated cancer patients in remission or undergoing chronic therapy. All former cancer patients should undergo surveillance for recurrence and second malignancies and be monitored for long-term effects of treatment; however, nearly all recurrences are detected because of symptoms. Health promotion and disease prevention with age- and sex-specific routine screening tests (e.g., colonoscopy, Pap smears, mammography, human papillomavirus vaccination, dual-energy x-ray absorptiometry scans) should be a focus of survivorship care along with psychosocial well-being. Annual mammography should start no later than 10 years after breast radiation. Patients receiving radiation fields encompassing thyroid tissue should have regular thyroid examinations and TSH testing. Localized pain or palpable abnormality in a previously radiated field should prompt radiographic evaluation. Patients treated with alkylating agents or topoisomerase inhibitors should have a complete blood count every 6–12 months, and cytopenias, abnormal cells on peripheral smear, or macrocytosis should be evaluated with bone marrow biopsy and aspirate and include cytogenetics, flow cytometry, or fluorescence in situ hybridization (FISH) studies as appropriate.

As the population of cancer survivors increases and patients live longer, cancer survivorship has become increasingly important, and the Institute of Medicine and National Research Council have published a monograph entitled *From Cancer Patient to Cancer Survivor: Lost in Transition.* The monograph proposes a plan that would inform clinicians caring for cancer survivors of the complete details of patients' previous treatments, complications thereof, signs and symptoms of late effects, and recommended screening and follow-up procedures.

OUTLOOK

Survivorship care is a burgeoning problem facing oncologists today. The challenge is to develop cancer treatments that maximize clinical benefit including cure of disease while also mitigating the risks of long-term toxicity. As cancer treatments continue to improve, the prevalence of cancer survivors increases along with an increase in life expectancy. Further, since emerging therapies often have improved tolerability profiles, a greater number of patients with advanced age or comorbid medical conditions will become cancer survivors with persistent treatment-related toxicities. As treatment paradigms continue to evolve, the nature and biologic basis for toxicities will change and pharmacovigilance of new therapies is critical. Advances in genomic medicine may allow for more risk-stratified personalized care. The choice of therapy needs to be tailored to the type of cancer, expected outcomes, and patient-related risk factors for both acute and long-term toxicities. After therapy is complete, longitudinal monitoring of the health and health-related quality of life of cancer survivors is critical since the incidence of late effects of treatment does not appear to plateau over time.

Section 2 Hematopoietic Disorders

101 Hematopoietic Stem Cells

David T. Scadden, Dan L. Longo

All of the cell types in the blood and some cells in every tissue of the body are derived from hematopoietic (*hemo*: blood; *poiesis*: creation) stem cells. If the hematopoietic stem cell is damaged and can no longer function (e.g., due to a nuclear accident), a person would survive 2–4 weeks in the absence of extraordinary support measures. With the clinical use of hematopoietic stem cells, tens of thousands of lives are saved each year **(Chap. 119)**. Stem cells produce hundreds of billions of blood cells daily from a stem cell pool that is estimated to be only 20,000–200,000. How stem cells do this, how they persist for many decades despite the production demands, and how they may be better used in clinical care are important issues in medicine.

The study of blood cell production has become a paradigm for how other tissues may be organized and regulated. Basic research in hematopoiesis includes defining stepwise molecular changes accompanying functional changes in maturing cells, aggregating cells into functional subgroups, and demonstrating hematopoietic stem cell regulation by a specialized microenvironment; these concepts are worked out in hematology and offer models for other tissues. Moreover, these concepts may not be restricted to normal tissue function but extend to malignancy.

CARDINAL FUNCTIONS OF HEMATOPOIETIC STEM CELLS

All stem cell types have two cardinal functions: self-renewal and differentiation **(Fig. 101-1)**. Stem cells exist to generate, maintain, and repair tissues. They function successfully if they can replace a wide variety of shorter-lived mature cells over prolonged periods. The process of self-renewal (see below) assures that a stem cell population can be sustained over time. Without self-renewal, the stem cell pool would become exhausted and tissue maintenance would not be possible. The process of differentiation leads to production of the effectors of tissue function: mature cells. Without proper differentiation, the integrity of tissue function would be compromised and organ failure or neoplasia would ensue.

In the blood, mature cells have variable average life spans, ranging from hours for mature neutrophils to a few months for red blood cells to many years for memory lymphocytes. However, the stem cell pool is the central, durable source of all blood and immune cells, maintaining a capacity to produce a broad range of cells from a single cell source, yet keeping itself vigorous over decades of life. As an individual stem cell divides, it has the capacity to accomplish one of three division outcomes: two stem cells, two cells destined for differentiation, or one stem cell and one differentiating cell. The former two outcomes are the

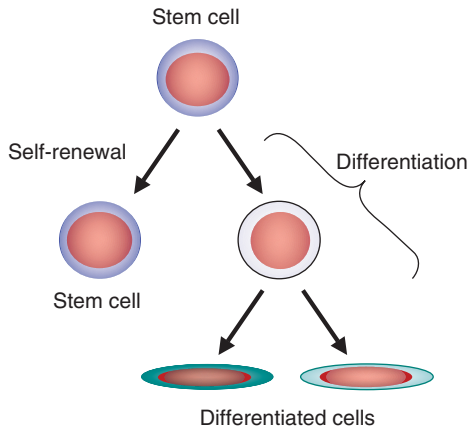

FIGURE 101-1 Signature characteristics of the stem cell. Stem cells have two essential features: the capacity to differentiate into a variety of mature cell types and the capacity for self-renewal. Intrinsic factors associated with self-renewal include expression of *Bmi-1, Gfi-1, PTEN, STAT5, Tel/Atv6, p21, p18, MCL-1, Mel-18, RAE28,* and *HoxB4.* Extrinsic signals for self-renewal include Notch, Wnt, SHH, angiogenin, and Tie2/Ang-1. Based mainly on murine studies, hematopoietic stem cells express the following cell surface molecules: CD34, Thy-1 (CD90), c-Kit receptor (CD117), CD133, CD164, and c-Mpl (CD110, also known as the thrombopoietin receptor).

result of symmetric cell division, whereas the latter indicates a different outcome for the two daughter cells—an event termed asymmetric cell division. The relative balance for these types of outcomes may change during development and under particular kinds of demands on the stem cell pool.

DEVELOPMENTAL BIOLOGY OF HEMATOPOIETIC STEM CELLS

During development, blood cells are produced at different sites. Initially, the yolk sac provides oxygen-carrying red blood cells and many of the macrophage-like cells that are resident in tissues: cells like microglia in the brain. The placenta and several sites of intraembryonic blood cell production then become involved in sequential order. These move from the genital ridge at a site where the aorta, gonadal tissue, and mesonephros are emerging to the fetal liver and then, in the second trimester, to the bone marrow and spleen. As the location of stem cells changes, the cells they produce also change. The yolk sac provides red cells expressing embryonic hemoglobins and tissue-resident macrophages. Intraembryonic sites of hematopoiesis generate stem cells, red cells, platelets, and the circulating cells of innate immunity. The production of the cells of adaptive immunity occurs then as well but becomes robust as the thymus forms and the bone marrow is colonized in the second trimester. Stem cell proliferation remains high, even in the bone marrow, until shortly after birth, when it appears to dramatically decline. The cells in the bone marrow are thought to arrive by the bloodborne transit of cells from the fetal liver after calcification of the long bones has begun. The presence of stem cells in the circulation is not unique to a time window in development, however, as hematopoietic stem cells circulate throughout life. The time that stem cells spend freely circulating appears to be brief (measured in minutes in the mouse), but the stem cells that do circulate are functional and can be used for transplantation. The number of stem cells that circulate can be increased in a number of ways to facilitate their harvest and transfer to the same or a different host.

MOBILITY OF HEMATOPOIETIC STEM CELLS

Cells entering and exiting the bone marrow do so through a series of molecular interactions. Circulating stem cells (through CD162 and CD44) engage the lectins (carbohydrate binding proteins) P- and E-selectin on the endothelial surface to slow the movement of the cells to a rolling phenotype. Stem cell integrins are then activated and accomplish firm adhesion between the stem cell and vessel wall, with a particularly important role for stem cell VCAM-1 engaging endothelial VLA-4. The chemokine CXCL12 (SDF1) interacting with stem cell CXCR4 receptors and ionic calcium interacting with the calcium-sensing receptor are important in the process of stem cells getting from the circulation to where they engraft in the bone marrow. This is particularly true in the developmental move from fetal liver to bone marrow.

In the adult, the role for CXCR4 is in retention of stem cells in the bone marrow as well as getting them there. Interrupting that retention process through specific molecular blockers of the CXCR4/CXCL12 interaction, cleavage of CXCL12, or downregulation of the CXCR4 receptor can result in the release of stem cells into the circulation. This process is an increasingly important aspect of recovering stem cells for therapeutic use as it has permitted the harvesting process to be done by leukapheresis rather than bone marrow punctures in the operating room. Granulocyte colony-stimulating factor and plerixafor, a macrocyclic compound that can block CXCR4, are both used clinically to mobilize marrow hematopoietic stem cells for transplant.

HEMATOPOIETIC STEM CELL MICROENVIRONMENT

The concept of a specialized microenvironment, or stem cell niche, was first proposed to explain why cells derived from the bone marrow of one animal could be used in transplantation and again be found in the bone marrow of the recipient. This niche is more than just a housing site for stem cells, however. It is an anatomic location where regulatory signals are provided that allow the stem cells to thrive, to expand if needed, and to provide varying amounts of descendant daughter cells. In addition, unregulated growth of stem cells may be problematic based on their undifferentiated state and self-renewal capacity. Thus, the niche also regulates the number of stem cells produced. In this manner, the niche has the dual function of serving as a site of nurture but imposing limits for stem cells: in effect, acting as both a nutritive and constraining home.

The niche for blood stem cells changes with each of the sites of blood production during development, but for most of human life, it is located in the bone marrow. Within the bone marrow, the perivascular space particularly in regions of trabecular bone serves as a niche. The mesenchymal and endothelial cells of the marrow microvessels produce kit ligand and CXCL12, both known to be important for hematopoietic stem cells. Other cell types, such as sympathetic neurons, nonmyelinating Schwann cells, macrophages, megakaryocytes, osteoclasts, and osteoblasts, have been shown to regulate stem cells, some by direct and others by indirect effects. Extracellular matrix proteins like osteopontin and heparan sulfates also affect stem cell function. The endosteal region appears to be particularly important for transplanted cells, in part because many of the mesenchymal cells and sinusoidal blood vessels of the central marrow are disrupted by the conditioning regimens used to prepare a patient for transplantation. The functioning of the niche as a supportive context for stem cells is of obvious importance for maintaining hematopoiesis and in transplantation. An active area of study involves determining whether the niche is altered in disease as experimental models have shown that mutations in niche cells can lead to myeloid malignancies.

EXCESS CAPACITY OF HEMATOPOIETIC STEM CELLS

In the absence of disease, one never runs out of hematopoietic stem cells. Indeed, serial transplantation studies in mice suggest that sufficient stem cells are present to reconstitute several animals in succession, with each animal having normal blood cell production. The fact that allogeneic stem cell transplant recipients also never run out of blood cells over decades argues that even the limiting numbers of stem cells provided to them are sufficient. How stem cells respond to different conditions to increase or decrease their mature cell production remains poorly understood. Clearly, negative feedback mechanisms affect the level of production of most of the cells, leading to the normal tightly regulated blood cell counts. However, many of the regulatory mechanisms that govern production of more mature progenitor cells do not apply or apply differently to stem cells. Similarly, most of the molecules shown to be able to change the size of the stem cell pool have little effect on more mature blood cells. For example, the growth

factor erythropoietin, which stimulates red blood cell production from precursor cells, has no effect on stem cells. Similarly, granulocyte colony-stimulating factor drives the rapid proliferation of granulocyte precursors but has little or no effect on the cell cycling of stem cells. Rather, it changes the location of stem cells by indirect means, altering molecules such as CXCL12 that tether stem cells to their niche. Molecules shown to be important for altering the proliferation, self-renewal, or survival of stem cells, such as cyclin-dependent kinase inhibitors, transcription factors like Bmi-1, microRNA-processing enzymes like Dicer, or even metabolic regulators like pyruvate kinase isoforms, have little or different effects on progenitor cells. Hematopoietic stem cells have governing mechanisms that are distinct from the cells they generate.

HEMATOPOIETIC STEM CELL DIFFERENTIATION

Hematopoietic stem cells sit at the base of a branching hierarchy of cells culminating in the many mature cell types that compose the blood and immune system **(Fig. 101-2)**. The maturation steps leading to terminally differentiated and functional blood cells take place both as a consequence of intrinsic changes in gene expression and external, niche-directed or cytokine-directed changes in the cells. Our knowledge of the details remains incomplete. As stem cells mature to progenitors, precursors, and, finally, mature effector cells, they undergo a series of functional changes. These include the acquisition of functions defining mature blood cells, such as phagocytic capacity or hemoglobin synthesis. They also include the progressive loss of plasticity (i.e., the ability to become other cell types). For example, some myeloid progenitors can make all cells in the myeloid series but none in the lymphoid series. As common myeloid progenitors mature, they become precursors for either monocytes and granulocytes or erythrocytes and megakaryocytes, but not both. Some amount of reversibility of this process may exist early in the differentiation cascade, but that is lost beyond a distinct stage in normal physiologic conditions.

As cells differentiate, they may also lose proliferative capacity **(Fig. 101-3)**. Mature granulocytes are incapable of proliferation and only increase in number by increased production from precursors. The exceptions to the rule are some tissue-resident macrophages, which appear capable of proliferation, and lymphoid cells. Lymphoid cells retain the capacity to proliferate but have linked their proliferation to the recognition of particular proteins or peptides by specific antigen

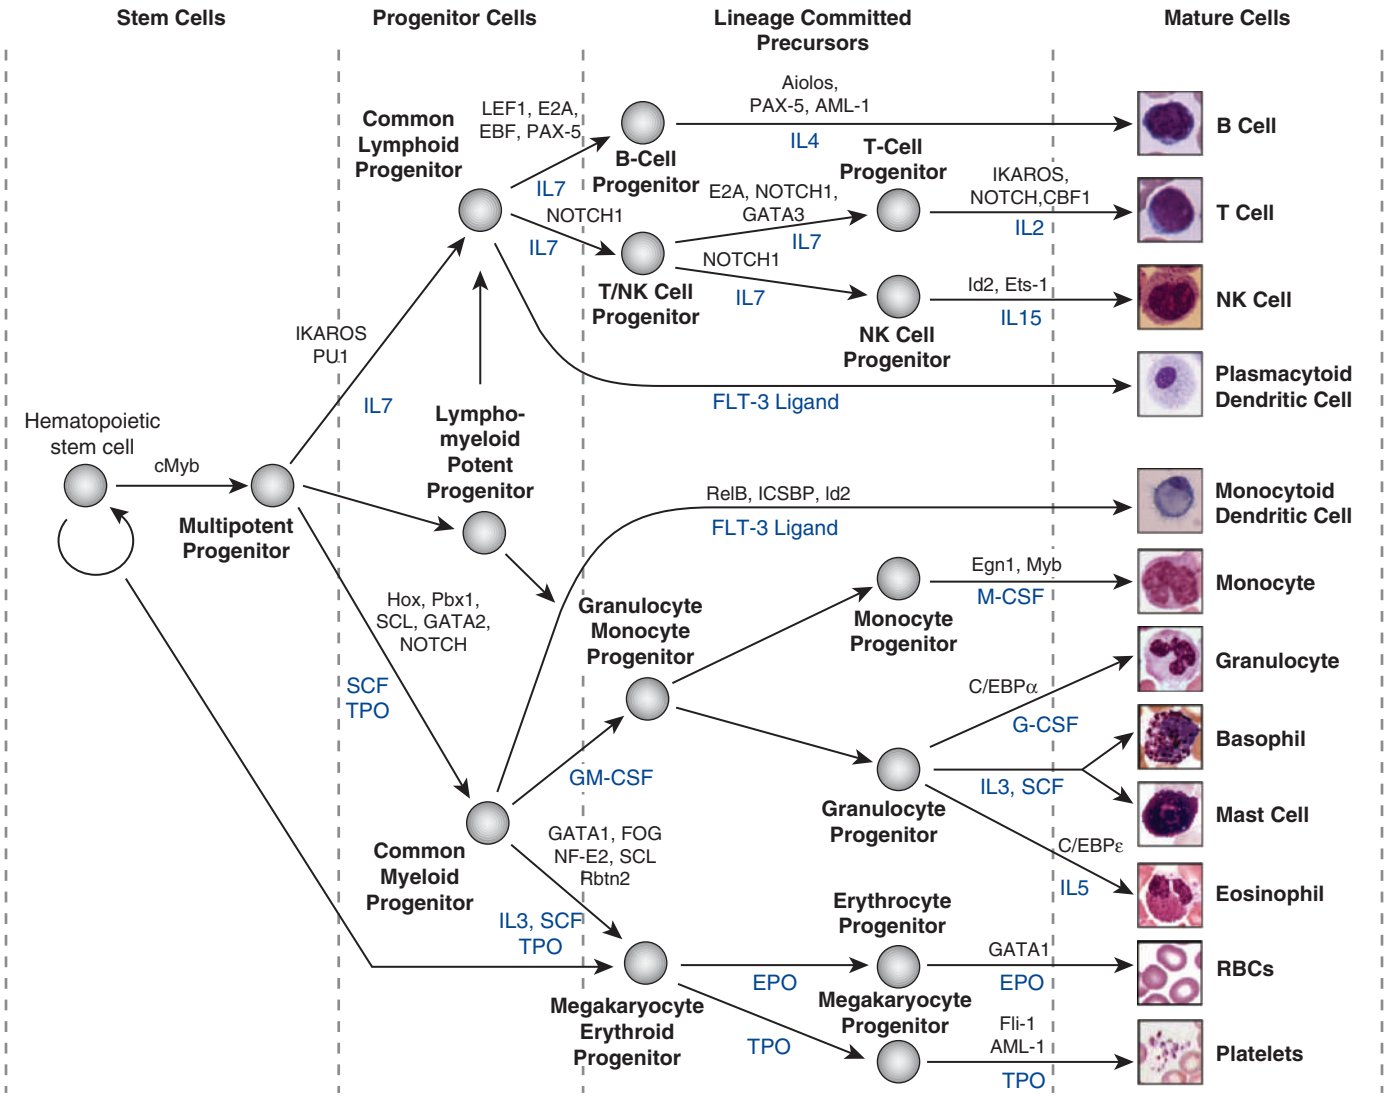

FIGURE 101-2 Hierarchy of hematopoietic differentiation. *Stem cells* are multipotent cells that are the source of all descendant cells and have the capacity to provide either long-term (measured in years) or short-term (measured in months) cell production. *Progenitor cells* have a more limited spectrum of cells they can produce and are generally a shorter-lived, highly proliferative population also known as transient amplifying cells. *Precursor cells* are cells committed to a single blood cell lineage but with a continued ability to proliferate; they do not have all the features of a fully mature cell. *Mature cells* are the terminally differentiated product of the differentiation process and are the effector cells of specific activities of the blood and immune system. Progress through the pathways is mediated by alterations in gene expression. The regulation of the differentiation by soluble factors and cell-cell communications within the bone marrow niche are still being defined. The transcription factors that characterize particular cell transitions are illustrated on the *arrows*; the soluble factors that contribute to the differentiation process are in *blue*. This picture is a simplification of the process. Active research is revealing multiple discrete cell types in the maturation of B cells and T cells and has identified cells that are biased toward one lineage or another (rather than uncommitted) in their differentiation. EPO, erythropoietin; RBC, red blood cell; SCF, stem cell factor; TPO, thrombopoietin.

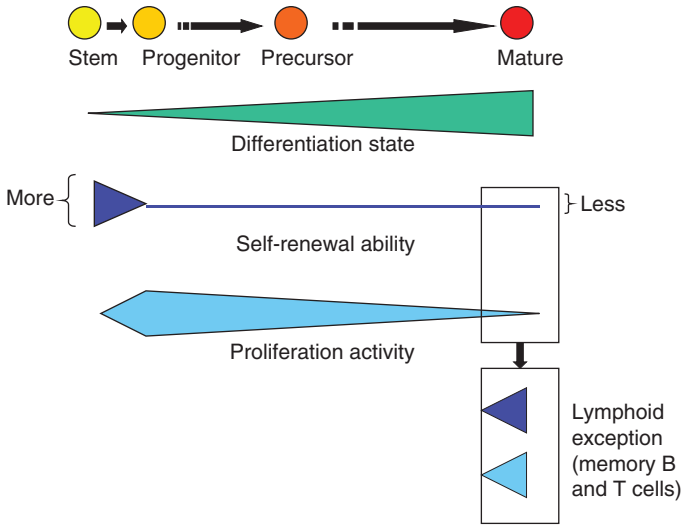

FIGURE 101-3 Relative function of cells in the hematopoietic hierarchy. The boxes represent distinct functional features of cells in the myeloid (*upper box*) versus lymphoid (*lower box*) lineages.

receptors on their surface. Like many tissues with short-lived mature cells such as the skin and intestine, blood cell proliferation is largely accomplished by a more immature progenitor population. In general, cells within the highly proliferative progenitor cell compartment are also relatively short-lived, making their way through the differentiation process in a defined molecular program involving the sequential activation of particular sets of genes. For any particular cell type, the differentiation program is difficult to speed up. The time it takes for hematopoietic progenitors to become mature cells is ~10–14 days in humans, evident clinically by the interval between cytotoxic chemotherapy and blood count recovery in patients.

Although hematopoietic stem cells are generally thought to have the capacity to form all cells of the blood, individual stem cells are heterogeneous in their differentiation potential. That is, some stem cells are "biased" to become mature cells of a particular type. In addition, individual stem cells may respond differently to proliferation or cell death signals. Therefore, the stem cell population is an aggregate of cells with somewhat distinctive properties that have the collective characteristics ascribed to hematopoietic stem cells.

SELF-RENEWAL AND CLONAL DYNAMICS

Self-renewal is the ability to divide while preserving an undifferentiated state. This stem cell characteristic is generally not seen in progenitor or mature cells where proliferation is coupled with progressive differentiation. Stem cells being able to asymmetrically divide, such that one daughter cell is the product of self-renewal and the other enters into the differentiating progenitor pool, enables the hematopoietic system to have a modestly sized pool of stem cells yet produce seven orders of magnitude greater numbers of mature blood cells each day.

Self-renewal has its risks, however. Genetic mutations that occur in a stem cell will durably persist in stem cells because of self-renewal. In contrast, mutations in progenitors will largely be lost as the cells terminally differentiate and die. It is the stem cell then that has greater potential to accumulate genetic mutations, a setting that can lead to cancer. Countering this risk is the small number of stem cells, the radioprotective environment of their bone localized niche, and the relative quiescence of stem cells.

Stem cells have distinctive cell cycle regulation. Some are deeply quiescent, serving as a deep reserve, whereas others are more proliferative and replenish the short-lived progenitor population. Hematopoietic stem cells are generally cytokine-resistant, remaining dormant even when cytokines drive bone marrow progenitors to proliferation rates measured in hours. Stem cells, in contrast, are thought to divide at far longer intervals, measured in months to years, for the most quiescent cells. This quiescence is difficult to overcome in vitro, limiting the ability to effectively expand human hematopoietic stem cells. The process may be controlled by particularly high levels of cyclin-dependent kinase inhibitors like p57 or CDKN1c that restrict entry of stem cells into the cell cycle by blocking the G_1-S transition. Exogenous signals from the niche also appear to enforce quiescence, including angiogenin, interleukin 18, and perhaps angiopoietin 1.

Individual stem cells may vary in their proliferation and self-renewal features. This can lead to distortions in the representation of any given clone of stem cells, a feature commonly seen with aging and often associated with acquired somatic mutations. Hematopoietic stem cells are estimated to acquire 17 somatic mutations with each year of life based on deep sequencing studies. Some of these appear to provide a fitness advantage to the stem cell as the presence of mutated or "variant" alleles contributing to >1% of blood cells is virtually uniform by age 70. Furthermore, it is estimated that 10–20 such clones exist in individuals by 70, and in aggregate, those clones provide between 30 and 60% of the blood cells. Thus, the diversity of active stem cell clones declines with age with a likely accompanying reduced diversity of functions that each clone provides. Whether this contributes to immune alterations or other aspects of aging is to be determined. However, some expanded clones are associated with "driver" mutations observed in myelodysplasia and myeloid leukemias. These clones do have a low frequency of progression to overt neoplastic disease, and at least one of them, an inactivating mutation of *TET2*, can also increase adverse outcomes from a number of chronic inflammatory conditions.

The most common mutations associated with clonal hematopoiesis are of epigenetic regulatory genes. For example, inactivating mutations of the DNA methyl transferase *DNMT3a* or the dioxygenase involved in DNA demethylation, *TET2*, are commonly found, as are mutations in *ASXL1*, a member of the polycomb family of genes whose products alter chromatin structure, a high-order DNA organization that affects transcription. Therefore, epigenetic control appears to be critical for homeostasis of the hematopoietic stem cell pool and constraining the outgrowth of potentially pathogenic stem cell clones.

THE RELATIONSHIP OF STEM CELLS TO CANCER

Some cancers have been shown to have a cellular hierarchy similar to normal tissues, with stem-like cells having the capacity to self-renew and differentiate. These stem-like cells can be experimentally transplanted into immunodeficient animals and initiate a new cancer. It is hypothesized that these stem-like cells may be the basis for disease relapse after therapy as they have distinctive molecular features from other cells in the cancer that may render them less vulnerable to therapies. Myeloid leukemias have been experimentally shown to be consistent with this model. Focusing therapies on the stem-like cells as opposed to the bulk population of the cancer cells as a means to improve cure rates is an active area of investigation.

Given that hematopoietic stem cells can accumulate genetic mutations by virtue of their self-renewal, it is logically appealing to regard them as the likely cell source of leukemias. Experimental testing of this hypothesis has shown that stem cells are more likely to result in malignancy following an oncogenic mutation. However, some more mature populations with less well-defined self-renewal capability can also be transformed to malignancy. Therefore, self-renewal may also be acquired by mutation, and cancer stem-like cells need not have originated in normal stem cells.

STEM CELLS AS TARGETS OF GENE THERAPY OR GENE EDITING

The hematopoietic stem cell is the ideal cell target for genetic therapies intended to durably change the genome of blood cells. Because stem cells can persist for the lifetime of an individual, genetically modifying them can provide curative therapies for genetic disorders such as hemoglobinopathies or congenital immunodeficiencies. The extensive cell proliferation with limited or no self-renewal among progenitor populations makes them less able to provide durable benefit if they are genetically modified. Therefore, modification of stem cells is critical and requires integration of the genetic therapy into the host cell's

genome to persist. This is challenging because the relative quiescence of stem cells makes them less susceptible to the molecular events of integration of a transgene or editing of a target gene. Yet, many of these technical challenges have been overcome sufficiently that there are medicines composed of hematopoietic stem cells bearing a gene to offset a missing or defective gene for active cerebral adrenoleukodystrophy, β thalassemia, and sickle cell anemia. These are termed gene therapies as a full coding sequence of the abnormal gene is provided. There is also a gene-edited therapy for β thalassemia and sickle cell anemia based on CRISPR-based technology. CRISPR-Cas allows for selected deletion of regions of genes and is thus called gene editing. In the case of the hemoglobinopathies, a gene that suppresses fetal hemoglobin, *BLC11A*, is the target. Reducing *BLC11A* expression by editing leads to fetal hemoglobin expression that overcomes the abnormal adult β hemoglobins causing β thalassemia and sickle cell anemia.

These therapies are powerful new ways in which hematopoietic stem cells can be medically beneficial. By modifying the patient's own cells, this type of hematopoietic stem cell therapy does not require immunologic matching with a donor and avoids graft-versus-host disease. At present, it still involves myeloablative conditioning of the patient prior to receiving the cells as they are modified outside the body and must compete with endogenous stem cells in the bone marrow. Efforts to enable gene editing in vivo and thereby avoid transplantation are being actively investigated.

102 Iron Deficiency and Other Acquired Anemias Due to Decreased Erythrocyte Production

Clara Camaschella, Domenico Girelli

This chapter provides basic information on iron metabolism as an introduction to common anemias due to iron deficiency, inflammation, and aging, conditions in which alterations of iron balance play a prominent role. The pathogenetic mechanism of the anemia is hypoproliferation of the marrow precursors.

IRON METABOLISM

Iron is indispensable for multiple cell functions, including oxygen delivery, DNA replication and repair, metabolism, and energy production: hence, it is conserved and reutilized. However, to prevent potential toxicity due to the propensity of free iron to generate reactive oxygen species, iron is always bound to proteins, and its homeostasis is tightly regulated. Body iron cycle and distribution are illustrated in **Fig. 102-1**. Iron is provided to all cells by transferrin, a bilobed glycoprotein of hepatic origin abundant in plasma (204–360 mg/dL), that binds iron within a single (monoferric) or both lobes (diferric transferrin). Transferrin carries only 3–4 mg of iron but has a fast turnover. To produce about 200 billion erythrocytes daily, erythroid precursors need about 20–25 mg of iron, mainly supplied by macrophage recycling since dietary iron absorption is limited to 1–2 mg daily. Diferric transferrin binds with high affinity the iron importer transferrin receptor in all cells. The ligand-receptor complex is internalized via clathrin-coated pits to form the endosome. Released by low pH, iron is exported to cytosol by divalent metal transporter 1 (DMT1) and mainly used for heme and iron-sulfur cluster biosynthesis in mitochondria. Apotransferrin and transferrin receptor are recycled to cell surface and reutilized. Excess iron is safely sequestered by cytosolic ferritin, a large hollow shell formed by 24 (heavy and light) subunits in variable combination that stores iron into its central cavity, a process especially efficient in spleen macrophages. Ferritin is also secreted in blood where its concentration may be a marker of stored iron. In iron deficiency, cells can recover iron from ferritin by an autophagic process called ferritinophagy. Diferric transferrin also binds with lower affinity the iron sensor transferrin receptor 2 on hepatocyte **(Fig. 102-2*A*)** and erythroid cell surface. Erythroblasts express the highest number of transferrin receptors (~300,000–400,000/cell) and take up iron only from transferrin. Receptors not bound to transferrin are protease cleaved and released into blood where their concentration as soluble receptor is an estimate of total or iron-deficient erythropoiesis. Transferrin receptor is indispensable to all hematopoietic cells from stem cells to neutrophils. Lymphocyte function is strongly iron-dependent, as shown by the immunodeficiency resulting from rare mutations in transferrin receptor that hamper iron uptake. In the liver, transferrin receptor has the extra function of hepcidin regulator, binding and sequestering the hemochromatosis protein HFE (Fig. 102-2*A*). Liver, pancreas, and heart, but not erythroblasts, can take up non-transferrin-bound-iron (NTBI), which appears in the circulation when transferrin saturation exceeds 60%. No regulated mechanism for iron excretion exists. Physiologic iron loss occurs only through cell desquamation and menses in females and roughly balances the amount of daily absorbed iron (Fig. 102-1).

REGULATION OF IRON HOMEOSTASIS

Systemic iron homeostasis is regulated by *hepcidin*, a 25-amino-acid peptide mainly produced by hepatocytes that, blocking iron export and degrading the iron exporter ferroportin, inhibits plasma iron flux from duodenal enterocytes, iron-recycling macrophages, and iron-storing hepatocytes (Fig. 102-1). High hepcidin levels decrease, while low hepcidin levels increase, iron delivery to plasma. Hepcidin expression is increased by high plasma and liver iron that activate the BMP (bone morphogenetic protein)-SMAD (suppressors of mothers against decapentaplegic) signaling pathway. The proteins HFE, transferrin receptor 2, and hemojuvelin, whose mutations lead to different forms of hemochromatosis **(Chap. 426)**, contribute to hepcidin upregulation. Hepcidin is increased also by inflammatory cytokines, through interleukin (IL) 6 signal transducer and activator of transcription 3 (STAT3) pathway **(Fig. 102-2*A*)**.

Hepcidin expression is suppressed in iron deficiency by the hepatic transmembrane serine protease TMPRSS6 that antagonizes the BMP pathway. Another powerful inhibitor is erythroferrone **(Fig. 102-2*B*)**, the hormone secreted by erythroblasts upon erythropoietin stimulation, such as after a hemorrhage or in hypoxia, which sequesters the BMPs. Other hepcidin inhibitors include testosterone, which adapts iron supply to male erythropoiesis; fibrinogen-like protein 1 (FGL1), released by hepatocytes; and platelet-derived growth factor BB produced by many cell types in hypoxia.

At the cellular level, the iron regulatory proteins (IRPs) control the synthesis of transferrin receptor, ferritin, and ferroportin by interacting with the iron-responsive elements in their mRNA, thus coordinating cell iron uptake, with storage and efflux, according to the cell iron need. IRPs also tune erythropoiesis by regulating hypoxia-inducible factor (HIF) 2α and thus erythropoietin and the first enzyme of heme biosynthesis 5′-aminolevulinate synthase 2.

Intestinal Iron Absorption Iron needs change during life according to age and gender **(Table 102-1)**. In adults, only about 1–2 mg of iron are absorbed from the diet. Dietary iron content is closely related to caloric intake, with 6–7 mg elemental iron every 1000 calories: hence Western diet contains about 15 mg iron daily. The food composition

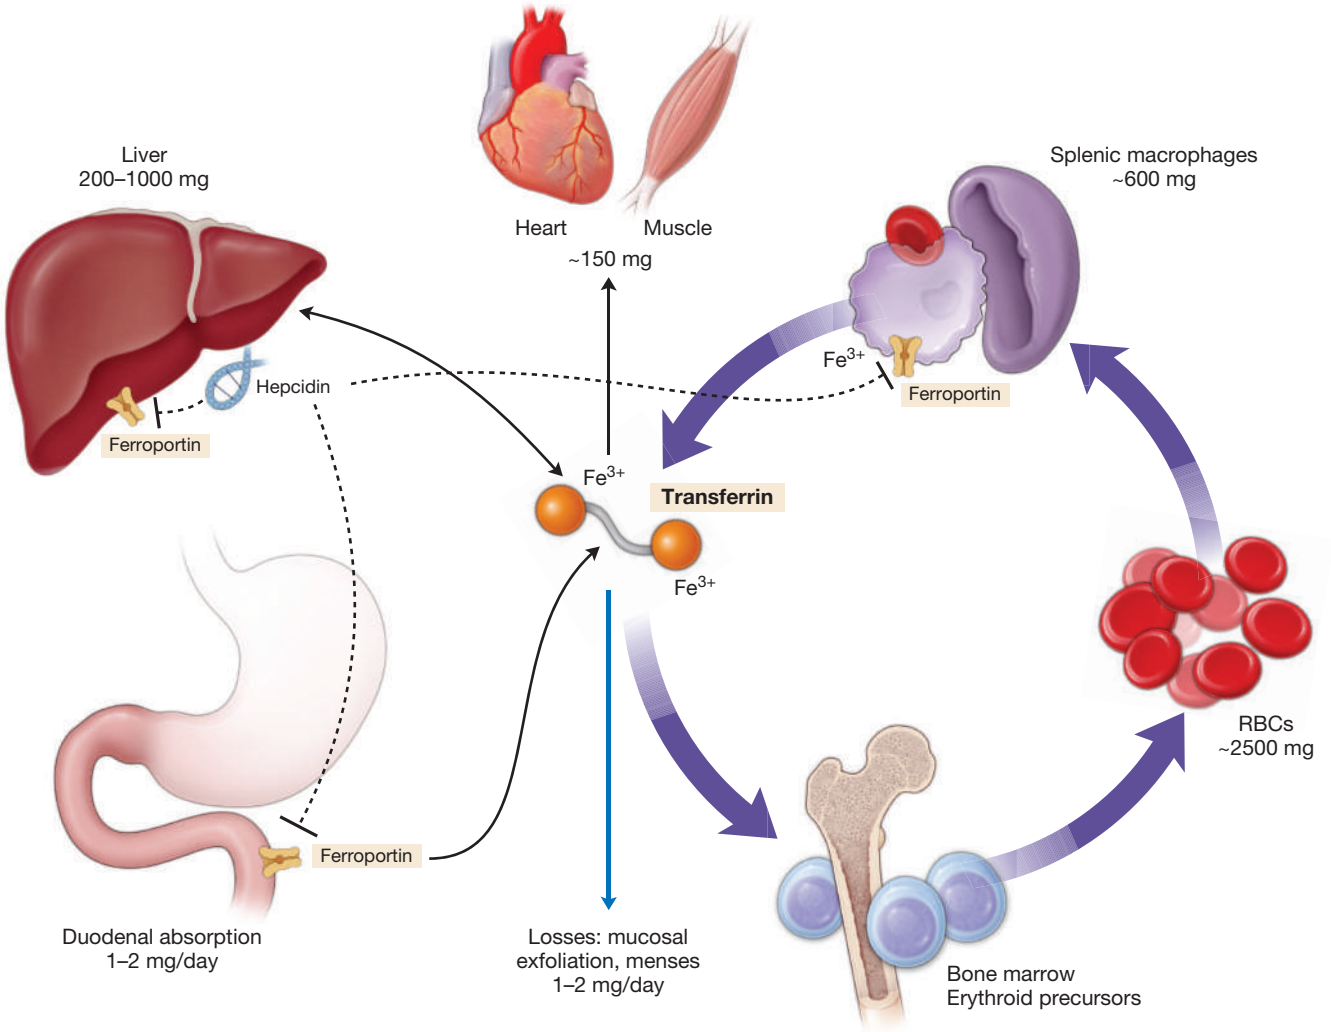

FIGURE 102-1 The iron cycle. Transferrin is central to iron trafficking. Most iron is recycled from macrophages, while only 1–2 mg are derived from intestinal absorption; mg indicates iron content of organs/tissues. Iron flux to plasma is controlled by hepcidin, a peptide produced by the liver that inhibits the activity of the iron exporter ferroportin in enterocytes, macrophages, and hepatocytes. Iron loss balances iron absorption.

affects iron bioavailability. Heme contained in red meat is easily taken up by enterocytes through a still undefined mechanism. Nonheme ferric (Fe^{3+}) iron is converted to ferrous (Fe^{2+}) iron by the low local pH and by the ferrireductase duodenal cytochrome B (DCYTB) before being imported from the lumen by DMT1. Phytates and phosphates contained in vegetables and cereals and tannin contained in tea and coffee reduce, while ascorbic acid enhances, inorganic iron absorption. Absorption takes place prevalently in duodenal enterocytes where iron can be utilized or released to plasma transferrin by ferroportin upon oxidation by hephaestin. Surplus iron is stored in cytosolic ferritin and lost by enterocytes sloughed into the lumen. Duodenal iron absorption depends both on the local levels of HIF-2α that enhance the expression of the absorption machinery components (DMT1, DCYTB, ferroportin) and on the hepcidin-mediated suppression of iron export. In iron deficiency, high levels of HIF-2α that favor luminal iron uptake and low hepcidin that facilitates export to plasma cooperate to maximize the absorption process. Iron in the gut may reshape the local microbiome, whose influence is emerging as modulator of body iron.

Macrophage Iron Recycling Specialized liver and spleen macrophages remove senescent erythrocytes (0.8–1% daily) and recycle to plasma the iron recovered from heme (Fig. 102-1). The high (20–25 mg daily) macrophage flux maintains steady-state iron supply to erythropoiesis and may further increase to compensate for hypoferremia or accelerated erythropoiesis. In contrast, decreased iron recycling, as caused by high hepcidin levels in inflammation, leads to anemia, with iron stored in macrophages. Because of its essential role in iron recycling, ferroportin is regulated at multiple levels, the most important being hepcidin-dependent. In intravascular hemolysis, hepatocytes and macrophages recover iron from hemoglobin-haptoglobin and heme-hemopexin complexes.

Iron Utilization Erythropoiesis utilizes a large amount of iron for heme/hemoglobin production and facilitates its own iron supply by releasing erythroferrone (Fig. 102-2*B*) upon erythropoietin stimulation. The release is transient; chronic erythroferrone production in ineffective erythropoiesis, as in non-transfusion-dependent β thalassemia (Chap. 103), leads to iron overload. In every cell, iron is mainly utilized in mitochondria to produce heme and iron/sulfur clusters, components of enzymes and complexes involved in the cell cycle, oxidative phosphorylation and energy production, fundamental processes in heart, skeletal muscle, and brain. Although bone marrow consumes most available iron, excessive erythroid use at the expense of other organs is prevented; one impeding mechanism is the iron export by erythroid ferroportin that contributes to serum iron levels in hypoferremia.

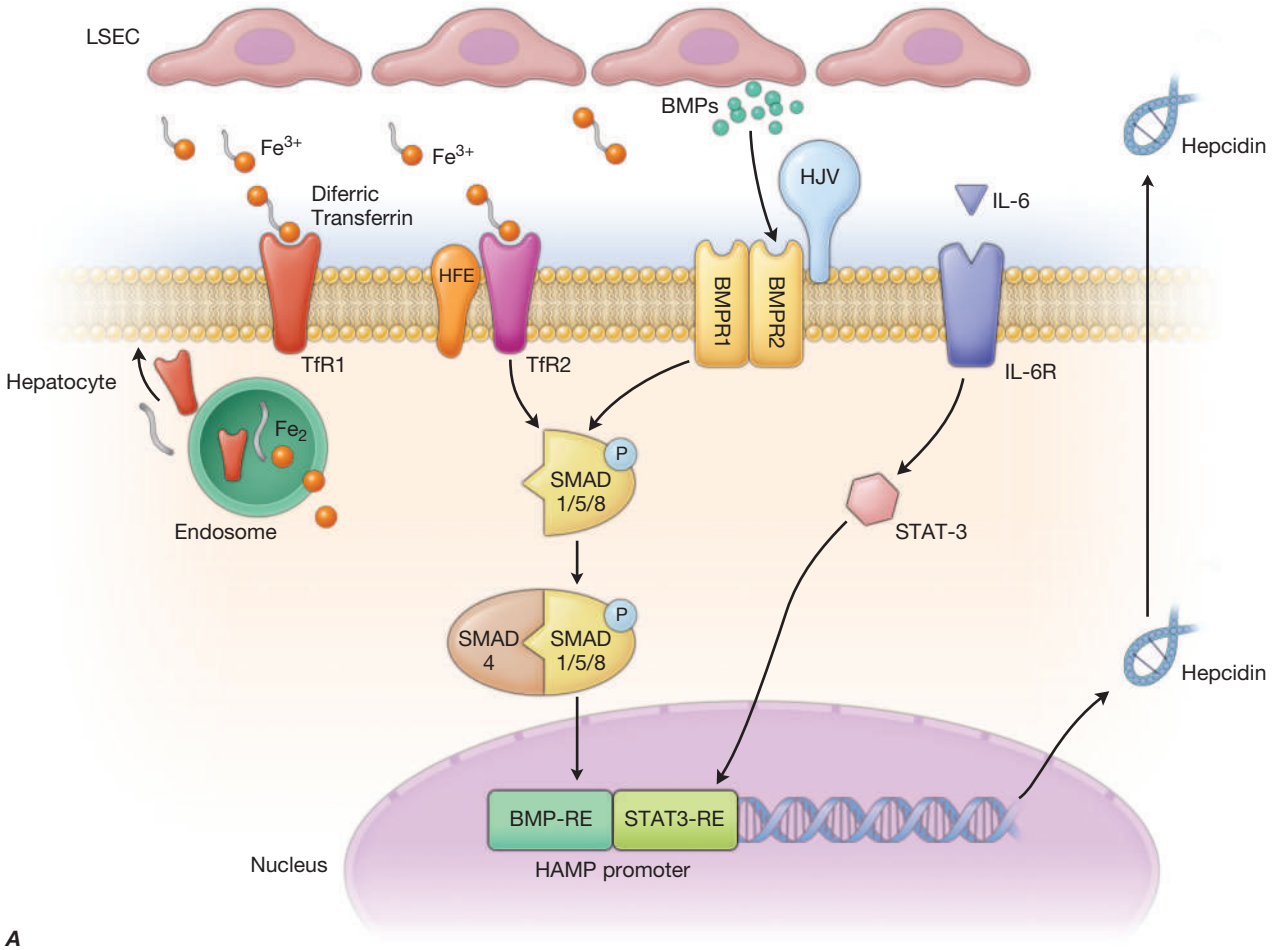
IRON DEFICIENCY AND IRON-DEFICIENCY ANEMIA

Iron deficiency and iron-deficiency anemia are global health problems affecting billions of people and a main cause of years lived with disability, especially among women. In isolated iron deficiency, iron stores are depleted while hemoglobin levels are still normal. In iron-deficiency

anemia, stores are depleted and iron is insufficient for erythropoiesis. Iron deficiency is *absolute* when the stores are exhausted and *functional* when erythropoiesis is iron-restricted but the stores are adequate or even increased.

PATHOPHYSIOLOGY

Isolated iron deficiency with low/absent iron stores is a common condition induced by rapid growth, inadequate nutrition, abundant menses. When iron is still sufficient for erythropoiesis, erythrocytes are normochromic and normocytic while ferritin is decreased (<15–30 μg/L). Isolated iron deficiency may progress to anemia of variable degrees. With transferrin saturation <15–20% iron supply to erythropoiesis is insufficient and erythrocytes become hypochromic and microcytic, the classical feature of iron-deficiency anemia. Though anemia is the most evident outcome, other organs, such as heart, muscles, and brain, are affected by iron deficiency. In chronic heart failure (CHF), iron deficiency causes symptoms even independently from anemia. Immune response may be blunted because lymphocytes require iron during the metabolic burst that mounts adaptative defense against infectious agents.



The relevance of low hepcidin in iron deficiency is clearly documented. Mutations of the negative regulator of hepcidin *TMPRSS6* cause a rare form of hereditary iron-refractory iron-deficiency anemia (IRIDA), characterized by reduced iron absorption and refractoriness to oral iron supplementation. Similarly, in inflammation, high hepcidin levels sequester iron into stores, leading to functional iron deficiency and iron-restricted erythropoiesis with low serum iron and transferrin saturation in the presence of elevated ferritin levels. Not infrequently, absolute and functional iron deficiency coexist, as in inflammatory bowel diseases, chronic kidney disease (CKD), and aging. Functional iron deficiency may be caused also by erythrocyte-stimulating agents (ESA) that, expanding erythropoiesis, unbalance iron demand and supply.

CAUSES OF IRON DEFICIENCY

Causes of absolute iron deficiency are detailed in **Table 102-2**. In general, iron supply is inadequate for iron needs because of excessive demand, insufficient intake, defective absorption, or blood loss. In clinical practice, multiple causes frequently co-occur, especially in the elderly and in patients with multimorbidity. Several genome-wide association studies showed that variants of iron genes, such as *TMPRSS6* and *TF* (encoding transferrin), may confer a genetic susceptibility to iron deficiency.

EPIDEMIOLOGY

Iron-deficiency anemia is estimated to affect ~1.2 billion individuals, roughly half of the world anemic population. The high iron requirements explain its high prevalence in preschool children (estimated ~25%), young women (37–40%), and pregnant women (>40% presenting with severe forms in low-income countries). Isolated iron deficiency is even more common, though precise figures are lacking. Both conditions are especially frequent in low-income countries, although high-income countries are not spared. In the United States, the prevalence of iron deficiency and iron-deficiency anemia in females aged 12–21 years based on ferritin <30 μg/L has been recently reported to be 38.6 and 6.3%, respectively. Anemia of inflammation,

A

FIGURE 102-2 A. Molecular regulation of hepcidin in iron deficiency. In steady state, diferric transferrin binds TFR1 to release iron to hepatocytes and interacts with TFR2 to signal iron concentration. Liver sinusoidal endothelial cells (LSECs) produce bone morphogenic proteins (BMPs) that interact with BMP receptors type 1 and 2 (BMPR1 and BMPR2, respectively) to activate cytosolic suppressors of mothers against decapentaplegic (SMAD) 1/5/8, with the cooperation of the coreceptor hemojuvelin (HJV) and HFE bound to TFR2. SMAD 1/5/8 complex with SMAD 4 and translocate to the nucleus, where they interact with BMP responsive elements (BMPRE) in hepcidin (*HAMP*) promoter to upregulate its expression. In inflammation, hepcidin is upregulated also through the interleukin 6 (IL-6)–IL-6 receptor–STAT3 pathway.

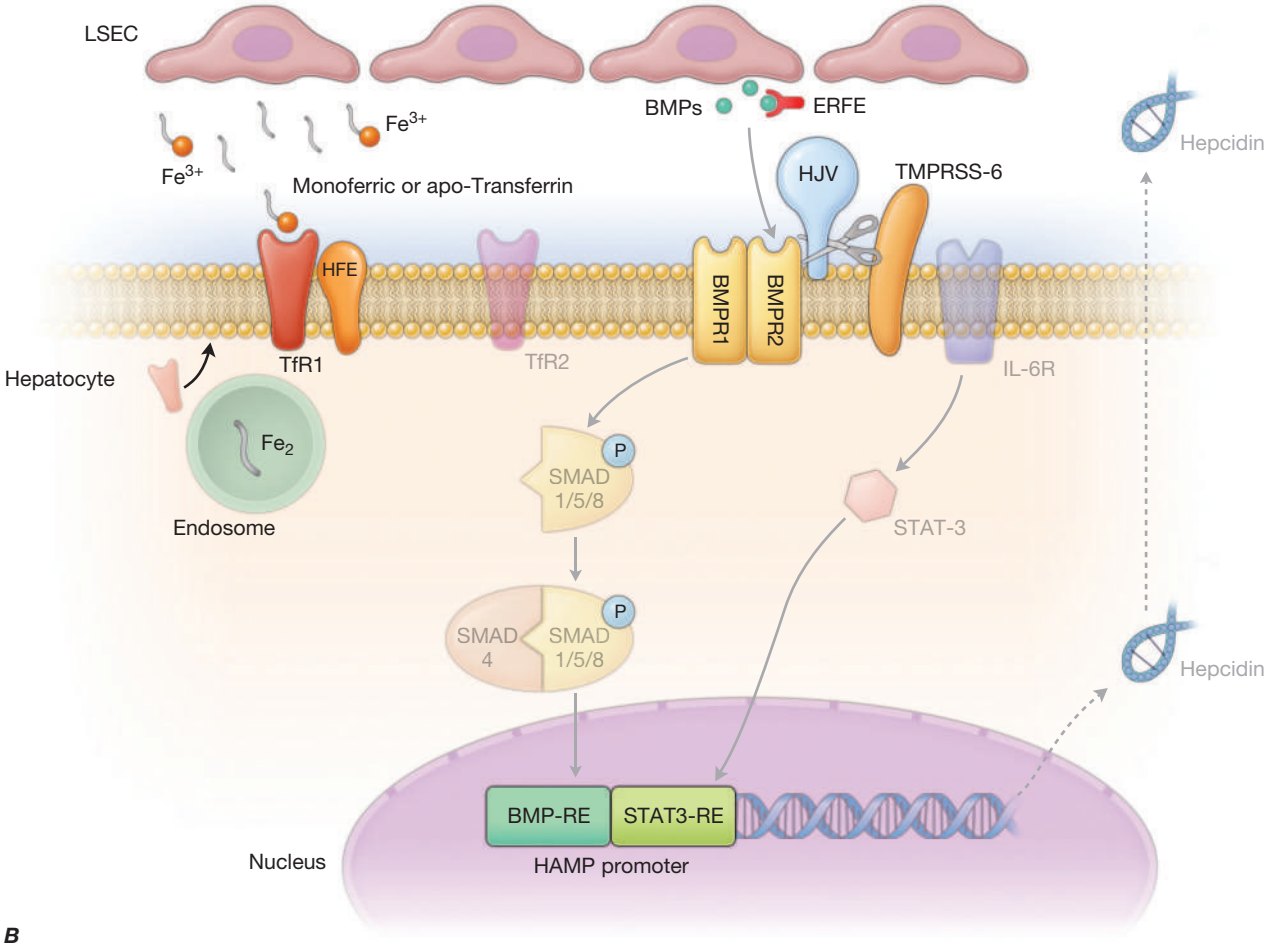


FIGURE 102-2 B. Molecular regulation of hepcidin in iron deficiency. In iron deficiency, transferrin is prevalently mono- or apotransferrin, the production of BMP by LSEC is scarce, the BMP coreceptor HJV is cleaved from the cell surface by the serine protease TMPRSS6, and TFR1 cannot transport iron inside the cell since it is bound to HFE. The SMAD and STAT3 pathways are inactive (indicated by *faint arrows*), and hepcidin is low/ undetectable.

due to functional iron deficiency, is the second most common anemia worldwide, especially in hospitalized patients, although precise figures are not available.

CLINICAL PRESENTATION

Anemia develops only in the late stage of iron deficiency, since the erythron is relatively spared compared to heart and skeletal muscle that may become iron depleted earlier. Because of slow progression and efficient compensatory mechanisms, anemia often remains undetected, especially in young people, until hemoglobin level falls below 8 g/dL. Isolated iron deficiency should not be underestimated since the resulting suboptimal metabolic function of myocytes, cardiomyocytes, and neurons may lead to fatigue, irritability, poor concentration, restless legs syndrome, and reduced exercise capability. As iron deficiency progresses, classical symptoms of anemia may appear (Chap. 66). Clinical clues pointing to iron-deficiency anemia include pica (craving and compulsive ingestion of nonnutritive substances such as ice, soil, or clay), nail fragility and koilonychia, hair loss, cheilosis, atrophic glossitis, and dysphagia caused by formation of esophageal webs (Plummer-Vinson syndrome). Clinical history is important to identify such symptoms as well as symptoms of any underlying disorder (Table 102-2).

TABLE 102-1 Daily Iron Requirements (mg) According to Age and Gender

Children	0.5–1.0
Adolescents	1.2–1.5
Adult males	1.0
Females (fertile age)	1.20–1.50
Pregnancy second trimester	2.8–3.0
Pregnancy third trimester	4.0–5.0
Breastfeeding	1.0-1.15
Females (postmenopausal)	1.0

Laboratory Iron Studies The diagnosis of iron deficiency with or without anemia is a two-step process that first requires laboratory tests, and then the identification of the cause(s) (Table 102-2). The laboratory diagnosis is usually simple, while tracing the cause may require imaging and endoscopy, procedures essential in males and postmenopausal females to rule out malignancy or other severe causes of bleeding. The absence of stainable iron in the bone marrow remains the gold standard for iron deficiency, although it is rarely needed and unacceptably invasive. The mainstay of absolute iron deficiency is low serum ferritin, which reflects reduced/exhausted iron stores. Although the precise cutoff is debated and varies in different settings, ferritin levels <30 μg/L have sufficiently high sensitivity and specificity (92 and 98%, respectively) to be used as a single test for diagnosing iron deficiency. Serum iron is reduced, but diurnal fluctuations prevent its use as a single test. Transferrin saturation (serum iron/total iron-binding capacity ratio) measures iron available for erythropoiesis, which becomes iron restricted for values <15–20%. Mean corpuscular volume (MCV) is <80 fL in established iron deficiency, but can be normal in early stages. Red cell distribution width (RDW) is often elevated, a measure of anisocytosis. Laboratory diagnosis may be demanding in patients with comorbidities. Classical microcytosis and hypochromia can be absent in elderly patients or masked by concomitant folate

TABLE 102-2 Causes of Absolute Iron Deficiency With or Without Anemia

MECHANISM	CONDITIONS
Increased iron needs	• Children, adolescents (growth spurt) • Pregnancy and breastfeeding • Treatment with erythropoiesis-stimulating agents
Inadequate iron intake	• Vegan or vegetarian diet • Malnutrition, poverty • Prolonged breastfeeding
Decreased iron absorption	• Gastrectomy, bariatric surgery • Celiac disease • *Helicobacter pylori* gastritis • Atrophic/autoimmune gastritis • Proton pump inhibitors[a] • Excess consumption of iron absorption inhibitors (e.g., tea, calcium) • IRIDA (*TMPRSS6* mutations)
Chronic blood losses	*Gastrointestinal* • Erosive esophagitis/gastritis • Peptic ulcer • Large hiatal hernia • Antral gastric ectasia (watermelon stomach) • Benign lesions (e.g., large polyps) • Meckel's diverticulum • Angiodysplasias (including Heyde's syndrome with concurrent aortic stenosis and acquired von Willebrand disease) • Malignancy (especially right colon cancer) • Large hemorrhoids • Inflammatory bowel diseases • Parasites (hookworms, others) *Gynecologic* • Heavy menstrual bleeding[b] • Fibroids • Uterine cancers *Urinary* • Intravascular hemolysis (e.g., PNH, prosthetic heart valves, march hemoglobinuria) • Urinary schistosomiasis (*Schistosoma haematobium*) • Bladder or renal cancer *Pulmonary* • Pulmonary hemosiderosis • Severe hemoptysis *Iatrogenic* • Hemodialysis • Surgical blood losses • Excess blood drawn for diagnostic testing • Drugs inducing or facilitating GI bleeding (aspirin, nonsteroidal anti-inflammatory drugs, corticosteroids, antithrombotic drugs) *Bleeding disorders* • von Willebrand disease, other coagulation defects, platelet disorders • Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease) *Frequent blood donors* *Self-inflicted in psychiatric disorders* (Munchausen's syndrome)

[a]Unlikely the sole cause. [b]May be exacerbated by undiagnosed von Willebrand disease or platelet disorders.

Abbreviations: IRIDA, iron-refractory iron-deficiency anemia; PNH, paroxysmal nocturnal hemoglobinuria.

and/or vitamin B_{12} deficiency in malabsorption disorders. **Table 102-3** lists all potentially useful laboratory parameters. Levels of soluble transferrin receptor increase in iron deficiency, since the receptor is highly expressed and released by erythroid precursors. Reduced reticulocyte hemoglobin content and increased percentage of hypochromic red cells reflect insufficient iron availability for erythropoiesis a few days or 2–3 months before testing, respectively. Serum levels of hepcidin are low/undetectable in absolute iron deficiency, a mechanism that maximizes dietary iron absorption. They are elevated in inflammation and in the rare IRIDA due to mutations of *TMPRSS6*. Overall, the clinical use of laboratory biomarkers other than ferritin and transferrin saturation is currently hampered by limited standardization and/or accessibility. Table 102-3 provides the differential diagnosis of iron deficiency based on iron parameters.

Severe iron-deficiency anemia may be accompanied by thrombocytosis due to prevalent megakaryocyte commitment of the common erythroid-platelet progenitor in the presence of insufficient iron.

TREATMENT

Both anemic patients and those with symptomatic isolated iron deficiency should receive iron replacement therapy. This includes oral and intravenous preparations **(Table 102-4)**, with different pharmacokinetic properties. The choice of the administration route depends mainly on the severity of anemia and the individual probability of iron absorption. To be efficacious, oral compounds require the integrity of the first digestive tract and full suppression of hepcidin. Iron salts, as iron sulfate, containing 65–100 mg of elemental iron per tablet, are the first choice in mild to moderate anemia, being widely available and cheap. Traditionally they were given once or twice daily, preferably before meals (Table 102-4). Gastrointestinal side effects, such as abdominal discomfort, nausea, epigastric burning, metallic taste, diarrhea, or stypsis, are common (30–60% of cases) and due to the toxicity of unabsorbed iron on the intestinal mucosa as a result of its limited absorption rate. The unabsorbed fraction can induce changes in the gut microbiome from harmless lactobacilli to pathogenic enterobacteria, promoting infectious diarrhea in children from low- to middle-income countries.

Another potential drawback that may reduce patient adherence to oral therapy is the need for prolonged administration, usually at least 3 months, to ensure recovery of hemoglobin levels and replenishment of iron stores to prevent early recurrence. Studies tracing iron absorption with stable isotopes are changing the paradigm of oral iron administration. An alternate-day schedule maximizes iron absorption as compared to daily administration, which induces a transient peak of hepcidin; moreover, it is better tolerated. Addition of 80 mL of orange juice (but not of pharmacologic doses of ascorbic acid) maximizes the fraction of absorbed iron, indicating that the best regimen is alternate-day iron salts plus "natural" vitamin C. Lack of reticulocytosis after 1 week or a <1 g/dL hemoglobin increase after 2 weeks of treatment defines the response as inadequate and should prompt a search for the cause, such as lack of compliance, ongoing blood loss, or malabsorption.

Intravenous iron preparations (Table 102-4) are best used in case of intolerance to oral iron or malabsorption and for rapid correction of severe anemia (hemoglobin ≤8 g/dL). These nanodrugs share a common structure with a shell of carbohydrate moieties surrounding an iron hydroxide core. Their use has long been limited by safety concerns, especially anaphylaxis reactions that occurred with early preparations, such as the high-molecular-weight dextran, that are no longer on the market. The latest generation of compounds show a good safety profile, do not elicit IgE-mediated response, and are highly stable, allowing the administration of the therapeutic dose in a single infusion or two infusions. A dose test is no longer required. The nanoparticles are taken up by macrophages, and iron is slowly released to transferrin through ferroportin. Infusion reactions may occur if a small fraction of iron is rapidly released from the nanoparticle core, depending on the stability of the shell. Reactions occur in <0.1% of cases and are usually mild and self-limited. More severe reactions, possibly complement mediated (complement activation–related pseudo-allergy), are extremely rare. Other side effects are flu-like symptoms 2–5 days after the infusion and hypophosphatemia, more commonly reported with ferric carboxymaltose and mediated by the increase of the phosphaturic hormone fibroblast growth factor 23. Hypophosphatemia is

TABLE 102-3 Laboratory Biomarkers for Differential Diagnosis of Iron Deficiency

	IRON DEFICIENCY	ANEMIA OF INFLAMMATION	MIXED FORMS	THALASSEMIA TRAIT
Ferritin (μg/L)	Low (≤15–30)	Normal to high (>100)	Low to normal (<70–100)	Normal to high
Serum iron (μmol/L)	Low	Low	Low	Normal to high
Transferrin saturation (%)	Low (<10)	Low (<20)	Low (<20)	Normal to high
MCV (fL)	Low (<80)	Low to normal	Low to normal	Low
RDW	High	Normal	Normal to high	Low to normal
% HYPO	High (>6%)	High	High	High
CHr	Low	Low	Low	Low
sTfR	High	Low to normal	Normal to high	Normal to high
sTfR/log ferritin	>2	<1	>2	NA
Hepcidin[a]	Very low	Normal to high	Low	Low to normal
Zn-PP[b] (μM/mol heme)	High (>80)	Normal to high	High (>80)	High

[a]Serum hepcidin levels are not routinely measured; reference values are not standardized. [b]Zn-PP indicate zinc protoporphyrins, which reflect iron/zinc competition in the last step of heme synthesis; used in screening programs.

Note: % HYPO (percentage of hypochromic red blood cells) and CHr (hemoglobin content of reticulocytes) are measured by automated analyzers and available upon request.

Abbreviations: MCV, mean corpuscular volume; NA, not assessed; RDW, red cell distribution width; sTfR, soluble transferrin receptor.

transient and asymptomatic in most cases, whereas patients undergoing multiple high-dose infusions or with micronutrient deficiencies are at risk of developing osteomalacia and bone fractures.

Overall, the latest generation of compounds have revolutionized iron supplementation because of easy administration, reduction of hospital visits, and reassuring safety profile. Consequently, indications have been expanded to treat severe anemia in the second and third trimesters of pregnancy and in complex conditions, such as CHF, perioperative anemia, and anemia in the emergency department (see below).

Iron-deficiency anemia should not be treated with blood transfusions unless patients have hemodynamic instability or are rapidly deteriorating.

TABLE 102-4 Iron Preparations for Replacement Therapy

Oral Compounds		
	ELEMENTAL IRON CONTENT,[a] mg	DOSAGE
Iron sulfate	65–105	65–100 mg 1–2 times a day or 65–100 mg on alternate day
Iron gluconate	27–38	1–2 doses per day
Iron fumarate	29–105	1–2 doses per day
Sucrosomial iron[b]	30	30 mg/d
Polysaccharide iron complexes (tablet or elixir)	50–200 15/mL 125/mL	50–200 mg/d
Ferric maltol	30	30 mg 2 times a day
Ferric citrate	45–210	3 doses per day in chronic kidney disease patients with hyperphosphatemia
Intravenous Compounds		
	IRON CONTENT, mg/mL	MAXIMUM SINGLE DOSE
Iron sucrose	20	200–300
Iron gluconate	12.5	125, slow infusion
Low-molecular-weight dextran	50	1000, over 1 h
Iron carboxymaltose	50	750–1000, over 15 min infusion
Iron derisomaltose	100	Up to 20/kg, rapid infusion
Ferumoxytol	30	510, rapid infusion

[a]The content of *elemental* iron in sulfates, gluconate, and fumarate varies from 10 to 33% (e.g., an iron sulfate tablet contains 100 mg of *elemental* iron in 325 mg of the total salt).

[b]Sucrosomial iron consists of ferric pyrophosphate conveyed by a phospholipid and sucrester matrix.

PREVENTION

Prevention is fundamental in low- to middle-income countries where iron-deficiency anemia is common due to the combination of malnutrition and increased blood loss by helminth infections. In this setting, prevention of iron deficiency at the population level employing food fortification or oral iron administration must take into account the infectious risk. Iron deficiency confers some protection from malaria in endemic areas, whereas iron supplementation may favor malaria progression by enhancing parasite trophism for reticulocytes that are increased during anemia recovery. In view of such bidirectional association, in malaria-endemic regions, the World Health Organization recommends iron supplementation only when concomitant strategies to prevent and treat malaria are implemented. Proposed preventive strategies for pregnancy to improve maternal and infant outcome are either routine prenatal supplementation or regular checking of hemoglobin/iron status and on-demand treatment. Frequent blood donors are another population at risk, considering that each unit of blood contains ~200 mg of iron. Prolonging the interdonation interval and monitoring ferritin levels are prevention measures, especially in female donors, who may eventually require iron supplementation. Iron deficiency in patients undergoing major surgery predisposes to anemia due to blood loss during the procedure and the frequent diagnostic testing. Preoperative screening and treatment of iron deficiency is one pillar of patient blood management strategies that aim to reduce perioperative complications and length of hospital stay and save cost. Intravenous route is preferred if surgery is within 6 weeks from the diagnosis of iron deficiency.

ANEMIA OF INFLAMMATION

Anemia of chronic diseases indicates the multifactorial anemia observed in a heterogeneous group of disorders, including infections, autoimmunity, malignancies, and inflammatory bowel diseases, that share mechanisms of immune activation and cytokine production. Similar mechanisms account for the anemia that develops in acute conditions such as sepsis, severe trauma, and after major surgery so that the broader term *anemia of inflammation* is now preferred. This type of anemia spans the whole spectrum of clinical inflammatory disorders, from hyperacute, exemplified by macrophage activation syndrome, to subclinical, as in CHF, diabetes, and obesity.

PATHOPHYSIOLOGY

At least three cytokine-driven mechanisms account for the diminished red cell production in inflammation (Fig. 102-3). Increased hepcidin levels, mainly induced by IL-6, cause macrophage iron sequestration and restrict iron reutilization. Erythropoietin (EPO) production is suppressed by IL-1β and tumor necrosis factor α (TNF-α). Response of erythroid progenitors to EPO is blunted by interferon-γ (IFN-γ)

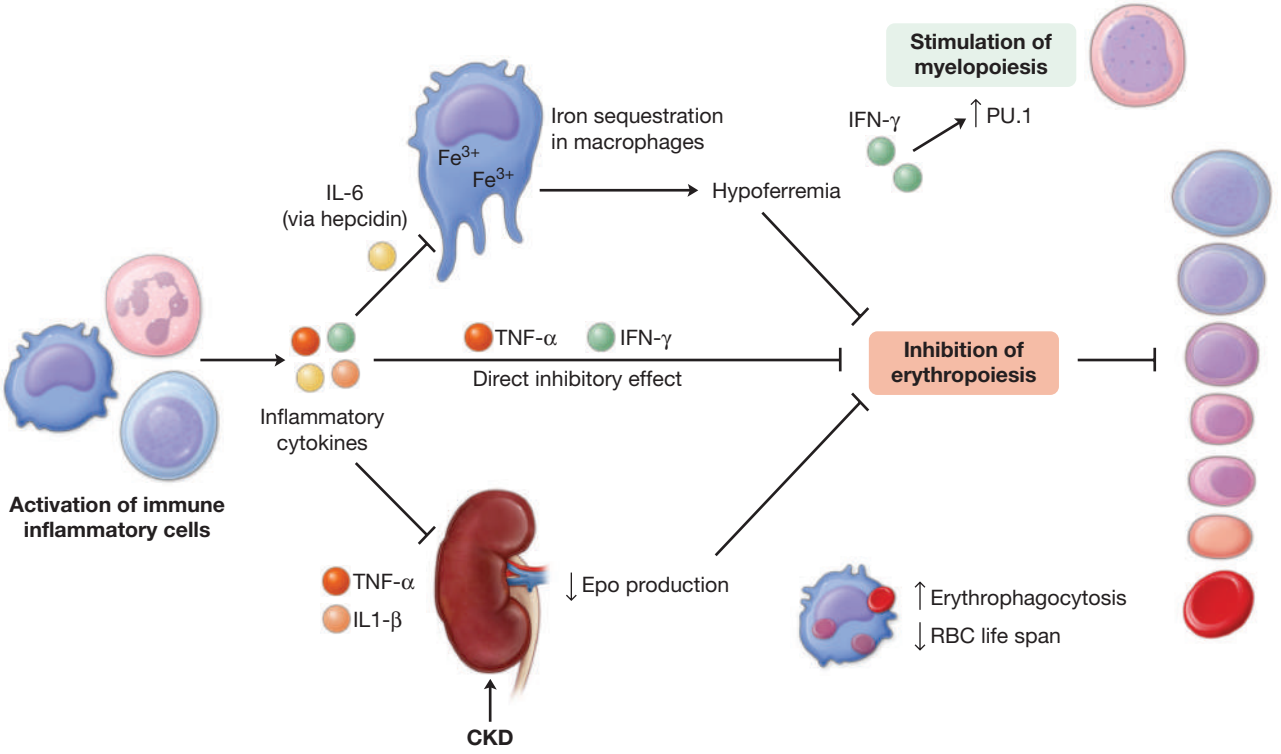

FIGURE 102-3 Pathophysiology of anemia of inflammation. Activation of immune cells leads to the production of inflammatory cytokines. IL-6 induces macrophage iron sequestration via hepcidin, tumor necrosis factor α (TNF-α) and interferon γ (IFN-γ) reduce erythropoietin (EPO) production and erythropoietic response; activation of PU.1 transcript induces myelopoiesis. Hemolysis of red cells phagocytosed by macrophages variably contribute to the pathophysiology of anemia, especially in acute inflammation.

and TNF-α. Moreover, bone marrow progenitor commitment is reprogrammed toward the myeloid lineage through increased activity of PU.1 and other transcription factors. In acute inflammation, immature white blood cells may be released to the circulation, the so-called "emergency myelopoiesis," as observed in severe COVID-19. A mild decrease of erythrocyte life span contributes to anemia. Iron sequestration in stores and hypoferremia are central to anemia of inflammation, emphasizing that it is a disorder of iron distribution. The contribution of the other mechanisms varies in different conditions. EPO deficiency is key in CKD. Massive red cell destruction is the main driver of anemia only in hyperinflammation, such as Still's disease and hemophagocytic lymphohistiocytosis. Mechanistically, hepcidin hyperexpression and hypoferremia are part of the innate immune response, aimed at depriving iron from and blocking the growth of the invading pathogens. However, in the long term and in noninfectious disorders, hypoferremia becomes a maladaptive response that leads to anemia.

CLINICAL FINDINGS AND DIAGNOSIS

Anemia of inflammation is mild to moderate, normocytic, and normochromic with low reticulocyte count. It can become microcytic when longstanding, due to iron-restricted erythropoiesis. It can be asymptomatic or contribute to disease burden, worsening the prognosis, as in CHF and CKD. A biochemical hallmark of inflammation is hyperferritinemia (Table 102-3). Ferritin, especially its heavy chain, is an acute phase reactant; thus, it cannot be used as an iron marker in inflammation. The combination of hypoferremia and hyperferritinemia in inflammatory disorders defines "functional" iron deficiency, indicating insufficient erythroid iron notwithstanding the presence of adequate stores. The boundaries between absolute and functional iron deficiency are not unequivocal, as shown by inflammatory bowel diseases, colon cancer, CKD, and CHF. Detecting true iron deficiency in these settings is challenging as both a universal definition and biomarkers are lacking. Ferritin <100 μg/L is the most accepted diagnostic threshold. In CHF and CKD, absolute iron deficiency is also defined by transferrin saturation <20%, irrespective of ferritin levels. A proposed diagnostic tool is the soluble transferrin receptor (sTfR)/log ferritin ratio (Table 102-3). The clinical usefulness of other laboratory parameters needs confirmation.

In CKD, anemia commonly develops when >50% of kidney function is lost and progresses in parallel with the reduction of glomerular filtration rate. It is a negative prognostic factor, predisposing to cardiovascular complications, hospitalization, and mortality. EPO deficiency, systemic inflammation, and negative iron balance are key contributors to the complex pathophysiology of anemia in CKD. Impaired iron absorption, chronic bleeding due to platelet dysfunction, and blood loss in the dialysis apparatus are causes of absolute iron deficiency, whereas increased production and decreased clearance of hepcidin result in functional iron deficiency. Deficiency of folate and vitamin B_{12} and a hemolytic component in uremic patients may contribute to anemia.

In CHF patients, the prevalence of anemia and iron deficiency is reported to be as high as 50–60% with negative prognostic impact. Besides mild inflammation, mechanisms include malnutrition, reduced iron absorption, and blood loss caused by the use of antithrombotic drugs. Current guidelines recommend periodic screening for iron deficiency in CHF patients. Supplementing intravenous iron may improve symptoms and quality of life, although influence on mortality is not proven.

Anemia is common in cancer, especially in hematologic malignancies such as myelodysplasia and multiple myeloma. It is multifactorial as it may be associated with iron and vitamin deficiency, blood loss, and chemotherapy side effects. Moderate to severe anemia is frequent in critically ill patients and is associated with unfavorable outcomes such as prolonged hospitalization and even mortality. Nearly 50% of patients admitted to an intensive care unit (ICU) have a hemoglobin level <9 g/dL, and most discharged survivors have persistent anemia. Anemia in ICU reflects anemia of inflammation, with the addition of blood losses due to blood sampling (up to 40 mL/d) for laboratory monitoring.

A mild anemia is common in elite endurance athletes, especially females. It is multifactorial and due to reduced iron absorption, iron losses, and increased hepcidin caused by both mild inflammation and indirect activation of the hepatic SMAD pathway by lactic acid.

TREATMENT

Treatment of the underlying disorder controls anemia of inflammation, as shown by the effect of anti-IL-6 agents in Castleman's disease and rheumatoid arthritis. Standard treatment of anemia in CKD is based on ESAs **(Chap. 322)** with a target hemoglobin established at <11.5 g/dL to avoid cardiovascular complications. Since iron deficiency leads to ESA hyporesponsiveness, iron supplementation is usually required, mostly parenterally, because in advanced CKD high hepcidin levels prevent iron absorption. Intravenous iron is administered at high or refracted doses, ideally to maintain transferrin saturation at 30–40% and ferritin between 200 and 700 μg/L. Iron supplementation may lower the dose of ESA required to maintain the hemoglobin target. An oral alternative to intravenous iron is ferric citrate, which, binding intestinal phosphate, provides iron while reducing phosphate levels. Prolyl hydroxylase inhibitors that stabilize HIF-2α have been approved in some countries with the aim of replacing with a single oral drug both ESA and iron, since HIF upregulates EPO production as well as duodenal iron absorption. Although these novel antianemic drugs are efficacious, safety concerns still exist for their long-term use.

Intravenous iron can be used in cancer-related anemia to reduce the need of transfusions, especially with ferritin <100 μg/L and before elective surgery. ESAs are used in low-risk myelodysplastic syndromes and in patients receiving chemotherapy notably when cancer is deemed uncurable. Intravenous iron supplementation is currently recommended in CHF patients with either ferritin <100 μg/L or transferrin saturation <20% with ferritin of 100–300 μg/L. Nonetheless, there is still some uncertainty as to whether this represents the best definition of iron deficiency in CHF. Novel drugs targeting the hepcidin-ferroportin axis to counteract iron maldistribution are under investigation.

Blood transfusions remain the therapeutic option for severe anemia in the ICU, with guidelines increasingly recommending restrictive hemoglobin thresholds (7–8 g/dL) for hemodynamically stable patients. Intravenous iron is proposed to minimize the use of transfusions, with some studies reporting improved clinical outcomes, although the risk of infections and hypophosphatemia are of concern in these fragile patients.

ANEMIA OF AGING

Prevalence of anemia in the elderly is ~10% at the age of 65 years, 25% in people >85 years, and 50% in those affected by multimorbidity, hospitalized, or institutionalized. Anemia is typically mild (hemoglobin 11–12 g/dL) and multifactorial, and its impact is frequently underestimated. Mounting evidence strengthens its negative influence on quality of life, muscle weakness, and the risk of falls and fractures, as well as its independent association with mortality. The adverse effects of anemia are seen in black patients at hemoglobin levels ~1 g/dL lower than in white patients.

Approximately one-third of the cases are estimated to be due to nutritional causes, especially iron deficiency; one-third are due to inflammation, including CKD; and one-third remain without a detectable origin and are defined "unexplained anemia of aging." Age-related decline in testosterone levels in males, stem cell exhaustion, and EPO reduction might contribute. Absolute iron deficiency is common, due to poor dietary iron intake, impaired absorption by chronic gastritis, or the use of proton pump inhibitors and blood losses. A gastrointestinal malignancy should always be ruled out in anemic elderly patients, but chronic bleeding may also result from nonmalignant intestinal lesions such as angiodysplasias and the use of antithrombotic drugs for common disorders such as atrial fibrillation. A recent study has shown that 100 mg of daily aspirin given for primary cardiovascular prevention in elderly subjects was associated with a 20% higher risk of anemia and iron deficiency as compared to placebo. The proposed ferritin cutoff for iron deficiency (45–70 μg/L) is higher than in younger patients. Treatment of iron deficiency may mitigate the negative prognostic implications of anemia.

Functional iron deficiency due to overt or subclinical inflammation often contributes, complicating the laboratory diagnosis. Traditionally "bone marrow senescence," now known as clonal hematopoiesis of indeterminate potential (CHIP), is present in >10% of otherwise-healthy individuals aged 70 years and increases sharply to >60% in the eighties. CHIP is associated with a chronic low-grade inflammatory status that worsens anemia and cardiovascular risk. Patients should be followed up for the risk of developing myelodysplastic syndromes **(Chap. 107)**. The unexplained anemia of aging is usually characterized by an EPO level that is lower than expected for the degree of anemia. EPO can increase the hemoglobin level, but it is unclear whether that change has an influence on the hospitalization, frailty, and mortality risks associated with the anemia.

103 Disorders of Hemoglobin

Vijay G. Sankaran, Martin H. Steinberg

Hemoglobinopathies result from changes in the amino acid sequence of globin; in thalassemia, synthesis of normal globin is insufficient. Together the disorders of hemoglobin compose the most common Mendelian genetic diseases. In addition, they are responsible for most instances of hemolytic anemia. Sickle cell disease and the hemoglobin E (HbE)–associated syndromes are the most prevalent hemoglobinopathies; β and α thalassemia are the most prevalent thalassemias. In addition to these common disorders of hemoglobin, rare globin mutations cause hemoglobin instability, cause increased or decreased affinity of hemoglobin for oxygen (O_2), and allow spontaneous oxidation of hemoglobin, reducing its O_2 transport. O_2 transport can also be reduced by exposure to carbon monoxide (CO) and extrinsic oxidizing agents **(Table 103-1)**.

HEMOGLOBIN

Easy access to erythrocytes to study hemoglobin structure and function, reticulocytes to examine hemoglobin biosynthesis, and leukocyte DNA to define the mutations of hemoglobin, with the availability of hematopoietic stem and progenitor cells from blood and bone marrow, has placed hemoglobin disorders in the forefront of molecular medicine. The biology of hemoglobin provides the background for understanding the pathophysiology of its many genetic and acquired disorders and approaches to their treatment.

TABLE 103-1 Disorders of Hemoglobin

I. **Hemoglobinopathies**—hemoglobin variants with amino acid sequence variants that alter the physical, chemical, or functional properties of hemoglobin
- A. Common variants with unusual properties
  1. HbS—polymerization
  2. HbE—reduced biosynthesis
  3. HbC—hemoglobin-membrane interaction
- B. Altered oxygen affinity
  1. High affinity—erythrocytosis
  2. Low affinity—cyanosis, anemia
- C. Hemoglobins that oxidize readily
  1. Unstable hemoglobins—hemolytic anemia, jaundice
  2. M hemoglobins—methemoglobinemia, cyanosis

II. **Thalassemias**—defective biosynthesis of globin chains
- A. α Thalassemias
- B. β Thalassemias
- C. Complex thalassemias

III. **Hereditary persistence of fetal hemoglobin**—persistence of higher than normal levels of HbF into adult life
- A. Deletions within the *HBB* cluster—15–30% HbF in heterozygotes, pancellular HbF
- B. Point mutations in *HBG2/1* promoters—5–30% HbF in heterozygotes; pancellular or heterocellular HbF

IV. **Acquired hemoglobinopathies**
- A. Methemoglobin due to toxic exposures
- B. Sulfhemoglobin due to toxic exposures
- C. Carboxyhemoglobin
- D. HbH in erythroleukemia
- E. Elevated HbF in myelodysplasia

DEVELOPMENTAL BIOLOGY

Successive waves of erythropoiesis direct the synthesis of different hemoglobin molecules that result from sequential activation and silencing of globin genes **(Fig. 103-1)**. Hemoglobin is a tetramer of two pairs of unlike globin polypeptide chains, each containing a tetrapyrrole heme group. O_2 binds to heme as erythrocytes traverse the lungs and is released in the tissues. Heme is nestled within a protective pocket of each globin subunit.

GLOBIN GENE CLUSTERS

Globin is encoded in two nonallelic gene clusters. The β-globin gene cluster is on chromosome 11; the α-globin gene cluster is on chromosome 16 (Fig. 103-1). Tetramers of α-like and β-like globins form embryonic, fetal, and adult hemoglobins. Fetal hemoglobin (HbF, $\alpha_2\gamma_2$) production begins at 6–8 weeks' gestation, peaks during mid-gestation, then falls to <1% of total hemoglobin during the first 6 months of extrauterine life. Adult hemoglobin A (HbA, $\alpha_2\beta_2$) production follows a pattern reciprocal to that of HbF. The hemoglobin composition of normal adults is >95% HbA, ~1% HbF, and 2–3% HbA_2 ($\alpha 2\delta 2$). HbF and HbA_2 are not functionally important in normal adults because of their low concentrations. Measuring their levels can provide helpful diagnostic clues for thalassemia and some hemoglobinopathies. Hemoglobin is subject to posttranslational modifications. Most important clinically is the nonenzymatic glycosylation of HbA forming the adduct HbA_{1c}, which is useful in the management of diabetes mellitus.

HEMOGLOBIN STRUCTURE

All globin polypeptides have similar but not identical primary structures. α-Globins contain 141 amino acids, and β-like globins have 146 amino acids. This primary structure dictates, according to the constraints of protein folding, the secondary structure of globin into α-helical sections joined by small nonhelical stretches. Each globin chain folds into a tertiary conformation known as the globin fold, whereby charged amino acid residues face the exterior of the molecules while uncharged residues face the hydrophobic interior. The iron-containing tetrapyrrole heme moiety is protected from oxidation and located between two of the helical segments; O_2 loading and unloading occur when heme iron is in its reduced ferrous form. Globin gene mutations affecting critical heme-binding amino acid residues allow iron to be oxidized, forming methemoglobin, which has high O_2 affinity and does not release O_2 in tissues. Dimers of α- and non-α-globin chains reversibly assemble into the tetrameric quaternary structure.

HEMOGLOBIN FUNCTION

Hemoglobin transports O_2 from lungs to tissues and carbon dioxide (CO_2) from tissues to lungs. As a nitrate reductase, it releases nitric oxide (NO) from nitrite to promote vasodilation. Oxygen binding is defined by the hemoglobin-O_2 dissociation curve. P_{50} is a point on this sigmoidal curve that indicates the partial pressure of O_2 where hemoglobin is half saturated **(Fig. 103-2)**. Normal P_{50} is ~26 mmHg; low P_{50} indicates that hemoglobin has high O_2 affinity, decreasing O_2 delivery

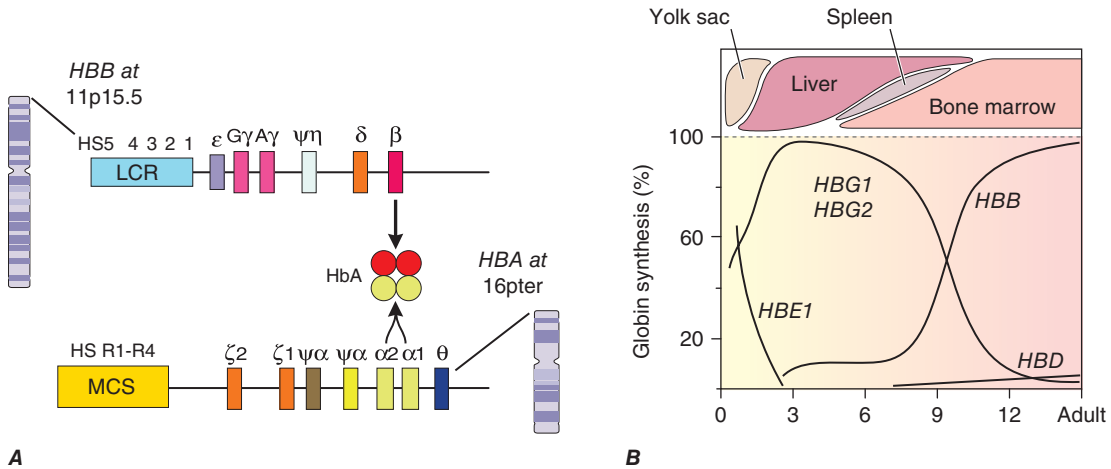

FIGURE 103-1 Globin gene clusters and their hemoglobin products during gestation. ***A.*** The order of globin genes in the β- and α-globin gene clusters along with their upstream enhancers, the β-globin locus control region (LCR) and α-globin multispecies conserved sequences (MCS), which contain critical regulatory elements. Normal hemoglobin tetramers contain two α-globin chains and two non-α-globin chains. In the example shown, this is adult HbA. The β-globin gene cluster contains an embryonic ε-globin gene (*HBE*), two nearly identical fetal γ-globin genes (*HBG2, HBG1*), a major adult β-globin gene (*HBB*), and a minor adult δ-globin gene (*HBD*). The α-globin gene cluster contains an embryonic ζ-globin gene (*HBZ*) and duplicated α-globin genes (*HBA2, HBA1*) coding for identical proteins. Embryonic hemoglobins include Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), Portland I ($\zeta_2\gamma_2$), and Portland II ($\zeta_2\beta_2$). Fetal hemoglobin (HbF, $\alpha_2\gamma_2$) production begins at 6–8 weeks' gestation, peaks during mid-gestation, then falls to <1% of total hemoglobin during the first 6 months of extrauterine life. ***B.*** Sites of erythropoiesis and globin synthesized from the yolk sac and the early embryo (months 1–3), the fetus (months 3–9), after delivery (months 9–12), and afterward (adult).

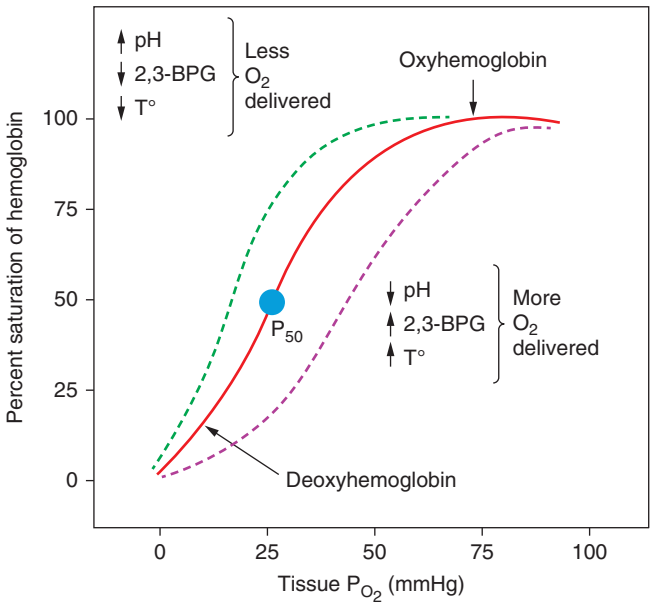

FIGURE 103-2 Hemoglobin-oxygen dissociation curve. The P_{50} is influenced by the binding of 2,3-bisphosphoglycerate (2,3-BPG), a product of glycolysis, in the central cavity of hemoglobin, pH, and temperature. The hemoglobin tetramer can bind up to four molecules of oxygen (O_2) in the iron-containing sites of the heme molecules. As O_2 is bound, 2,3-BPG and carbon dioxide (CO_2) are expelled. Salt bridges are broken, and each of the globin molecules changes its conformation to facilitate O_2 binding. O_2 release to the tissues is the reverse process, with salt bridges being formed and 2,3-BPG and CO_2 bound. Deoxyhemoglobin does not bind O_2 efficiently until the cell returns to conditions of higher pH, the most important modulator of O_2 affinity (Bohr effect). When acid is produced in the tissues, the dissociation curve shifts to the right, facilitating O_2 release and CO_2 binding. Alkalosis has the opposite effect, reducing O_2 delivery.

to tissues; high P_{50} indicates that hemoglobin has low O_2 affinity, releasing more O_2 to tissues. The conformation of hemoglobin fully saturated with O_2 is known as the R or relaxed state; desaturated hemoglobin is in the T or tense state. The transition between T and R states occurs when two or three O_2 molecules are bound. Cooperativity describes the progressively more rapid binding of O_2 once the first molecule is bound. Hemoglobin variants that decrease P_{50} are characterized by isolated erythrocytosis as compensation for hypoxia; variants with increased P_{50} sometimes are accompanied by cyanosis and anemia as hemoglobin becomes unsaturated and O_2 delivery is enhanced. Mutations of residues critical for heme binding, R-T transitions, or tetramer stability cause hemoglobinopathies characterized by hemolytic anemia, methemoglobinemia, erythrocytosis and cyanosis.

GLOBIN GENE SWITCHING

The sequential activation and inactivation of globin genes during development is called "hemoglobin switching." Transcription factors along with epigenetic elements, such as DNA and histone methyltransferases and demethylases, interact with enhancers "upstream" of the gene clusters that contact globin gene promoters, silencing the embryonic and fetal genes. Developmental factors such as RNA-binding factors and microRNAs also impact hemoglobin switching.

β-Globin Gene Switching HbF reactivation by drugs and gene therapy is a prime therapeutic goal for treating sickle cell disease and β thalassemia, meriting a discussion of the controls of HbF gene silencing. An upstream enhancer called the β-globin locus control region (LCR) binds erythroid-specific and ubiquitous transcription factors. The LCR interacts directly with globin gene promoters; transcription factors that silence and activate genes also interact with elements of the globin genes. Competition among the β-like genes for the LCR and autonomous silencing of the embryonic and fetal globin genes depends on transcription factors. Silencing, first of the embryonic gene *HBE* and then of the two fetal genes, *HBG2* and *HBG1*, favors the interaction of the LCR with *HBB* allowing its expression (Fig. 103-1). The transcription factors BCL11A (2p16) and ZBTB7A (19p13) are the major repressors of HbF gene expression. BCL11A, a zinc finger protein that represses HbF genes, binds TGACCA motifs, the most important at position −115 in the promoter of each γ-globin gene. ZBTB7A binds 85 nucleotides upstream of these BCL11A binding sites. Mutations in these binding sites abolish the normal silencing of the HbF genes, leading to one type of the benign condition called hereditary persistence of fetal hemoglobin (HPFH). When binding of either BCL11A or ZBTB7A is disrupted, *HBG2* and *HBG1* are derepressed. *BCL11A* single nucleotide variants (SNVs) are common and are thought to underlie a large portion of the interindividual variation in HbF levels. Disruption of the *BCL11A* regulatory elements or the promotor binding sites for BCL11A and other repressive factors by gene editing in patient hematopoietic stem cells using CRISPR/Cas leads to 30–50% HbF with possible "cure" of sickle cell disease and β thalassemia, with the former strategy receiving U.S. Food and Drug Administration (FDA) approval for both conditions.

α-Globin Gene Switching A less complex switch takes place in the α-globin gene cluster. A regulatory locus of four elements termed R1–R4 is present within introns of the gene *NPRL3* that is upstream of *HBA2*. R1–R4 are critical for α-globin gene expression, as demonstrated by natural deletions causing thalassemia. A developmental switch from embryonic ζ- to adult α-globin gene expression occurs at about 6 weeks' gestation.

Modulation of HbF Level and Haplotypes of the β-Globin Gene Cluster Variations in three quantitative trait loci (QTL), *BCL11A*, *MYB* (6q23), and a locus linked to the *HBB* cluster (11p15), are associated with HbF variation among normal individuals and patients with sickle cell anemia and β thalassemia. The *MYB* gene is essential for hematopoiesis and erythroid differentiation. *MYB* inhibits HbF expression directly by activation of *KLF1* and other repressors and indirectly through alteration of the kinetics of erythroid differentiation. The third QTL is marked by a common variant 158 nucleotides upstream of the transcription start site of *HBG2*. Five common haplotypes associated with the *HBB* cluster have been defined by its SNVs. Sickle cell anemia patients with the Senegal and Arab-Indian HbS gene-associated haplotypes have the common −158 C-T variant in the *HBG2* promoter. They have higher HbF levels than patients with Benin, Bantu, and Cameroon haplotypes. When young, they might have a milder clinical course.

GENERAL ASPECTS OF HEMOGLOBIN DIAGNOSIS

α-Globin gene mutations are expressed in the embryo and fetus and persist throughout life; HbF mutations are expressed in the fetus and in the first months of life, vanishing from notice afterward; δ-globin gene mutations are innocuous and usually not detected; β-globin gene mutations can become clinically apparent after the synthesis of HbF dwindles to stable adult levels.

With rare exceptions, all disorders of hemoglobin are autosomal recessive or co-dominant disorders; a family history, usually of anemia, a common feature of most symptomatic hemoglobinopathies and thalassemias, is often present. In addition to pallor and jaundice, splenomegaly is often present. A small number of laboratory tests can confirm the diagnosis starting with a complete blood count that includes a reticulocyte count with a careful review of a peripheral blood film. A sustained increase in reticulocyte count indicates the presence of hemolytic anemia. Hemoglobin fractionation by high-performance liquid chromatography (HPLC) or capillary electrophoresis, especially when, in addition to the index case, family members are available for study, is often sufficient to confirm a diagnosis at the level of hemoglobin phenotype. DNA sequencing of the globin genes allows definitive diagnosis; available from excellent reference laboratories, it is a prerequisite for genetic counseling.

Sickle cell disease and β thalassemia are chronic hemolytic anemias sharing hemolysis-related complications like venous thrombosis, leg ulcers, and pulmonary hypertension. Differences are that only deoxyHbS polymerizes, while ineffective erythropoiesis is the key

pathophysiologic feature of β thalassemia. Both diseases are "cured" by successful allogeneic hematopoietic stem cell transplantation and gene therapy as discussed below.

SICKLE CELL DISEASE

Sickle cell disease is a clinical and hematologic phenotype caused by an assortment of genotypes (Table 103-2). Sickle cell anemia, defined as homozygosity for the sickle hemoglobin mutation ($\alpha_2\beta^S_2$; glutamic acid [E] 7 valine [V] *GAG-GTG*), is the most common of these genotypes, followed by HbSC disease or compound heterozygosity for HbS and HbC ($\alpha_2\beta^C_2$; E 7 lysine [K] *GAG-AAG*) genes. Many different thalassemia mutations contribute to the HbS-β thalassemias. Compound heterozygous genotypes are less common than HbS homozygotes. HbS has been described in compound heterozygotes with many other variant hemoglobins. Few of these genotypes, other than $HbSO^{Arab}$, HbSE, and $HbSD^{Punjab}$ are symptomatic.

ORIGIN, SPREAD, AND EPIDEMIOLOGY

HbS originated in Africa between 7000 and 22,000 years ago, reaching high frequencies because of the increased genetic fitness of heterozygotes under selective pressure from *Plasmodium falciparum*. HbS gene haplotypes have a loose association with the severity of disease because each haplotype has a different average level of HbF. In some regions of Africa, India, and the Middle East, nearly half the population have sickle cell trait. Nigeria alone has ~150,000 newborns each year with sickle cell anemia, about one-third of the world's total newborns; most die before age 5. Coerced and free population movement has spread the HbS gene throughout the world. The HbS carrier, or sickle cell trait, prevalence is 2–15% in emigrant populations; ~100,000 patients in the United States have sickle cell disease. In the United States, death in childhood is rare; the median age of death in patients with sickle cell anemia is in the fifth or sixth decade.

PATHOPHYSIOLOGY

Pathophysiologic features of sickle cell disease are summarized in Fig. 103-3. HbS is physiologically like HbA in most respects except it polymerizes when deoxygenated. Contacts between one of the β^7 valine residues of deoxyHbS and specific amino acid residues of β- and α-globin culminate in fascicles of hemoglobin that injure the sickle erythrocyte. A delay occurs between the initiation of polymerization and the accumulation of sufficient polymer to damage the cell. It is unclear how much polymer is needed for cell injury, but polymer leads directly and indirectly to the multiple abnormalities of the sickle erythrocyte that generate the pathophysiology of disease. Prominent among these abnormalities are HbS polymer penetration of the membrane causing vesiculation with membrane microparticle release; increased activity of the Gardos, K/CL cotransport, and P_{sickle} channels that dehydrate the cell, increasing mean corpuscular sickle hemoglobin concentration (MC[HbS]C), reducing cellular deformability, and increasing the polymerization potential of HbS; translocation of amino phospholipids such as phosphatidylserine to the outer leaflet of the membrane; and oxidation of erythrocyte contents. These and other abnormalities lead to the formation of irreversibly sickled cells (ISCs), which are sickle erythrocytes that are forever deformed because of permanent membrane damage regardless of whether HbS remains polymerized. Damaged sickle erythrocytes are responsible for initiating the vasoocclusive, hemolytic, and inflammatory features of the disease shown in Fig. 103-3.

DIAGNOSIS

Although sickle cell disease can appear in any ethnic group, most often it is present in people of African, Middle Eastern, Mediterranean, and Indian descent. The chief presenting symptom is pain. This might be an arthritis-like hand-foot syndrome in young children or the typical acute painful episode in older children and adults. In HbSC disease and HbS-β^+ thalassemia, acute vasoocclusive episodes occur at about half the rate as in sickle cell anemia while complications develop later; rarely, patients with these genotypes are asymptomatic. The key elements of laboratory diagnosis are outlined in Table 103-2 showing typical hematologic findings and hemoglobin fractions. Figure 103-4 displays HPLC profiles and blood films in typical patients with sickle cell trait, sickle cell anemia, and HbSC disease. Clinical and basic laboratory diagnosis is sufficient for general management and counseling; genetic counseling and family planning usually require DNA-based diagnosis.

TABLE 103-2 Common Sickle Hemoglobinopathies

GENOTYPE	CLINICAL ABNORMALITIES	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV, fL	HEMOGLOBIN FRACTIONS (%)
Sickle cell trait (HbAS)	8% of African Americans; hematuria, papillary necrosis, hyposthenuria, increased incidence of chronic kidney disease; 2–4 times increased VTE risk;? stroke; splenic infarction at altitude; rhabdomyolysis	Normal	HbA: 60–70 HbS: 30–40 Percent HbS dependent on presence or absence of α thalassemia
Sickle cell anemia (HbSS)	Vasoocclusion related: pain, acute chest syndrome, osteonecrosis, splenic infarction Hemolysis related: stroke, pulmonary and systemic vasculopathy, nephropathy, leg ulceration gallstones, priapism	70–100 (7–10)/80–100	HbS: >75 HbF: 2–25 HbA_2: 3–4
HbS-β^0 thalassemia	Rate of complications similar to HbSS	80–100 (8–11)/60–85	HbS: >75 HbF: 2–15 HbA_2: 5–6
HbS-β^+ thalassemia	Rate of complications about half the rate of HbSS depending on percent HbA	100–140 (10–14)/70–80	HbS: 60–90 HbA: 5–40 HbF: 1–10 HbA_2: 5–6
Hemoglobin SC disease (HbSC)	Nearly asymptomatic to disease as severe as HbSS; about half the rate of complications as HbSS. Increased risk of retinopathy	100–140 (10–14)/70–100	HbS: 50 HbC: 50
HbSE	Resembles clinically HbS-β^+ thalassemia; symptoms delayed; often Asian/Indian ancestry	90–130 (9–13)/65–75	HbS: 65 HbE: 35 HbF: 1–5
HbSS-α thalassemia	Present in 30% of HbSS; phenocopies HbS-β^0 thalassemia because of microcytosis and high HbA_2; like HbSS but with fewer strokes and leg ulcers and less pulmonary vascular and renal disease	80–100 (8–11)/60–85	HbS: >75 HbF: 2–15 HbA_2: 4–5

Note: Laboratory values are averages in untreated adults.

Abbreviation: VTE, venous thromboembolism.

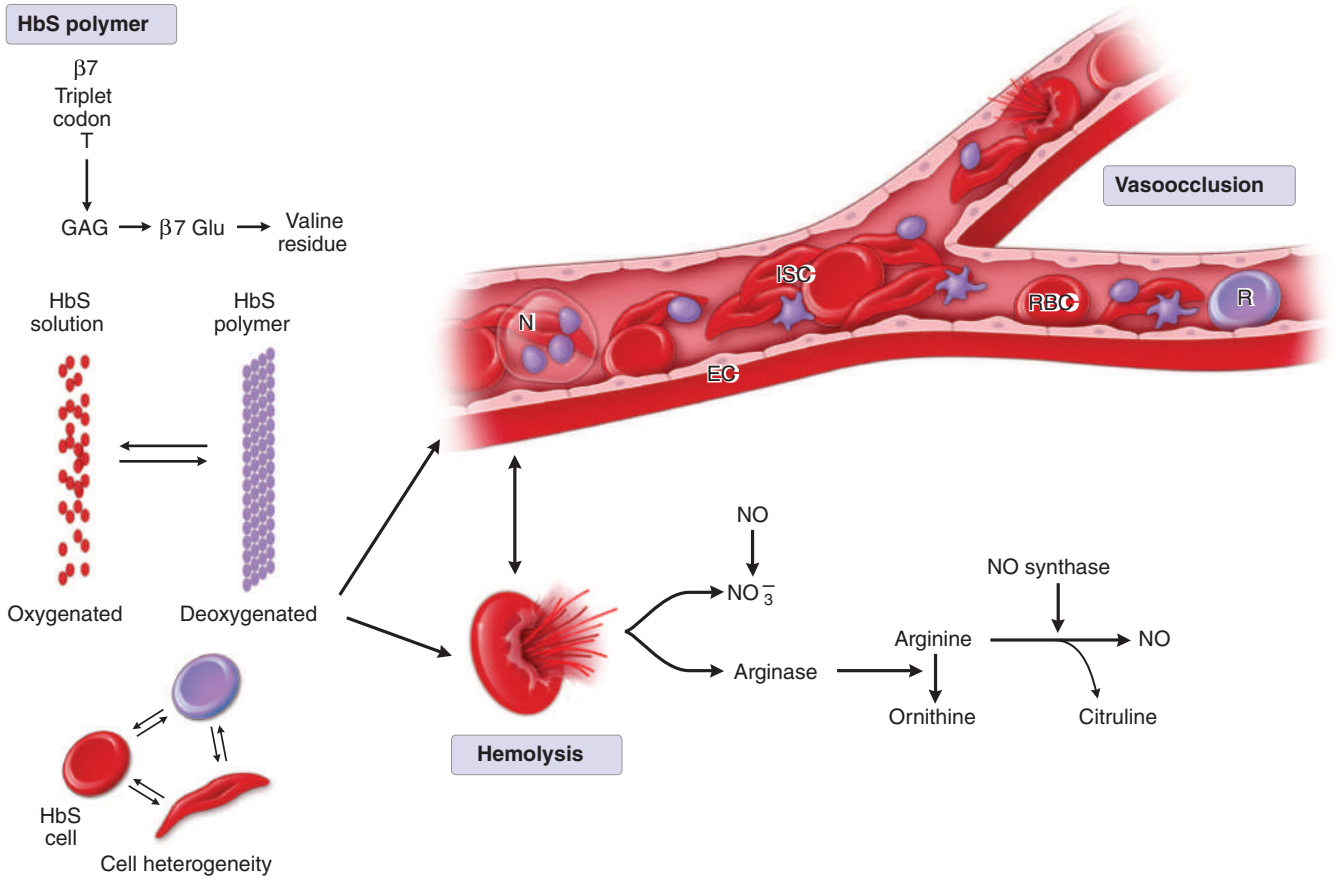

FIGURE 103-3 Pathophysiology of sickle cell disease. HbS is in solution when oxygenated but reversibly polymerizes when deoxygenated. Polymerization is dependent on the 30th power of hemoglobin concentration. In the sickle cell, this means that small changes in hemoglobin concentration or cell hydration can have large effects on polymerization. Polymerization begins seconds to minutes following deoxygenation. Erythrocyte deformation, or sickling, is initially reversible, but after an undetermined number of cell sickling events, the cell becomes irreversibly deformed. These are known as irreversibly sickled cells (ISCs). Their membrane is permanently damaged, although depending on their oxygen (O_2) content, HbS could be in solution. Sickle erythrocytes lead to the clinical and laboratory phenotypes of disease. Sickle cells interact with endothelial cells and other blood cells, occluding flow in small and sometimes large vessels and causing the many complications thought to be a result of vasoocclusion. Sickle cells also live <20 days (normal ~120 days) hemolyzing intra- and extravascularly. Intravascular hemolysis depletes haptoglobin and hemopexin while liberating heme, arginase, and other danger-associated molecular patterns (DAMPs) into the blood. This scavenges nitric oxide (NO), activates platelets and endothelium, reduces antioxidant activity, causes vasoconstriction, and is proinflammatory.

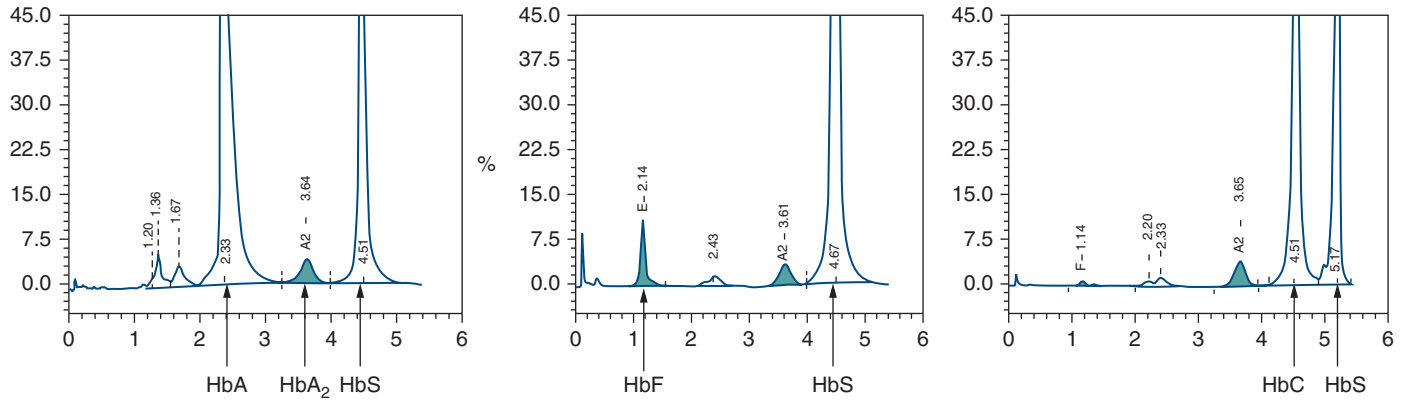

COMPLICATIONS

Complications of sickle cell disease can be grouped into those that likely are a consequence of the related entities of sickle vasoocclusion and those due to intravascular hemolysis (Fig. 103-3). Complications associated with vasoocclusion seem to respond best to induction of HbF. Some complications of disease are presented in Table 103-3.

Acute Painful Episodes Characterized by unprovoked severe pain in extremities or the torso that is often symmetrical and stereotypical for each patient and that usually requires treatment with strong opioids in the emergency department, acute painful episodes are the most common acute events in sickle cell disease. They are the chief cause of concern for patients, most of whom have them at some time in their life. Their frequency varies; most patients have one to two episodes a year; some rarely have them; others are hardly ever without them. Acute painful episodes last days to weeks. Pain in sickle cell disease can also be chronic from osteonecrosis, osteoporosis, or leg ulcers. Chronic and acute pain can overlap. Pain can also be induced by the opioids. Most of the time, patients have some degree of pain that does not reach the intensity of the acute episode. This can be treated with oral opioids dispensed monthly.

No diagnostic test can confirm or refute the presence of an acute pain episode whose cause is uncommonly identified. Physical examination is not often useful diagnostically. Some patients will have pain on pressure over an affected area, perhaps accompanied by swelling; mild fever is common. Often a 1–2 g/dL decrease in hemoglobin level and a modest increase in the leukocyte count are noted. The presence of ISCs and the reticulocyte count are of no diagnostic value. Drastic decreases in hemoglobin and platelet levels with more extreme leukocytosis can portend development of severe acute chest syndrome or multiorgan failure.

Some patients die suddenly shortly after admission for an acute painful episode. The cause of this sudden unexpected death is usually unknown; among the possibilities are arrhythmias and pulmonary embolism. Admitting patients to monitored beds or using continuous pulse oximetry for the first 48–72 h of hospitalization might prevent some of these deaths and help identify early acute chest syndrome that follows within 72 h in about a quarter of admissions for acute pain. After searching for possible precipitants such as infection or dehydration and treating these appropriately, the foundation of treatment is the proper dosing of opioid analgesics. By the time a patient presents at the emergency department or clinic requesting treatment, they have usually tried nonsteroidal anti-inflammatory drugs (NSAIDs) and oral opioids. In most patients, relief of pain requires intravenous opioids. Many patients are opioid tolerant, requiring higher than usual doses for satisfactory relief. Dosing should not be on an "as-needed" schedule; patient-controlled analgesia or frequent fixed doses of opioids with rescue doses for breakthrough pain are the preferred means of treatment, with frequent assessments to ensure pain relief without excessive sedation. Adjunctive treatment includes incentive spirometry to forestall pulmonary complications, maintaining hydration with half-normal saline with care not to overhydrate, prophylaxis for thromboembolism, and antihistamines and laxatives to counter expected side effects of opioids. Unless hypoxia is present, supplemental O_2 is unnecessary. NSAIDs have little value in patients receiving intravenous opioids.

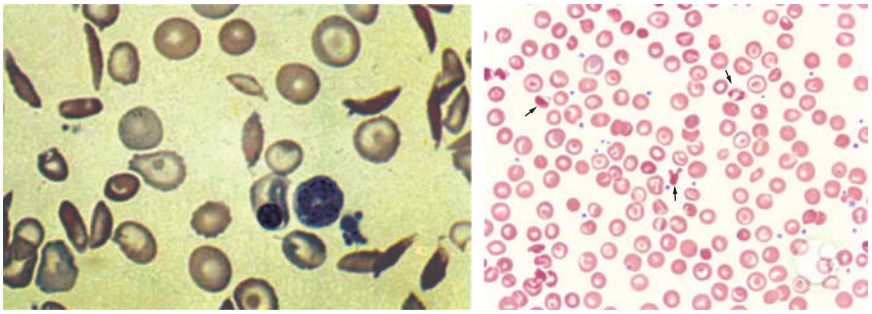

FIGURE 103-4 Diagnosis of sickle cell disease. ***A.*** From *left to right*, high-performance liquid chromatography separation in sickle cell trait, sickle cell anemia, and HbSC disease. Beneath each chromatogram, the individual protein peaks are identified. ***B.*** *Left:* Dense, elongated, and pointed cells are the irreversibly sickled cells characteristic of the sickle cell anemia and sickle cell-β^0 thalassemia. Target cells and nucleated red cells are also present. *Right:* Target cells, cells with squared ends of HbC crystals, cells folded like tacos, and contracted microspherocytes are typical of HbSC disease. *(Source: B [right]: Reproduced with permission from American Society of Hematology.)*

TABLE 103-3 Complications of Sickle Cell Disease

COMPLICATION	INCIDENCE, DIAGNOSIS, AND FEATURES	TREATMENT
Priapism	~30% of males; can be episodic and short duration (stuttering); severe episodes can cause impotence; associated with markers of hemolysis	Many therapies including α-adrenergic agonists, stilbesterol; consult urology for treatment, which is time-critical
Stroke and silent infarction	10–15% of all cases; infarction in early childhood into adulthood; hemorrhagic in adults; neurocognitive abnormalities in adults even without apparent stroke; associated with markers of hemolysis	Transcranial Doppler screening in children ages 2–16; transfusion for at-risk patients; hydroxyurea
Gallstones/surgery	~40% of patients; bilirubin levels and stones related to polymorphisms of *UGT1A*; in surgery requiring general anesthesia, simple preoperative transfusion to a hemoglobin of 10 g/dL is recommended	If asymptomatic, usually let be; otherwise, laparoscopic cholecystectomy
Hepatic disease	>80% of patients have hepatomegaly; intrahepatic cholestasis can have bilirubin ~100 mg/dL; viral hepatitis, iron overload, RBC sequestration, extrahepatic cholestasis also contribute	Exchange transfusion for intrahepatic cholestasis; transplant for end-stage liver failure
Nephropathy	~30% of adults age >30 years; hyperfiltration in children, renal failure in adults; early albuminuria, later nephrotic-range proteinuria; associated with markers of hemolysis	Screen for microalbuminuria by age 10 years; avoid NSAIDs; use ACE inhibitors or receptor antagonists for albuminuria; erythropoietin for symptomatic anemia; dialysis or transplant for renal failure
Lung/pulmonary hypertension	Restrictive disease; asthma common; 5–10% have pulmonary hypertension by right heart catheterization; 30% have increased TRV that portends poor prognosis; associated with markers of hemolysis	Consult expert pulmonologist; screen yearly by echocardiography measurement of TRV
Retinopathy	30% in HbSC disease, 3% in HbSS[a]; develops in peripheral retina; vitreous hemorrhage and retinal detachment can cause blindness	Screen annually starting at age 10 tears with fluorescein angiography; laser photocoagulation for proliferative disease
Acute anemic episodes	B19 parvovirus infection, folic acid deficiency, splenic sequestration, delayed hemolytic transfusion reaction with destruction of transfused and sometimes autologous red cells	RBC transfusion if symptomatic; splenectomy if more than 1 or 2 episodes of sequestration; anti-parvovirus IgM positive in acute infection, IgG in past infection
Multiorgan failure	Can accompany severe acute chest syndrome; often confused with sepsis and can coexist with sepsis; CNS liver, muscle, lung, kidney affected	Exchange transfusion, ICU support
Pregnancy	Screening both partners for hemoglobin disorders with risk counseling is critical component of family planning	All pregnancies are "high risk"; transfuse if sickle cell events increase, if previous miscarriage, multiple fetuses

[a]Sickle cell anemia (HbSS).

Abbreviations: ACE, angiotensin-converting enzyme; CNS, central nervous system; ICU, intensive care unit; NSAIDs, nonsteroidal anti-inflammatory drugs; RBC, red blood cell; TRV, tricuspid regurgitant jet velocity.

Acute Chest Syndrome This pneumonia-like illness is the second most frequent acute sickle cell–related event. It occurs in >50% of patients, often more than once. Acute chest syndrome can be mild, especially in children, in whom it can result from viral infection, or devastating, where multiple lobes of the lung are affected with severe hypoxia, multiorgan failure, and death. Chest pain, cough, fever, and hypoxia and a pulmonary infiltrate on chest x-ray are the major diagnostic criteria. The etiology includes in situ thrombosis, emboli, any type of infection, and postoperative hypoventilation. Management in adults is dictated by the severity of the episode and the need for supplemental oxygen. Patients who are hypoxic and febrile can be admitted directly to the intensive care unit. Antibiotics are almost always used in these patients even though a causative bacterium is not often cultured. Supplemental O_2 is given for an O_2 saturation <95%. Overhydration and excessive opioids can compound dyspnea and hypoxia. Hypoxic patients who are febrile with leukocytosis with more than a trivial infiltrate on x-ray are transfused. In the severely ill patient, exchange transfusion, if possible, is the preferred modality. However, if transfusion of the severely ill patient is indicated and hours are needed to arrange red cell exchange, simple or top-up transfusion should be started first. Simple transfusions also suffice for less severely affected patients. Most patients survive acute chest syndrome, but in the most severe cases, often caused by embolization of necrotic bone marrow, death can be rapid even with prompt and proper treatment. Thrombocytopenia, leukocyte counts >20,000/dL, and rapidly developing acute anemia often portend severe acute chest syndrome with its possibility of acute respiratory distress syndrome and multiorgan failure. Asthma is very common in patients with sickle cell disease. Some adults have chronic lung disease with reduced diffusing capacity for CO that could be a sequela of acute chest syndrome.

Osteonecrosis This painful and sometimes crippling complication that most often affects hips bilaterally occurs in about half of all patients with sickle cell anemia and is also common in HbSC disease; shoulders are less often affected. Beginning with chronic pain that can become severe, loss of function, especially in the hips, is often the final stage. Magnetic resonance imaging (MRI) can detect the earliest stages, whereas x-ray is less sensitive. Physical therapy and NSAIDs provide some initial relief; oral opioids are sometimes required. Joint replacement can restore lost mobility while relieving pain. Life span of prosthetic joints is finite, so surgery should be delayed as long as mobility is satisfactory and pain tolerable.

Leg Ulcers The incidence of leg ulcers is highly dependent on geography and hemoglobin genotype. They are far less common in HbSC disease and HbS-β^+ thalassemia than in sickle cell anemia and HbS-β^0 thalassemia. In temperate climates, 10–20% of patients are affected; tropical and subtropical areas have an incidence rate up to 75%; ulcers rarely occur in patients from the Middle East. Leg ulcers can be small and superficial or deep and encompass most of the lower leg. They can be extraordinarily painful. Long-standing, recurrent large ulcers are difficult to treat. Wet-to-dry dressings and Unna boots are reasonable choices for initial treatment.

SICKLE CELL TRAIT (CARRIERS, OR SIMPLE HETEROZYGOSITY FOR THE HBS GENE)

Carriers of sickle cell trait outnumber patients with the disease by 25 to 1. Although testing for sickle cell disease is part of most perinatal cord blood screening programs, counseling and follow-up of detected carriers are imperfect, so adolescents and adults can be unaware they carry sickle cell trait. Counseling carriers about the complications of sickle cell trait and their likelihood of having offspring with sickle cell disease is essential. Carriers should be counseled prior to participation in sports because of the risk, albeit small, of sudden death from heat-related exertional rhabdomyolysis. Optimal hydration before and during exercise can prevent most episodes of heat-related illness. Usually a benign condition with a normal life expectancy, some complications are shown in Table 103-2.

TREATMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

Patients should, if possible, be referred to a sickle cell center for initial consultation, institution of therapy, and follow-up. Cooperation among primary care providers, hematologists, and other specialists provides the best preventive care and management of complications. The frequency at which a patient is seen depends on their therapeutic regimen and complications.

Remarkable changes in the treatment landscape have occurred with the promise of even greater benefits from new curative approaches. The following discussion focuses on treatment to prevent the complications of disease.

Hydroxyurea Hydroxyurea is the standard of care for all patients with sickle cell anemia and HbS-β^0 thalassemia regardless of symptoms. Although in some symptomatic patients with HbSC disease, its benefits in this genotype are understudied. The major mechanism of action of hydroxyurea is to induce high levels of HbF. Hydroxyurea increases HbF unevenly among red cells (heterocellularly), so some cells have greater protection from HbS polymerization than others. When started in adults, where the average baseline HbF is ~5%, HbF increases to ~10%. Nevertheless, pain and acute chest syndrome are reduced by about half, hemoglobin concentration increases by ~1 g/dL, and after 17.5 years of follow-up, mortality was reduced by 49%. In contrast, all young children respond robustly to hydroxyurea. When started at <1 year of age at a dose of ~27 mg/kg, HbF levels were 33.3 ± 9.1% and hemoglobin concentration was 10.1 ± 1.3 g/dL. Acute events were markedly reduced with little toxicity. Based on these and other studies in high- and low-resource countries, unless there is a contraindication, hydroxyurea should be given to all infants with sickle cell anemia and HbS-β^0 thalassemia starting at 9 months of age at a dose of ~20 mg/kg and titrated to the maximal tolerated dose based on neutrophil and platelet counts.

Voxelotor Voxelotor increases the affinity of the hemoglobin molecule for O_2. At a dose of 1500 mg daily, hemoglobin concentration increased ~1 g/dL in 59% of patients with a reduction in the biomarkers of hemolysis. Its effects on acute vasoocclusive events are unclear. Many questions remain about the long-term effects of voxelotor. Less hemolysis reduces the propensity for stroke, nephropathy, pulmonary hypertension, leg ulcers, and priapism. Will voxelotor be accompanied by these long-term benefits? Could the high O_2 affinity of a modified hemoglobin be harmful for some patients? The answers to these important questions require further study.

Crizanlizumab Downstream effects of HbS polymerization include adhesive interactions among endothelial cells, leukocytes, platelets, and erythrocytes. P-selectin is one molecule involved in these interactions; blocking selectins prevents sickle cell–endothelial cell adhesion. Crizanlizumab, a P-selectin-blocking monoclonal antibody given intravenously every month, reduced acute painful episodes by ~45%. Hemolysis was unaffected. A follow-up trial failed to replicate the results of the rigorous study that led to FDA approval.

L-Glutamine The mechanism of action of this agent, presumed to be the reduction of oxidative stress in sickle erythrocytes, is unsettled. A phase 3 placebo-controlled trial showed that L-glutamine was associated with a 25% reduction in painful episodes and 33% reduction in hospitalization.

There is little consensus regarding how these recently approved drugs should be integrated into treatment with hydroxyurea. The effects of voxelotor and crizanlizumab appear to be additive to those of hydroxyurea. Voxelotor can be added to hydroxyurea if the benefits of hydroxyurea alone are insufficient, as they are in most adults. If both hydroxyurea and voxelotor are taken at effective doses and acute vasoocclusive complications continue, crizanlizumab might then be added. The dropout rates in the crizanlizumab and L-glutamine trials were ~35%, so adherence to these therapeutics could be problematic.

Transfusion Transfusions are overutilized and underutilized. Major indications for transfusion include severe symptomatic anemia; treatment and prevention of stroke; increasing hemoglobin level to ~10 g/dL before surgery requiring general anesthesia; and severe acute chest syndrome. Sometimes transfusions are given during pregnancy when there is a history of complications or fetal loss. Transfusions should usually be avoided in acute pain episodes and for repair of stable chronic anemia. Automated red cell exchange transfusion is preferred in acute stroke, severe acute chest syndrome, or multiorgan failure or when chronic transfusions are planned. Expert guidelines recommended extended red cell antigen profiling, if possible, before the first transfusion and antigen matching for Rh (C, E or C/c, E/e) and K antigens in addition to ABO/RhD. Complications of transfusion include hyperviscosity, alloimmunization (which occurred in 18.6% of patients transfused between 1979 and 1984 and 27.3% of patients transfused between 2001 and 2011), iron overload, and delayed hemolytic transfusion reactions with hyperhemolysis.

Stem Cell Transplantation Given the excellent results of human leukocyte antigen (HLA)–identical related donor transplants, which have an event-free survival of >95%, this option might be extended to all patients with a suitable donor. Unfortunately, only 15% of patients have a fully matched donor. New approaches to haploidentical transplants are improving event-free survival in these patients.

Gene Therapy Two forms of ex vivo gene therapy are approved for sickle cell disease. Both use mobilized autologous CD34+ stem cells and increase levels of a hemoglobin that inhibits HbS polymerization. In one approach, an HbA gene containing the β^{T87Q} mutation responsible for the antipolymerization effects of HbF is introduced into stem cells via a lentiviral vector. In the second, the major enhancer of the HbF repressor, *BCL11A*, is disrupted using CRISPR/Cas9 gene editing. In both approaches, following myeloablative conditioning, engineered cells are reinfused and engraft. Both treatments have resulted in near pancellular distribution of 30–50% HbF or HbA^{T87Q}, reduced hemolysis, and total hemoglobin concentrations of >12 g/dL, with nearly total prevention of acute vasoocclusive events. Long-term safety and cure rate will take many more years of follow-up to establish.

Preventive Measures and Screening Cord blood screening for sickle cell disease is done in many countries and all 50 states. Affected patients are then directed to clinics that can initiate early preventive care. In childhood, transcranial Doppler screening beginning at age 2 years and repeated annually until age 16 years, prophylactic penicillin (125 mg for children younger than 3 years; 250 mg for children 3 years and older) twice daily until age 5 years, and vaccination with pneumococcal vaccines are the main measures to prevent stroke and invasive pneumococcal infection. Folic acid, 1 mg daily, is given to prevent megaloblastic erythropoiesis; it is probably unnecessary in people with nutritious diets.

All women planning pregnancy should be screened for disorders of hemoglobin by blood counts, erythrocyte indices, and HPLC analysis of hemoglobin. Individuals with HbS or β thalassemia trait should have their partners tested. Only then is it possible to know the risks of a fetus having sickle cell disease (Table 103-2). Antenatal diagnosis using chorionic villus sampling or cell free DNA testing is widely available.

THALASSEMIA

Thalassemia is caused by reduced accumulation of either α- or β-globin chains causing a relative excess of the unaffected chain. Unbalanced globin synthesis is the hallmark of thalassemia and the proximate cause of its pathophysiology; unpaired globin chains damage the developing erythroblast. Like the HbS mutation and many other red cell traits, thalassemia reached polymorphic levels in tropical and subtropical populations because heterozygotes are protected from severe forms of *P. falciparum* infection. Estimates are that 1–5% of the world's population carries a thalassemia mutation; in some locales, most people have a thalassemia mutation. These mutations can affect any globin gene, but clinically, β and α thalassemia are the most important. With nearly 500 unique thalassemia-causing mutations (*www.globin.bx.psu.edu*) that can interact with each other and with hemoglobinopathies, thalassemia syndromes are remarkably diverse. Where resources permit and the mutation is known, genetic counseling can be provided and antenatal diagnosis is possible.

HbE (β^{27} glu-lys) is a common variant whose biosynthesis is reduced because the site of the mutation alters its mRNA processing. Its reduced biosynthesis leads to a deficit of β^{E}-globin chains and features of β thalassemia. Hemoglobin Constant Spring is caused by a mutation of the termination codon of *HBA2* that leads to the synthesis of an elongated α-globin chain that is unstable and suboptimally synthesized. This variant therefore behaves as an α thalassemia variant.

β THALASSEMIA

EPIDEMIOLOGY

Once known as Mediterranean anemia, because of the concentration of cases in Italy, Greece, and other countries bordering the Mediterranean Sea, or as Cooley's anemia after the physician first describing cases, β thalassemia is common in most areas of the world where malaria was endemic, including the Mediterranean region, Asia, and the Middle East. Effective programs of screening, counseling, and antenatal diagnosis have reduced the birth of new cases in a number of regions. About 40,000 β thalassemia patients are born yearly. In the United States, there are ~1000 cases of severe β thalassemia.

CLASSIFICATION

β^0 Thalassemia mutations totally prevent the accumulation of any globin from the affected gene; β^+ thalassemia mutations cause minor or moderate reductions in β-globin synthesis. β Thalassemia major and β thalassemia intermedia are now categorized as transfusion-dependent and non-transfusion-dependent based on the number and frequency of transfusions required to sustain a good quality of life.

Pathophysiology Single nucleotide changes are the most common β thalassemia mutations, but gene deletions also occur. A partial listing of the classes of mutations causing β thalassemia include mutations in the promoter elements affecting gene transcription causing mild and sometimes silent β^+ thalassemia; mutations in the junctions between exons and introns that affect mRNA processing causing β^0 and β^+ thalassemia; introduction of alternative splice sites into introns or exons usually causing β^+ thalassemia; 3′ end-processing sequence mutations preventing RNA polyadenylation leading to mild or silent β^+ thalassemia; mutations preventing initiation of translation causing β^0 thalassemia; and introduction of stop codons that prematurely terminate translation (nonsense mutations) producing reading frameshifts and resulting in truncated globin mRNA and β^0 thalassemia. In addition, rare causes of β thalassemia have been identified that are unlinked from the β globin locus and caused by mutations in general transcription regulators, such as SUPT5H and TFIIH, or erythroid transcription factors like GATA1.

In β thalassemia, the deficit in β-globin chain synthesis allows α-globin chains to accumulate in excess. Without a non-α-globin chain partner in dimer and tetramer formation, unpaired α-globin chains are unstable, cannot form a tetramer, and precipitate within the developing erythroblast, causing membrane lipid oxidation and damage. The predominant cause of anemia is intramedullary destruction of erythroid precursors, known as ineffective erythropoiesis. Reduced deformability and phosphatidyl serine exposure also cause extra- and intravascular hemolysis of those erythrocytes that gain entrance into the circulation. In poorly treated β thalassemia, severe anemia leads to bone marrow expansion; hepatosplenomegaly; iron accumulation in liver, heart, and endocrine organs; pulmonary hypertension; and thromboembolic disease.

Frightening pictures of children with severe β thalassemia permeate the literature. These examples of near-terminal disease should be relegated to history because treatment with transfusion and iron chelation can prevent their occurrence, hematopoietic stem cell transplantation can "cure" patients who have suitable donors, and efficacious gene therapies are now approved.

DIAGNOSIS

Heterozygous β thalassemia, also known as β thalassemia trait and β thalassemia minor, has mild or no anemia but microcytic/hypochromic erythrocytes with minimal or no increase in reticulocyte count. After recognizing these hematologic abnormalities and excluding iron deficiency, finding an elevated level of HbA_2 and perhaps HbF by HPLC is sufficient to establish this diagnosis. The hematologic characteristics of this heterozygous carrier state are listed in **Table 103-4**. Sometimes, the spleen is enlarged. Before genetic counseling and antenatal diagnosis are considered after carrier identification by red cell indices and quantitation of HbA_2, the thalassemia-causing mutation should be identified. Sequencing is the key to preventing homozygotes or compound heterozygotes with transfusion-dependent thalassemia.

The more severe forms of β thalassemia are hemolytic anemias with hypochromia, microcytosis, reticulocytosis, marked anisocytosis, and poikilocytosis with variable numbers of circulating nucleated red cells **(Fig. 103-5)**.

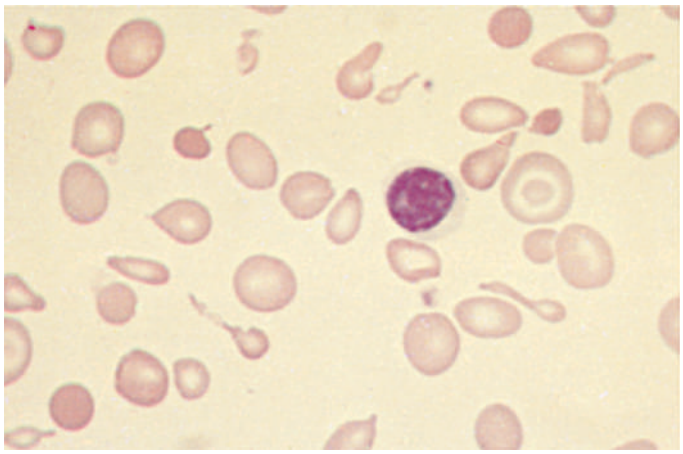

FIGURE 103-5 α Thalassemia intermedia. Target cells and marked variation in cell size and shape but with general hypochromia and microcytosis characterize the blood film. A lymphocyte is shown for size comparison.

COMPLICATIONS

Complications of severe β thalassemia are many. They are a consequence of chronic hemolytic anemia, chronic transfusion, and iron loading. Increased iron absorption is especially common in non-transfusion-dependent thalassemia. Most complications, listed in **Table 103-5**, develop because of either inadequate blood transfusion and/or poor iron chelation and iron loading. Even when chelation is optimized, some complications attributable to iron toxicity will develop. Many complications have complex and multifactorial etiologies. Iron stores are estimated by serum ferritin levels; MRI is the most widespread means of noninvasively measuring iron accumulation in liver and heart.

MANAGEMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

Heterozygote screening and counseling couples at risk for affected fetuses, with antenatal diagnosis, if needed, is an effective preventive approach. Severe thalassemia should be dealt with in specialized centers where these and other services are available and managed by a team led by a hematologist experienced with this disease with help from endocrinologists, cardiologists, transfusion medicine specialists, and social services.

Transfusion and Iron Chelation Transfusion every 2–4 weeks with a goal pretransfusion hemoglobin concentration of 9–10.5 g/dL to suppress ineffective erythropoiesis, coupled with iron chelation to prevent the accumulation of excess toxic iron that accompanies transfusion, has prevented the development of cardiomyopathy and endocrinopathies while extending life to at least 50 years. When to begin transfusions, whether partial exchange transfusion is preferable to simple transfusion, and the choice of blood product require consultation with experts. To be effective, transfusions and iron chelation must be started early, be uninterrupted, and continue lifelong. Older patients who did not have the advantage of effective chelation are more likely to develop multiple disease-related morbidities such as osteoporosis, endocrinopathies, liver disease, and renal failure. Two orally effective chelating agents, deferasirox and deferiprone, and one intravenous chelator, deferoxamine, are available.

Improving Ineffective Erythropoiesis Luspatercept is a fusion protein containing the extracellular domain of human activin type IIB receptor and the Fc domain of human IgG. By binding transforming growth factor β superfamily ligands and reducing Smad2/3 signaling, luspatercept enhances late-stage erythropoiesis. Given subcutaneously, 1 mg/kg every 3 weeks, it was associated with a 33% reduction in transfusion requirements.

TABLE 103-4 β Thalassemias

CLASSIFICATION	HEMOGLOBIN (g/dL)/MCV (fL)	HEMOGLOBIN FRACTIONS (%)	CLINICAL FEATURES
β-Thalassemia trait	100–140 (10–14)/60–80	HbA: 94 HbF:1–2 HbA_2: 4–6	Heterozygosity for β^+ or β^0 thalassemia mutations; "silent" carriers can have normal HbA_2 and red cell indices.
Non-transfusion-dependent β thalassemia (thalassemia intermedia)	70–120 (7–12)/65–80	HbA: 60–90 HbF: 10–40 HbA_2: 4–6	Defined by infrequent or no transfusion requirement; caused by many different genotypes including homozygosity for "mild" β^+ mutations, combinations of β and α thalassemia, homozygous β thalassemia with high HbF-producing capacity, and many others. Iron loading, thromboembolic disease, and pulmonary hypertension are major clinical events.
Transfusion-dependent β thalassemia (Thalassemia major)	20–40 (2–4)/50–80	HbA: 0–5 HbF: 90–100 HbA_2: 2–5	Caused by many different genotypes including homozygosity and compound heterozygosity for β^0 and β^+ mutations, combinations of β and α thalassemia; transplantation curative; iron chelation required.
HbE-β thalassemia	50–80 (5–8)/60–70	HbE: 50–70 HbF: 30–50	Common in Southeast Asian populations; in some parts of the world, the most prevalent severe thalassemia; in HbE-β^0 thalassemia, only HbE and HbF are found; in HbE-β^+ thalassemia, HbA is present. Transfusion dependence depends in part on the thalassemia mutation.
δβ Thalassemia and Hb Lepore	110–120 (11–12)/65–75	HbA: 70 HbF: 7–13 HbA_2: 2	Rare; deletions removing the δ- and β-globin genes cause δβ thalassemia; Lepore hemoglobins are fusion globin chains; values are for heterozygotes; homozygotes have 100% HbF with hemoglobin 10–11 g/dL.
Gene deletion hereditary persistence of fetal hemoglobin (HPFH)	120–140 (12–14)/75–85	HbA: 70 HbF: 15–30 HbA_2: 2	Rare; large deletions removing the δ- and β-globin genes; values are for heterozygotes; homozygotes, who are asymptomatic, have 100% HbF without anemia.

Note: Laboratory results are averages in adults.

TABLE 103-5 Complications of β Thalassemia

COMPLICATION	INCIDENCE, DIAGNOSIS, AND FEATURES
Growth retardation	Most often a feature of delayed or inadequate transfusions but can occur in well-transfused children.
Delayed puberty; secondary amenorrhea	50% and 25%, respectively.
Splenomegaly	Can trap 1–40% of red blood cell volume; increases plasma volume, worsening heart failure. Splenectomy indicated when transfusion requirement to maintain ideal hemoglobin increases. Prophylactic penicillin after splenectomy.
Heart	Due to chronic anemia, heightened sensitivity to iron toxicity, thromboembolic pulmonary hypertension, other causes. Progresses through stages to congestive failure and arrhythmias. Assessed by T2* on magnetic resonance imaging (MRI). The available chelating agents might have differential effects on different measure of cardiac function and can be used in combination.
Leg ulcers	Common in thalassemia intermedia.
Hepatic disease	Fibrosis progressing to cirrhosis is related to hepatic iron concentration that can be monitored by MRI. Hepatitis also plays a role.
Lung disease/ pulmonary hypertension	Fibrosis, chronic thromboembolic disease, restrictive pathophysiology, intravascular hemolysis, and reduced nitric oxide bioavailability.
Thromboembolism	Multifactorial etiology, including platelet activation, red cell–endothelial interactions, thrombocytosis, endothelial activation, splenectomy.
Endocrinopathies	Diabetes, hypothyroidism, hypoparathyroidism, adrenal insufficiency; hypogonadism; hypothalamic-pituitary axis might be especially sensitive to iron.
Bone disease	Caused by bone marrow expansion, severe iron loading, hypogonadism; osteoporosis in ~50% of patients, even those well treated. Extramedullary hematopoietic masses are a feature of thalassemia intermedia.
Infections	Transfusion associated; linked to iron overload (*Yersinia*); malaria.

Hematopoietic Stem Cell Transplantation There is consensus that patients with available donors should be offered transplantation because of the difficulty of lifelong transfusion and chelation and its imperfect efficacy. Quality of life in successfully transplanted patients exceeds that in patients treated with transfusion and chelation. Transplantation from matched sibling donors is curative in >80% of all cases. Unfortunately, only a third of patients have matched donors. The best results are in the youngest patients who have been effectively chelated and received fewer transfusions. Graft failure, graft rejection, graft-versus-host disease, and a mortality of 5–20% depending on risk factors are the major drawbacks of this procedure. Results of haploidentical and unrelated donor transplants are improving but lag those of matched sibling donors.

Gene Therapy The same gene therapy approaches approved for sickle cell disease are approved for transfusion-dependent β thalassemia (see Sickle Cell Disease). CRISPR/Cas editing to downregulate *BCL11A* has resulted in increases in total hemoglobin ≥12 g/dL and HbF ≥10 g/dL, leading to transfusion independence in >90% of 52 patients aged between 12 and 35 years with transfusion-dependent β thalassemia. Results of lentiviral-mediated HbA^{T87Q} additive gene therapy were best with non-β^0/β^0 genotypes, although some individuals with β^0/β^0 genotypes could be effectively treated as higher viral titers were used in subsequent gene therapy protocols.

α THALASSEMIA

In some respects, the obverse of β thalassemia, clinically consequential α thalassemia is less common than severe β thalassemia. α Thalassemia is most often found in Asian populations and is usually caused by deletion of α-globin genes rather than point mutations.

EPIDEMIOLOGY

Carriers of the most common α thalassemia chromosomes **(Table 103-6)** are found in 5–80% of people from tropical and subtropical regions of Africa, the Middle East, Asia, and Melanesia. About 30% of African Americans carry the common $-\alpha^{3.7}$ chromosome that contains a single functional α-globin gene. HbH disease, the chief clinically important α thalassemia, is most prevalent in southern China and Southeast Asia. Estimates are that in Thailand ~3500 patients with severe α thalassemia are born yearly. Pregnancies affected by hemoglobin (Hb) Bart's hydrops fetalis occur mainly in southern China and southeastern Asia.

CLASSIFICATION

Each normal chromosome 16 contains two α-globin genes; normal diploid individuals have four α-globin genes. A classification of inherited α thalassemia, as summarized in Table 103-6, is based on the number of functional α-globin genes. If one or two α-globin genes are missing or poorly expressed, these people have α thalassemia

TABLE 103-6 α Thalassemias

CLASSIFICATION	α-GLOBIN GENE ARRANGEMENT	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV (fL)	CLINICAL FEATURES
α-Thalassemia trait	$-\alpha/\alpha\alpha$ $-\alpha/-\alpha$ $--/\alpha\alpha$ $\alpha^T\alpha/\alpha\alpha$	120–150 (12–15)/65–80	The chromosome with one deleted α gene (—α/) is called α^+ thalassemia (α thalassemia-2); the chromosome with both deleted α genes is α^0 thalassemia (α thalassemia-1); non–gene deletion α thalassemias (α^T) often have a more severe phenotype.
Hemoglobin H disease	$--/-\alpha$ $\alpha^T\alpha/--$ $\alpha^T\alpha/\alpha^T\alpha$	50–120 (5–12)/60–70	Mild to moderate anemia depending on genotype; non–gene deletion forms of α thalassemia can produce severe HbH disease.
Hb Bart's hydrops fetalis	−−/−−		Fatal in utero or at birth with rare survivors. Hydrops can also result from combinations of gene deletion and non–gene deletion α thalassemia.
α Thalassemia/intellectual disability syndromes (ATR-16) (ATR-X)	$--/\alpha\alpha$ or $--/-\alpha$ in ATR-16 $\alpha\alpha/\alpha\alpha$ in ATR-X		ATR-16: Large deletions and rearrangements in chr16p. ATR-X: No α-globin gene deletion or mutation, *ATRX* mutations, X-linked.
α Thalassemia with myelodysplasia (ATMDS)	$\alpha\alpha/\alpha\alpha$		Mutations in *ATRX*; striking male predominance. Hematologic findings of HbH disease.

Note: Laboratory values are averages in adults. αα/denotes the chromosome with two intact α-globin genes; −α/chromosome with one α-globin gene deleted; −−/chromosome with both α-globin genes deleted; α^T represents non–gene deletion α thalassemia caused by point mutations. The −α/chromosome, referred to as α^+ or α thalassemia-2, most often has a deletion of 3.7 kb of DNA ($-\alpha^{3.7}$) or 4.2 kb of DNA ($-\alpha^{4.2}$) that leaves a single α-globin gene intact. The chromosome where both α-globin genes are deleted (−−/) is called α^0 thalassemia or α thalassemia-1. These chromosomes are caused by different-sized deletions that are usually named after their regions of highest frequency such as -SEA, -MED, -FI, and -THAI.

trait. Their hematologic abnormalities are almost always trivial. HbH disease is usually caused by deletion or malfunction of three α-globin genes. Hb Bart's hydrops fetalis fetuses have no normally functioning α-globin genes. Hundreds of different-sized deletions and rarer point mutations affect the production of α-globin and the magnitude of imbalanced globin synthesis. Because of this mutational complexity, many different variations of the common α thalassemia syndromes are found.

PATHOPHYSIOLOGY

Reduced accumulation of α-globin leaves non-α-globins unpaired and unable to participate in the formation of functional hemoglobin tetramers. In the fetus, absent or reduced synthesis of α-globin allows unpaired γ-globin chains, part of the HbF tetramer, to form γ_4 or Hb Bart's; in adults, when γ-globin synthesis is mostly silenced, unpaired β-globin chains, lacking a suitable partner to form HbA, tetramerize as β_4 or HbH. Both Hb Bart's and HbH have very high O_2 affinity and do not unload O_2 in tissues; HbH is also unstable. Severe anemia in Hb Bart's hydrops fetalis is a result of absent normal hemoglobin and ineffective erythropoiesis; in HbH disease, unstable HbH leads to oxidative membrane damage with extravascular hemolysis in the spleen and ineffective erythropoiesis.

DIAGNOSIS

Microcytosis/hypochromia with nearly normal hemoglobin concentrations, in the absence of iron deficiency and the increased level of HbA_2 that is diagnostic of β thalassemia, is sufficient for a presumptive diagnosis of α thalassemia trait. When genetic counseling is needed and antenatal diagnosis contemplated, the molecular basis of the presumed α thalassemia is required. HbH disease, which is usually due to compound heterozygosity for one chromosome with both α-globin genes deleted and one chromosome with only a single α-globin gene, is defined by the hematologic findings shown in Table 103-6 along with varying levels of reticulocytosis. At birth, when hemoglobin is separated by HPLC, 20–30% Hb Bart's is present; in adults, traces to 40% HbH are present along with residual Hb Bart's in some cases. HbH inclusions can be induced in some red cells after incubation and staining with brilliant cresyl blue. Hemoglobin composition in Hb Bart's hydrops fetalis is predominantly Hb Bart's with some Hb Portland if the deletion removing α-globin genes preserves the ζ-globin gene.

COMPLICATIONS

HbH disease is very heterogeneous because of the different combinations of genotypes that can cause this phenotype. Generally, when non–gene deletion mutants, such as Hb Constant Spring, contribute to the genotype, the disease is more severe, and intermittent or regular transfusions are necessary. In the most common – –/–α genotype, mean hemoglobin in adults is ~11 g/dL. Hepatosplenomegaly, jaundice, thalassemic bone changes in the face, and growth impairment are seen in 20–50% of cases, depending on the underlying genotype. Iron loading occurs but is not the severe problem it is in β thalassemia. Pregnancy in these patients should be considered high risk and managed accordingly. Mothers of infants with Hb Bart's hydrops fetalis have a history of stillbirth and develop preeclampsia, polyhydramnios, and antepartum hemorrhage and have difficult labor and delivery. Intrauterine transfusion of the fetus is possible.

MANAGEMENT, SCREENING, COUNSELING, AND ANTENATAL DIAGNOSIS

When planning families, couples from regions where α thalassemia is common who have red cell indices that suggest the possibility of carrying an α thalassemia gene should have genetic counseling based on DNA analysis of their globin genes. Iron should be avoided in non-iron-deficient individuals with α thalassemia trait and microcytosis. Transfusions are not usually needed in HbH disease. Nevertheless, depending on the genotype of disease, transfusions might be necessary especially when anemia becomes more severe, for example, with acute anemic episodes or pregnancy. Iron stores should be checked periodically by measuring serum ferritin or MRI; chelation does not appear to be needed.

Hb Bart's hydrops fetalis is best prevented by screening couples at risk and antenatal diagnosis. Intrauterine therapy and perinatal intensive care have permitted survival of some infants with Hb Bart's hydrops fetalis. As growth retardation affects ~40% and neurodevelopmental delay is present in 20% of survivors, prevention is the best approach.

OTHER HEMOGLOBINOPATHIES OF CLINICAL IMPORTANCE (TABLE 103-7)

More than 1500 mutations affecting hemoglobin structure have been described (*www.globin.bx.psu.edu*). Most are clinically silent. HbC and HbE are common. HbC is found in people of African descent and HbE in South China and Southeast Asia. Heterozygotes for HbC and HbE are unaffected clinically. Even individuals homozygous for these mutations, where the variant hemoglobin comprises >90% of the hemolysate, are clinically well with very mild anemia and microcytosis. The major importance of these variants is the interaction of HbC with HbS and HbE with β thalassemia, as outlined in Tables 103-2 and 103-4. A definitive diagnosis for all rare variants depends on DNA analysis.

TABLE 103-7 HbC, HbE, and Rare Hemoglobinopathies

CLASSIFICATION	CLINICAL ABNORMALITIES	HEMOGLOBIN LEVEL, g/L (g/dL)/MCV, fL	HEMOGLOBIN FRACTIONS (%)
HbC trait	2% of African Americans; target cells; no disease	Normal	HbC: 30–40 HbA_2: 2–3
HbC disease	Target cells; HbC crystals; mild reticulocytosis; splenomegaly	100–130 (10–13)/60–70	HbC: >95 HbF: 2–4 HbA_2: 2–3
HbE trait	50% incidence in some Asian populations; a few target cells; clinically normal	120–140 (12–14)/80–90	HbE: 27–31 HbF: 1 HbA_2: 3
HbE disease	No hemolysis; 20–80% target cells; no splenomegaly	100–120 (10–12)/65–75	HbE: 85–95 HbF: 3–7 HbA_2: 3
High O_2 affinity hemoglobins	Isolated erythrocytosis; often familial; no splenomegaly; no $JAK2^{V617F}$ mutation	150–200 (15–20)	Variants in α- and β-globin genes; patients are heterozygotes; ~25–50% variant
Low O_2 affinity hemoglobins	Asymptomatic mild anemia; cyanosis	100–140 (10–14)	~50% variant
Unstable hemoglobins	Pigmenturia; hemolysis; reticulocytosis; splenomegaly	90–140 (9–14)/70–90	20–35% variant; rare hyperunstable variants can be undetectable and have the phenotype of thalassemia
M hemoglobins	Some have mild hemolysis; few symptoms	100–140 (10–14)/80–90	20–50% variant depending on gene affected

Note: Laboratory values are averages in adults. As noted for HbAS, the amount of HbC and HbE in heterozygotes depends on the number of α-globin genes.

Unexpected low O_2 saturation by pulse oximetry (SpO_2) with normal O_2 saturation of arterial blood is occasionally seen in rare hemoglobin variants with clinical phenotypes. Asymptomatic patients with unexpectedly low SpO_2 should not be subjected to unneeded cardiopulmonary investigations in search of the cause of their "hypoxemia" until the existence of a hemoglobin variant is excluded.

M HEMOGLOBINS

M (met) hemoglobins are characterized by oxidation of the heme-iron from its ferrous (Fe^{++}) to ferric (Fe^{+++}) form. The major clinical feature of these disorders is asymptomatic cyanosis. Thirteen M hemoglobin variants have been described. In nine, the mutation involves histidine residues that interact with heme. Asymptomatic slate gray/brownish pseudocyanosis is the main clinical finding. Spectrophotometric recording of the visible spectrum of the hemolysate is diagnostic. To distinguish M hemoglobins from methemoglobinemia due to drugs or cytochrome b5 reductase (*CYB5R3*) deficiency, potassium cyanide (KCN) can be added to the hemolysate; methemoglobin-containing blood will turn red, but KCN has no effect on M hemoglobin. Treatment is not needed.

UNSTABLE HEMOGLOBINS

Sometimes referred to as congenital Heinz body hemolytic anemias, some mutations result in a hemoglobin tetramer that is unstable and precipitates intracellularly. One-hundred-fifty-six such variants have been described and are often a result of a new mutation that affects the tertiary or quaternary structure of the molecule. The most common class of mutations introduce a proline residue in the α helix or a polar amino acid into the interion of the molecule. Heinz bodies are intraerythrocytic precipitates that are detectable as dark globular aggregates after staining with a dye such as brilliant cresyl blue. Three unstable hemoglobins are the most common. Hemoglobin Köln (β^{99} val-met) has been found in multiple families, Hb Hasharon (α^{47} asp-his) is found in Ashkenazi Jews, and Hb Zurich (β^{63} his-arg) is susceptible to oxidant drug-induced hemolysis. Unstable variants present with nonspherocytic hemolytic anemia, but presentation is highly variable. The associated disease is usually mild and does not require transfusion. Heating blood to 50°C or incubation with isopropanol precipitates unstable hemoglobins but must be done with careful controls. Some variants can be detected by HPLC.

HEMOGLOBINS WITH HIGH OXYGEN AFFINITY AND LOW OXYGEN AFFINITY

Rare mutations in areas involved in the R-T transition, at critical interfaces between globin chains of the tetramer that reduce the affinity for 2,3-bisphosphoglycerate, or present in the heme pocket account for most of these variants. High O_2 affinity hemoglobins (103) outnumber low O_2 affinity variants (48). Isolated erythrocytosis in the absence of splenomegaly suggests the presence of a high O_2 affinity hemoglobin. High O_2 affinity hemoglobin variants shift the hemoglobin-O_2 dissociation curve leftward, causing a low P_{50} and thereby stimulating erythropoiesis. Many of these variants are due to new mutations. The clinical course is benign, and phlebotomy because of erythrocytosis is usually not required. Early diagnosis is important to forestall unnecessary diagnostic procedures and therapeutics such as cardiac catheterization to exclude congenital heart disease or treatment for polycythemia vera. Low O_2 affinity variants often present with cyanosis. Their hemoglobin-O_2 dissociation curve is right-shifted with high P_{50}. HPLC might reveal the presence of a hemoglobin variant. Treatment is often not necessary.

ACQUIRED DISORDERS OF HEMOGLOBIN

CO binds hemoglobin with high affinity forming carboxyhemoglobin. Carboxyhemoglobin levels can be accurately measured by co-oximetry of arterial blood. Standard pulse oximeters cannot accurately make this measurement. Some newly developed pulse oximeters can measure both carboxyhemoglobin and methemoglobin. Bound CO inhibits the transport of O_2; the hemoglobin-O_2 binding curve is left-shifted. Acute and chronic CO intoxication, caused by occupational exposure and other sources of incomplete combustion of hydrocarbons, presents with headache, altered mental status, and other constitutional symptoms. High-flow O_2 via facemask is the preferred treatment; criteria have been developed to guide the use of hyperbaric O_2.

Acquired methemoglobinemia and methemoglobinemia due to deficiency of *CYB5R3* are more common than the M hemoglobins. *CYB5R3* is required for the reduction of methemoglobin by NADH. Affected individuals with "toxic" methemoglobinemia can be cyanotic and symptomatic. As in carboxyhemoglobinemia, O_2 transport is reduced and reflected by the left shift in the hemoglobin-O_2 binding curve. *CYB5R3* deficiency usually affects only erythrocytes (type I), causing a mild disorder; when all cells are affected (type II), a severe disease results. Intravenous methylene blue is the preferred treatment in symptomatic patients with acquired methemoglobinemia and 40–60% methemoglobin. The usual dose is 1–2 mg/kg. Alternative treatment with ascorbic acid is preferable in people who are glucose-6-phosphate dehydrogenase deficient. Methylene blue interferes with co-oximetry, reducing the value of co-oximetry for monitoring treatment.

Many drugs and chemicals can induce methemoglobin in the absence of *CYB5R3* deficiency. Dapsone and topical anesthetics such as benzocaine are the most common offending agents.

104 Megaloblastic Anemias

A. Victor Hoffbrand

The megaloblastic anemias are a group of disorders characterized by the presence of distinctive morphologic appearances of the developing red cells in the bone marrow. The marrow is usually hypercellular, and the anemia is based on ineffective erythropoiesis. The cause is usually a deficiency of either cobalamin (vitamin B_{12}) or folate, but megaloblastic anemia may occur because of genetic or acquired abnormalities that affect the metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate **(Table 104-1)**.

COBALAMIN

Cobalamin (vitamin B_{12}) exists in a number of different chemical forms. All have a cobalt atom at the center of a corrin ring. In nature, the vitamin is mainly in the 2-deoxyadenosyl (ado) form, which is located in mitochondria. It is the cofactor for the enzyme L-methylmalonyl

TABLE 104-1 Causes of Megaloblastic Anemia

Cobalamin deficiency or abnormalities of cobalamin metabolism **(see Tables 104-3, 104-4)**
Folate deficiency or abnormalities of folate metabolism **(see Table 104-5)**
Therapy with antifolate drugs (e.g., methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
Some cases of acute myeloid leukemia, myelodysplasia
Therapy with drugs interfering with synthesis of DNA (e.g., cytosine arabinoside, hydroxyurea, 6-mercaptopurine, azidothymidine [AZT])
Orotic aciduria (responds to uridine)
Thiamine-responsive

coenzyme A (CoA) mutase. The other major natural cobalamin is methylcobalamin, the form in human plasma and in cell cytoplasm. It is the cofactor for methionine synthase. Minor amounts of hydroxocobalamin are also present to which methyl- and ado-cobalamin are converted rapidly by exposure to light.

DIETARY SOURCES AND REQUIREMENTS

Cobalamin is synthesized solely by microorganisms. Ruminants obtain cobalamin from the foregut, but the only source for humans is food of animal origin, for example, meat, fish, and dairy products. Vegetables, fruits, and other foods of nonanimal origin are free from cobalamin unless they are contaminated by bacteria. A normal Western diet contains 5–30 μg of cobalamin daily. Adult daily losses (mainly in the urine and feces) are 1–3 μg (~0.1% of body stores), and because the body does not have the ability to degrade cobalamin, daily requirements are also about 1–3 μg. Body stores are of the order of 2–3 mg, sufficient for 3–4 years if supplies are completely cut off.

ABSORPTION

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through buccal, duodenal, and ileal mucosa; it is rapid but extremely inefficient, with <1% of an oral dose being absorbed by this process. The normal physiologic mechanism is active; it occurs through the ileum and is efficient for small (a few micrograms) oral doses of cobalamin, and it is mediated by gastric intrinsic factor (IF). Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum, and jejunum; it combines rapidly with a salivary glycoprotein that belongs to the family of cobalamin-binding proteins known as haptocorrins (HCs). In the intestine, the HC is digested by pancreatic trypsin and the cobalamin is transferred to IF.

IF (gene at chromosome 11q13) is produced in the gastric parietal cells of the fundus and body of the stomach, and its secretion parallels that of hydrochloric acid. Normally, a vast excess of IF is available. The IF-cobalamin complex passes to the ileum, where IF attaches to a specific receptor (cubilin) on the microvillus membrane of the enterocytes. Cubilin also is present in yolk sac and renal proximal tubular epithelium. Cubilin appears to traffic by means of amnionless (AMN), an endocytic receptor protein that directs sublocalization and endocytosis of cubilin with its ligand IF-cobalamin complex. The cobalamin-IF complex enters the ileal cell, where IF is destroyed. After a delay of about 6 h, the cobalamin appears in portal blood attached to transcobalamin (TC) II.

Between 0.5 and 5 μg of cobalamin enter the bile each day. This binds to IF, and a major portion of biliary cobalamin normally is reabsorbed together with cobalamin derived from sloughed intestinal cells. Because of the appreciable amount of cobalamin undergoing enterohepatic circulation, cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, in whom reabsorption of biliary cobalamin is intact.

TRANSPORT

Two main cobalamin transport proteins exist in human plasma; they both bind cobalamin—one molecule for one molecule. One an HC, also known as transcobalamin (TC) I, is closely related to other cobalamin-binding HCs in milk, gastric juice, bile, saliva, and other fluids. The gene *TCNL* is at chromosome 11q11-q12.3. These HCs differ from each other only in the carbohydrate moiety of the molecule. TC I is derived primarily from the specific granules in neutrophils. Normally, it is about two-thirds saturated with cobalamin, which it binds tightly. TC I does not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are involved in the removal of TC I from plasma, and TC I may play a role in the transport of cobalamin analogues (which it binds more effectively than does IF) to the liver for excretion in bile.

The other major cobalamin transport protein in plasma is transcobalamin, also known as TC II. The gene is on chromosome 22q11-q13.1. As for IF and HCs, there are nine exons. The three proteins are likely to have a common ancestral origin. TC II is synthesized by liver and by other tissues, including macrophages, ileum, and vascular endothelium. It normally carries only 20–60 ng of cobalamin per liter of plasma and readily gives up cobalamin to marrow, placenta, and other tissues, which it enters by receptor-mediated endocytosis involving the TC II receptor and megalin (encoded by the *LRP-2* gene). The TC II cobalamin is internalized by endocytosis via clathrin-coated pits; the complex is degraded, but the receptor probably is recycled to the cell membrane as is the case for transferrin. Export of "free" cobalamin is via the ATP-binding cassette drug transporter alias multidrug resistance protein 1.

FOLATE

DIETARY FOLATE

Folic (pteroylglutamic) acid is a yellow, crystalline, water-soluble substance. It is the parent compound of a large family of natural folate compounds, which differ from it in three respects: (1) they are partly or completely reduced to dihydrofolate (DHF) or tetrahydrofolate (THF) derivatives, (2) they usually contain a single carbon unit **(Table 104-2)**, and (3) 70–90% of natural folates are folate-polyglutamates. These usually have a chain of four to six glutamate moieties rather than one, as in the monoglutamate folic acid. The whole family is known as folate or vitamin B_9.

Most foods contain some folate. The highest concentrations are found in liver, yeast, spinach, other greens, and nuts (>100 μg/100 g). The total folate content of an average Western diet is 400–500 μg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water. Total-body folate in the adult is ~10 mg, with the liver containing the largest store. Daily adult requirements are 100–200 μg, and so stores are sufficient for only 3–4 months in normal adults, and severe folate deficiency may develop rapidly.

ABSORPTION

Folates are absorbed rapidly from the upper small intestine. The absorption of folate polyglutamates is less efficient than that of monoglutamates; on average, ~50% of food folate is absorbed. Polyglutamate forms are hydrolyzed to the monoglutamate derivatives either in the lumen of the intestine or within the mucosa. All dietary folates are converted to 5-methyl-THF (5-MTHF) within the small intestinal mucosa before entering portal plasma. Monoglutamates are actively transported across the enterocyte by a proton-coupled folate transporter (PCFT, SCL46A1). This is situated at the apical brush border and is most active at pH 5.5, which is about the pH of the duodenal and jejunal surface. Genetic mutations of this protein underlie hereditary malabsorption of folate (see below). Pteroylglutamic acid at doses >400 μg is absorbed largely unchanged and converted to natural folates in the liver. Lower doses are converted to 5-MTHF during absorption through the intestine.

About 60–90 μg of folate enter the bile each day and are excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

TRANSPORT

Folate is transported in plasma; about one-third is loosely bound to albumin, and two-thirds are unbound. In all body fluids (plasma, cerebrospinal fluid, milk, bile), folate is largely, if not entirely, 5-MTHF

TABLE 104-2 Biochemical Reactions of Folate Coenzymes

REACTION	COENZYME FORM OF FOLATE INVOLVED	SINGLE CARBON UNIT TRANSFERRED	IMPORTANCE
Formate activation	THF	–CHO	Generation of 10-formyl-THF
Purine synthesis			
Formation of glycinamide ribonucleotide	5,10-Methylene-THF	–CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate-limiting
Formylation of aminoimidazole carboxamide ribonucleotide (AICAR)	10-Formyl (CHO)THF		
Pyrimidine synthesis			
Methylation of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methylene-THF	$-CH_3$	Rate limiting in DNA synthesis Oxidizes THF to DHF Some breakdown of folate at the C-9–N-10 bond
Amino acid interconversion			
Serine-glycine interconversion	THF	$=CH_2$	Entry of single carbon units into active pool
Homocysteine to methionine	5-Methyl(M)THF	$-CH_3$	Demethylation of 5-MTHF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP, and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	–HN–CH=	

Abbreviations: DHF, dihydrofolate; THF, tetrahydrofolate.

(the monoglutamate form). Three types of folate-binding protein are involved. A reduced folate transporter (RFC, SLC19A1) is the major route of delivery of plasma folate (5-MTHF) to cells. Two folate receptors, FR2 and FR3 embedded in the cell membrane by a glycosyl phosphatidylinositol anchor, transport folate into the cell via receptor-mediated endocytosis. The third protein, proton-coupled folate transporter (PCFT), transports folate at low pH from the vesicle to the cell cytoplasm. The reduced folate transporter also mediates uptake of methotrexate by cells.

BIOCHEMICAL FUNCTIONS

Folates (as the intracellular polyglutamate derivatives) act as coenzymes in the transfer of single-carbon units (**Fig. 104-1** and Table 104-2). Two of these reactions are involved in purine synthesis and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is also a coenzyme for methionine synthesis, in which methylcobalamin is also involved and in which THF is regenerated. THF is the acceptor of single carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for *S*-adenosylmethionine (SAM), the universal methyl donor involved in >100 methyltransferase reactions (Fig. 104-1).

During thymidylate synthesis, 5,10-methylene-THF is oxidized to DHF. The enzyme DHF reductase converts this to THF. The drugs methotrexate, pyrimethamine, and (mainly in bacteria) trimethoprim inhibit DHF reductase and so prevent formation of active THF coenzymes from DHF. A small fraction of the folate coenzyme is not recycled during thymidylate synthesis but is degraded at the C9-N10 bond.

BIOCHEMICAL BASIS OF MEGALOBLASTIC ANEMIA

The common feature of all megaloblastic anemias is a defect in DNA synthesis that affects rapidly dividing cells in the bone marrow. Conditions that give rise to megaloblastic changes have in common a disparity in the availability of the four immediate precursors of DNA or a block in their condensation to form DNA. The four precursors are the deoxyribonucleoside triphosphates (dNTPs)—dA(adenine)TP and dG(guanine)TP (purines), dT(thymine)TP, and dC(cytosine)TP (pyrimidines). In deficiencies of either folate or cobalamin, conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), the precursor of deoxythymidine triphosphate (dTTP) (Fig. 104-1) fails. This occurs because folate is needed as the coenzyme 5,10-methylene-THF polyglutamate for conversion of dUMP to dTMP. The availability of 5,10-methylene-THF is reduced in either cobalamin or folate deficiency. Because of the shortage of one or more precursor, DNA replication from multiple origins along the chromosome is slower than normal during mitosis, and the incomplete replicons fail to join up with resulting single-stranded DNA breaks. An alternative and less likely theory for megaloblastic anemia in cobalamin or folate deficiency is misincorporation of uracil into DNA because of the accumulation of deoxyuridine triphosphate (dUTP) at the DNA replication fork as a consequence of the block in conversion of dUMP to dTMP.

COBALAMIN-FOLATE RELATIONS

Folate is required for many reactions in mammalian tissues (Table 104-2). Only two reactions in the body are known to require cobalamin. Methylmalonyl-CoA isomerization requires adocobalamin, and the methylation of homocysteine to methionine requires both methylcobalamin and 5-MTHF (Fig. 104-1). This reaction is the first step in the pathway by which 5-MTHF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate coenzymes. The coenzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase can use only THF, not 5-MTHF, as substrate. In cobalamin deficiency, 5-MTHF accumulates in plasma, and intracellular folate concentrations fall due to failure of formation of THF, the substrate on which folate polyglutamates are built. This has been termed *THF starvation*, or the *methylfolate trap*. This trap also occurs at the polyglutamate level with accumulation of the methyl form at the expense of the other one-carbon forms.

This theory explains the abnormalities of folate metabolism that occur in cobalamin deficiency (high serum folate, low cell folate, positive purine precursor aminoimidazole carboxamide ribonucleotide [AICAR] excretion) (Table 104-2) and also why the anemia of cobalamin deficiency responds to folic acid in large doses, which overcome the methylfolate trap (Fig 104-1).

CLINICAL FEATURES

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood count. The main clinical features in more severe cases are those of anemia. Anorexia is usually marked, and weight loss, diarrhea, or constipation may be present. Glossitis, angular cheilosis, a mild fever in more severely anemic patients, jaundice (unconjugated), and reversible melanin skin hyperpigmentation also may occur with a deficiency of either folate or cobalamin. Thrombocytopenia sometimes leads to bruising, and this may be aggravated by vitamin C deficiency or alcohol in malnourished patients. The anemia and low leukocyte count may predispose to infections, particularly of the respiratory and urinary tracts. Cobalamin

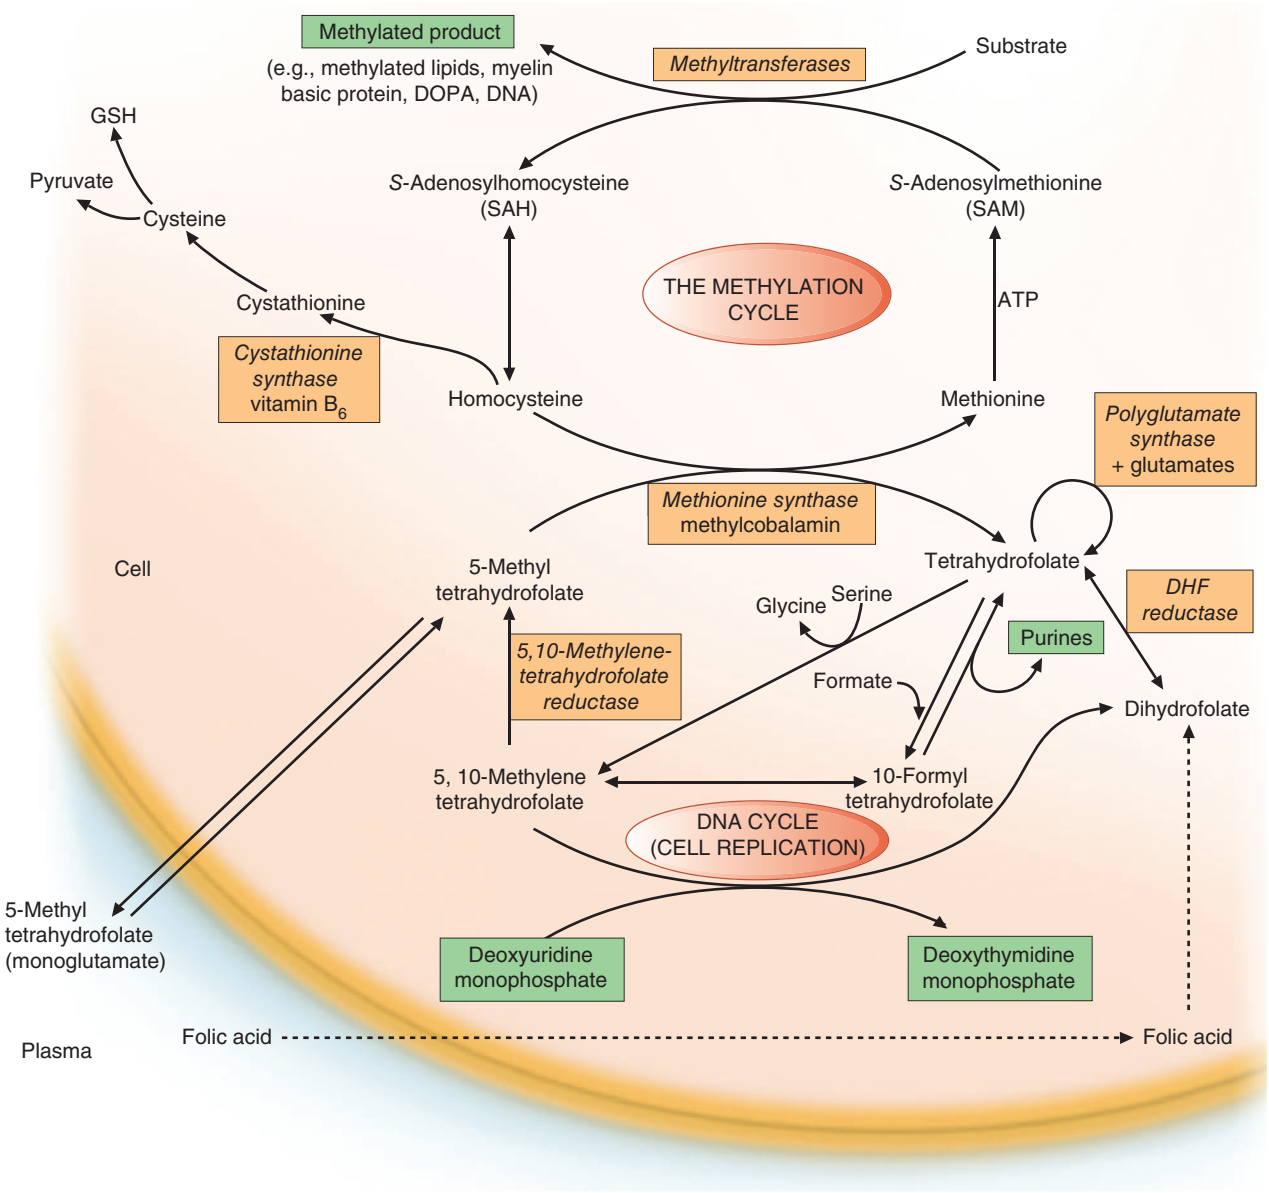

FIGURE 104-1 The role of folates in DNA synthesis and in formation of *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. DHF, dihydrofolate; GSH, glutathione. *(Reproduced with permission from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005.)*

deficiency has also been associated in a few studies with impaired bactericidal function of phagocytes and with osteoporosis.

Neurologic Manifestations Cobalamin is needed for the myelination of the central nervous system. Its deficiency may cause a bilateral peripheral neuropathy or degeneration (demyelination) of the cervical and thoracic posterior and lateral (pyramidal) tracts of the spinal cord and, less frequently, of the cranial nerves and of the white matter of the brain. Optic atrophy and cerebral symptoms including dementia, depression, psychotic symptoms, and cognitive impairment may be prominent. Anosmia and loss of taste may occur. Magnetic resonance imaging (MRI) may show the "spongy" degeneration of the cord.

The patient, more frequently male, typically presents with paresthesias, muscle weakness, or difficulty in walking but sometimes may present with dementia, psychotic disturbances, or visual impairment. Loss of proprioception and vibration sensation is usually present with positive Romberg and Lhermitte signs. Gait may be ataxic with spasticity (hyperreflexia). Autonomic nervous dysfunction can result in postural hypotension, impotence, and incontinence.

Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. In infancy, feeding difficulties, lethargy, and coma may be noted. Convulsions and myoclonus have been described. An important clinical problem is the nonanemic patient with neurologic or psychiatric abnormalities and a low or borderline serum cobalamin level. In such patients, it is necessary to try to establish whether significant cobalamin deficiency is present, for example, by careful examination of the blood film for macrocytosis or hypersegmented neutrophils (see below), tests for pernicious anemia (PA) by serum gastrin level and antibodies to IF or parietal cells, and serum methylmalonic acid (MMA) measurement. A trial of cobalamin therapy for at least 3 months will usually also be needed to determine whether the symptoms improve.

The biochemical basis for cobalamin neuropathy remains obscure. Its occurrence in the absence of methylmalonic aciduria in TC II deficiency suggests that the neuropathy is related to the defect in homocysteine-methionine conversion. Accumulation of *S*-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions, has been suggested. Folate deficiency has been suggested to cause organic neurologic disease, but this is uncertain, although methotrexate injected into the cerebrospinal fluid may cause brain or spinal cord damage.

Psychiatric disturbance, as discussed above, is common in both folate and cobalamin deficiencies. This, like the neuropathy, has been attributed to a failure of the synthesis of SAM, which is needed in

methylation of biogenic amines (e.g., dopamine) as well as that of proteins, phospholipids, and neurotransmitters in the brain (Fig. 104-1).

GENERAL TISSUE EFFECTS OF COBALAMIN AND FOLATE DEFICIENCIES

Epithelial Surfaces After the marrow, the next most frequently affected tissues are the epithelial cell surfaces of the mouth (with glossitis), stomach, small intestine, and respiratory, urinary, and female genital tracts. The cells show macrocytosis with increased numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of Pregnancy The gonads are also affected, and infertility is common in both men and women with severe deficiency of either vitamin. Maternal folate deficiency has been implicated as a cause of prematurity, and both folate and cobalamin deficiencies have been implicated in recurrent fetal loss and neural tube defects.

Neural Tube Defects Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy can reduce by ~80% the incidence of neural tube defects (NTDs) (anencephaly, meningomyelocele, encephalocele, and spina bifida) in the fetus. Most of this protective effect can be achieved by taking folic acid, 0.4 mg daily, before and at the time of conception.

The incidence of cleft palate and harelip also can be reduced by prophylactic folic acid. No clear simple relationship exists between maternal folate status and these fetal abnormalities, although for NTDs, it has been established that the lower the maternal folate, the greater is the risk to the fetus. NTDs also can be caused by antifolate and antiepileptic drugs.

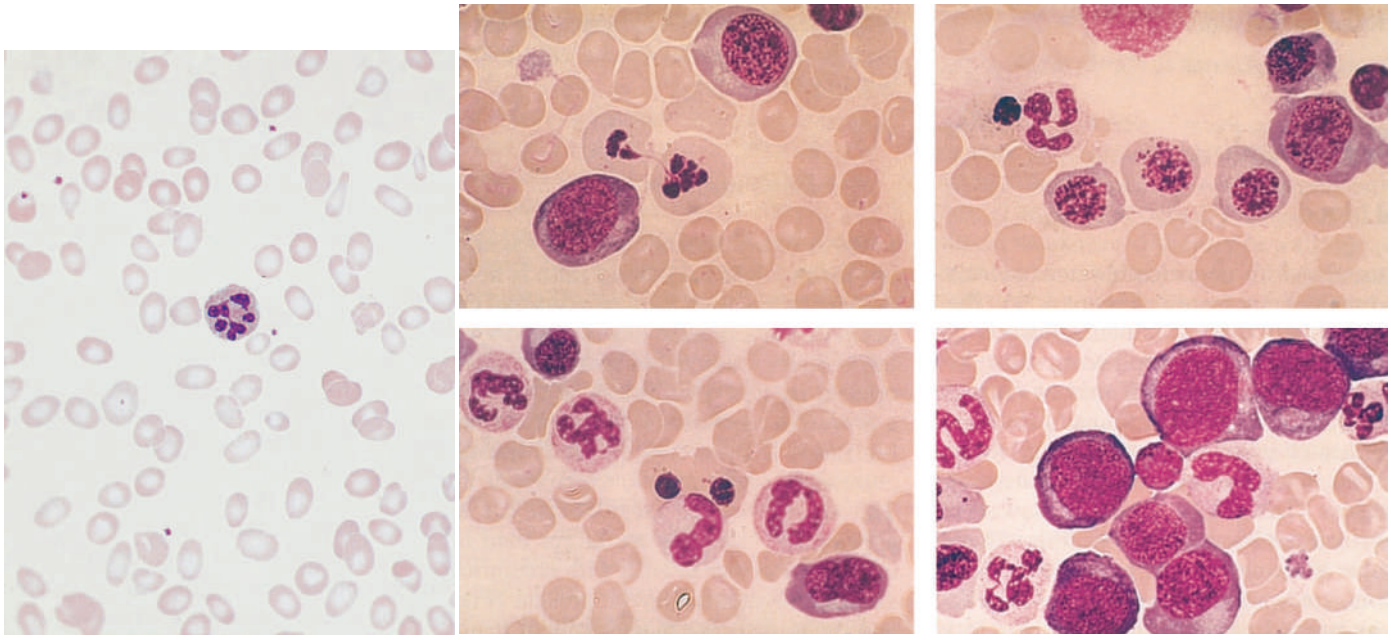
An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylene-THF reductase (MTHFR) (Fig. 104-1) caused by a common C677T polymorphism in the *MTHFR* gene. In one study, the prevalence of this polymorphism was found to be higher than in controls in the parents of NTD fetuses and in the fetuses themselves: homozygosity for the TT mutation was found in 13% of cases compared with 5% of control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in a lower mean serum and red cell folate level compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, for example, methionine synthase and serine–glycine hydroxymethylase, have been negative. Serum cobalamin levels are also lower in the sera of mothers of NTD infants than in controls. In addition, maternal TC II receptor polymorphisms are associated with increased risk of NTD births. However, no studies have been undertaken that show that dietary fortification with cobalamin reduces the incidence of NTDs.

Cardiovascular Disease Children with severe homocystinuria (blood levels ≥100 μmol/L) due to deficiency of one of three enzymes (methionine synthase, MTHFR, or cystathionine synthase; Fig. 104-1) have vascular disease, for example, ischemic heart disease, cerebrovascular disease, or pulmonary embolus, as teenagers or in young adulthood. Lesser degrees of raised serum homocysteine and low levels of serum folate and homozygous inherited mutations of *MTHFR* have been found to be associated with cerebrovascular, peripheral vascular, and coronary heart disease and with deep vein thrombosis. Prospective randomized trials of lowering homocysteine levels with supplements of folic acid, vitamin B_{12}, and vitamin B_6 against placebo over a 5-year period in patients with vascular disease or diabetes have not, however, shown a reduction of first event fatal or nonfatal myocardial infarction, nor have these supplements reduced the risk of recurrent cardiovascular disease after an acute myocardial infarct. Meta-analysis showed an 18% reduction in strokes. The benefit for stroke prevention has been confirmed by a large (>20,000 subjects) randomized prospective study in hypertensive subjects in China. This showed a significant reduction in the first incidence of stroke in subjects receiving enalapril and folic acid compared to enalapril alone. The effect was especially marked in the subjects commencing the prospective trial with the lowest serum folate levels. Venous thrombosis has been reported to be more frequent in folate-deficient or cobalamin-deficient subjects than in controls and to occur at unusual sites such as cerebral venous sinuses. This tendency was ascribed to raised plasma homocysteine levels in folate or cobalamin deficiency, but no evidence exists that folic acid or cobalamin supplements reduce the prevalence of venous thrombosis.

Cognitive Decline Association between low serum folate or cobalamin levels and higher homocysteine levels with the development of decreased cognitive function and of dementia in Alzheimer's disease has been reported. A meta-analysis of randomized, placebo-controlled trials of homocysteine-lowering B-vitamin supplementation of individuals with and without cognitive impairment, however, showed that supplementation with vitamin B_{12}, vitamin B_6, and folic acid alone or in combination did not improve cognitive function or slow cognitive decline. It is unknown whether prolonged treatment with these B vitamins can reduce the risk of dementia in later life.

Malignancy Prophylactic folic acid in pregnancy has been found in some but not all studies to reduce the subsequent incidence of acute lymphoblastic leukemia (ALL) in childhood. A significant negative association has also been found with the *MTHFR* C677T polymorphism and leukemias with mixed lineage leukemia (MLL) translocations, but a positive association was found with hyperdiploidy in infants with ALL or acute myeloid leukemia or with childhood ALL. A second polymorphism in the *MTHFR* gene, A1298C, is also strongly associated with hyperdiploid leukemia. Various positive and negative associations are noted between polymorphisms in folate-dependent enzymes and the incidence of adult ALL. The C677T polymorphism is thought to lead to increased thymidine pools and "better quality" of DNA synthesis by shunting one-carbon groups toward thymidine and purine synthesis. This may explain its reported association with a lower risk for colorectal cancer. Most but not all studies suggest that prophylactic folic acid also protects against colon adenomas. Other tumors that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer, and gastric cancer.

A meta-analysis of 50,000 individuals given folic acid (0.5–40 mg daily) or placebo in cardiovascular (n = 10) or colon adenoma prevention (n = 3) trials found that folic acid supplementation did not significantly increase or decrease the overall incidence of cancer or of any site-specific cancer during a weighted average scheduled treatment duration of 5.7 years. Because folic acid may "feed" tumors, it probably should be avoided in those with established tumors unless severe megaloblastic anemia due to folate deficiency is present.



HEMATOLOGIC FINDINGS

PERIPHERAL BLOOD

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main feature **(Fig. 104-2*A*)**. The MCV is usually >100 fL unless a cause of microcytosis (e.g., iron deficiency or thalassemia trait) is present. Some of the neutrophils are hypersegmented (more than five nuclear lobes). There may be leukopenia due to a reduction in granulocytes and lymphocytes, but this is usually $>1.5 \times 10^9$/L; the platelet count may be moderately reduced, rarely to $<40 \times 10^9$/L. The severity of all these changes parallels the degree of anemia. In a nonanemic patient, the presence of a few macrocytes and hypersegmented neutrophils in the peripheral blood may be the only indication of the underlying disorder.

BONE MARROW

In a severely anemic patient, the marrow is hypercellular with an accumulation of primitive cells due to selective death by apoptosis of more mature forms. The erythroblast nucleus maintains a primitive, fine chromatin appearance despite maturation and hemoglobinization of the cytoplasm. The cells are larger than normoblasts, and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present **(Fig. 104-2*B*)**. Giant and abnormally shaped metamyelocytes and enlarged hyperpolyploid megakaryocytes are characteristic. In severe cases, the accumulation of primitive cells ("blasts")

A B

FIGURE 104-2 ***A.*** The peripheral blood in severe megaloblastic anemia. ***B.*** The bone marrow in severe megaloblastic anemia. *(Reprinted from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005; with permission.)*

may mimic acute myeloid leukemia, whereas in less anemic patients, the changes in the marrow may be difficult to recognize. The terms *intermediate*, *mild*, and *early* have been used. The term *megaloblastoid* is best avoided. It has been used to describe cells with both immature-appearing nuclei and defective hemoglobinization refractory to folic acid or cobalamin therapy, especially seen in myelodysplasia.

CHROMOSOMES

Bone marrow cells, transformed lymphocytes, and other proliferating cells in the body show a variety of chromosomal changes, including random breaks, reduced contraction, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and over-prominent satellites. Similar abnormalities may be produced by antimetabolite drugs (e.g., cytarabine, hydroxyurea, thioguanine, and methotrexate) that interfere with either DNA replication or folate metabolism and that also cause megaloblastic appearances.

INEFFECTIVE HEMATOPOIESIS

Unconjugated bilirubin accumulates in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins, positive urine hemosiderin, and raised serum lactate dehydrogenase. A weakly positive direct antiglobulin test due to complement only can lead to a false diagnosis of autoimmune hemolytic anemia.

CAUSES OF COBALAMIN DEFICIENCY

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake.

INADEQUATE DIETARY INTAKE

Adults Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese, and other animal products from their diet. The largest group in the world consists of Hindus, and it is likely that many millions of Indians are at risk of deficiency of cobalamin on a nutritional basis. Subnormal serum cobalamin levels are found in up to 50% of randomly selected, young, adult Indian vegans, but the deficiency usually does not progress to megaloblastic anemia since the diet of most vegans is not totally lacking in cobalamin and the enterohepatic circulation of cobalamin is intact. Dietary cobalamin deficiency may also arise rarely in nonvegetarian individuals who exist on grossly inadequate diets because of poverty or psychiatric disturbance.

Infants Cobalamin deficiency has been described in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anemia at about 3–6 months of age, presumably because they are born with low stores of cobalamin and because they are fed breast milk with low cobalamin content. The babies have also shown growth retardation, impaired psychomotor development, and other neurologic sequelae. MRI shows delayed myelination and brain atrophy.

GASTRIC CAUSES OF COBALAMIN MALABSORPTION

See Tables 104-3 and 104-4.

Formerly, the pathogenesis of cobalamin malabsorption was distinguishable based on the results of a Schilling test in which a radioactive form of cobalamin was administered orally and its appearance in the urine was a sign of absorption. Radioactive cobalamin is no longer available, and Schilling tests are no longer performed. Other approaches to the differential diagnosis of cobalamin malabsorption are now employed.

Pernicious Anemia PA, the dominant cause of severe cobalamin deficiency in Western countries, may be defined as a severe lack of IF due to gastric atrophy. It is a common disease in northern Europeans but occurs in all countries and ethnic groups. It is more frequent in people of African than Asian ancestry. The overall incidence is about

TABLE 104-3 Causes of Cobalamin Deficiency Sufficiently Severe to Cause Megaloblastic Anemia

NUTRITIONAL	VEGANS
Malabsorption	Pernicious anemia
Gastric causes	Congenital absence of intrinsic factor or functional abnormality
	Total or partial gastrectomy
Intestinal causes	Intestinal stagnant loop syndrome: jejunal diverticulosis, ileocolic fistula, anatomic blind loop, intestinal stricture, etc.
	Ileal resection and Crohn's disease
	Selective malabsorption with proteinuria
	Tropical sprue
	Transcobalamin II deficiency
	Fish tapeworm

TABLE 104-4 Malabsorption of Cobalamin May Occur in the Following Conditions but Is Not Usually Sufficiently Severe and Prolonged to Cause Megaloblastic Anemia

Gastric causes
Simple atrophic gastritis (food cobalamin malabsorption)
Zollinger-Ellison syndrome
Gastric bypass or bariatric surgery
Use of proton pump inhibitors
Intestinal causes
Gluten-induced enteropathy
Severe pancreatitis
HIV infection
Radiotherapy
Graft-versus-host disease
Deficiencies of cobalamin, folate, protein,? riboflavin,? nicotinic acid
Therapy with colchicine, para-aminosalicylate, neomycin, slow-release potassium chloride, anticonvulsant drugs, metformin,[a] cytotoxic drugs
Alcohol

[a]It is now thought that metformin lowers serum vitamin B_{12} level by lowering the level of transcobalamin I.

120 per 100,000 population in the United Kingdom (UK). The ratio of incidence in men and women among whites is ~1:1.6, and the median age of onset is 70–80 years, with only 10% of patients being <40 years of age. However, in some ethnic groups, notably blacks and Latin Americans, the age at onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives and in persons with other organ-specific autoimmune diseases, for example, thyroid diseases, vitiligo, hypoparathyroidism, type 1 diabetes, and Addison's disease. It is also associated with hypogammaglobulinemia, premature graying or blue eyes, and persons of blood group A. An association with human leukocyte antigen (HLA) 3 has been reported in some but not all series and, in those with endocrine disease, with HLA-B8, -B_{12}, and -BW15. Life expectancy is normal in women once regular treatment has begun. Men had in earlier decades a slightly subnormal life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects, but current data on their life expectancy are unavailable. Gastric output of hydrochloric acid, pepsin, and IF is severely reduced. The serum gastrin level is raised, and serum pepsinogen I levels are low.

Gastric Biopsy A single endoscopic examination is recommended if PA is diagnosed. Gastric biopsy usually shows atrophy of all layers of the body and fundus, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate, and perhaps intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. These are directed against gastric H/K-ATPase. The antral mucosa is usually well preserved. *Helicobacter pylori* infection occurs infrequently in PA, but it has been suggested that *H. pylori* gastritis occurs at an early phase of atrophic gastritis and presents in younger patients as iron-deficiency anemia and in older patients as PA. *H. pylori* is suggested to stimulate an autoimmune process directed against parietal cells. It has been suggested that *H. pylori* infection is replaced, in some individuals, by the autoimmune process.

Serum Antibodies Two types of IF immunoglobulin G antibody may be found in the sera of patients with PA. The "blocking," or type I, antibody prevents the combination of IF and cobalamin, whereas the "binding," or type II, antibody prevents attachment of IF to ileal mucosa. Type I occurs in the sera of ~55% of patients, and type II in 35%. IF antibodies cross the placenta and may cause temporary IF deficiency in a newborn infant. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxedema, Hashimoto's disease, or diabetes mellitus and in relatives of PA patients. IF antibodies have also been detected in gastric juice in ~80% of PA patients. These gastric antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF. Patients with PA also show cell-mediated immunity to IF.

Parietal cell antibody is present in the sera of almost 90% of adult patients with PA but is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects age >60 years. The parietal cell antibody is directed against the α and β subunits of the gastric proton pump (H^+, K^+-ATPase).

JUVENILE PERNICIOUS ANEMIA

This usually occurs in older children and resembles PA of adults. Gastric atrophy, achlorhydria, and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About one-half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison's disease, or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

CONGENITAL INTRINSIC FACTOR DEFICIENCY OR FUNCTIONAL ABNORMALITY

An affected child usually presents with megaloblastic anemia in the first to third year of life; a few have presented as late as the second decade. The child usually has no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomal recessive. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically but is unstable or functionally inactive, unable to bind cobalamin or to facilitate its uptake by ileal receptors.

GASTRECTOMY

After total gastrectomy, cobalamin deficiency is inevitable, and prophylactic cobalamin therapy should be commenced immediately after the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. The exact incidence and time of onset are most influenced by the size of the resection and the preexisting size of cobalamin body stores.

FOOD COBALAMIN MALABSORPTION

Failure of release of cobalamin from binding proteins in food is responsible for this condition, which is more common in the elderly. It is associated with low serum cobalamin levels, with or without raised serum levels of MMA and homocysteine. Typically, these patients have normal cobalamin absorption, as measured with crystalline cobalamin, but show malabsorption when a modified test using food-bound cobalamin is used. It is usually due to mild forms of atrophic gastritis or therapy with proton pump inhibitors. Bariatric surgery is likely to be an increasing cause of this form of cobalamin malabsorption and deficiency. The frequency of progression to severe cobalamin deficiency and the reasons for this progression are not clear.

INTESTINAL CAUSES OF COBALAMIN MALABSORPTION

Intestinal Stagnant Loop Syndrome Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonization of the upper small intestine by fecal organisms. This may occur in patients with jejunal diverticulosis, entero-anastomosis, or an intestinal stricture or fistula or with an anatomic blind loop due to Crohn's disease, tuberculosis, or an operative procedure.

Ileal Resection Removal of ≥1.2 m of terminal ileum causes malabsorption of cobalamin. In some patients after ileal resection, particularly if the ileocecal valve is incompetent, colonic bacteria may contribute further to the onset of cobalamin deficiency.

Selective Malabsorption of Cobalamin with Proteinuria (Imerslund's Syndrome; Imerslund-Gräsbeck Syndrome; Congenital Cobalamin Malabsorption; Autosomal Recessive Megaloblastic Anemia; MGA1) This autosomal recessive disease is the most common cause of megaloblastic anemia due to cobalamin deficiency in infancy in Western countries. More than 200 cases have been reported with familial clusters in Finland, Norway, the Middle East, and North Africa. The patients secrete normal amounts of IF and gastric acid but are unable to absorb cobalamin. In Finland, impaired synthesis, processing, or ligand binding of cubilin due to

inherited mutations is found. In Norway, mutation of the gene for *AMN* has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show nonspecific proteinuria, but renal function is otherwise normal, and renal biopsy has not shown any consistent renal defect. A few have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

Tropical Sprue Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin. This may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic and, in the early stages, folic acid therapy.

Fish Tapeworm Infestation The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering the cobalamin unavailable for absorption. Individuals acquire the worm by eating raw or partly cooked fish. Infestation was common around the lakes of Scandinavia, Germany, Japan, North America, and Russia. Megaloblastic anemia or cobalamin neuropathy occurs only in those with a heavy infestation.

Gluten-Induced Enteropathy Malabsorption of cobalamin occurs in ~30% of untreated patients (presumably those in whom the disease extends to the ileum). Cobalamin deficiency is not severe in these patients and is corrected with a gluten-free diet.

Severe Chronic Pancreatitis In this condition, lack of trypsin is thought to cause dietary cobalamin attached to gastric non-IF (HC) binder to be unavailable for absorption. It also has been proposed that, in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption.

HIV Infection Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Malabsorption of cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Cobalamin deficiency sufficiently severe to cause megaloblastic anemia or neuropathy is rare.

Zollinger-Ellison Syndrome Malabsorption of cobalamin has been reported in the Zollinger-Ellison syndrome. It is thought that there is a failure to release cobalamin from HC binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Radiotherapy Both total-body irradiation and local radiotherapy to the ileum (e.g., as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin.

Graft-Versus-Host Disease This commonly affects the small intestine. Malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is common.

Drugs The drugs that have been reported to cause malabsorption of cobalamin are listed in Table 104-4. However, megaloblastic anemia due to these drugs is rare. It has been suggested that metformin lowers serum cobalamin by lowering TC I level rather than causing malabsorption of cobalamin.

ABNORMALITIES OF COBALAMIN METABOLISM

Congenital Transcobalamin II Deficiency or Abnormality Infants with TC II deficiency usually present with megaloblastic anemia within a few weeks of birth. Serum cobalamin and folate levels are normal, but the anemia responds to massive (e.g., 1 mg three times weekly) injections of cobalamin. Some cases show neurologic complications. The protein may be present but functionally inert. Genetic abnormalities found include mutations of an intraexonic cryptic splice site, extensive deletion, single nucleotide deletion, nonsense mutation, and an RNA editing defect. Malabsorption of cobalamin occurs in all cases, and serum immunoglobulins are usually reduced. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to irreversible neurologic damage.

Congenital Methylmalonic Acidemia and Aciduria Infants with this abnormality are ill from birth with vomiting, failure to thrive, severe metabolic acidosis, ketosis, and intellectual disability. Anemia, if present, is normocytic and normoblastic. The condition may be due to a functional defect in either mitochondrial methylmalonyl-CoA mutase or its cofactor adocobalamin. Mutations in the methylmalonyl-CoA mutase are not responsive or are only poorly responsive to treatment with cobalamin. A proportion of infants with failure of adocobalamin synthesis respond to cobalamin in large doses. Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin coenzymes. This usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia, and megaloblastic anemia.

Acquired Abnormality of Cobalamin Metabolism: Nitrous Oxide Inhalation Nitrous oxide (N_2O) irreversibly oxidizes methylcobalamin to an inactive precursor; this inactivates methionine synthase. Megaloblastic anemia has occurred in patients undergoing prolonged N_2O anesthesia (e.g., in intensive care units). A neuropathy resembling cobalamin neuropathy has been described in dentists and anesthetists who are exposed repeatedly to N_2O. Methylmalonic aciduria does not occur as adocobalamin is not inactivated by N_2O.

CAUSES OF FOLATE DEFICIENCY
(Table 104-5)

NUTRITIONAL
Dietary folate deficiency is common except in countries that fortify their diet with folic acid. In most patients with folate deficiency, a nutritional element is present. Certain individuals are particularly prone to have diets containing inadequate amounts of folate (Table 104-5). In the United States and other countries where fortification

TABLE 104-5 Causes of Folate Deficiency

Dietary[a]
Particularly in: old age, infancy, poverty, alcoholism, chronic invalids, and the psychiatrically disturbed; may be associated with scurvy or kwashiorkor
Malabsorption
Major causes of deficiency
Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency
Minor causes of deficiency
Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple's disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, sulfasalazine (Salazopyrin)
Excess utilization or loss
Physiologic
Pregnancy and lactation, prematurity
Pathologic
Hematologic diseases: chronic hemolytic anemias, sickle cell anemia, thalassemia major, myelofibrosis
Malignant diseases: carcinoma, lymphoma, leukemia, myeloma
Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria
Metabolic disease: homocystinuria
Excess urinary loss: congestive heart failure, active liver disease
Hemodialysis, peritoneal dialysis
Antifolate drugs[b]
Anticonvulsant drugs (phenytoin, primidone, barbiturates), sulfasalazine
Nitrofurantoin, tetracycline, antituberculosis (less well documented)
Mixed causes
Liver diseases, alcoholism, intensive care units

[a]In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present. [b]Drugs inhibiting dihydrofolate reductase are discussed in the text.

of the diet with folic acid has been adopted, the prevalence of folate-deficient megaloblastic anemia has dropped dramatically and is now restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy and in infants with repeated infections or those who are fed solely on goats' milk, which has a low folate content.

MALABSORPTION

Malabsorption of dietary folate occurs in tropical sprue and in gluten-induced enteropathy. In the rare congenital recessive syndrome of selective malabsorption of folate due to mutation of the PCFT, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anemia, which responds to physiologic doses of folic acid given parenterally but not orally. They also show intellectual disability, convulsions, and other central nervous system abnormalities. Minor degrees of malabsorption may also occur after jejunal resection or partial gastrectomy, in Crohn's disease, and in systemic infections, but in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition. Malabsorption of folate has been described in patients receiving sulfasalazine (Salazopyrin), cholestyramine, and triamterene.

EXCESS UTILIZATION OR LOSS

Pregnancy Folate requirements are increased by 50% daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus but mainly because of increased folate catabolism due to cleavage of folate coenzymes in rapidly proliferating tissues. A dietary folate intake of 600 μg daily is recommended. Megaloblastic anemia due to folate deficiency is prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries before prophylaxis with folic acid, but the incidence is much higher in countries where the general nutritional status is poor. During lactation, folate requirements are increased about 25 and a dietary intake of 500 μg of folate daily is advised.

Prematurity A newborn infant, whether full term or premature, has higher serum and red cell folate concentrations than an adult. However, a newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis, and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and are liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (<1500 g birth weight) and those who have feeding difficulties or infections or have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Hematologic Disorders Folate deficiency frequently occurs in chronic hemolytic anemias, particularly in sickle cell disease, autoimmune hemolytic anemia, and congenital spherocytosis. In these and in other conditions of increased cell turnover (e.g., myelofibrosis, malignancies), folate deficiency arises because it is not completely reutilized after performing coenzyme functions.

Inflammatory Conditions Chronic inflammatory diseases such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis, and chronic bacterial infections cause deficiency by reducing the appetite and increasing the demand for folate. Systemic infections also may cause malabsorption of folate. Severe deficiency is virtually confined to the patients with the most active disease and the poorest diet.

Homocystinuria This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilization because of compensatory increased conversion of homocysteine to methionine.

Long-Term Dialysis Because folate is only loosely bound to plasma proteins, it is easily removed from plasma by dialysis. In patients with anorexia, vomiting, infections, and hemolysis, folate stores are particularly likely to become depleted. Routine folate prophylaxis is now given.

Congestive Heart Failure and Liver Disease Excess urinary folate losses of >100 μg per day may occur in some of these patients. It appears to be due to release of folate from damaged liver cells.

ANTIFOLATE DRUGS

A large number of people with epilepsy receiving long-term therapy with phenytoin or primidone, with or without barbiturates, develop low serum and red cell folate levels. The exact mechanism is unclear. Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anemia that will respond to normal quantities of dietary folate or to physiologic doses of folic acid only if alcohol is withdrawn. Macrocytosis of red cells is associated with chronic alcohol intake even when folate levels are normal. Inadequate folate intake is the major factor in the development of deficiency in spirit-drinking alcoholics. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit DHF reductase include methotrexate, pyrimethamine, and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is likely to cause megaloblastic anemia only when used in conjunction with sulfamethoxazole in patients with preexisting folate or cobalamin deficiency. The activity of pyrimethamine is intermediate. The antidote to these drugs is a reduced form of folate, folinic acid (5-formyl-THF).

CONGENITAL ABNORMALITIES OF FOLATE METABOLISM

Some infants with congenital defects of folate enzymes (e.g., cyclohydrolase or methionine synthase) have had megaloblastic anemia.

DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCIES

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and analysis of the blood levels of the vitamins.

COBALAMIN DEFICIENCY

Serum Cobalamin This is measured by an automated enzyme-linked immunosorbent assay (ELISA) or competitive-binding luminescence assay (CBLA). Normal serum levels range from 118–148 pmol/L (160–200 ng/L) to ~738 pmol/L (1000 ng/L). In patients with megaloblastic anemia due to cobalamin deficiency, the level is usually <74 pmol/L (100 ng/L). In general, the more severe the deficiency, the lower is the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are very low even in the absence of anemia. Values between 74 and 148 pmol/L (100 and 200 ng/L) are regarded as borderline. They may occur, for instance, in pregnancy, in patients with megaloblastic anemia due to folate deficiency. They may also be due to heterozygous, homozygous, or compound heterozygous mutations of the gene *TCN1* that codes for HC (TC I). There is then no clinical or hematologic abnormality. The serum cobalamin level is sufficiently robust, cost-effective, and most convenient to rule out cobalamin deficiency in the vast majority of patients suspected of having this problem. However, problems have arisen with commercial CBLA assays involving IF in PA patients with intrinsic antibodies in serum. These antibodies may cause false normal serum cobalamin levels in up to 50% of cases tested. Where clinical indications of PA are strong, a normal serum cobalamin does not rule out the diagnosis. Serum MMA levels will be elevated in untreated PA (see below).

Folate deficiency, TC I (HC) deficiency, oral contraceptives, and multiple myeloma have all been associated with low serum cobalamin levels that do not indicate cobalamin deficiency. On the other hand, high serum cobalamin levels are usually due to raised serum TC I levels and can be due to the presence of liver, renal, or myeloproliferative diseases or to cancer of the breast, colon, or liver.

Serum Methylmalonate and Homocysteine In patients with cobalamin deficiency sufficient to cause anemia or neuropathy, the serum MMA level is raised. Sensitive methods for measuring MMA

and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin deficiency, even in the absence of hematologic abnormalities or subnormal levels of serum cobalamin. Serum MMA levels fluctuate, however, in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 258 pmol/L (350 ng/L) and normal serum folate levels; 15% of elderly subjects, even with cobalamin levels >258 pmol/L (>350 ng/L), have this pattern of raised metabolite levels. These findings bring into question the exact cutoff points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences.

Serum homocysteine is raised in both early cobalamin and folate deficiency but may be raised in other conditions, for example, chronic renal disease, alcoholism, smoking, pyridoxine deficiency, hypothyroidism, and therapy with steroids, cyclosporin, and other drugs. Levels are also higher in serum than in plasma, in men than in premenopausal women, in women taking hormone replacement therapy or in oral contraceptive users, and in elderly persons and patients with several inborn errors of metabolism affecting enzymes in trans-sulfuration pathways of homocysteine metabolism. Thus, homocysteine levels must be carefully interpreted for diagnosis of cobalamin or folate deficiency.

Tests for the Cause of Cobalamin Deficiency Only vegans, strict vegetarians, or people living on a totally inadequate diet will become cobalamin deficient because of inadequate intake. Studies of cobalamin absorption once were widely used, but difficulty in obtaining radioactive cobalamin and ensuring that IF preparations are free of viruses has made these tests obsolete. Tests to diagnose PA include serum gastrin, which is raised; serum pepsinogen I, which is low in PA (90–92%) but also in other conditions; and gastric endoscopy. Tests for IF and parietal cell antibodies are also used, as well as tests for individual intestinal diseases.

Patients with atrophic gastritis may also have sufficient occult gastrointestinal blood loss to have iron deficiency as well as cobalamin deficiency. Iron deficiency may blunt the development of macrocytosis. Iron deficiency is much more common than cobalamin deficiency. In people older than age 60 years, cobalamin deficiency may accompany iron deficiency in 15–20% of cases. Thus, older patients diagnosed with iron-deficiency anemia should have cobalamin levels assessed, and those diagnosed with cobalamin deficiency should have their iron status assessed.

FOLATE DEFICIENCY

Serum Folate This is also measured by a chemiluminescence immunoassay or ELISA technique. In most laboratories, the normal range is from 11 nmol/L (2 μg/L) to ~82 nmol/L (15 μg/L). The serum folate level is low in all folate-deficient patients. It also reflects recent diet. Because of this, serum folate may be low before there is hematologic or biochemical evidence of deficiency. Serum folate rises in severe cobalamin deficiency because of the block in conversion of 5-MTHF to THF inside cells; raised levels have also been reported in the intestinal stagnant-loop syndrome due to absorption of bacterially synthesized folate.

Red Cell Folate The red cell folate assay is a valuable test of body folate stores. It is less affected than the serum assay by recent diet and traces of hemolysis. In normal adults, concentrations range from 880 to 3520 μmol/L (160–640 μg/L) of packed red cells. Subnormal levels occur in patients with megaloblastic anemia due to folate deficiency but also in nearly two-thirds of patients with severe cobalamin deficiency. False-normal results may occur if a folate-deficient patient has received a recent blood transfusion or if a patient has a raised reticulocyte count. Serum homocysteine assay is discussed earlier.

Tests for the Cause of Folate Deficiency The diet history is important. Tests for transglutaminase antibodies are performed to confirm or exclude gluten–induced enteropathy. If positive, duodenal biopsy is needed. An underlying disease causing increased folate breakdown should also be excluded.

TREATMENT

Cobalamin and Folate Deficiency

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anemia and to treat only with the appropriate vitamin. In patients who enter the hospital severely ill, however, it may be necessary to treat with both vitamins in large doses once blood samples have been taken for cobalamin and folate assays and a bone marrow biopsy has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly, one or two units only, with the usual treatment for heart failure if present. Occasionally, an excessive rise in platelets occurs after 1–2 weeks of therapy. Antiplatelet therapy, for example, aspirin, should be considered if the platelet count rises to >800 × 10^9/L.

COBALAMIN DEFICIENCY

It is usually necessary to treat patients who have developed severe cobalamin deficiency, as from PA, with lifelong regular cobalamin injections. In the UK, hydroxocobalamin is used; in the United States, cyanocobalamin. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for example, fish tapeworm, tropical sprue, or an intestinal stagnant loop that is amenable to surgery. The indications for starting cobalamin therapy are a well-documented megaloblastic anemia or other hematologic abnormalities and/or neuropathy due to the deficiency. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and, if necessary, given cobalamin replacement.

Replenishment of body stores should be complete with six 1000-μg IM injections of hydroxocobalamin given at 3- to 7-day intervals. More frequent doses are usually used in patients with cobalamin neuropathy, but there is no evidence that they produce a better response. Allergic reactions are rare and may require desensitization or antihistamine or glucocorticoid cover. For maintenance therapy, 1000 μg hydroxocobalamin IM once every 3 months is satisfactory. Because of the poorer retention of cyanocobalamin, protocols generally use higher and more frequent doses, for example, 1000 μg cyanocobalamin IM, monthly, for maintenance treatment.

Because a small fraction of cobalamin can be absorbed passively through mucous membranes even when there is complete failure of physiologic IF-dependent absorption, large daily oral doses (1000–2000 μg) of cyanocobalamin may be used in PA for replacement (especially in Canada and Sweden) and maintenance of normal cobalamin status. Sublingual therapy has also been proposed for those in whom injections are difficult because of a bleeding tendency and who may not tolerate parenteral therapy. If oral therapy is used, it is important to monitor compliance, particularly with elderly, forgetful patients. This author prefers parenteral therapy for initial treatment for PA, particularly in severe anemia or if a neuropathy is present, and for maintenance.

Treatment of patients with subnormal serum cobalamin levels with a normal MCV and no hypersegmentation of neutrophils and a negative IF antibody is, however, problematic. Some (perhaps 15%) cases may be due to TC I (HC) deficiency. Homocysteine and/or MMA measurements may help, but in the absence of these tests and with otherwise normal gastrointestinal function, repeat serum cobalamin assay after 6–12 months may help one decide whether to start cobalamin therapy. Oral cyanocobalamin therapy with low doses (e.g., 50 μg daily) has a large role in treating patients thought to have food malabsorption of cobalamin.

Cobalamin injections are used in a wide variety of diseases, often neurologic, despite normal serum cobalamin and folate levels and a normal blood count and in the absence of randomized, double-blind, controlled trials. These conditions include multiple sclerosis and chronic fatigue syndrome/myalgic encephalomyelitis (ME). It seems probable that any benefit is due to the placebo effect of a usually

painless, pink injection. In ME, oral cobalamin therapy, despite providing equally large amounts of cobalamin, has not been beneficial, supporting the view of the effect of the injections being placebo only.

FOLATE DEFICIENCY

Oral doses of 5–15 mg of folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months, when all folate-deficient red cells will have been eliminated and replaced by new folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected; otherwise, cobalamin neuropathy may develop as the deficiency progresses despite a response of the anemia of cobalamin deficiency to folate therapy.

Long-term folic acid therapy is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for example, in chronic dialysis or chronic hemolytic anemias. It may also be necessary in gluten-induced enteropathy that does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g., once-yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic Acid (5-Formyl-THF) This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other DHF reductase inhibitors, for example, trimethoprim or cotrimoxazole.

PROPHYLACTIC FOLIC ACID

Prophylactic folic acid is used in chronic dialysis patients and in parenteral feeds. Prophylactic folic acid has been used to reduce homocysteine levels to prevent cardiovascular disease and for cognitive function in the elderly, but there are no firm data to show any benefit.

Pregnancy In over 80 countries (but none in Europe), food is fortified at a level of 120–250 μg/100 g with folic acid (in grain, flour, or rice) to reduce the risk of NTDs. In all countries that have studied this, fortification has led to a lower prevalence of NTD pregnancies and births. Nevertheless, folic acid, 400 μg daily, should also be given as a supplement before and throughout pregnancy to prevent megaloblastic anemia and reduce the incidence of NTDs, even in countries with fortification of the diet. Most if not all the folic acid used in fortification and eaten over three meals a day will be converted during absorption to 5-MTHF. This compound at the levels achieved by fortification will not correct the anemia in cobalamin deficiency. Studies in the United States suggest that there is no increase in the proportion of individuals with low serum cobalamin levels and no anemia since food fortification with folic acid. It is unknown if there has been a change in incidence of cobalamin neuropathy, but no country has reported this since mandating fortification.

Data in early pregnancy show significant lack of compliance with taking folic acid supplements, emphasizing the need for food fortification. In women who have had a previous fetus with an NTD and others at high risk (e.g., diabetes, sickle cell anemia), a dose of 5 mg daily is recommended when pregnancy is contemplated and throughout the subsequent pregnancy.

Infancy and Childhood The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g., 1 mg daily) should be given routinely to those weighing <1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections, or vomiting and diarrhea.

The World Health Organization currently recommends routine supplementation with iron and folic acid in children in countries where iron deficiency is common and child mortality, largely due to infectious diseases, is high. However, some studies suggest that in areas where malaria rates are high, this approach may increase the incidence of severe illness and death. Even where malaria is rare, there appears to be no survival benefit.

MEGALOBLASTIC ANEMIA NOT DUE TO COBALAMIN OR FOLATE DEFICIENCY OR ALTERED METABOLISM

This may occur with many antimetabolite drugs (e.g., hydroxyurea, cytarabine, mercaptopurine, thioguanine) that inhibit DNA replication. Antiviral nucleoside analogues used in treatment of HIV infection may also cause macrocytosis and megaloblastic marrow changes. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anemia, there is a genetic defect in the high-affinity thiamine transporter (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This defect leads to reduced nucleic acid production. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow. The explanation is unclear for megaloblastic changes in the marrow in some patients with acute myeloid leukemia and myelodysplasia.

The most frequent causes of macrocytosis without megaloblastic changes are alcohol, liver disease, hypothyroidism, and pregnancy. Myelodysplasia, myeloma and other paraproteinemias, aplastic anemia, and smoking are other causes.

105 Hemolytic Anemias

Lucio Luzzatto, Lucia De Franceschi

DEFINITIONS

Turnover is typical of all blood cells, including erythrocytes, that have a finite life span. Hence, a logical, time-honored classification of anemias is in three groups: (1) decreased production of red cells, (2) increased destruction of red cells, and (3) acute blood loss. Decreased production is covered in **Chaps. 102, 103, and 107**; acute blood loss in **Chap. 106**; increased destruction is covered in this chapter.

All patients who are anemic as a result of either increased destruction of red cells or acute blood loss have one important element in common: the anemia results from overconsumption of red cells from the peripheral blood, whereas the supply of cells from the bone marrow is normal (indeed, it is usually increased). However, with blood loss, as in acute hemorrhage, the red cells are physically lost *from* the body itself; this is fundamentally different from destruction of red cells *within* the body, as in hemolytic anemias (HAs).

With respect to primary etiology, HAs may be *inherited* or *acquired*; from a clinical point of view, they may be more *acute* or more *chronic*, and they may vary from mild to very severe; the site of hemolysis may be predominantly *intravascular* or *extravascular*. With respect to mechanisms, HAs may be due to *intracorpuscular* causes or to *extracorpuscular* causes **(Table 105-1)**. But before reviewing the individual types of HA, it is appropriate to consider what general features they have in common, in terms of clinical aspects and pathophysiology.

GENERAL CLINICAL AND LABORATORY FEATURES

The clinical presentation of a patient with anemia is greatly influenced in the first place by whether the onset is abrupt or gradual, and HAs are no exception. A patient with autoimmune HA or with favism may be a medical emergency, whereas a patient with mild hereditary spherocytosis (HS) or with cold agglutinin disease (CAD) may be diagnosed after years. This is due in large measure to the remarkable ability of the body to adapt to anemia when it is slowly progressing **(Chap. 66)**.

What differentiates HAs from other anemias is that the patient has signs and symptoms arising directly from hemolysis **(Table 105-2)**. At the clinical level, the main sign is *jaundice*; in addition, the patient may report discoloration of the urine. In many cases of HA, the spleen is enlarged because it is a preferential site of hemolysis; in some cases, the liver may be enlarged as well; and gallstones are common. In all severe congenital forms of HA, there may also be skeletal changes due to overactivity of the bone marrow: they are never as severe as in thalassemia major because ineffective erythropoiesis is less, or even absent. Since several forms of HA are inherited, it is important to include family history in the initial appraisal.

TABLE 105-1 Classification of Hemolytic Anemias[a]

	INTRACORPUSCULAR DEFECTS	EXTRACORPUSCULAR FACTORS
Inherited	Hemoglobinopathies Enzymopathies Membrane-cytoskeletal defects	Familial (atypical) hemolytic-uremic syndrome
Acquired	Paroxysmal nocturnal hemoglobinuria (PNH)	Mechanical destruction (microangiopathic) Toxic agents Drugs Infectious Autoimmune

[a]Hereditary causes correlate with intracorpuscular defects because these defects are due to inherited mutations; the one exception is PNH because the defect is due to an acquired somatic mutation. Conversely, acquired causes correlate with extracorpuscular factors because mostly these factors are exogenous; the one exception is familial hemolytic-uremic syndrome (HUS; often referred to as atypical HUS [aHUS]) because here an inherited abnormality permits complement activation triggered by exogenous factors to become excessive, with bouts of production of membrane attack complex capable of destroying normal red cells. Interestingly, in both PNH and aHUS, hemolysis is complement-mediated.

TABLE 105-2 Features Common to Most Patients with a Hemolytic Disorder

GENERAL EXAMINATION	JAUNDICE, PALLOR
Other physical findings	Spleen may be enlarged; bossing of skull in severe congenital cases
Hemoglobin level	From normal to severely reduced
MCV, MCH	Usually increased
Reticulocytes	Usually increased
Bilirubin	Almost always increased (mostly unconjugated)
LDH	Increased (up to 10× normal with intravascular hemolysis)
Haptoglobin	Reduced to absent if hemolysis is at least in part intravascular

Abbreviations: LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume.

The laboratory features of HA are related to (1) hemolysis per se and (2) the erythropoietic response of the bone marrow. In most cases, hemolysis is largely extravascular, and it produces an increase in unconjugated bilirubin and aspartate aminotransferase (AST) in the serum; urobilinogen will be increased in both urine and stool. If hemolysis is mainly intravascular, the telltale sign is hemoglobinuria (often associated with hemosiderinuria); in the serum, there is free hemoglobin, lactate dehydrogenase (LDH) is increased, and haptoglobin is reduced. In contrast, the serum bilirubin level may be normal or only mildly elevated. The main sign of the erythropoietic response by the bone marrow is an increase in reticulocytes (a test all too often neglected in the initial workup of a patient with anemia). Usually the increase will be reflected in both the percentage of reticulocytes (the more commonly quoted figure) and in the absolute reticulocyte count (the more definitive parameter). The increased number of reticulocytes is associated with an increased mean corpuscular volume (MCV) in the blood count. On the blood smear, this is reflected in the presence of macrocytes; polychromasia is also present, and sometimes one sees nucleated red cells. In most cases, a bone marrow aspirate is not necessary in the diagnostic workup; if it is done, it will show erythroid hyperplasia. In practice, once an HA is suspected, specific tests will usually be required for a definitive diagnosis of a specific type of HA.

GENERAL PATHOPHYSIOLOGY

The mature red cell is the product of a developmental pathway that brings the phenomenon of differentiation to an extreme. An orderly sequence of events produces synchronous changes, whereby the gradual accumulation of a huge amount of hemoglobin in the cytoplasm (to a final level of 340 g/L, i.e., about 5 m*M*) goes hand in hand with the gradual loss of cellular organelles and of biosynthetic abilities. In the end, the erythroid cell undergoes a process that has features of apoptosis, including nuclear pyknosis and eventually extrusion of the nucleus. However, the final result is more altruistic than suicidal; the cytoplasmic body, instead of disintegrating, is now able to provide oxygen to all cells in the human organism for some remaining 120 days of the red cell life span.

As a result of this unique process of differentiation and maturation, intermediary metabolism is drastically curtailed in mature red cells **(Fig. 105-1)**; for instance, cytochrome-mediated oxidative phosphorylation has been lost with the loss of mitochondria (through a process of physiologic autophagy); therefore, there is no backup to anaerobic glycolysis, which in the red cell is the only provider of adenosine triphosphate (ATP). Also, the capacity of making protein has been lost with the loss of ribosomes. This places the cell's limited metabolic apparatus at risk, because if any protein component deteriorates, it cannot be replaced, as it would be in most other cells; and in fact, the activity of most enzymes gradually decreases as red cells age. At the same time, during their long time in circulation, various red cell

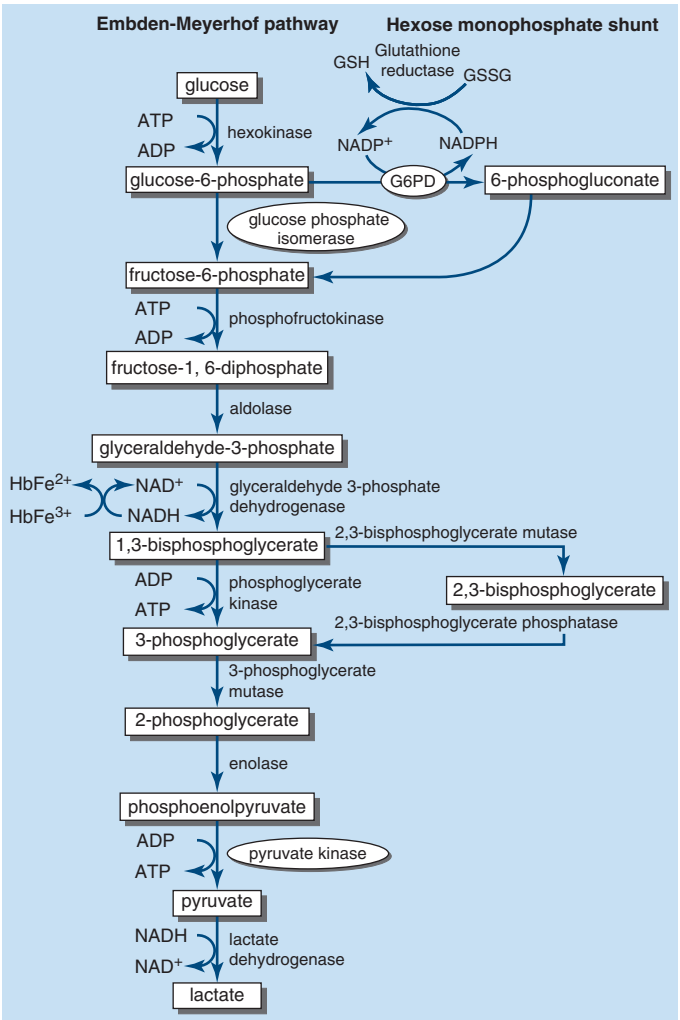

FIGURE 105-1 Red blood cell (RBC) metabolism. The Embden-Meyerhof pathway (glycolysis) generates ATP required for cation transport and for membrane maintenance. The generation of NADH maintains hemoglobin iron in a reduced state. The hexose monophosphate shunt generates NADPH that is used to reduce glutathione, which protects the red cell against oxidant stress; the 6-phosphogluconate, after decarboxylation, can be recycled via pentose sugars to glycolysis. Regulation of the 2,3-bisphosphoglycerate level is a critical determinant of oxygen affinity of hemoglobin. Enzyme deficiency states in order of prevalence: glucose-6-phosphate dehydrogenase (G6PD) > pyruvate kinase > glucose-6-phosphate isomerase > rare deficiencies of other enzymes in the pathway. The more common enzyme deficiencies are encircled.

components inevitably accumulate damage and become physically denser. The anion exchanger known as band 3 is the most abundant protein in the red cell membrane **(Fig. 105-2 and Table 105-3)**, with about 1.2 million molecules per red cell. As red cells age and become denser, probability is increased that a region of the band 3 molecule becomes exposed on the cell surface and contributes to creating an antigenic site recognizable by low-avidity naturally occurring anti–band 3 IgG antibodies. This process might be enhanced by the clustering of band 3 molecules favored by the antibody itself and by the binding of hemichromes arising from hemoglobin degradation. Senescent red cells thus become opsonized, and this is the signal for phagocytosis by macrophages in the spleen, in the liver, and elsewhere. This process may become accelerated in various ways in HA.

Another consequence of the relative simplicity of red cells is that they have a limited range of ways to manifest distress under hardship; in essence, any sort of metabolic failure will eventually lead either to structural damage to the membrane or to failure of the cation pump. In either case, the life span of the red cell is reduced, which is the definition of a *hemolytic disorder*. If the rate of red cell destruction exceeds the capacity of the bone marrow to produce more red cells, the hemolytic disorder will manifest as HA.

Thus, the essential pathophysiologic process common to all HAs is an increased red cell turnover; in many HAs, this is due at least in part to an acceleration of the senescence process described above. The gold standard for proving that the life span of red cells is reduced (compared to the normal value of ~120 days) is a *red cell survival* study, which can be carried out by labeling the red cells with ^{51}Cr and measuring the fall in radioactivity over several days or weeks (this classic test can now be replaced by a methodology using the nonradioactive isotope ^{15}N). If the hemolytic event is transient, it does not usually cause any long-term consequences, except for an increased requirement for erythropoietic factors, particularly folic acid. However, if hemolysis is recurrent or persistent, the increased bilirubin production favors the formation of gallstones. If a considerable proportion of hemolysis takes place in the spleen, as is often the case, splenomegaly may become increasingly a feature, and hypersplenism may develop, with consequent neutropenia and/or thrombocytopenia.

The increased red cell turnover has important consequences. In normal subjects, the iron from effete red cells is very efficiently recycled by the body; however, with chronic intravascular hemolysis, the persistent hemoglobinuria will cause considerable iron loss, needing replacement. With chronic extravascular hemolysis, the opposite problem, iron overload, is more common, especially if the patient needs frequent blood transfusions. Even without blood transfusion, when erythropoiesis is massively increased, the release of erythroferrone from erythroid cells suppresses hepcidin, causing increased iron absorption. In the long run, in the absence of iron-chelation therapy, iron overload will cause secondary hemochromatosis; this will cause damage particularly to the liver, eventually leading to cirrhosis, and to the heart muscle, eventually causing heart failure.

Compensated Hemolysis versus Hemolytic Anemia Red cell destruction is a potent stimulus for erythropoiesis, which is mediated by erythropoietin (EPO) produced by the kidney. This mechanism is so effective that in many cases the increased output of red cells from the bone marrow can fully balance an increased destruction of red cells. In such cases, we say that hemolysis is *compensated*. The pathophysiology of compensated hemolysis is similar to what we have just described, except there is no anemia. This notion is important from the diagnostic point of view, because a patient with a hemolytic condition, even an inherited one, may present without anemia; and it is also important from the point of view of management because compensated hemolysis may become "decompensated," i.e., anemia may suddenly appear in certain circumstances, for instance in pregnancy, folate deficiency, or renal failure interfering with adequate EPO production. Another general feature of chronic HAs is seen when any intercurrent condition, such as an acute infection, depresses erythropoiesis. When this happens, in view of the increased rate of red cell turnover, the effect will be predictably much more marked than in a person who does not have hemolysis. The most dramatic example is infection by parvovirus B19, which may cause a rather precipitous fall in hemoglobin—an occurrence sometimes referred to as *aplastic crisis*.

INHERITED HEMOLYTIC ANEMIAS

The red cell has three essential components: (1) hemoglobin, (2) the membrane-cytoskeleton complex, and (3) the metabolic machinery necessary to keep hemoglobin and the membrane-cytoskeleton complex in working order. Diseases caused by inherited abnormalities of hemoglobin, or hemoglobinopathies, are covered in **Chap. 103**. Here we will deal with diseases of the other two components.

Hemolytic Anemias due to Abnormalities of the Membrane-Cytoskeleton Complex The detailed architecture of the red cell membrane is complex, but its basic design is relatively simple (Fig. 105-2). The lipid bilayer incorporates phospholipids and cholesterol, and it is spanned by a number of proteins that have their hydrophobic transmembrane domain(s) embedded in the membrane; most of these proteins also extend to both the outside (extracellular domains) and the inside of the cell (cytoplasmic domains). Other proteins are tethered to the membrane through a glycosylphosphatidylinositol (GPI) anchor; these have only an extracellular domain. Membrane proteins include energy-dependent ion transporters, ion channels, receptors

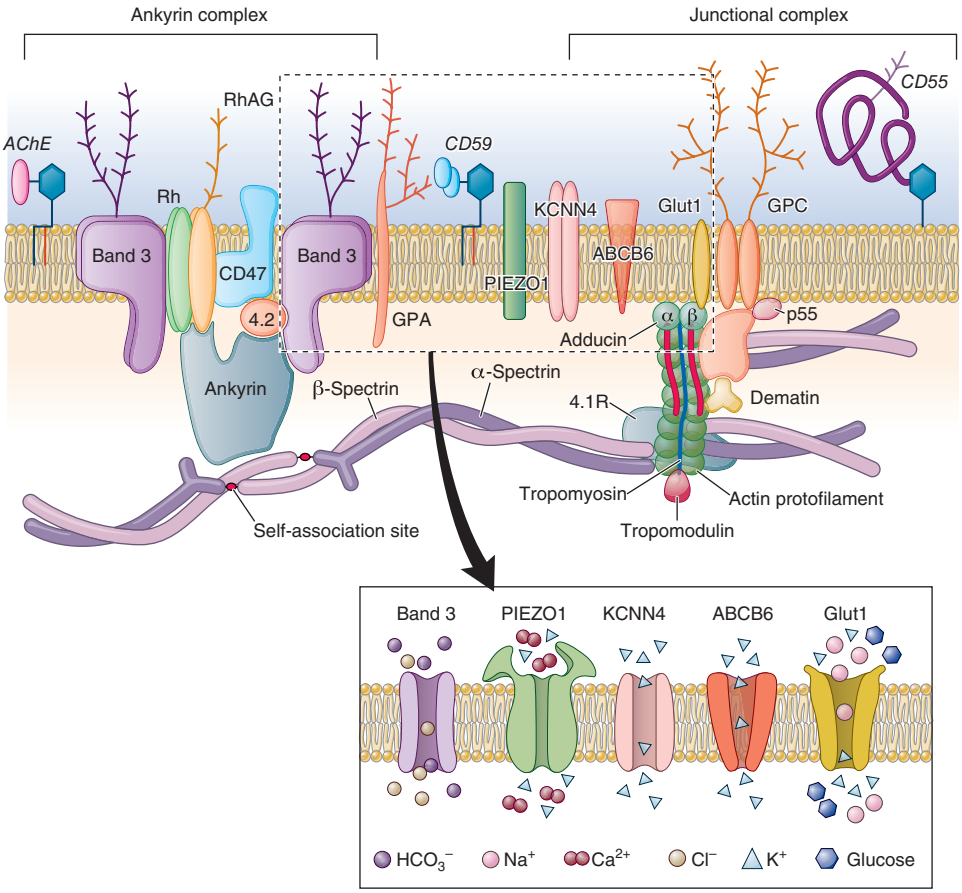

FIGURE 105-2 The red cell membrane and cytoskeleton schematic diagram. Within the membrane lipid bilayer, several integral membrane proteins are shown (see inset). Other proteins, e.g., acetylcholinesterase (AChE) and the two complement-regulatory proteins CD59 and CD55, are tethered to the membrane through the glycosylphosphatidylinositol (GPI) anchor: in these cases, the entire polypeptide chain is extracellular. Many of the membrane proteins bear polypeptide and/or carbohydrate red cell antigens. Underneath the membrane, the α-β spectrin dimers, which associate head-to-head into tetramers, together with actin and other proteins, form most of the cytoskeleton. The *ankyrin complex*, which also involves the band 4.2 protein, and the *junctional complex*, which involves the band 4.1 protein and dematin, connect the membrane to the cytoskeleton. The ankyrin complex provides mainly radial (also called vertical) connections; the junctional complex provides mainly tangential (also called horizontal) connections. Pathogenic changes in the former can cause spherocytosis, whereas pathogenic changes in the latter can cause elliptocytosis; pathogenic changes in spectrin can cause either. Branched lines symbolize carbohydrate moiety of proteins. The various molecules are obviously not drawn to the same scale. ***Inset.*** Schematic diagram of membrane transporters, abnormalities of which underlie channelopathies. Band 3 (anion exchanger 1 [AE1]) is the most abundant. Mutations of *SLC4A1* (encoding band 3) can inactivate anion exchange, causing cation leak or negatively affecting interactions with neighboring membrane proteins. PIEZO1 is a huge protein that is embedded in the membrane as a homo-trimer with a three-bladed, propeller-shaped structure; it is a mechano-sensitive cation channel. *KCNN4* encodes a Ca^{2+} activated K^+ channel, also known as the Gardos channel. *PIEZO1* mutations can be associated with abnormal Ca^{2+} entry, resulting in overactivation of the Gardos channel; this promotes K^+ efflux and red cell dehydration Mutations on KCC4 induce alterations of channel properties (kinetic or ion trafficking), resulting again in abnormal K^+ efflux and red cell dehydration. *ABCB6* encodes a mitochondrial porphyrin transporter, but some mutations can cause increased K^+ efflux from red cells and stomatocytosis. Glut1 facilitates glucose transport; it is encoded by *SLC2A1*, and mutations can block the glucose transport and induce Na^+, K^+ leakage. *(Modified from N Young et al: Clinical Hematology. Philadelphia, Elsevier, 2006; and from A Iolascon et al: Br J Haematol 187:13, 2019.)*

for complement components, and receptors for other ligands. The most abundant red cell membrane proteins are glycophorins and the so-called band 3, an anion transporter that is an integral membrane protein. The extracellular domains of many of these proteins are heavily glycosylated, and they carry antigenic determinants that correspond to blood groups. Underneath the membrane, and tangential to it, is a network of other proteins that make up the cytoskeleton. The main cytoskeletal protein is the spectrin tetramer, consisting of a head-to-head association of two α-spectrin-β-spectrin heterodimers. The cytoskeleton is linked to the membrane through the *ankyrin complex* (that includes also band 4.2) and the *junctional complex* (that includes adducin and band 4.1) (Fig. 105-2). These multiprotein complexes make membrane and cytoskeleton intimately connected to each other, thus supporting membrane stability and at the same time providing the erythrocyte with the important property of deformability.

The membrane-cytoskeleton complex has essentially three functions: it is an envelope for the red cell cytoplasm; it maintains the normal red cell shape; and it provides cross-membrane transport of electrolytes and of metabolites such as glucose and amino acids. In the membrane-cytoskeleton complex, the individual components are so intimately associated with each other that an abnormality of almost any of them will be disturbing or disruptive, causing mechanical instability of the membrane and/or reduced red cell deformability, ultimately causing hemolysis. These abnormalities are almost invariably inherited mutations; thus, diseases of the membrane-cytoskeleton complex belong to the category of inherited HAs. Before the red cells lyse, they often exhibit more or less specific changes that alter the normal biconcave disk shape. Thus, the majority of the diseases in this group have been known for over a century as hereditary spherocytosis (HS) and hereditary elliptocytosis (HE). More recently, a third morphologic entity, whereby on a blood smear the round-shaped central pallor of a red cell is replaced by a linear-shaped central pale area, has earned the name *stomatocytosis*; because this abnormal shape is related to abnormalities of channel molecules, the underlying disorders are also referred to as channelopathies. From an understanding of the molecular basis of these disorders, it has emerged (Table 105-3) that, although these disorders are predominantly monogenic, no one-to-one correlation exists between a certain gene and a certain disorder. Rather, what has been regarded as a single disorder (e.g., HS) can arise through mutation of one of several genes; conversely, what have been regarded as different disorders can arise through different mutations of the very same gene **(Fig. 105-3)**.

HEREDITARY SPHEROCYTOSIS This is most common among this group of HAs, with an estimated prevalence of 1:2000–1:5000 in populations of European ancestry. Its identification is credited to Minkowksy and Chauffard, who, at the end of the nineteenth century, reported families who had spherocytes in their peripheral blood **(Fig. 105-4*A*)**. In vitro studies revealed that the red cells were abnormally susceptible to lysis in hypotonic media; indeed, the increase in *osmotic fragility* became the main diagnostic test for HS. Today we know that HS, thus defined, is genetically heterogeneous; i.e., it can arise from a variety of mutations in one of several genes (Table 105-3). It has been also recognized that the inheritance of HS is not always autosomal dominant (with the patient being heterozygous); indeed, some of the most severe forms are instead autosomal recessive (with the patient being homozygous).

Clinical Presentation and Diagnosis The spectrum of clinical severity of HS is broad. Severe cases may present in infancy with severe anemia, whereas mild cases may present in young adults or even later in life. The main clinical findings are jaundice, an enlarged spleen, and often gallstones; indeed, it may be the finding of gallstones in a young person that triggers diagnostic investigations.

TABLE 105-3 Inherited Diseases of the Red Cell Membrane-Cytoskeleton Complex

GENE	CHROMOSOMAL LOCATION	PROTEIN PRODUCED	DISEASE(S) WITH CERTAIN MUTATIONS (INHERITANCE)	COMMENTS
SPTA1	1q22-q23	α-Spectrin	HS (recessive) HE (dominant)	Rare Mutations of this gene account for about 65% of HE. More severe forms may be due to coexistence of an otherwise silent mutant allele.
SPTB	14q23-q24.1	β-Spectrin	HS (dominant) HE (dominant)	Rare Mutations of this gene account for about 30% of HE, including some severe forms.
ANK1	8p11.2	Ankyrin	HS (dominant)	May account for majority of HS.
SLC4A1	17q21	Band 3; also known as AE (anion exchanger) or AE1	HS (dominant) Southeast Asia ovalocytosis (dominant) Stomatocytosis (cryohydrocytosis)	Mutations of this gene may account for about 25% of HS. Polymorphic mutation (deletion of nine amino acids); in heterozygotes, clinically asymptomatic and protective against *Plasmodium falciparum.* Certain specific missense mutations shift protein function from anion exchanger to cation conductance.
EPB41	1p33-p34.2	Band 4.1	HE (dominant)	Mutations of this gene account for about 5% of HE, mostly with prominent morphology but little/no hemolysis in heterozygotes; severe hemolysis in homozygotes.
EPB42	15q15-q21	Band 4.2	HS (recessive)	Mutations of this gene account for about 3% of HS.
RHAG	6p21.1-p11	Rhesus-associated glycoprotein	Chronic nonspherocytic hemolytic anemia (recessive)	Very rare; associated with total loss of all Rh antigens. One specific mutation in this gene entails loss of stomatin from the cell membrane, causing overhydrated stomatocytosis.
PIEZO1	16q23-q24	PIEZO1 (mechanosensitive ion channel component 1 channel)	Dehydrated hereditary stomatocytosis (dominant)	Also known as xerocytosis with pseudohyperkalemia. Patients may present with perinatal edema.
KCNN4	19q13.31	KCNN4 Intermediate conductance calcium-activated potassium channel protein 4 (Gardos channel)	Dehydrated hereditary stomatocytosis (dominant)	Clinical presentation similar to that of *PIEZO1* mutants.
ABCB6	2q35-q36	ATP-binding cassette subfamily B member 6	Familial pseudohyperkalemia (dominant)	Increased potassium leakage upon storage in blood bank condition: this can cause hyperkalemia in the recipient. *ABCB6* mutation is present in 0.3% of blood donors.
SLC2A1	1p34.2	GLUT1 glucose transporter	Overhydrated hereditary stomatocytosis	Associated with serious neurologic manifestations.

Note: PIEZO1, KCNN4, ABCB6, and *GLUT1* are channel molecules; conditions associated with mutations in the respective genes are appropriately named channelopathies.
Abbreviations: HE, hereditary elliptocytosis; HS, hereditary spherocytosis.

The variability in clinical manifestations that is observed among patients with HS is largely due to the different underlying molecular lesions (Table 105-3). Not only are mutations of several genes involved, but also different mutations of the same gene can give very different clinical manifestations. In milder cases, hemolysis is often compensated (see above), but changes in clinical expression may be seen even in the same patient because intercurrent conditions (e.g., pregnancy, infection) may cause decompensation. The anemia is usually normocytic with the characteristic morphology that gives the disease its name. An increased mean corpuscular hemoglobin concentration (MCHC >34 g/dL) and increased red cell distribution width (RDW >14%) associated with normal or slightly decreased MCV on an ordinary blood count report should raise the suspicion of HS. The spleen plays a key role in HS through a dual mechanism. On one hand, because HS red cells are less deformable, transit through the splenic circulation makes them more prone to vesiculate; on the other hand, like in many other HAs, the spleen itself is a major site of destruction through phagocytosis by macrophages.

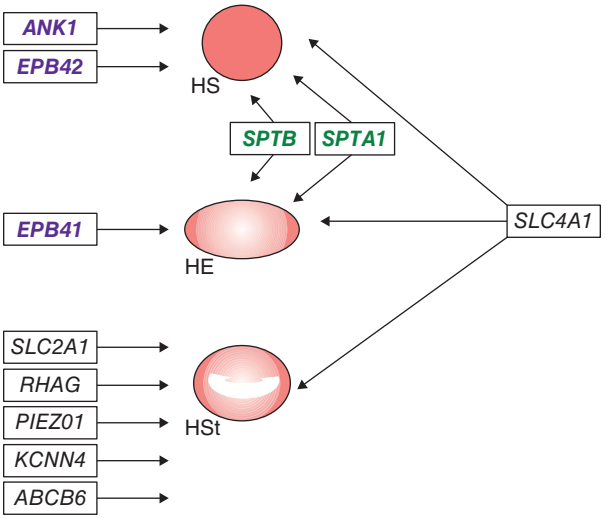

FIGURE 105-3 Hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and hereditary stomatocytosis (HSt) are three morphologically distinct forms of congenital hemolytic anemia. It has emerged that each one can arise from mutation of one of several genes and that different mutations of the same gene can give one or another form. (See also Table 105-3.) Genes encoding membrane proteins are in *black*; genes encoding cytoskeleton proteins are in *green*; genes encoding proteins in the junctional and ankyrin complexes are in *purple*.

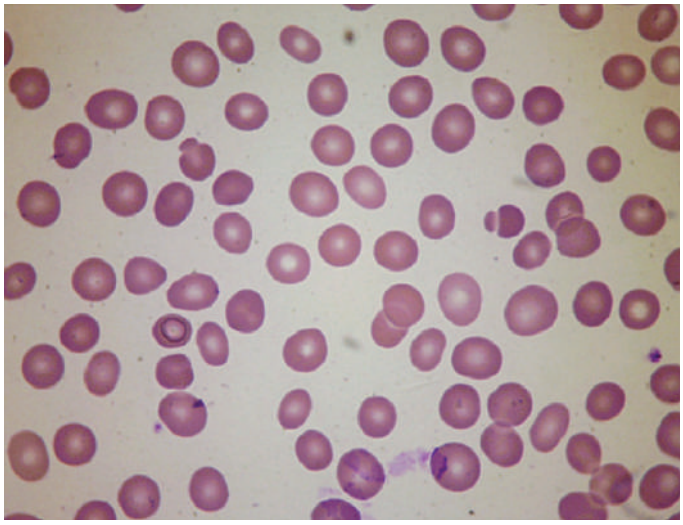
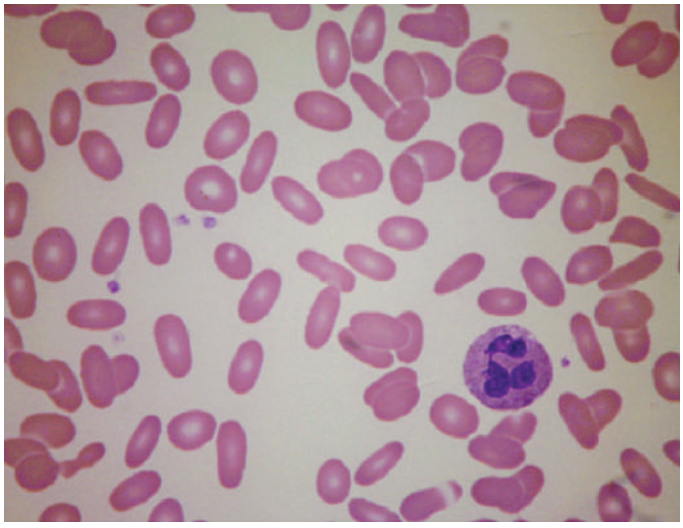
When there is a family history, it is usually easy to make a diagnosis based on features of HA and typical red cell morphology. However, family history may be negative for at least two reasons. First, the patient may have a de novo mutation, i.e., a mutation that has taken place in a germ cell of one of the patient's parents or early after zygote formation. Second, the patient may have a recessive form of HS (Table 105-3). In such cases, more extensive laboratory investigations are required, including osmotic fragility, the acid glycerol lysis test, the eosin-5′-maleimide (EMA)–binding test, sodium dodecyl sulfate (SDS)-gel electrophoresis of membrane proteins, and ektacytometry (testing red cell deformability as a function of shear stress at different osmolality); these tests are usually carried out in laboratories with special expertise in this area. Sometimes a definitive diagnosis can be obtained only by molecular studies demonstrating a mutation in one of the genes underlying HS (Table 105-3).

TREATMENT



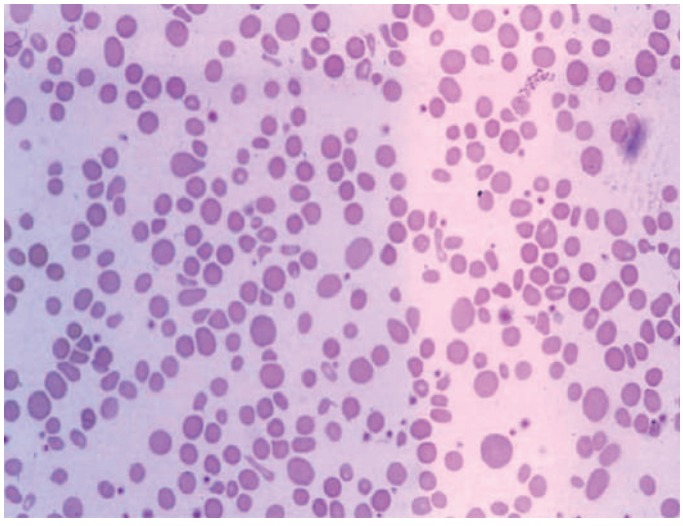
Hereditary Spherocytosis

We do not have a causal treatment for HS; i.e., no way has yet been found to correct the basic defect in the membrane-cytoskeleton structure. Given the special role of the spleen in HS (see above), splenectomy is often beneficial. Current recommendations are to proceed with splenectomy at the age of 4–6 years in severe cases, to delay splenectomy until puberty in moderate cases, and to avoid splenectomy in mild cases. Partial splenectomy can be considered in certain cases, and it is helpful to know about the outcome of splenectomy in the patient's affected relatives. Before splenectomy, vaccination against encapsulated bacteria (*Neisseria meningitidis* and *Streptococcus pneumoniae*) is imperative; penicillin prophylaxis after splenectomy is controversial. Along with splenectomy, cholecystectomy should not be carried out automatically, but it should be carried out, usually by the laparoscopic approach, whenever it is clinically indicated, mainly when gallstones are symptomatic. The most severe cases of HS (estimated at <10%) are transfusion dependent, and in infants with severe HS, erythropoietin may prove to be transfusion sparing.



HEREDITARY ELLIPTOCYTOSIS HE is at least as heterogeneous as HS, both from the genetic point of view (Table 105-3, Fig. 105-3) and from the clinical point of view. The global incidence of HE is 1:2000–4000 subjects. Again, it is the shape of the red cells **(Fig. 105-4*B*)** that gives the name to the condition, but there is no direct correlation between the elliptocytic morphology and clinical severity. In fact, some mild or even asymptomatic cases may have nearly 100% elliptocytes (or ovalocytes). Indeed, the diagnosis of HE is generally incidental, because hemolysis may be compensated and there may be no anemia, although this may become evident in the course of infection. One particular in-frame deletion of nine amino acids in the *SLC4A1* gene encoding band 3 underlies the so-called Southeast Asia ovalocytosis (SAO): it is not a disease, but rather a polymorphism with a frequency of up to 5–7% in certain populations (e.g., Papua New Guinea, Indonesia, Malaysia, Philippines), presumably as a result of malaria selection. It is asymptomatic in heterozygotes and probably lethal in homozygotes. The cases of HE with the most severe HA are those with biallelic mutations of one of the genes involved (see Fig. 105-3), and these are said to have hereditary pyropoikilocytosis (HPP): here the instability of the cytoskeleton protein network may result from decreased tetramerization of spectrin dimers. The red cell volume is decreased (MCV: 50–60 fL), and all kinds of bizarre poikilocytes are seen on the blood smear **(Fig. 105-4*C*)**. HPP patients have splenomegaly and often benefit from splenectomy.

Channelopathies These rare conditions (see Fig. 105-3) are characterized by abnormalities in red cell ion content and alteration of erythrocyte volume. Cation leak can cause hyperkalemia; in some cases, this leak is accelerated in the cold (the resulting spuriously high serum K^+ is then referred to as pseudo-hyperkalemia). The less rare form, dehydrated stomatocytosis (DHS; also referred to as xerocytosis), is a (usually compensated) macrocytic hemolytic disorder, with increased MCHC (generally >36 g/dL) associated with mild jaundice. Mutations in either *PIEZO1*, encoding an ion channel activated by pressure (mechanoreceptor), or in *KCCN4*, encoding the Ca^{2+} activated K^+ channel (Gardos channel) have been recognized to cause DHS (see Table 105-3).



Another form is overhydrated stomatocytosis (OHS). OHS is also macrocytic (MCV >110 fL), but the MCHC is low (<30 g/dL). The underlying mutation is in the Rhesus gene *RHAG*, which encodes an ammonia channel. Yet other patients with stomatocytosis (Table 105-3) have mutations in *SLC4A1* (encoding band 3) and *SLC2A1* (encoding the glucose transporter GLUT1). Mutations of the latter are responsible for *cryohydrocytosis*, a channelopathy in which the red cells swell and burst when they are cooled. In vivo hemolysis can vary from relatively mild to quite severe. Familial hyperkalemia has been recently linked to mutations in *ABCB6*, resulting in abnormal cation leak with extracellular release of a large amount of K^+ (hyperkalemia). Mutations in *ABCB6* have been identified in almost 0.3% of blood donors. However, splenectomy is contraindicated in stomatocytosis due to the significant proportion of severe thromboembolic complications observed in splenectomized DHS patients.

FIGURE 105-4 Peripheral blood smear from patients with membrane-cytoskeleton abnormalities. ***A.*** Hereditary spherocytosis. ***B.*** Hereditary elliptocytosis, heterozygote. ***C.*** Pyropoikilocytosis, with both alleles of the α-spectrin gene mutated.

Laser diffraction analysis, or *ektacytometry*, can measure the deformability of red blood cells subjected to either increasing shear stress or to an osmotic stress. This technique has been used extensively to investigate membrane-cytoskeleton abnormalities, and it can differentiate stomatocytosis from spherocytosis.

Enzyme Abnormalities When an important defect in a component of the membrane-cytoskeleton complex is present, hemolysis is a direct consequence of the fact that the very structure of the red cell is compromised. Instead, when one of the enzymes is defective, the consequences will depend on the precise role of that enzyme in the metabolic machinery of the red cell. This machinery has two main functions: (1) to provide energy in the form of ATP, and (2) to prevent oxidative damage to hemoglobin and to other proteins by providing sufficient reductive potential; the key molecule for this is NADPH, required for regeneration of glutathione (GSH) and for degradation of H_2O_2.

ABNORMALITIES OF THE GLYCOLYTIC PATHWAY Because red cells, in the course of their differentiation, have sacrificed not only their nucleus and their ribosomes but also their mitochondria, they rely exclusively on the anaerobic portion of the glycolytic pathway for producing ATP, most of which is required by the red cell for cation transport against a concentration gradient across the membrane. If this fails due to a defect of any of the enzymes of the glycolytic pathway (Table 105-4), the result will be hemolytic disease.

Pyruvate Kinase Deficiency Abnormalities of the glycolytic pathway are all inherited and all rare. Among them, deficiency of pyruvate kinase (PK) is the least rare, with an estimated prevalence in most populations of 1:10,000. However, recently, a polymorphic PK mutation (E277K) was found in some African populations with heterozygote frequencies of 1–7%, suggesting that this may be another malaria-related polymorphism. HA secondary to PK deficiency is an autosomal recessive disease (Fig. 105-5).

The clinical picture of homozygous (or biallelic) PK deficiency is that of an HA that often presents in the newborn with severe neonatal jaundice, requiring nearly always phototherapy and frequently exchange transfusion; the jaundice often persists, and it is often associated with reticulocytosis. The anemia is of variable severity; sometimes it is so severe as to require regular blood transfusion treatment, whereas sometimes it is mild, bordering on a nearly compensated hemolytic disorder. As a result, the diagnosis may be delayed: in some cases, it is made, for instance, in a young woman during her first pregnancy, when the anemia may get worse. The delay in diagnosis may be caused in part by the fact that the anemia is often remarkably well tolerated because the metabolic block at the last step in glycolysis causes an increase in 2,3-bisphosphoglycerate (or DPG; Fig. 105-1), a major effector of the hemoglobin-oxygen dissociation curve; thus, for a certain level of hemoglobin, the oxygen delivery to the tissues is enhanced, a remarkable compensatory feat.

TREATMENT

Pyruvate Kinase Deficiency

Until recently, the management of PK deficiency has been supportive. Folic acid supplements should be given constantly. Blood transfusion should be used as necessary, and iron chelation may be required even in some patients who, though not receiving blood transfusion, may be developing iron overload (see "General Pathophysiology" above). About one-half of patients sooner or later undergo splenectomy, which usually provides a modest but significant increase in hemoglobin (paradoxically, reticulocytes also often increase, because they were previously trapped in the

TABLE 105-4 Red Cell Enzyme Abnormalities Causing Hemolysis

ENZYME (ACRONYM)	GENE SYMBOL; CHROMOSOMAL LOCATION	PREVALENCE OF ENZYME DEFICIENCY (RANK)	CLINICAL MANIFESTATIONS EXTRA-RED CELL	COMMENTS
Glycolytic Pathway				
Hexokinase (HK)	*HK1*; 10q22	Very rare		May benefit from splenectomy; BMT[c]
Glucose-6-phosphate isomerase (G6PI)	*GPI*; 19q31.1	Rare (4); at least 60 cases reported[a]	NM, CNS	May benefit from splenectomy
Phosphofructokinase (PFK)[b]	*PFKM*; 12q13	Very rare	Myopathy; myoglobinuria	
Aldolase	*ALDOA*; 16q22-24	Very rare	Myopathy	
Triose phosphate isomerase (TPI)	*TPI1*; 12p13.31	Very rare	CNS (severe), NM	
Glyceraldehyde 3-phosphate dehydrogenase (GAPD)	*GAPDH*; 12p13.31	Very rare	Myopathy	
Bisphosphoglycerate mutase (BPGM)	*BPGM*; 7q33	Very rare		Erythrocytosis rather than hemolysis; some of the rare mutations are in the enzyme active site
Phosphoglycerate kinase (PGK)	*PGK1*; Xq21.1	Very rare	CNS, NM	May benefit from splenectomy; BMT[c]
Pyruvate kinase (PK)	*PKLR*; 1q22	Rare (2)[a]		May benefit from splenectomy; BMT[c]
Redox				
Glucose-6-phosphate dehydrogenase (G6PD)	*G6PD*; Xq28	Common (1)[a]	Very rarely granulocytes	In almost all cases, only AHA from exogenous trigger
Glutathione synthase	*GSS*; 20q11.22	Very rare	CNS	
Glutathione reductase	*GSR*; 8p12	Very rare	Cataracts	AHA from exogenous trigger (favism)
γ-Glutamylcysteine synthase	*GCLC*; 6p12.1	Very rare	CNS	Mutations affect catalytic subunit
Cytochrome b5 reductase	*CYB5R3*; 22q13.2	Rare	CNS	Methemoglobinemia rather than hemolysis
Nucleotide Metabolism				
Adenylate kinase (AK)	*AK1*; 9q34.11	Very rare	CNS	May benefit from splenectomy
Pyrimidine 5′ nucleotidase (P5N)	*NTSC3A*; 7p14.3	Rare (3)[a]		May benefit from splenectomy

[a]The numbers from (1) to (4) indicate the ranking order of these enzymopathies in terms of frequency. [b]PFK deficiency is associated with increased glycogen in muscle, and it is also known as glycogen storage disease type VII or Tarui's disease. [c]Occasional report of successful treatment of the hematologic manifestations by BMT.

Abbreviations: AHA, acquired hemolytic anemia; BMT, bone marrow transplantation; CNS, central nervous system; NM, neuromuscular.

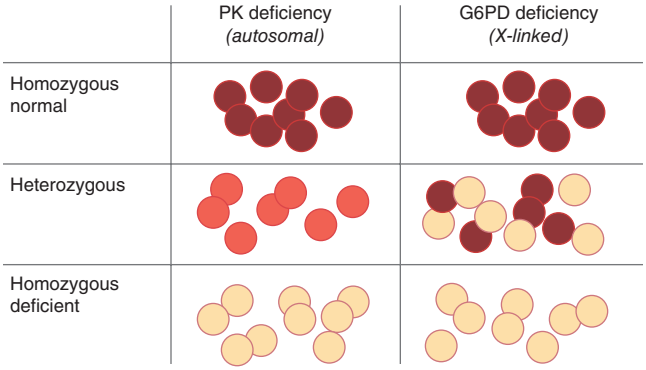

FIGURE 105-5 Different phenotypes of heterozygotes for red cell enzymopathies. In a heterozygote for deficiency of pyruvate kinase (PK), encoded by an autosomal gene (see Table 105-4), the level of enzyme is about one-half of normal in all red cells. Because this level of enzyme is sufficient, there are no clinical consequences, i.e., PK deficiency is recessive. In a heterozygote for deficiency of glucose-6-phosphate dehydrogenase (G6PD), encoded by an X-linked gene, the situation is quite different: X-chromosome inactivation generates red cell mosaicism, whereby some red cells are entirely normal and others are G6PD deficient. Therefore, G6PD deficiency is expressed in heterozygotes; it is not recessive.

spleen). Cholecystectomy may also be required. A major advance has been the introduction of *mitapivat*, an allosteric activator of PK, and the first drug for a red cell enzymopathy, approved on grounds of a significant increase in hemoglobin in one-half of PK-deficient patients—those in whom either one or both *PKLR* mutations are of the missense type. Some patients with severe disease have received bone marrow transplantation (BMT) from human leukocyte antigen (HLA)-identical PK-normal sibling. Prenatal diagnosis has been carried out in a mother who had already had an affected child. Rescue of inherited PK deficiency through lentiviral-mediated human PK gene transfer has been successful in mice and is currently undergoing a clinical trial in patients.

Other Glycolytic Enzyme Abnormalities All of these defects are rare to very rare (Table 105-4), and most of them cause HA with varying degrees of severity. It is not unusual for the presentation to be in the guise of severe neonatal jaundice, which may require exchange transfusion; if the anemia is less severe, it may present later in life, or it may even remain asymptomatic and be detected incidentally when a blood count is done for unrelated reasons. The spleen is often enlarged. When other systemic manifestations occur, they can involve the central nervous system (sometimes entailing severe intellectual disability, particularly in the case of triose phosphate isomerase deficiency), the neuromuscular system, or both (see Table 105-4). This is not altogether surprising if we consider that these are housekeeping genes, i.e., expressed in all tissues. The diagnosis of HA is usually not difficult, thanks to the triad of normo-macrocytic anemia, reticulocytosis, and hyperbilirubinemia. Enzymopathies should be considered in the differential diagnosis of any chronic Coombs-negative HA. Unlike with membrane disorders, in most cases of glycolytic enzymopathies, morphologic abnormalities are conspicuous by their absence. A definitive diagnosis can be made only by demonstrating the deficiency of an individual enzyme by quantitative assays; these are carried out in only a few specialized laboratories. If a particular molecular abnormality is already known in the family, then one could test directly for that defect at the DNA level, thus bypassing the need for enzyme assays. Of course, the time may be getting nearer when a patient will present with their exome already sequenced, and we will need to concentrate on which genes to look up within the file. The principles for the management of these conditions are similar as for PK deficiency. In isolated clinically severe cases of glycolytic enzyme abnormalities, BMT has been carried out successfully, although unfortunately, nonhematologic manifestations, if any, are not reversed.

ABNORMALITIES OF REDOX METABOLISM • Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency G6PD is a housekeeping enzyme critical in the redox metabolism of all aerobic cells (Fig. 105-1). In red cells, its role is even more critical because it is the only source of NADPH, which directly and via GSH defends these cells against oxidative stress **(Fig. 105-6)**. G6PD deficiency–related HA is a prime example of an HA due to interaction between an intracorpuscular cause and an extracorpuscular cause; indeed, in the vast majority of cases, hemolysis is triggered by an exogenous agent. Although the G6PD activity is decreased in most tissues of G6PD-deficient subjects, in other cells, the decrease is much less pronounced than in red cells, and it does not seem to impact on clinical expression.

GENETIC CONSIDERATIONS

The G6PD gene is X-linked, and this has important implications. First, because males have only one G6PD gene (i.e., they are hemizygous for this gene), they must be either normal or G6PD deficient. By contrast, females, who have two G6PD genes, can be either normal or deficient (homozygous) or intermediate (heterozygous). Second, as a result of the phenomenon of X chromosome inactivation, heterozygous females are genetic mosaics (see Fig. 105-5), with a highly variable ratio of G6PD-normal to G6PD-deficient cells and an equally variable degree of clinical expression; some heterozygotes can be just as affected as hemizygous males. The enzymatically active form of G6PD is either a dimer or a tetramer of a single protein subunit of 514 amino acids. G6PD-deficient subjects have been found invariably to have mutations in the coding region of the G6PD gene. Almost all of the over 230 different mutations known are single missense point mutations, entailing single amino acid replacements in the G6PD protein. In most cases, these mutations cause G6PD deficiency by decreasing the in vivo stability of the protein; thus, the physiologic decrease in G6PD activity that takes place with red cell aging is greatly accelerated. In some cases, an amino acid replacement can also affect the catalytic function of the enzyme. The genetic heterogeneity of G6PD deficiency is clinically important, and for the variants that are widespread, it also has public health implications. Therefore, the World Health Organization (WHO) has worked out a classification **(Table 105-5)**.

Among these mutations, those underlying chronic nonspherocytic hemolytic anemia (CNSHA; see below) are a discrete subset. This much more severe clinical phenotype can be ascribed in some cases to adverse qualitative changes (e.g., a decreased affinity for the substrate glucose-6-phosphate) or simply to the fact that the enzyme deficit is more extreme because of a more severe instability of the enzyme. For instance, a cluster of mutations map at or near the dimer interface, and clearly, they compromise severely the formation of the dimer.

Epidemiology G6PD deficiency is widely distributed in tropical and subtropical parts of the world (Africa, southern Europe, the Middle East, Southeast Asia, and Oceania) **(Fig. 105-7)** and wherever people from those areas have migrated. A conservative estimate is that at least 500 million people have a G6PD deficiency gene. In several of these areas, the frequency of a G6PD deficiency gene may be as high as 20% or more. It would be quite extraordinary for a trait that causes significant pathology to spread widely and reach high frequencies in many populations without conferring some biologic advantage. Indeed, G6PD is one of the best-characterized examples of genetic polymorphisms in the human species. Clinical field studies and in vitro experiments strongly support the view that G6PD deficiency has been selected by *Plasmodium falciparum* malaria because it confers a relative resistance against this highly lethal infection. As in other cases of balanced polymorphism, it is heterozygotes, therefore females, who are protected. Different G6PD variants (class B) underlie most of the prevalence of G6PD deficiency in different parts of the world. Examples of widespread variants are G6PD Mediterranean on the shores of that sea, in the Middle East, and elsewhere; G6PD A– in Africa, in the Middle East, and in southern Europe; G6PD Orissa in India; G6PD Viangchan and G6PD Mahidol in Southeast Asia; G6PD Kaiping and G6PD Canton in China; and G6PD Union worldwide. The heterogeneity of polymorphic G6PD variants is proof of their independent origin, further supporting the notion of selection by a common environmental

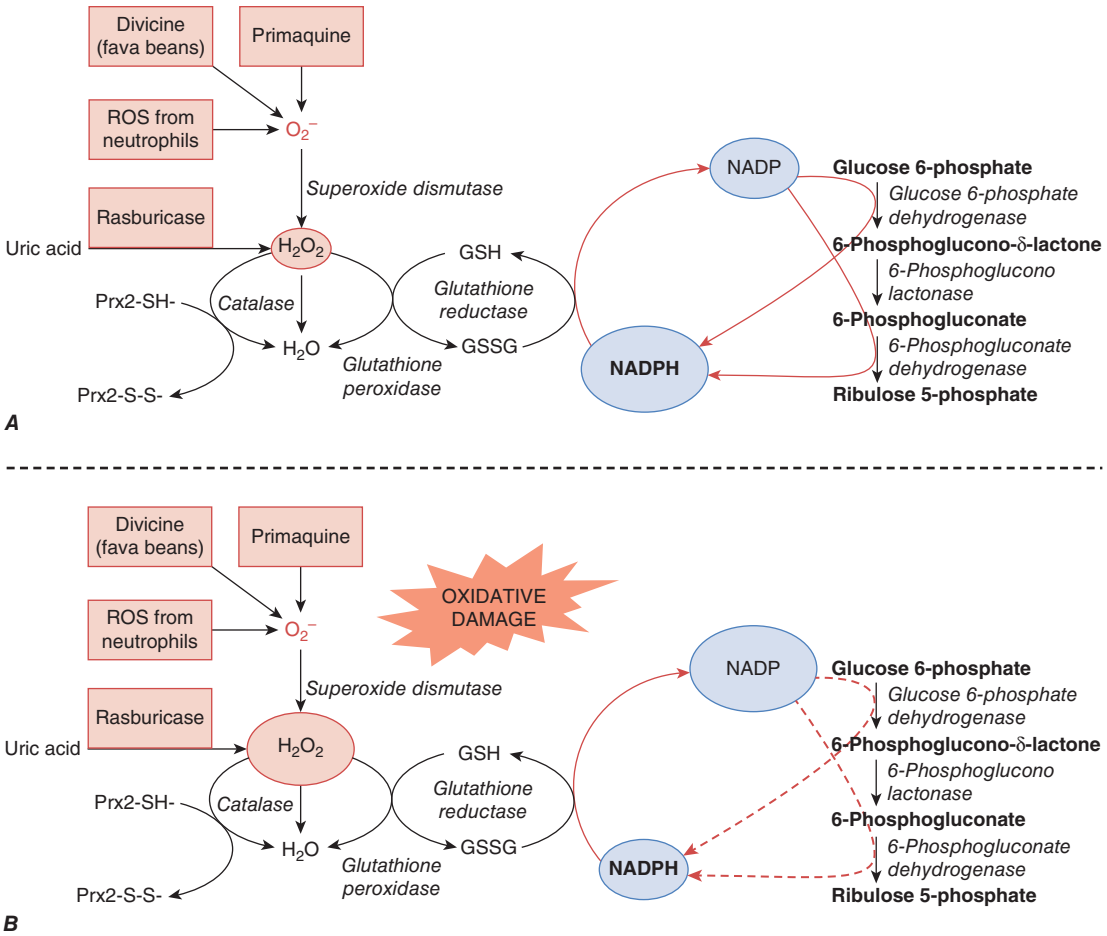

FIGURE 105-6 The role of glucose-6-phosphate dehydrogenase (G6PD) in protecting red cells from oxidative damage. ***A.*** In G6PD-normal red cells, G6PD and 6-phosphogluconate dehydrogenase—two of the enzymes of the pentose phosphate pathway—provide ample supply of NADPH, which in turn regenerates glutathione (GSH) when this is oxidized by reactive oxygen species (e.g., O_2^- and H_2O_2). Thus when O_2^- (meant here to represent itself and other reactive oxygen species [ROS]) is produced by pro-oxidant compounds such as primaquine, or the glucosides in fava beans (divicine), or the oxidative burst of neutrophils, these ROS are rapidly neutralized; similarly, when rasburicase administered to degrade uric acid produces an equimolar amount of hydrogen peroxide, this is rapidly degraded by the combined action of glutathione peroxidase, catalase, and Prx2 (peroxiredoxin-2; all three mechanisms are NADPH dependent). ***B.*** In G6PD-deficient red cells, where the enzyme activity is reduced, NADPH production is limited, and it may not be sufficient to cope with the excess ROS generated by pro-oxidant compounds and the consequent excess hydrogen peroxide. This diagram also explains why a defect in GSH reductase has very similar consequences to G6PD deficiency.

agent, namely malaria, in keeping with the concept of convergent evolution (Fig. 105-7).

Clinical Manifestations The vast majority of people with G6PD deficiency remain clinically asymptomatic throughout their lifetime; however, all of them have an increased risk of developing neonatal jaundice (NNJ) and a risk of developing acute HA (AHA) when challenged by a number of oxidative agents. NNJ related to G6PD deficiency is rarely present at birth; the peak incidence of clinical onset is between day 2 and day 3, and in most cases, the anemia is not severe. However, NNJ can be very severe in some G6PD-deficient babies, especially in association with prematurity, infection, and/or environmental factors (e.g., naphthalene-camphor balls, which may be used in babies' bedding and clothing); and the risk of severe NNJ is also increased by the coexistence of a monoallelic or biallelic mutation in the uridyl transferase gene (*UGT1A1*; the same mutations are associated with Gilbert's syndrome). It is imperative to manage promptly NNJ associated with G6PD deficiency because it can produce kernicterus and permanent neurologic damage.

AHA can develop as a result of three types of triggers: (1) fava beans, (2) infections, and (3) drugs (Table 105-6). Typically, a hemolytic attack starts with malaise, weakness, and abdominal or lumbar pain. Within a time frame of several hours to 2–3 days, the patient develops jaundice and often dark urine. The onset can be extremely abrupt, especially with favism in children. The anemia is moderate to extremely severe, usually normocytic and normochromic, and due partly to intravascular hemolysis; hence, it is associated with hemoglobinemia, hemoglobinuria, high LDH, and low or absent plasma haptoglobin. The blood film shows anisocytosis, polychromasia, and spherocytes; in addition, the most typical feature of G6PD deficiency is the presence of bizarre poikilocytes, with red cells that appear to have unevenly distributed hemoglobin ("hemighosts") and red cells that appear to have had parts of them bitten away ("bite cells" or "blister cells") (Fig. 105-8). A classical test, now rarely carried out, is supravital staining with methyl violet, which, if done promptly, reveals the presence of Heinz bodies (consisting of precipitates of denatured hemoglobin and hemichromes), which are regarded as a signature of oxidative damage to red cells (they are

TABLE 105-5 Current World Health Organization Classification of Glucose 6-Phosphate Dehydrogenase (G6PD) Variants

G6PD VARIANT CLASS	MEDIAN OF G6PD ACTIVITY (% OF NORMAL)	ASSOCIATED CLINICAL MANIFESTATIONS
A[a]	<20%[b]	Chronic hemolytic anemia
B[c]	<45%	Neonatal jaundice; acute hemolytic anemia triggered by certain medicines, fava beans, and infections
C[a]	>60%	None reported
U[d]	Any	Uncertain clinical significance

[a]Class A corresponds to former class I; class C corresponds to former class IV. [b]A variant with <20% activity will be in class A only if it is associated with chronic hemolytic anemia. [c]In view of the extensive overlap in enzyme activity and in clinical expression of variants in former class II and class III, these have been merged into class B. [d]A temporary assignment for variants for which there is currently insufficient information regarding clinical manifestations.

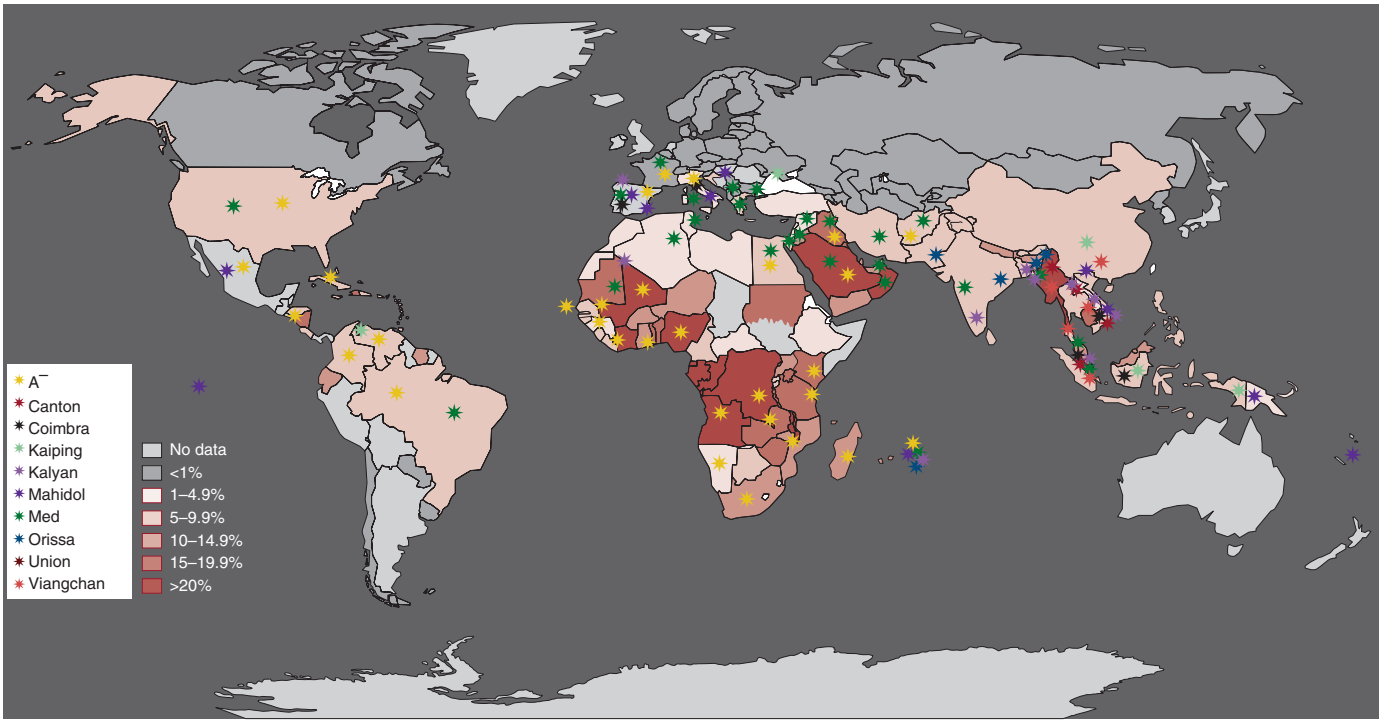

FIGURE 105-7 Epidemiology of glucose-6-phosphate dehydrogenase (G6PD) deficiency throughout the world. Each country on the map is shaded in a color based on the best estimate of the mean frequency of G6PD deficiency allele(s) in that country (this is the same as the frequency of G6PD-deficient males). The small panel on the left gives the key to color shadings corresponding to each country. The larger panel gives a color-coded list of 10 common G6PD variants associated with G6PD deficiency: *asterisk-shaped symbols* in the corresponding colors are shown in the countries where these variants have been observed (for graphic reasons, symbols could not be inserted in all countries). *(Reproduced with permission from L Luzzatto, M Ally, R Notaro. Glucose-6-phosphate dehydrogenase deficiency. 136:1225, 2020.)*

also seen with unstable hemoglobins). Since there is also a substantial component of extravascular hemolysis, unconjugated bilirubin is high and there is often clinical icterus. The most serious threat from AHA in adults is the development of acute renal failure (this is exceedingly rare in children). Once the threat of acute anemia is over and in the absence of comorbidity, full recovery from AHA associated with G6PD deficiency is the rule.

It was primaquine (PQ)-induced AHA that led to the discovery of G6PD deficiency, but this drug has not been very prominent subsequently because it is not necessary for the treatment of life-threatening *P. falciparum* malaria. Today there is a revival in the use of PQ for two reasons. First, it is the only effective agent for eliminating the gametocytes of *P. falciparum* (thus preventing further transmission): a small single dose (0.25 mg/kg) is required, and it is safe for G6PD-deficient persons. Second, a 14-day course of PQ is the standard treatment for eliminating the hypnozoites of *Plasmodium vivax* (thus preventing endogenous relapse) **(Chap. 231)**. In countries aiming to eliminate malaria, there may be a call for mass administration of PQ; this ought

TABLE 105-6 Drugs That Carry Risk of Clinical Hemolysis in Persons with Glucose 6-Phosphate Dehydrogenase Deficiency

	RISK OF ACUTE HEMOLYTIC ANEMIA		
DRUG CLASS	HIGH	MEDIUM TO LOW	
Antimalarials	Primaquine Tafenoquine	Chloroquine Hydroxychloroquine Quinine	
Sulphonamides/ sulphones	Dapsone	Sulfadimidine Sulfamethoxazole Sulfasalazine	
Antibacterial/ antibiotics		Chloramphenicol Ciprofloxacin Cotrimoxazole Nalidixic acid Nitrofurantoin Norfloxacin *p*-Aminosalicylic acid	
Anti-helmint		Niridazole	
Antipyretic/ analgesics	Acetylsalicylic acid high dose (>3 g/d)	Acetaminophen Acetanilide Phenacetin Phenazopyridine	
Other	Rasburicase Pegloticase Methylene blue Toluidine blue	Ascorbic acid (>1 g) Doxorubicin Probenecid Vitamin K analogues	

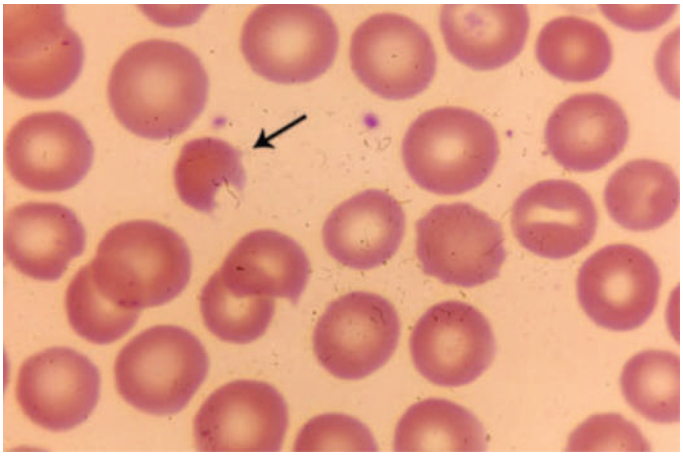

FIGURE 105-8 Peripheral blood smear from a glucose-6-phosphate dehydrogenase (G6PD)-deficient boy experiencing hemolysis. Note the red cells that are misshapen and called "bite" cells. *(From MA Lichtman et al: Lichtman's Atlas of Hematology: http://www.accessmedicine.com. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)*

to be associated with G6PD testing. At the other end of the historic spectrum, the latest additions to the list of potentially hemolytic drugs (Table 105-6) are rasburicase and pegloticase; again, G6PD testing ought to be made mandatory before giving either of these drugs because fatal cases have been reported upon using one of these drugs, which generate hydrogen peroxide, in newborns with kidney injury and in children and adults with tumor lysis syndrome.

Although drug-induced AHA has been prominent in the study of G6PD deficiency, the most common clinical manifestations are in fact NNJ and favism, both of which are of public health importance in many populations. Contrary to beliefs that are still widespread, fava bean pollen inhalation does not cause favism, and other beans are safe.

A very small minority of subjects with G6PD deficiency, those who have a class A variant, suffer from CNSHA of variable severity. The patient is nearly always a male, usually with a history of NNJ, who may present with anemia, unexplained jaundice, or gallstones later in life. The spleen may be enlarged. The severity of anemia ranges in different patients from borderline to transfusion dependent. The anemia is usually normo-macrocytic, with reticulocytosis. Bilirubin and LDH are increased. Although hemolysis is, by definition, chronic in these patients, they are also vulnerable to acute oxidative damage, and therefore, the same agents that can cause AHA in people with the ordinary type of G6PD deficiency will cause severe exacerbations in people with CNSHA associated with G6PD deficiency. In some cases of CNSHA, the deficiency of G6PD is so severe in granulocytes that it limits their capacity to produce an oxidative burst, with consequent increased susceptibility to some bacterial infections.

Laboratory Diagnosis The suspicion of G6PD deficiency can be confirmed by semiquantitative methods often referred to as screening tests, which are suitable for population studies and can correctly classify male subjects, in the steady state, as G6PD normal or G6PD deficient. However, in clinical practice, a diagnostic test is usually needed when the patient has had a hemolytic attack, whereby the oldest, most G6PD-deficient red cells have been selectively destroyed, and young red cells, having higher G6PD activity, are being released into the circulation. Under these conditions, only a quantitative test can give a definitive result. In males, this test will identify normal hemizygotes and G6PD-deficient hemizygotes; among females, some heterozygotes will be missed, but those who are at most risk of hemolysis will be identified. Of course, G6PD deficiency also can be diagnosed by DNA testing. Currently easy-to-use point-of-care tests for G6PD deficiency are becoming available, geared especially to the prospect of mass administration of PQ or of the newly introduced derivative tafenoquine.

TREATMENT

G6PD Deficiency

The AHA of G6PD deficiency is largely preventable by avoiding exposure to triggering factors of previously screened subjects. Of course, the practicability and cost-effectiveness of screening depend on the prevalence of G6PD deficiency in each individual community. Favism is entirely preventable in G6PD-deficient subjects by not eating fava beans. Drug-induced hemolysis can be prevented by testing for G6PD deficiency before prescribing; in many cases, one can use alternative drugs. When AHA develops and once its cause is recognized, no specific treatment is needed in most cases. However, if the anemia is severe, it may be a medical emergency, especially in children, requiring immediate action, including blood transfusion. This has been the case with an antimalarial drug combination containing dapsone (called Lapdap, introduced in 2003) that has caused severe acute hemolytic episodes in children with malaria in several African countries; after a few years, the drug was taken off the market. If there is acute renal failure, hemodialysis may be necessary, but if there is no previous kidney disease, recovery is the rule. The management of NNJ associated with G6PD deficiency is no different from that of NNJ due to other causes.

In cases with CNSHA, if the anemia is not severe, regular folic acid supplements and regular hematologic surveillance will suffice. It will be important to avoid exposure to potentially hemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in concomitance with intercurrent infection. In rare patients, regular blood transfusions may be required, in which case appropriate iron chelation should be instituted. Unlike in HS, there is no evidence of selective red cell destruction in the spleen; however, in practice, splenectomy has proven beneficial in severe cases.

Other Abnormalities of the Redox System As mentioned previously, GSH is a key player in the defense against oxidative stress. Inherited defects of GSH metabolism are exceedingly rare, but each one can give rise to chronic HA (Table 105-4). A rare, peculiar, and severe but usually self-limited HA occurring in the first month of life, called *infantile poikilocytosis*, may be associated with deficiency of glutathione peroxidase (GSHPX) due not to an inherited abnormality, but to transient nutritional deficiency of selenium, an element essential for the activity of GSHPX.

PYRIMIDINE 5′-NUCLEOTIDASE (P5N) DEFICIENCY P5N is a key enzyme in the catabolism of nucleotides arising from the degradation of nucleic acids that takes place in the final stages of erythroid cell maturation. How exactly its deficiency causes HA is not well understood, but a highly distinctive feature of this condition is a morphologic abnormality of the red cells known as *basophilic stippling*. The condition is rare, but it probably ranks third in frequency among red cell enzyme defects (after G6PD deficiency and PK deficiency). The anemia is lifelong, is of variable severity, and may benefit from splenectomy.

Familial (Atypical) Hemolytic-Uremic Syndrome (aHUS)

This term is used to designate a group of rare disorders, mostly affecting children, characterized by microangiopathic HA with presence of fragmented erythrocytes in the peripheral blood smear, thrombocytopenia (usually mild), and acute renal failure. (The word *atypical* in this phrase should be consigned to history; it was introduced originally to distinguish this condition from the hemolytic-uremic syndrome [HUS] caused by infection with *Escherichia coli* producing the Shiga toxin, regarded as *typical*.) The disease is caused by dysregulation of the complement alternative pathway: in some cases, this results from anti–factor H autoantibodies, but in the majority of cases, it is a consequence of mutations in genes encoding proteins that are components or regulators of the complement system, i.e., *C3* (encoding complement component C3), *CFB* (encoding complement factor B), *CFH* (encoding complement factor H), *CD46* (encoding the membrane cofactor protein), *CFI* (encoding complement factor I), *THBD* (encoding thrombomodulin), and rarely others. Patients may have abnormalities in one, two, or even three of the above genes. Pathogenic variants of these genes predispose to HUS with autosomal dominant inheritance; because clinical aHUS requires a triggering factor, most commonly infection, the penetrance is incomplete. Thus, whereas all other inherited HAs are due to intrinsic red cell abnormalities, this group is unique in that hemolysis results from an inherited defect external to red cells (Table 105-1). Because the regulation of the complement cascade has considerable redundancy, in the steady state, any of the above abnormalities can be tolerated. However, when an intercurrent infection or some other trigger briskly activates complement, the deficiency of one of the complement regulators becomes critical. Endothelial cells get damaged, especially in the kidney. At the same time, and partly as a result of this, there will be brisk hemolysis; thus, the more common Shiga toxin–related HUS (Chap. 172) can be regarded as a phenocopy of aHUS. aHUS is a severe disease; before anticomplement therapy was available, mortality was up to 15% in the acute phase, and up to 50% of cases progressed to end-stage renal disease (ESRD). Not infrequently, aHUS undergoes spontaneous remission. Because it is an inherited abnormality, it is not surprising that, given renewed exposure to a trigger, the syndrome will tend to recur; when it does, the prognosis is always serious. The traditional treatment has been plasma exchange, which will supply the deficient complement regulator and clear complement activation products. This has changed since the introduction of the anti-C5 complement inhibitor eculizumab (see "Paroxysmal Nocturnal Hemoglobinuria"), which was found to greatly ameliorate the microangiopathic picture, with improvement in platelet counts and in

renal function, thus abrogating the need for plasma exchange, which is not always effective and not free of complications. Once a full remission is obtained, with urine dipstick negative for hemoglobinuria, within 3–6 months, eculizumab can be discontinued. Given the genetic background of aHUS, relapses are possible. Fortunately, patients who relapsed after discontinuing eculizumab have responded again. No current evidence supports continuing eculizumab indefinitely.

For the diagnosis of inherited red cell abnormalities, including those of the membrane-cytoskeleton, channelopathies, and enzymopathies, DNA sequencing of a gene panel (e.g., next-generation sequencing [NGS]) has become increasingly popular. This approach (which may or may not be more expensive) has the advantage of being potentially comprehensive and of providing definitive data. On the other hand, the mutations identified may be of uncertain significance, in which case, the diagnosis must be still confirmed by conventional methodology. Thus, the use of NGS is specially useful with unsolved cases of hereditary HAs.

ACQUIRED HEMOLYTIC ANEMIA

Mechanical Destruction of Red Cells Although red cells are characterized by the remarkable deformability that enables them to squeeze through capillaries narrower than themselves for thousands of times in their lifetime, there are at least two situations in which they succumb to shear, if not to wear and tear; the result is intravascular hemolysis, resulting in hemoglobinuria (Table 105-7). One situation is acute and self-inflicted, *march hemoglobinuria*. Why sometimes a marathon runner may develop this complication, whereas on another occasion, this does not happen, we do not know (perhaps their footwear needs attention). A similar syndrome may develop after prolonged barefoot ritual dancing or intense playing of bongo drums. The other situation is chronic and iatrogenic (it has been called *microangiopathic hemolytic anemia*). It takes place in patients with prosthetic heart valves, especially when paraprosthetic regurgitation is present. If the hemolysis consequent on mechanical trauma to the red cells is mild, and if the supply of iron is adequate, the loss may be largely compensated; if more than mild anemia develops, reintervention to correct regurgitation may be required.

Infection By far, the most frequent infectious cause of HA in endemic areas is malaria (Chap. 231). In other parts of the world, the most frequent direct cause is probably Shiga toxin–producing *E. coli* O157:H7, now recognized as the main etiologic agent of HUS, which is more common in children than in adults (Chap. 166). Life-threatening intravascular hemolysis, due to a toxin with lecithinase activity, occurs with *Clostridium perfringens* sepsis, particularly following open wounds, septic abortion, or as a disastrous accident due to a contaminated blood unit. Rarely, and if at all in children, HA is seen with sepsis or endocarditis from a variety of organisms. In addition, bacterial and viral infections can cause HA by indirect mechanisms (see Table 105-7).

Immune Hemolytic Anemias These can arise through at least two distinct mechanisms. First, when an antibody directed against a certain molecule (e.g., a drug) reacts with that molecule, red cells may get caught in the reaction (the so-called innocent bystander mechanism; see later section "Hemolytic Anemia from Toxic Agents and Drugs"), whereby they are damaged or destroyed. Second, and more frequently, a true autoantibody is directed against a red cell antigen, i.e., a molecule present on the surface of red cells. Autoimmune HAs have been originally classified into two types, depending on the thermal amplitude of the autoantibodies involved; this classification is valid because the two types have different pathophysiologic and clinical features.

AUTOIMMUNE HEMOLYTIC ANEMIA, WARM TYPE (WAIHA; FOR SIMPLICITY, WE WILL USE THE ACRONYM AIHA) AIHA has an estimated incidence in the United States of about 1–3:100,000 per year, and a prevalence of 17:100,000. AIHA can be serious because even with appropriate management the mortality is ~5–10%.

Clinical Features and Diagnosis The onset is often abrupt and can be dramatic. The hemoglobin level may drop, within days, to as low as 4 g/dL; the massive red cell removal will produce jaundice, and sometimes the spleen is enlarged. When this triad is present, the suspicion of AIHA must be high. The reticulocyte count is typically elevated, except when erythroid precursors are also targeted by the autoantibody attack. LDH may also be elevated. In some cases, AIHA can be associated, on first presentation or subsequently, with autoimmune thrombocytopenia. This double autoimmune condition, referred to as Evans syndrome, may be a manifestation of common variable immune deficiency, and in children, it may suggest one of several primary immune deficiency syndromes. Evans syndrome signals high-risk disease. Other predictors of the outcome and of the probability of relapse of AIHA are severe anemia (hemoglobin <6 g/dL), certain characteristics of the antibody, acute renal failure, and infection.

There are few situations in hematology where one laboratory test is as informative as the direct antiglobulin test developed in 1945 by R. R. A. Coombs and known since then by this name. The currently recommended version of this test uses in the first instance a "broad-spectrum" reagent, i.e., one that will detect not only immunoglobulins (Ig) but also complement (C) components (usually C3 fragments) bound to the surface of the patient's red cells. If the test is positive, it is, almost on its own, diagnostic of AIHA. False positives may occur as a result of previous blood transfusion or, much more rarely, following organ transplantation procedures or administration of antilymphocyte or immunoglobulin products. One can then determine, by using specific reagents, whether Ig or C or both are implicated. The sensitivity of the Coombs test varies depending on the techniques that are used. In general, the test is positive if there is an average of at least 400 molecules of Ig and/or C on each red cell; but with more advanced techniques involving flow cytometry analysis or enzyme-linked radiolabeled tests, the sensitivity can be pushed to as low as 30–40 molecules

TABLE 105-7 Diseases and Clinical Situations in Which Hemolysis Is Largely Intravascular

	ONSET/TIME COURSE	MAIN MECHANISM	APPROPRIATE DIAGNOSTIC PROCEDURE	COMMENTS
Mismatched blood transfusion	Abrupt	Nearly always ABO incompatibility	Repeat cross-match	
Paroxysmal nocturnal hemoglobinuria (PNH)	Chronic with acute exacerbations	Complement (C)-mediated destruction of CD59(–) red cells	Flow cytometry to display a CD59(–) red cell population	Exacerbations due to C activation through any pathway
Paroxysmal cold hemoglobinuria (PCH)	Acute	Immune lysis of normal red cells	Test for Donath-Landsteiner antibody	Often triggered by viral infection
Septicemia	Very acute	Exotoxins produced by *Clostridium perfringens*	Blood cultures	Other organisms may be responsible
Microangiopathic	Acute or chronic	Red cell fragmentation	Red cell morphology on blood smear	Different causes ranging from endothelial damage to hemangioma to leaky prosthetic heart valve
March hemoglobinuria	Abrupt	Mechanical destruction	Targeted history taking	Has been reported after extreme ritual dancing
Favism	Acute	Destruction of older fraction of G6PD-deficient red cells	G6PD assay	Triggered by ingestion of large dish of fava beans[a]

[a]The trigger of acute hemolytic anemia, often with hemoglobinuria, can be infection or a drug (see Table 105-5) rather than fava beans. Hemoglobinuria may or may not be reported by patient, but it is often macroscopic, i.e., recognizable by simple inspection of urine.

Abbreviation: G6PD, glucose 6-phosphate dehydrogenase.

per red cell. Therefore, liaison with a specialized laboratory is desirable; a dual direct antiglobulin test has also been developed. In the past, the diagnosis of "Coombs-negative AIHA" was regarded as a last resort, but it is important to know that a patient with this label may have severe AIHA, because if the antibody is powerful (high affinity/avidity), few molecules may be sufficient to opsonize red cells. Based on the Coombs test findings as well as on the thermal characteristics and the antigenic specificities of the autoantibodies (Table 105-8), AIHA has been classified into subtypes.

In AIHA, the autoantibody reacts best at 37°C, and it is usually Rhesus specific (sometimes specifically anti-e). The main mechanism of hemolysis in AIHA is that the Fc portion of the IgG antibody bound to red cells is recognized by the Fc receptor of macrophages. This will trigger erythrophagocytosis wherever macrophages are abundant, i.e., in the liver, in the bone marrow, but especially in red pulp of the spleen (Fig. 105-9), which, also because of its special anatomy, is often the predominant site of red cell destruction.

AIHA may be seen in isolation (and it is then called *idiopathic*) or as secondary to other disorders such as systemic autoimmune disorders (systemic lupus erythematosus [SLE]; sometimes, AIHA may be the first manifestation that leads to a diagnosis of SLE) or lymphoproliferative disorders (Table 105-8). Like all autoimmune diseases, AIHA must arise from a dysregulation of immunity. It is therefore not surprising that it is increasingly being recognized in chronic lymphocytic leukemia (CLL), whether treated or untreated; after BMT; and after solid organ transplantation entailing immunosuppressive treatment. Recently, warm antibody AIHA has also occurred as a side effect of the use of immune checkpoint inhibitors, such as nivolumab, in patients with various types of cancer.

TABLE 105-8 Classification of Acquired Immune Hemolytic Anemias

CLINICAL SETTING	TYPE OF ANTIBODY: COLD, MOSTLY IgM, OPTIMAL TEMPERATURE 4°C–30°C	TYPE OF ANTIBODY: WARM, MOSTLY IgG, OPTIMAL TEMPERATURE 37°C; OR MIXED
Primary	CAD	AIHA (idiopathic)
Secondary to viral infection	EBV CMV Other	Parvovirus B19 HIV HCV EBV Viral vaccines
Secondary to other infection	Mycoplasma infection: paroxysmal cold hemoglobinuria	Babesia
Secondary to/ associated with other disease	CAD in: Waldenström's disease Lymphoma	AIHA in: SLE, scleroderma, RA CLL Lymphoproliferative disorders Multiple myeloma Other malignancy Chronic inflammatory disorders (e.g., IBD) Thyroiditis (including Hashimoto) After allogeneic HSCT Common variable immunodeficiency After immune checkpoint modulating drugs
Secondary to drugs: drug-induced immune hemolytic anemia	Small minority (e.g., with lenalidomide)	Majority: currently most common culprit drugs are cefotetan, ceftriaxone, piperacillin, methyldopa, fludarabine
	Drug-dependent: antibody destroys red cells only when drug present (e.g., rarely penicillin) Drug-independent: antibody can destroy red cells even when drug no longer present (e.g., methyldopa)	
Associated with	Pregnancy	

Abbreviations: AIHA, autoimmune hemolytic anemia; CAD, cold agglutinin disease; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplantation; IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus; RA, rheumatoid arthritis.

TREATMENT

Warm Antibody Autoimmune Hemolytic Anemia

Severe acute AIHA can be a medical emergency. The immediate treatment almost invariably includes transfusion of red cells. This may pose a special problem because many or all of the blood units cross-matched may be incompatible. In these cases, it is often correct, if paradoxical, to transfuse ABO-matched but incompatible blood, with the rationale being that the transfused red cells will be destroyed no less—but no more—than the patient's own red cells, and in the meantime, the patient stays alive. A situation like this requires close liaison and understanding between the clinical unit treating the patient and the blood transfusion/serology lab. Whenever the anemia is not immediately life-threatening, blood transfusion should be withheld (because compatibility problems may increase with each unit of blood transfused) and medical treatment started immediately with prednisone (1 mg/kg per day), which will produce a remission promptly in at least one-half of patients. Rituximab (anti-CD20), previously regarded as second-line treatment, is increasingly being used at a relatively low dose (100 mg/week × 4), together with prednisone as part of first-line treatment. It is especially encouraging that this approach seems to reduce the rate of relapse, a common occurrence in AIHA.

For patients who do relapse or are refractory to medical treatment, additional therapeutic strategies are now available. Splenectomy does not cure the disease, but it can produce significant benefit by removing a major site of hemolysis, thus improving the anemia and/or reducing the need for other therapies (e.g., the dose of prednisone); of course, splenectomy is not free of risk, as it entails increased risk of sepsis and of thrombosis. The response rates to splenectomy and rituximab are similar. Since the introduction of rituximab, azathioprine, cyclophosphamide, cyclosporine, mycophenolate, and intravenous immunoglobulin have become second- or third-line agents. In very rare severe refractory cases, one may have to consider a high dose of cyclophosphamide (50 mg/kg per day for 4 days), followed by a myelo-stimulating agent, or the anti-CD52 agent alemtuzumab. Fostamatinib, an inhibitor of intracellular cell signaling (Syk kinase) mediating erythrophagocytosis, has shown beneficial effects in an open-label clinical study, becoming an interesting third-line therapeutic option (Fig. 105-9). When severe anemia is associated with inadequate reticulocyte output, the use of EPO may help to reduce or avoid the requirement for transfusion of red cells. Several new agents, including inhibitors of the neonatal Fc receptor and others, are currently under investigation.

PAROXYSMAL COLD HEMOGLOBINURIA (PCH) PCH is a rare form of AIHA occurring mostly in children, usually triggered by a viral infection, usually self-limited, and characterized by the so-called Donath-Landsteiner antibody. In vitro, this antibody has unique serologic features; it has usually anti-P specificity, and it binds to red cells only at a low temperature (optimally at 4°C), but when the temperature is shifted to 37°C, lysis of red cells takes place in the presence of complement. Consequently, in vivo, there is intravascular hemolysis, resulting in hemoglobinuria. Clinically the differential diagnosis must include other causes of hemoglobinuria (Table 105-7), but the presence of the Donath-Landsteiner antibody will prove PCH. Active supportive treatment, including blood transfusion, may be needed to control the anemia; subsequently, recovery is the rule.

COLD AGGLUTININ DISEASE This designation indicates the other main type of AIHA, which has quite different features when compared with warm antibody AIHA. First, cold agglutinin disease (CAD) is a

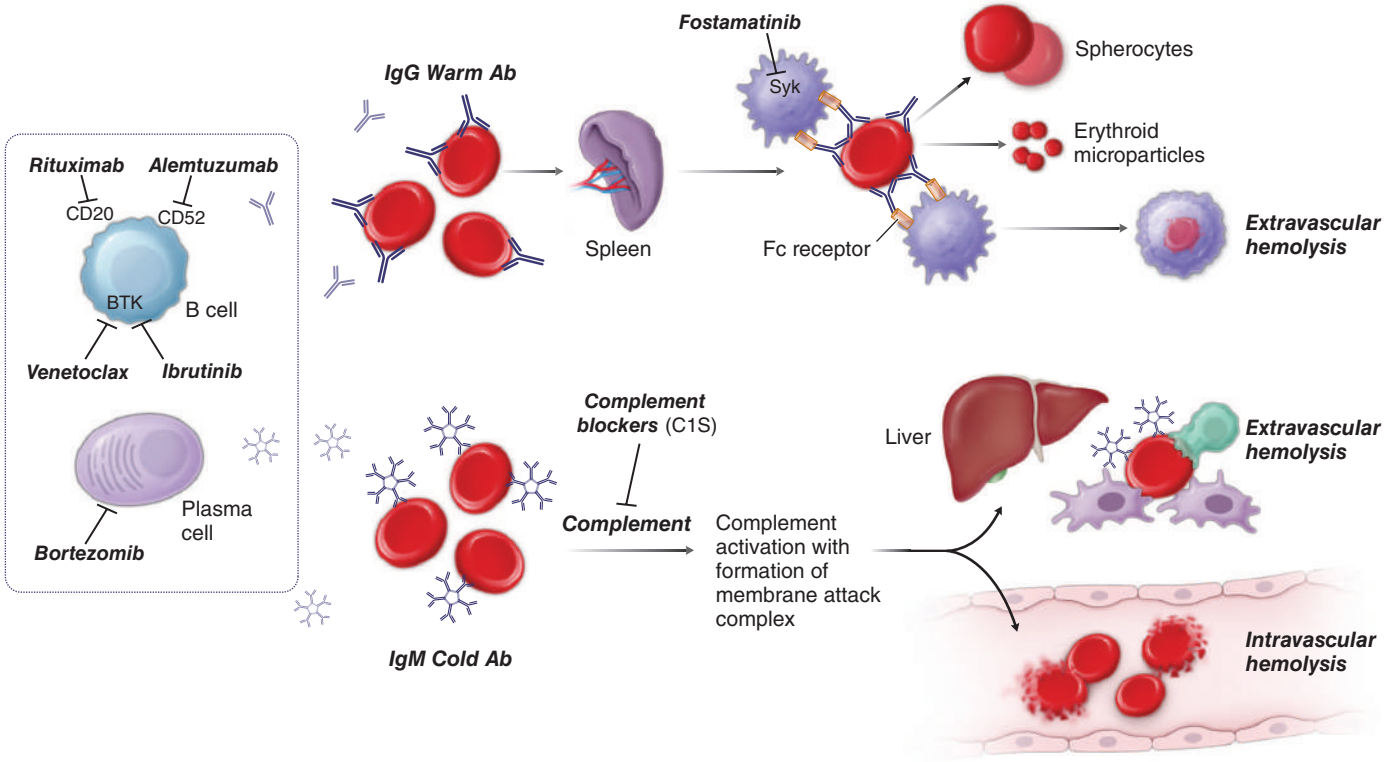

FIGURE 105-9 Basic mechanisms involved in warm antibody– and cold antibody-mediated autoimmune hemolytic anemias. ***Top.*** With warm antibodies (usually IgG), opsonized red cells are removed by Fc receptor–bearing macrophages, largely in the spleen (extravascular hemolysis); fragmentation and spherocyte formation also play a role, with the spleen again being the main site. ***Bottom.*** In cold agglutinin disease (CAD), the antibody is IgM, which, once bound to red cells, causes complement activation through the classic pathway, with consequent intravascular hemolysis. In addition, C3b-opsonized red cells will undergo erythrophagocytosis by Kupffer cells in the liver, with consequent extravascular hemolysis. The inset on the left illustrates the B cells that make these autoantibodies: polyclonal in the case of warm antibody–mediated autoimmune hemolytic anemia and monoclonal in the case of CAD. The new therapeutic approaches in addition to glucocorticoids for autoimmune hemolytic anemias are shown in red. The inset highlights drugs targeting immune cells involved in generation of antibodies. Ab, antibody; BTK, Bruton's tyrosine kinase; Syk, spleen tyrosine kinase.

chronic and more frequently indolent condition—in contrast to the abrupt onset of warm antibody AIHA. Second, the term *cold* refers to the fact that the autoantibody involved reacts with red cells poorly or not at all at 37°C, whereas it reacts strongly at lower temperatures. As a result, hemolysis is more prominent the more the body is exposed to the cold. Third, the antibody is produced by a clone of autoreactive B lymphocytes. Sometimes the antibody concentration in the serum is high enough to show up as a spike in plasma protein electrophoresis, thus qualifying CAD as an IgM monoclonal gammopathy; however, it differs from Waldenström macroglobulinemia by not having the characteristic *MYD88* mutation **(see Chap. 116)**; instead, a somatic mutation in the *KMT2D* gene, encoding a lysine histone methylase, is present in the B-cell clone of a majority of CAD patients: this seems to favor proliferation. The antibody produced by the B-cell clone is IgM; usually it has an anti-I specificity (the I antigen is present on the red cells of almost everybody), and it may have a very high titer (1:100,000 or more has been observed). IgM, when bound to red cells, is a powerful activator of the complement cascade, with ultimate formation of the membrane attack complex (see Fig. 105-9); this will directly cause destruction of red cells (*intravascular hemolysis*; indeed, CAD patients may present with hemoglobinuria). In addition, once complement is activated, C3b will bind to red cells that, thus opsonized, will be destroyed by macrophages (*extravascular hemolysis*); unlike in AIHA, the spleen is not predominant in this process.

In mild forms of CAD, avoidance of exposure to cold may be all that is needed to enable the patient to have a reasonably comfortable quality of life; but in more severe forms, the management of CAD is not easy. Plasma exchange will remove antibodies and is, therefore, in theory, a rational approach in severe cases. However, the management of CAD has changed significantly with the advent of the anti-CD20 antibody rituximab; up to 60% of patients respond. If remission is followed by relapse, a new course of rituximab may be again effective, and remissions may be more durable with a combination of rituximab with either fludarabine or bendamustine, in particular in CAD associated with a clinically manifested lymphoproliferative disorder. Therefore, even in the absence of a formal trial, rituximab has become de facto first-line treatment, especially since previously used immunosuppressive/cytotoxic agents, although they can reduce the antibody titer, have limited clinical efficacy and, in view of the chronic nature of CAD, their side effects may prove unacceptable. Unlike in AIHA, prednisone and splenectomy are ineffective. In the management of CAD in relapse, the B-cell receptor inhibitors venetoclax and ibrutinib, as well as for the proteasome inhibitor bortezomib, are emerging as effective agents. A different approach targeting complement inhibitors has been also explored by using sutimlimab (anti-C1s); a limitation of this approach is that hemolysis will be curbed only for as long as this agent is administered (Fig. 105-9).

In terms of supportive treatment, blood transfusion may be helpful, despite the fact that red cells from the donor, being I positive, will survive no longer than those of the patient. Both the blood bag and the patient's extremities must be kept warm during transfusion.

Hemolytic Anemia from Toxic Agents and Drugs A number of chemicals with oxidative potential, whether medicinal or not, can cause hemolysis even in people who are not G6PD deficient (for which, see above). Examples are hyperbaric oxygen (or 100% oxygen), nitrates, chlorates, methylene blue, dapsone, cisplatin, and numerous aromatic (cyclic) compounds. Other chemicals may be hemolytic through nonoxidative, largely unknown mechanisms; examples include arsine, stibine, copper, and lead. The HA caused by lead poisoning is characterized by basophilic stippling; it is in fact a phenocopy of that seen in P5N deficiency (see above), suggesting it is mediated at least in part by lead inhibiting this enzyme.

In these cases, hemolysis appears to be mediated by a direct chemical action on red cells. But drugs can cause hemolysis through at least two other mechanisms. (1) A drug can behave as a hapten and induce

antibody production; in rare subjects, this happens, for instance, with penicillin. Upon a subsequent exposure, red cells are caught, as innocent bystanders, in the reaction between penicillin and antipenicillin antibodies. Hemolysis will subside as soon as penicillin administration is stopped. (2) A drug can trigger, perhaps through mimicry, the production of an antibody against a red cell antigen. The best-known example is methyldopa, an antihypertensive agent no longer in use, which in a small fraction of patients stimulated the production of the Rhesus antibody anti-e. In patients who have this antigen, the anti-e is a true autoantibody, which then causes true AIHA (see above). Usually this will gradually subside once methyldopa is discontinued.

Severe intravascular hemolysis can be caused by the venom of certain snakes (cobras and vipers), and HA can also follow spider bites.

Paroxysmal Nocturnal Hemoglobinuria (PNH) PNH is an acquired chronic HA characterized by persistent intravascular hemolysis with occasional or frequent recurrent exacerbations. In addition to (1) hemolysis, there may be (2) pancytopenia and (3) a distinct tendency to venous thrombosis. This triad makes PNH a truly unique clinical condition; however, when not all of these three features are manifest on presentation, the diagnosis is often delayed, although it can always be made by appropriate laboratory investigations (see below).

PNH is encountered in all populations throughout the world, but it is a rare disease, with an estimated prevalence of 5–10 per million (it may be somewhat less rare in Southeast Asia and in the Far East). PNH has about the same frequency in men and women. PNH is not inherited, and it has never been reported as a congenital disease, but it can present in small children or as late as in the seventies, although most patients are young adults.

CLINICAL FEATURES When seeking medical attention, the patient may report that one morning, they "passed blood instead of urine." This distressing or frightening event may be regarded as the classic presentation; however, more frequently, this symptom is not noticed or not reported. Indeed, the patient often presents simply as a problem in the differential diagnosis of anemia, whether symptomatic or discovered incidentally. Sometimes the anemia is associated from the outset with neutropenia, thrombocytopenia, or both, thus signaling an element of bone marrow failure (see below). Some patients may present with recurrent attacks of severe abdominal pain eventually found to be related to thrombosis in abdominal veins, or attributable to nitric oxide depletion associated with intravascular hemolysis. When thrombosis affects the hepatic vein, it may produce acute hepatomegaly and ascites, i.e., a full-fledged Budd-Chiari syndrome, which, in the absence of liver disease, ought to raise the suspicion of PNH.

The natural history of PNH can extend over decades. In the past, with supportive treatment only, the median survival was estimated to be about 10–20 years, with the most common cause of death being venous thrombosis, followed by infection secondary to severe neutropenia and hemorrhage secondary to severe thrombocytopenia. Rarely (estimated 1–2% of all cases), PNH may terminate in acute myeloid leukemia. On the other hand, full spontaneous recovery from PNH has been documented, albeit rarely.

LABORATORY INVESTIGATIONS AND DIAGNOSIS The most consistent blood finding is anemia, which may range from mild to moderate to very severe. The anemia is usually normo-macrocytic, with unremarkable red cell morphology. If the MCV is high, it is usually largely accounted for by reticulocytosis, which may be quite marked (up to 20%, or up to 400,000/μL). The anemia may become microcytic if the patient is allowed to become iron deficient as a result of chronic iron loss through hemoglobinuria. Unconjugated bilirubin is mildly or moderately elevated; LDH is typically markedly elevated (values in the thousands are common); and haptoglobin is usually undetectable. All of these findings make the diagnosis of HA compelling. Hemoglobinuria may be overt in a random urine sample; if it is not, it may be helpful to obtain serial urine samples because hemoglobinuria can vary dramatically from day to day and even from hour to hour. The bone marrow is usually cellular, with marked to massive erythroid hyperplasia, often with mild to moderate dyserythropoietic features (these overlap with those seen in myelodysplastic syndromes, but PNH remains a separate entity). At some stage of the disease, the marrow may become hypocellular or even frankly aplastic (see below).

The definitive diagnosis of PNH must be based on the demonstration that a substantial proportion of the patient's red cells are deficient in proteins (notably CD59 and CD55) that normally protect the red cells from activated complement (C). The sucrose hemolysis test is unreliable; in contrast, the acidified serum (Ham) test is highly reliable. The gold standard today is flow cytometry, which can be carried out on granulocytes as well as on red cells and has a very high sensitivity. In PNH, characteristically, one sees a bimodal distribution of cells, with a discrete population that is CD59 and CD55 negative. Although very small populations of CD59(–) cells are of interest in terms of pathophysiology (particularly of aplastic anemia [AA]), no patient should be diagnosed with PNH unless the proportion is substantial: in first approximation, at least 5% of the total red cells and at least 20% of the total granulocytes.

PATHOPHYSIOLOGY Hemolysis in PNH is mainly intravascular and is due to an intrinsic abnormality of the red cell, which makes it exquisitely sensitive to activated C, whether C is activated through the alternative pathway or through an antigen-antibody reaction (classic pathway). The former mechanism is mainly responsible for chronic hemolysis in PNH; the latter explains why the hemolysis can be dramatically exacerbated in the course of a viral or bacterial infection. Hypersusceptibility to C is due to deficiency in the red cell membrane of several protective proteins **(Fig. 105-10)**, among which CD59 is the most important because it is able to hinder the insertion into the membrane of C9 polymers (the so-called membrane attack complex [MAC]). The molecular basis for the deficiency of these proteins has been pinpointed not to a defect in any of the respective genes, but rather to the shortage of a unique glycolipid molecule, GPI (Fig. 105-2), which, through a peptide bond, anchors these proteins to the surface membrane of cells. The shortage of GPI is due in turn to a somatic mutation in an X-linked gene, called *PIGA*, required for an early step in GPI biosynthesis. As a result, the patient's marrow is a mosaic of mutant and nonmutant cells, and the peripheral blood always contains both GPI-negative (PNH) cells and GPI-positive (non-PNH) cells; in most cases, the former prevail. Thrombosis is one of the most immediately life-threatening complications of PNH and yet one of the least understood in its pathogenesis. It could be that deficiency of CD59 on the PNH platelet causes inappropriate platelet activation; however, other mechanisms are possible. In very rare cases, PNH can be caused by biallelic mutations of the autosomal *PIGT* gene, which maps to chromosome 20q, in the absence of a *PIGA* mutation. In these cases, because GPI is produced but cannot bind to proteins, the clinical picture is further complicated by the coexistence of a chronic inflammatory state.

BONE MARROW FAILURE (BMF) AND RELATIONSHIP BETWEEN PNH AND AA It is not unusual that patients with firmly established PNH have a previous history of AA, sometimes well documented; in many cases, BMF preceding overt PNH may have passed unnoticed, but it is probably the rule rather than the exception. On the other hand, sometimes a patient with PNH becomes less hemolytic and more pancytopenic and ultimately has the clinical picture of AA. The relationship between PNH and AA manifested in the clinical course of patients reflects a close link in pathogenesis. AA is thought to be an organ-specific autoimmune disease, in which T cells cause damage to hematopoietic stem cells via an as yet unidentified molecular target. The same may be true of PNH, and in this condition, the target might be the GPI molecule itself. This would explain why GPI-negative (PNH) stem cells are spared; *PIGA* mutations can be demonstrated in normal people. Thus, PNH results from the combined action of two factors: failure of normal hematopoiesis and massive expansion of a PNH clone. There is evidence from mouse models that PNH stem cells do not expand on their own, and there is evidence from human patients that expansion is associated with negative selection against GPI-positive cells by GPI-specific T cells. Thus, PNH is a prime example of a clonal disease that is not malignant.

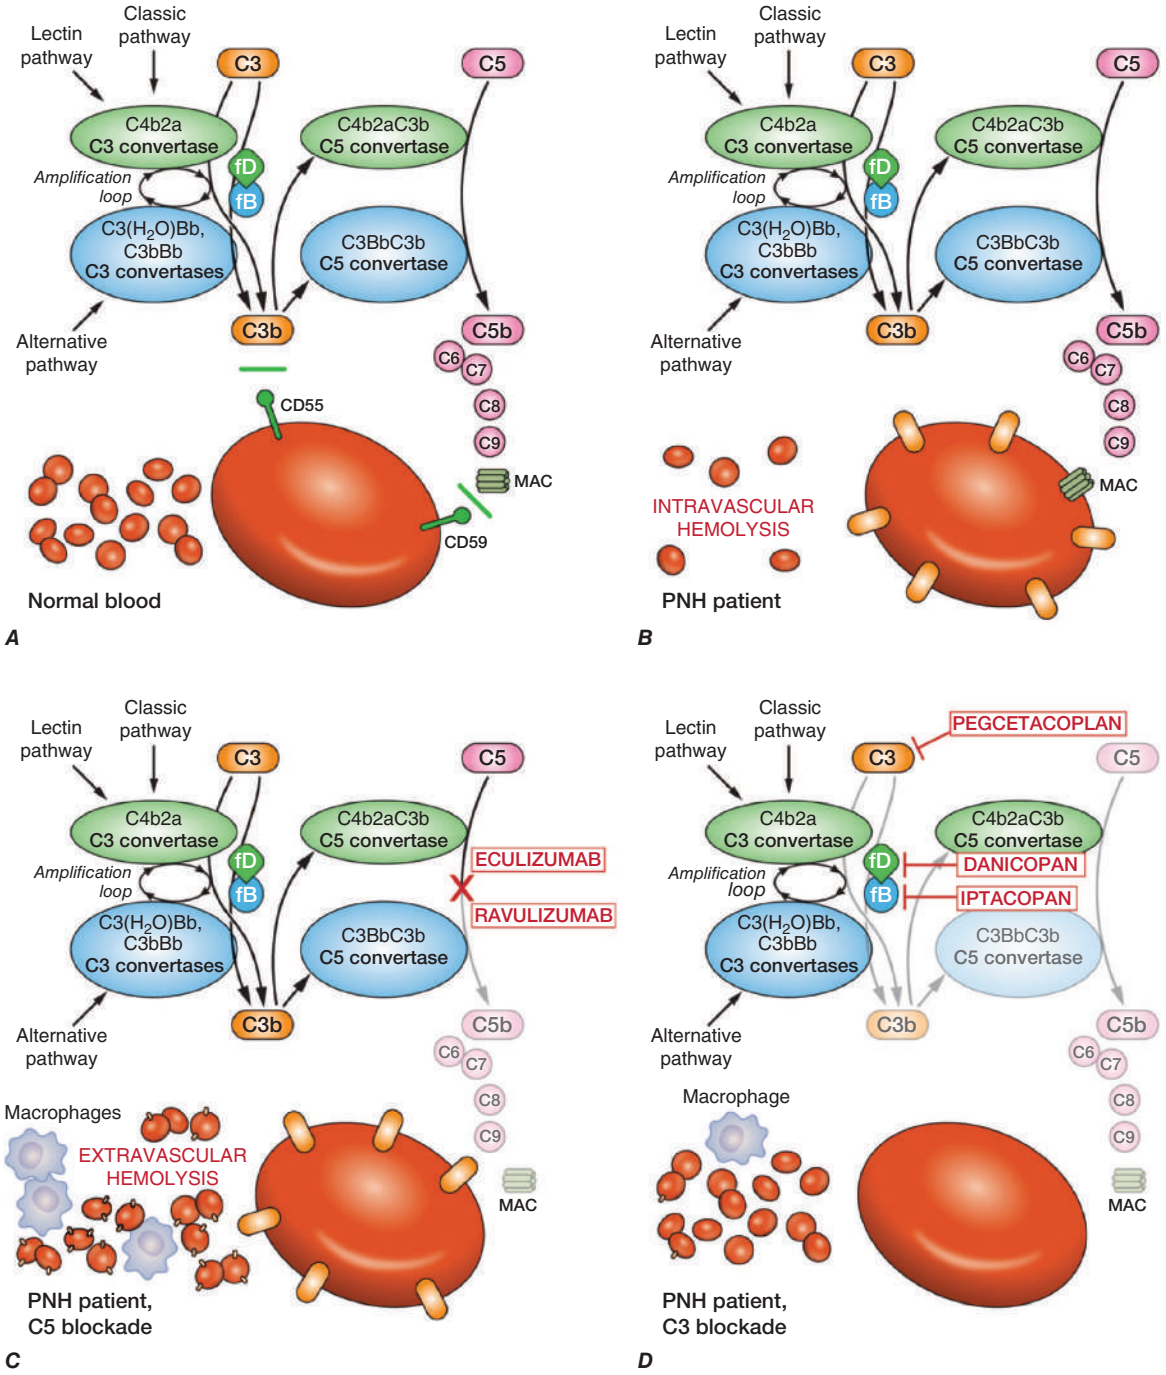

FIGURE 105-10 The complement cascade and the fate of red cells. ***A.*** In normal blood, when complement is activated, red cells are protected from lysis in several ways: primarily by the two glycosylphosphatidylinositol (GPI)-linked surface proteins CD55 (prevents binding of C3 fragments) and CD59 (prevents the membrane attack complex [MAC] from inserting into the membrane). ***B.*** Paroxysmal nocturnal hemoglobinuria (PNH) red cells are deficient in CD55 and CD59 because the glycosylphosphatidylinositol (GPI) biosynthetic pathway is blocked as a result of a PIGA mutation; therefore, C3 fragments, particularly C3d, bind to their surface, and the red cells are rapidly lysed by the action of the MAC. ***C.*** With drugs (monoclonal antibodies) that bind to C5 and prevent it from splitting into C5a and C5b, the entire distal pathway from C5 onward is blocked, MAC is not formed, and intravascular hemolysis (IVH) is abrogated. However, red cells opsonized by C3d will be destroyed in the spleen and elsewhere; this drug-induced extravascular hemolysis (EVH) varies in severity between patients. The Coombs test, which is characteristically negative in PNH, becomes positive (provided that a "broad-spectrum" or an anticomplement reagent is used). ***D.*** With a drug that targets C3, C3b formation is inhibited, and the distal pathway is not triggered by C3b. Therefore, again, no MAC is formed (abrogating IVH), and at the same time, opsonization of red cells by C3d is prevented, so that EVH is also curbed. The same is largely true for drugs that target factor B or factor D, although C3b can still be formed through the classical pathway. *(Reproduced with permission from L Luzzatto: Control of hemolysis in patients with PNH. Blood 138:1908, 2021.)*

TREATMENT

Paroxysmal Nocturnal Hemoglobinuria

Until around 20 years ago, there were essentially two treatment options for PNH: either allogeneic BMT, providing a definitive cure at the cost of nonnegligible risks; or continued supportive treatment for what, unlike other acquired HAs, may be a lifelong condition. A major advance has been the introduction in 2007 of a humanized monoclonal antibody, eculizumab, which binds to the complement component C5 near the site that, when cleaved, will trigger the distal part of the complement cascade leading to formation of the MAC. With C5 blocked by anti-C5, the patient is relieved of intravascular hemolysis and of its attendant consequences, including hemoglobinuria, with a reduced risk of thrombosis. In the majority of patients who needed regular blood transfusion, the transfusion requirement is either abolished or significantly reduced. For many

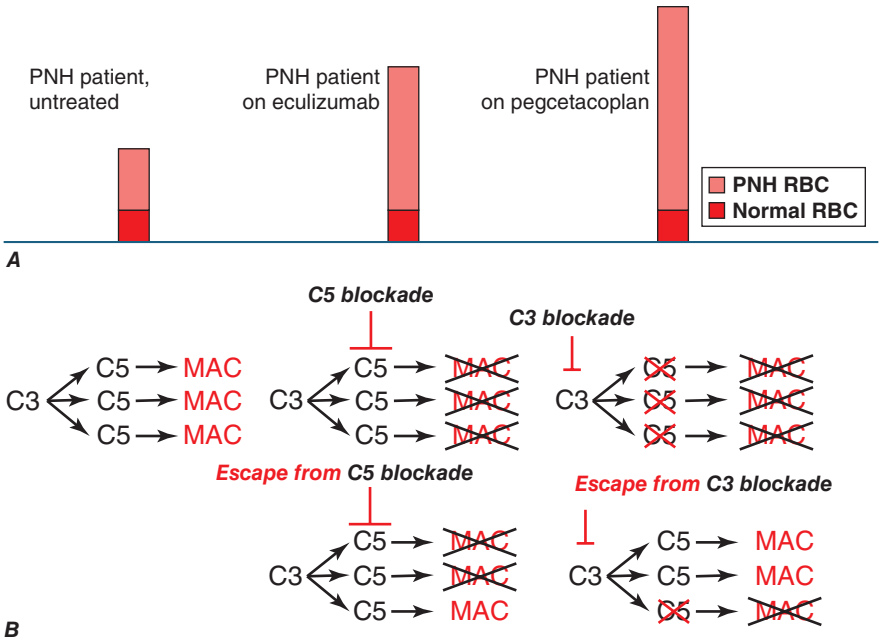

FIGURE 105-11 Impact and implications of anticomplement therapy in paroxysmal nocturnal hemoglobinuria (PNH). ***A.*** The *three vertical bars* symbolize red cell composition in examples of PNH patients. In the untreated patient, severe anemia is present with ~30% PNH red cells. In the patient on eculizumab, PNH red cells are protected from intravascular hemolysis, although at the expense of iatrogenic extravascular hemolysis (see text), and therefore, mild anemia is still present and can become severe. In the patient on pegcetacoplan, both intravascular and extravascular hemolysis are prevented, and the anemia is completely corrected. Note that the increase in red cells in the treated patients consists entirely of PNH red cells. ***B.*** Schematics of complement action and inhibition. In the untreated patient (*left*), the membrane attack complex (MAC) produces intravascular hemolysis. On eculizumab (*middle*), C5 blockade prevents MAC formation; if blockade is incomplete, some MAC is formed, with consequent *breakthrough hemolysis*. On pegcetacoplan (*right*), C5 convertase cannot be formed, and therefore, MAC formation is equally prevented; however, since there is an enzymatic cascade upstream of C5 cleavage, if blockade is incomplete, MAC formation will be more abundant with consequently more severe *breakthrough hemolysis,* potentially more massive as the PNH red cells are greatly increased in both relative and absolute terms. RBC, red blood cell.

PNH patients, eculizumab has meant a real transformation in the quality of life, as well as a decrease in complications, particularly thrombosis; thrombosis may still occur, but much more rarely. At the same time, it is important to know that in patients on eculizumab, the PNH red cells, now protected from being lysed through the MAC, do still bind C3 fragments and thus become opsonized; thus, the Coombs test becomes positive and hemolysis persists, which is now iatrogenic and mainly extravascular. The extent to which this happens depends in part on a genetic polymorphism of the complement receptor CR1. Based on its half-life, eculizumab must be administered intravenously every 14 days. Ravulizumab, a derivative of eculizumab with longer life in circulation, is administered at 8-week intervals, with obvious practical advantage. Patients who, upon C5 blockade, are still receiving blood transfusions are at risk of iron overload.

Persistent blood transfusion requirement and extravascular hemolysis in PNH patients on C5 blockade therapy have been a stimulus to developing agents that may inhibit complement activation more upstream, at the level of C3. This has been found not only to prevent intravascular hemolysis but also to avoid C3 opsonization of red cells, thus not causing extravascular hemolysis. Pegcetacoplan, an inhibitor of C3, and iptacopan, an inhibitor of factor B (which, once activated, becomes part of the alternative pathway C3 convertase) are already approved drugs; and danicopan, an inhibitor of factor D (required for the activation of factor B), has given promising results in clinical trials. Thus, several drug therapy options are available for an ultra-rare disease **(Fig. 105-11)**. Compared to C5 blockade, C3 blockade has a greater chance to completely correct anemia. We must consider that correction of anemia takes place by the buildup of a much larger population of PNH red cells than would ever be possible in an untreated PNH patient, and this population may undergo sudden lysis if complement blockade is abrogated, whether by omission or otherwise.

Eculizumab and the other complement inhibitors are very expensive and, for this reason, not accessible to patients in many parts of the world. Therefore, the management of PNH by supportive treatment is still very important. Folic acid supplements (at least 3 mg/d) are mandatory; the serum iron should be checked periodically, and iron supplements should be administered as appropriate. Transfusion of white cell-free red cells should be used whenever necessary, which, for some patients, means quite frequently. Long-term glucocorticoids are not indicated because there is no evidence that they have any effect on chronic hemolysis; in fact, they are contraindicated because their side effects are considerable. A short course of prednisone may be useful when an inflammatory process exacerbates hemolysis. Any PNH patient who has had venous thrombosis or who has been found after a thrombophilia screen to have a genetic risk factor should be on regular anticoagulant prophylaxis. With thrombotic complications that do not resolve otherwise, thrombolytic treatment with tissue plasminogen activator may be indicated.

Where anti-C5 therapy is available, the proportion of PNH patients receiving BMT has decreased significantly. However, when an HLA-identical sibling is available, BMT should be taken into consideration for any young patient with severe PNH, and for patients with the so-called PNH-AA syndrome, since C inhibitors have no effect on BMF. For these patients, immunosuppressive treatment with antithymocyte globulin and cyclosporine A may be an alternative, and it may be compatible with concurrent administration of eculizumab.

106 Anemia Due to Acute Blood Loss

Dan L. Longo

Blood loss causes anemia by two main mechanisms: (1) by the direct loss of red cells; and (2) if the loss of blood is protracted, it will gradually deplete iron stores, eventually resulting in iron deficiency. The latter type of anemia is covered in **Chap. 102**. Here, we are concerned with the former type, that is, *posthemorrhagic anemia*, which follows *acute* blood loss. This can be *external* (e.g., after trauma or obstetric hemorrhage) or *internal* (e.g., from bleeding in the gastrointestinal tract, rupture of the spleen, rupture of an ectopic pregnancy, subarachnoid hemorrhage, leaking aneurysm). In any of these cases, after the sudden loss of a large amount of blood, there are three clinical/pathophysiologic stages. (1) At first, the dominant feature is hypovolemia, which poses a threat particularly to organs that normally have a high blood supply, like the brain and the kidneys; therefore, loss of consciousness and acute renal failure are major threats. It is important to note that at this stage an ordinary blood count will not show anemia because the hemoglobin concentration is not affected. As hypovolemia is corrected with intravenous fluids acutely, the hemoglobin will gradually fall over several hours. On physical exam, tachycardia, tachypnea, decreased pulse pressure, cold skin that appears pale and mottled, and decreased urine output may be noted reflecting the efforts of the sympathetic nervous system to compensate. (2) Next, as an emergency response, baroreceptors and stretch receptors will cause release of vasopressin and other peptides, and the body will shift fluid from the extravascular to the intravascular compartment, producing hemodilution; thus, the hypovolemia gradually converts to anemia. The degree of anemia will reflect the amount of blood lost. If after 3 days the hemoglobin is, for example, 7 g/dL, it means that about half of the entire blood has been lost. (3) Provided bleeding does not continue, the bone marrow response will gradually ameliorate the anemia. In this phase of the process, the reticulocyte count and erythropoietin levels will be elevated. The physiologic increase in marrow red cell production reflected by the increase in reticulocytes is similar to the marrow response to hemolysis. Hemolysis and compensatory marrow increase in red blood cell (RBC) production are the two major mechanisms associated with anemia that is accompanied by an increase in reticulocyte count.

The diagnosis of acute posthemorrhagic anemia (APHA) is usually straightforward, although sometimes internal bleeding episodes (e.g., after a traumatic injury), even when large, may not be immediately obvious. When the scene is bloody, often the estimate of the volume of blood loss is overestimated. Always check the patient carefully. Look for physical findings that may help localize the bleeding if the site of bleeding is not obvious. Grey Turner sign (flank ecchymosis) may reflect retroperitoneal bleeding. Cullen sign (umbilical ecchymosis) may suggest intraperitoneal or retroperitoneal bleeding. Dullness to chest percussion may suggest intrapleural bleeding. Whenever an abrupt fall in hemoglobin has taken place, whatever history is given by the patient, APHA should be suspected. Supplementary history may have to be obtained by asking the appropriate questions, and appropriate investigations (e.g., a sonogram or an endoscopy) may have to be carried out.

If blood loss is mild, enhanced O_2 delivery is achieved through changes in the O_2–hemoglobin dissociation curve mediated by a decreased pH or increased CO_2 (*Bohr effect*). With acute blood loss, hypovolemia dominates the clinical picture, and the hematocrit and hemoglobin levels do not reflect the volume of blood lost. Signs of vascular instability appear with acute losses of 25% or more of the total blood volume. The donation of a unit of blood (~20% of the blood volume) is often minimally symptomatic. In patients who lose a larger percentage of the blood volume, the issue is not anemia but hypotension and decreased organ perfusion. When >30% of the blood volume is lost suddenly, patients are unable to compensate with the usual mechanisms of sympathetic nervous system increases in heart rate, vascular contraction, and changes in regional blood flow. The patient prefers to remain supine and will show postural hypotension and tachycardia. If the volume of blood lost is >40% (i.e., >2 L in the average-sized adult), signs of hypovolemic shock including confusion, dyspnea, diaphoresis, hypotension, and tachycardia appear. Such patients have significant deficits in vital organ perfusion and require immediate volume replacement.

Symptoms associated with more chronic or progressive anemia depend on the age of the patient and the adequacy of blood supply to critical organs. Symptoms associated with moderate anemia include fatigue, loss of stamina, breathlessness, and tachycardia (particularly with physical exertion). However, because of the intrinsic compensatory mechanisms that govern the O_2–hemoglobin dissociation curve, the gradual onset of anemia—particularly in young patients—may not be associated with signs or symptoms until the anemia is severe (hemoglobin <70–80 g/L [7–8 g/dL]). When anemia develops over a period of days or weeks, the total blood volume is normal to slightly increased, and changes in cardiac output and regional blood flow help compensate for the overall loss in O_2-carrying capacity. Changes in the position of the O_2–hemoglobin dissociation curve account for some of the compensatory response to anemia. With chronic anemia, intracellular levels of 2,3-bisphosphoglycerate rise, shifting the dissociation curve to the right and facilitating O_2 unloading. This compensatory mechanism can only maintain normal tissue O_2 delivery in the face of a 20–30 g/L (2–3 g/dL) deficit in hemoglobin concentration. Finally, further protection of O_2 delivery to vital organs is achieved by the shunting of blood away from organs that are relatively rich in blood supply, particularly the kidney, gut, and skin.

TREATMENT

Anemia Due to Acute Blood Loss

In patients who are hemodynamically unstable, the usual airway, breathing, and circulation assessments take priority. In the face of bleeding associated with hypotension, pharmacologic support with vasopressors is critical. With respect to anemia treatment, a two-pronged approach is imperative. (1) In many cases, the blood lost needs to be replaced promptly. Unlike with many chronic anemias, when finding and correcting the cause of the anemia is the first priority and blood transfusion may not be even necessary because the body is adapted to the anemia, with acute blood loss, the reverse is true. Because the body is not adapted to the anemia, blood transfusion takes priority. (2) While the emergency is being confronted, it is imperative to stop the hemorrhage and to eliminate its source.

In an acute hemorrhage situation, plasma may be preferred to saline for volume expansion since dilution of clotting factors with crystalloid may interfere with hemostasis. Furthermore, trauma can lead to vascular and platelet abnormalities that enhance the bleeding risk.

A special type of APHA is blood loss during and immediately after surgery, which can be substantial (e.g., up to 2 L in the case of a

radical prostatectomy). Of course, with elective surgical procedures, the patient's own stored blood may be available (through preoperative autologous blood donation), and in any case, blood loss ought to have been carefully monitored/measured. The fact that this blood loss is iatrogenic dictates that ever more effort should be invested in optimizing its management. The special features of transfusion medicine are discussed in **Chap. 118**.

A Holy Grail of emergency medicine for a long time has been the idea of a blood substitute that would be universally available, suitable for all recipients, easy to store and to transport, safe, and as effective as blood itself. Two main paths have been pursued: (1) fluorocarbon synthetic chemicals that bind oxygen reversibly, and (2) artificially modified hemoglobins, known as hemoglobin-based oxygen carriers (HBOCs). Although there are numerous anecdotal reports of the use of both approaches in humans, and although HBOCs have reached the stage of phase 2–3 clinical trials, no "blood substitute" has yet become standard treatment.

107 Bone Marrow Failure Syndromes Including Aplastic Anemia and Myelodysplasia

Neal S. Young, Emma M. Groarke

Bone marrow failure diseases include aplastic anemia, myelodysplastic syndrome (MDS), pure red cell aplasia (PRCA), and other single-lineage cytopenias. Low blood counts in marrow failure result from deficient hematopoiesis, as distinguished from blood count depression due to peripheral destruction of red cells (hemolytic anemias), platelets (idiopathic thrombocytopenic purpura [ITP] or due to splenomegaly), and granulocytes (as in the immune leukopenias). Marrow damage and dysfunction also may be secondary to infection, inflammation, or cancer.

Hematopoietic failure syndromes are classified by dominant morphologic features of the bone marrow **(Table 107-1)**. Although practical distinction among these syndromes usually is clear from the marrow pathology, some processes are so closely related that the diagnosis may be complex. Separation between aplastic anemia and hypoplastic MDS can be particularly difficult. Patients may seem to suffer from two or three related diseases simultaneously, or one diagnosis may appear to evolve into another. Many of these syndromes share an immune-mediated mechanism of marrow destruction and some element of genomic instability resulting in a higher rate of malignant transformation.

It is important that the internist and general practitioner recognize the marrow failure syndromes because quality of life and prognosis is poor if the patient is untreated; effective therapies are often available but sufficiently complicated in their choice and delivery so as to warrant the care of a hematologist or oncologist. While the identification of pathogenic mutations on genomic screen, often on testing ordered by the internist and pediatrician, has revolutionized the diagnosis of the marrow failure syndromes, these results often require the interpretation of the hematologist and oncologist.

APLASTIC ANEMIA

DEFINITION

Aplastic anemia is pancytopenia with bone marrow hypocellularity. Based on etiology, pathophysiology, and clinical features, an empty bone marrow may be the result of physical and chemical damage, of immune-mediated destruction of hematopoietic cells, or a component of an inherited syndrome **(Fig. 107-1)**. Acquired aplastic anemia, usually immune mediated, is distinguished from constitutional aplastic anemia, and within the acquired category, marrow damage as occurs consistently after intensive cytotoxic chemotherapy for cancer, conditioning for transplant, and occasionally as in accidental radiation poisoning, from sporadic immune aplastic anemia. Aplastic anemia can also be constitutional, due to germline genetic defects, termed the inherited bone marrow failure syndromes (IBMFS). Classical inherited syndromes such as Fanconi anemia and dyskeratosis congenita typically are diagnosed in early childhood in affected pedigrees and have characteristic physical anomalies. However, telomere biology disorders **(see Chap. 482)** and germline predisposition disorders, such as *GATA2* deficiency and *RUNX1* familial platelet disorder, can present as marrow failure in normal-appearing adults. Immune aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incriminated medical drug may precede the onset. The diagnosis in these instances is uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH; **Chap. 105**) and to MDS, and a clear distinction among these disorders may not be possible.

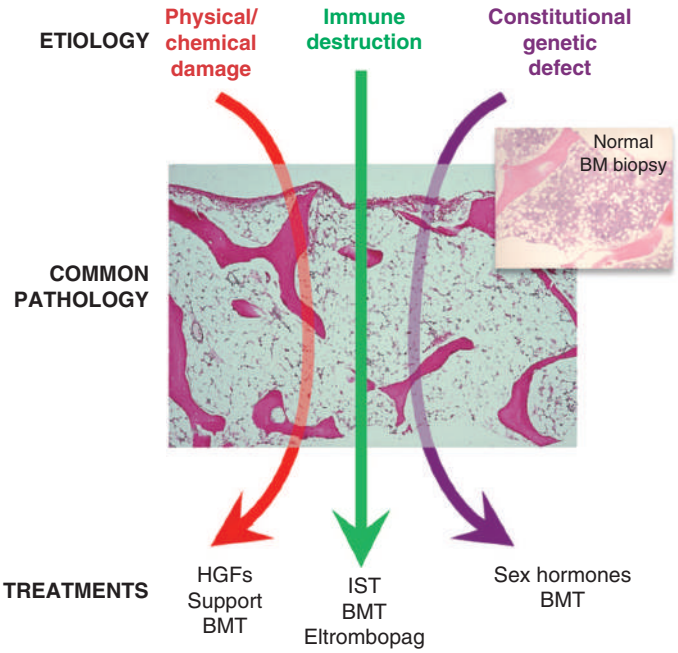

FIGURE 107-1 Pathophysiologies of aplastic anemia. The common pathology of the bone marrow replaced by fat can result from chemical or physical damage (iatrogenic; benzene); immune destruction (primarily T cell driven); and as a constitutional defect in genes important for cell maintenance and immune regulation. BM, bone marrow; BMT, bone marrow transplantation; HGF, hematopoietic growth factors; IST, immunosuppressive therapy.

EPIDEMIOLOGY

The incidence of acquired aplastic anemia in Europe and Israel is two cases per million persons annually. In Thailand and China, rates of five to seven per million have been established. Men and women are affected with equal frequency, but the age distribution is biphasic, with the major peak in the teens and twenties and a second in older adults.

ETIOLOGY

Historically, the origins of aplastic anemia were inferred from recurring clinical associations (Table 107-2); unfortunately, these relationships, as with a medical drug, may not be reliable in an individual patient, and associations are not equivalent to causation. In addition, although most cases of aplastic anemia are immune, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

Radiation Marrow aplasia is a major acute sequela of radiation, anticipated from medical radiation therapy and rarely after accidental and/or occupational exposure Radiation damages DNA; tissues dependent on active mitosis are particularly susceptible. Whereas the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient's prognosis and also to protect medical personnel from contact with radioactive tissue and excreta. MDS and leukemia, but probably not aplastic anemia, are late effects of radiation.

Chemicals Benzene is a notorious cause of bone marrow failure: epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. For leukemia, incidence is correlated with cumulative exposure, but susceptibility must also be important because only a minority of even heavily exposed workers develop myelotoxicity. Employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. The association between marrow failure and other chemicals is much less well substantiated. There is scant direct evidence of marrow failure as a late effect of exposure, even to benzene.

Drugs (Table 107-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose-dependent and will occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. A large international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Association does not equal causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or a preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, although individually devastating, are rare events. Risk estimates are usually lower when determined in population-based studies. Furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to just a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed persons.

Infections Transient, mild blood count depression is frequent in the course of many viral and bacterial infections. Aplastic anemia can

TABLE 107-2 Classification of Aplastic Anemia and Single Cytopenias

ACQUIRED	INHERITED/CONSTITUTIONAL
Aplastic Anemia	
Secondary	Fanconi anemia
Radiation	Dyskeratosis congenita/telomere disease
Drugs and chemicals	Shwachman-Diamond syndrome
Regular effects	Familial aplastic anemia/leukemia predisposition syndromes: *GATA2, RUNX1, CTLA4*, and others
Idiosyncratic reactions	
Viruses	
Epstein-Barr virus (infectious mononucleosis)	Nonhematologic syndromes (Down, Dubowitz, Seckel)
Hepatitis (non-A, non-B, non-C hepatitis)	
Parvovirus B19 (transient aplastic crisis, pure red cell aplasia [PRCA])	
HIV-1 (AIDS)	
Immune diseases	
Eosinophilic fasciitis	
Hypoimmunoglobulinemia	
Large granular lymphocytosis (LGL)	
Thymoma/thymic carcinoma	
Graft-versus-host disease in immunodeficiency

TABLE 107-3 Some Drugs and Chemicals Associated with Aplastic Anemia

Agents that regularly produce marrow depression as major toxicity in commonly used doses or normal exposures:
Cytotoxic drugs used in cancer chemotherapy: *alkylating agents, antimetabolites, antimitotics*, some antibiotics
Agents that frequently but not inevitably produce marrow aplasia:
Benzene
Agents associated with aplastic anemia but with a relatively low probability:
Chloramphenicol
Insecticides
Antiprotozoals: *quinacrine* and chloroquine, mepacrine
Nonsteroidal anti-inflammatory drugs (including *phenylbutazone*, indomethacin, ibuprofen, sulindac, aspirin)
Anticonvulsants (*hydantoins*, *carbamazepine*, phenacemide, felbamate)
Heavy metals (*gold*, arsenic, bismuth, mercury)
Sulfonamides: some antibiotics, antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), antidiabetes drugs (tolbutamide, chlorpropamide), carbonic anhydrase inhibitors (acetazolamide and methazolamide)
Antihistamines (*cimetidine*, chlorpheniramine)
D-Penicillamine
Estrogens (in pregnancy and in high doses in animals)
Agents whose association with aplastic anemia is more tenuous:
Other antibiotics (streptomycin, tetracycline, methicillin, mebendazole, trimethoprim/sulfamethoxazole, flucytosine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon)
Allopurinol
Methyldopa
Quinidine
Lithium
Guanidine
Potassium perchlorate
Thiocyanate
Carbimazole

Note: Terms set in italics show the most consistent association with aplastic anemia.

rarely follow infectious mononucleosis. Parvovirus B19 is a cause of pure red cell aplasia and rarely implicated in generalized bone marrow failure.

Immunologic Diseases Aplasia is a major consequence and the inevitable cause of death in transfusion-associated graft-versus-host disease (GVHD) that can occur after infusion of nonirradiated blood products to an immunodeficient recipient. Aplastic anemia occurs with the rare collagen vascular syndrome eosinophilic fasciitis that is characterized by painful induration of subcutaneous tissues **(Chap. 372)**. Thymoma and hypoimmunoglobulinemia can co-occur with aplastic anemia. Pancytopenia with marrow hypoplasia can be seen in systemic lupus erythematosus (SLE).

Hepatitis Posthepatitis marrow failure accounts for ~5% of etiologies in most series. Patients are usually young men who have recovered from a bout of liver inflammation 1–2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is seronegative (non-A, non-B, non-C); intensive laboratory efforts including deep sequencing have not disclosed an infectious agent, and the hepatitis is presumed to be immune-mediated. Fulminant liver failure in childhood can follow seronegative hepatitis, and marrow failure occurs at a high rate in these patients.

Pregnancy Aplastic anemia very rarely may complicate pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria An acquired mutation in the *PIG-A* gene in a hematopoietic stem cell is required for the development of PNH, but *PIG-A* mutations are also present in the marrow cells of normal individuals. If the *PIG-A* mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins **(Chap. 105)**. Clones of deficient cells can be detected by sensitive flow cytometry tests in one-half or more of patients with aplastic anemia at the time of presentation. Functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer later from hemolytic PNH years after recovery of blood counts.

Constitutional Syndromes Fanconi anemia, an autosomal recessive disorder, manifests as congenital developmental anomalies, progressive pancytopenia, and an increased risk of malignancy. Chromosomes in Fanconi anemia are susceptible to DNA cross-linking agents, the basis for a diagnostic assay. Patients with Fanconi anemia typically have short stature, café au lait spots, and anomalies involving the thumb, radius, and genitourinary tract. At least 23 different genetic defects have been defined; the most common, type A Fanconi anemia, is due to a mutation in *FANCA*. Most of the Fanconi anemia gene products form a protein complex that activates FANCD2 by monoubiquitination to play a role in the cellular response to DNA damage and especially interstrand cross-linking.

Diamond-Blackfan anemia (see below) and Shwachman-Diamond syndrome are ribosomopathies, genetic defects in ribosome assembly that are tissue specific. In Shwachman-Diamond syndrome, presentation is early in life with neutropenia, pancreatic insufficiency, and malabsorption; most patients have compound heterozygous mutations in *SBDS*.

In the telomere biology disorders, inherited genetic defects alter telomere repair or one of the shelterin protein components of the telomere. The pediatric syndrome dyskeratosis congenita is characterized by the triad of mucous membrane leukoplasia, dystrophic nails, reticular hyperpigmentation, and early development of aplastic anemia **(Chap. 482)**. Mutations in genes of the telomere repair complex, which acts to maintain telomere length in replicating cells, cause telomere biology disorders: the X-linked variety is due to mutations in the *DKC1* (*dyskerin*) gene; the autosomal dominant types are due to mutations in *TERC* and TERT, more rarely, mutations can also occur in genes such as *TINF2* that encode shelterin proteins, which bind telomere DNA. Mutations in *TERC* and *TERT*, which encode; the catalytic reverse transcriptase telomerase, can have subtle and milder effects on hematopoietic function; presentation in adults is not unusual, as moderate aplastic anemia, which can be chronic and not progressive, and isolated macrocytic anemia or thrombocytopenia. Physical anomalies are usually not present, but early hair graying is a clue to the diagnosis. A detailed personal and family history may disclose pulmonary fibrosis and hepatic cirrhosis. Variable penetrance means that *TERT* and *TERC* mutations represent risk factors for marrow failure, as family members with the same mutations may have normal or only slight hematologic abnormalities but more subtle evidence of (compensated) hematopoietic insufficiency. Patients can suffer pulmonary or liver fibrosis in the absence of hematologic abnormalities.

PATHOPHYSIOLOGY

Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen (Fig. 107-1) and magnetic resonance imaging (MRI) of the spine. Cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished, and in functional studies, committed and primitive progenitor cells are virtually absent; in vitro assays have suggested that the stem cell pool is reduced to ≤1% of normal in severe disease at the time of presentation.

Constitutional Genetic Syndromes An intrinsic stem cell defect exists for the constitutional aplastic anemias: in a critical DNA

repair pathway in Fanconi anemia, manifested in the laboratory as chromosome damage and cell death on exposure to certain chemical agents. In the telomere biology disorders, inability to repair telomeres or to protect chromosome ends is the result of mutations in genes of the telomerase complex or the shelterin proteins; telomere defects limit the cell's capacity to proliferate. Mutations in the *GATA2* and *RUNX1* genes affect signal transduction and transcriptional regulation in hematopoietic gene networks.

Chemical and Drug Injury Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptibility loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

Immune-Mediated Stem Cell Destruction The recovery of marrow function in some patients prepared for bone marrow transplantation with antilymphocyte globulin first suggested that aplastic anemia might be immune mediated. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves hematopoiesis in vitro. Increased numbers of activated cytotoxic T-cell clones, which can be visualized in sophisticated single-cell experiments (single-cell RNA sequencing, time-of-flight flow cytometry) usually decline with successful immunosuppressive therapy. Type 1 cytokines are implicated, and interferon γ (IFN-γ) induces Fas expression on CD34 cells, leading to apoptotic cell death. Immune selection can result in loss of human leukocyte antigen (HLA) expression on hematopoietic stem cells, and PNH clones are observed almost exclusively in immune marrow failure. The rarity of aplastic anemia despite common exposures (medicines, seronegative hepatitis) suggests that genetically determined features of the immune response can convert a normal physiologic response into a sustained abnormal autoimmune process, including polymorphisms in histocompatibility antigens, cytokine genes, and genes that regulate T-cell polarization (maturation toward helper or cytotoxic phenotypes) and effector function.

CLINICAL FEATURES

History Aplastic anemia can appear abruptly or insidiously. Bleeding is the most common early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and sometimes petechiae will have been noticed. With thrombocytopenia, massive hemorrhage is unusual, but small amounts of bleeding in the central nervous system can result in catastrophic intracranial or retinal hemorrhage. Symptoms of anemia are also frequent, including lassitude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occurs early). Patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. Prior medical drug use, chemical exposure, and preceding viral illnesses must often be elicited with directed questioning. A family history of hematologic diseases or blood abnormalities is suspicious for IBMFS. Specific features of the history can help: pulmonary or liver fibrosis or early hair graying points to a telomere biology disorder, and a family history of unusual infections and warts to *GATA2* deficiency.

Physical Examination Petechiae and ecchymoses are typical, and retinal hemorrhages may be present. Pallor of the skin and mucous membranes is common. Infection on presentation is unusual but may occur if the patient has been symptomatic for a few weeks. Lymphadenopathy and splenomegaly are highly atypical of aplastic anemia. Suggestive findings of IBMFS include café au lait spots and short stature for Fanconi anemia; peculiar nails and leukoplakia for dyskeratosis congenita; early graying (and use of hair dyes to mask it!) for a telomere biology disorder.

LABORATORY STUDIES

Blood The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of immature myeloid forms suggests leukemia or MDS; nucleated red blood cells (RBCs) suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

Bone Marrow The bone marrow is usually readily aspirated but dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a "dry tap" instead suggests fibrosis or myelophthisis. In severe aplasia, the smear of the aspirated specimen shows only red cells, residual lymphocytes, and stromal cells; the biopsy (which should be >1 cm in length) is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying <25% of the marrow space; sometimes, the biopsy is virtually all fat. The correlation between marrow cellularity and disease severity is imperfect; patients with moderate disease by blood counts can have "empty" iliac crest biopsies, whereas "hot spots" of hematopoiesis may be seen in severe cases. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are greatly reduced and usually absent. Granulomas may indicate an infectious etiology of the marrow failure.

Ancillary Studies Chromosome breakage studies of peripheral blood using diepoxybutane or mitomycin C should be performed on children and younger adults to diagnose Fanconi anemia. Very short telomere length of peripheral blood leukocytes is seen in telomere biology disorders, which can be pursued by family studies and nucleotide sequencing. Chromosome studies of bone marrow cells are often abnormal in MDS but should be negative in typical aplastic anemia. Flow cytometry offers a sensitive diagnostic test for PNH; a PNH clone is strongly suggestive of immune-mediated disease. Serologic studies may show evidence of recent viral infection, such as Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is seronegative.

Genomics Next-generation sequencing allows for a large number of genes to be tested for the presence of pathogenic mutations. Panels are available commercially and in academic laboratories. While expensive, they are very useful and sometimes critical in establishing the correct diagnosis. Germline gene panels examine 50 or more genes etiologic in constitutional bone marrow failure, including many for which functional assays (described above) are not available. A germline panel should be considered for all children and those adults with suspicious clinical features or family histories. Somatic mutations are sought when MDS is suspected using myeloid neoplasm gene panels that can query about 100 genes that are recurrently mutated in MDS and acute myeloid leukemia (AML). Pathogenic mutations in spliceosome genes and genes in the cohesion gene family are frequent in MDS and unexpected in aplastic anemia.

DIAGNOSIS

The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty bone marrow. Immune aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history of metastatic cancer or SLE, or miliary tuberculosis on chest radiograph (Table 107-1).

Diagnostic problems can occur with atypical presentations and among related hematologic diseases. Patients with bone marrow hypocellularity may have depression of only one or two of three blood lines, later progressing to pancytopenia. The most important differential diagnoses are between acquired and constitutional aplastic anemia, and between aplastic anemia and MDS. The bone marrow in constitutional aplastic anemia is usually morphologically indistinguishable from the aspirate in acquired disease (an exception is *GATA2* deficiency with its characteristic megakaryocyte atypia). The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated, sometimes subtle physical anomalies. Flow cytometry may show distinctive patterns to guide diagnosis, for sample, the absence of B and natural killer (NK) cells seen in *GATA2* deficiency. Genomic testing for pathogenic mutations in genes etiologic in constitutional marrow failure syndromes can discriminate acquired from inherited aplastic anemia (but results may not return for several weeks, a problem in the severely pancytopenic patient). AML and MDS in a pedigree should prompt screening for an inherited predisposition syndrome, such as familial *RUNX1* disorder. Aplastic anemia may be difficult to distinguish from hypocellular MDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities and somatic mutations on genomic screening of myeloid neoplasm genes (see above). There remains an unclear boundary between immune aplastic anemia and low-risk MDS: patients with deletion of 13q and 20q may respond well to immunosuppression, and mutations in genes such as *DNMT3A* and *ASXL1* occur in both diseases.

PROGNOSIS

The natural history of severe aplastic anemia is rapid deterioration and death. Historically, provision first of RBCs and later of platelet transfusions and effective antibiotics were of some benefit, but few patients showed spontaneous recovery. The major prognostic determinant is the blood count. Severe disease historically has been defined by the presence of two of three parameters: absolute neutrophil count <500/μL, platelet count <20,000/μL, and corrected reticulocyte count <1% (or absolute reticulocyte count <60,000/μL). In the era of effective immunosuppressive therapies, absolute numbers of reticulocytes (>25,000/μL) and lymphocytes (>1000/μL) are better predictors of response to treatment and long-term outcome.

Other prognostic factors include the presence of a PNH clone, short telomeres on presentation, and somatically mutated white cells. Even small PNH clones may indicate an immune pathophysiology and responsiveness to immunosuppressive therapies. Telomere shortening in the granulocytes of many patients likely reflects stem cell reserve, regenerative stress, and susceptibility to chromosomal instability; shorter telomeres in lymphocytes are more consistent with a telomere biology disorder. Collectively, the presence of mutations in the same myeloid neoplasia genes that are mutated in some clonal hematopoiesis of indeterminate potential (*ASXL1*) is associated with worse prognosis and clonal evolution.

TREATMENT

Aplastic Anemia

Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or it can be ameliorated by suppression of the immune system to allow recovery of the patient's residual bone marrow function. Glucocorticoids are not of value as primary therapy, and among their multiple toxicities is increased susceptibility to fungal infection. Suspicious drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

This is the first choice for the younger patient with a fully histocompatible sibling donor **(Chap. 119)**. HLA typing should be ordered as soon as the diagnosis of aplastic anemia is established in transplant-eligible patients. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatibility antigens. In general, limited numbers of blood products probably do not greatly affect outcome, especially when blood products are depleted of leukocytes. For allogeneic transplant from fully matched siblings, long-term survival rates for children are ~90% or better. Transplant morbidity and mortality are increased among adults, due to the higher risk of chronic GVHD and infections. Nevertheless, transplant should be considered early in all but the most elderly, including from alternative donors.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. More broadly, matched unrelated donors in large registries are available for the majority of Caucasian patients. With high-resolution matching at HLA, outcomes are similar to those with sibling donors, although complications (GVHD and infection) are more frequent. Cord blood also can be a source of stem cells, especially for children. Matched unrelated donor transplants are often considered as initial treatment in children and as salvage therapy for adults after failed immunosuppression. Transplantation from an HLA haploidentical family donor is increasingly popular, as a donor is almost always readily available. Posttransplant cyclophosphamide appears effective in preventing GVHD and is increasingly popular; lymphocyte depletion before donor cell infusions has been developed and employed. Transplant protocols for marrow failure, except in the case of alternative donor transplant, now usually do not include radiation in order to avoid late occurrence of cancer.

IMMUNOSUPPRESSION WITH ELTROMBOPAG

Early, serendipitous observation of spontaneous improvement of blood counts despite lack of engraftment of donor marrow led to speculation of an immune pathophysiology and also purposeful administration of antilymphocyte globulin as sole treatment. Addition of cyclosporine to antithymocyte globulin (ATG) increased the response rate, and cyclosporine helped maintain remissions. Many other attempts to improve on the regimen of ATG plus cyclosporine failed. Although hematopoietic growth factors generally are of little utility in immune aplastic anemia, thrombopoietic mimetics, surprisingly, rescued refractory aplastic anemia as monotherapy and increased both overall and complete response rates in combination with immunosuppression in treatment-naïve disease.

The current standard regimen of ATG, cyclosporine, and eltrombopag ("triple therapy") induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in 70–80% of patients. Children do especially well with immunosuppressive therapy, whereas older adult patients can suffer complications due to the presence of comorbidities. Children have less improvement in response with the addition of eltrombopag to immunosuppressive therapy than do adults. An early robust hematologic response correlates with long-term survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, the MCV remains elevated, and bone marrow cellularity returns toward normal very slowly if at all. Relapse (some degree of recurrent pancytopenia) is frequent, often occurring as cyclosporine or eltrombopag is tapered or discontinued; most, but not all, patients respond to reinstitution of therapy. Some patients become dependent on continued cyclosporine or eltrombopag administration. "Clonal evolution," isolated chromosomal abnormalities or the development of MDS, with typical cytogenetic aberrations and abnormal marrow morphology, occurs in ~10–15% of treated patients over a decade following initiation of ATG, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. A laboratory diagnosis of PNH can generally be made at the time of presentation of aplastic anemia by flow cytometry; recovered patients may have frank hemolysis if the PNH clone expands. Bone marrow examinations should be performed if there is an unfavorable change in blood counts.

Horse ATG is administered as intravenous infusions and requires hospitalization. Rabbit ATG is much less effective, perhaps because it reduces T-regulatory cell numbers in patients. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, may develop ~10 days after initiating treatment. Methylprednisolone is administered with ATG to ameliorate the immune consequences of heterologous protein infusion. (Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis.)

Cyclosporine is administered orally at an initial high dose, with subsequent adjustment according to blood levels. Its most important side effects are nephrotoxicity, hypertension, and seizures. Some centers replace cyclosporine with tacrolimus.

Eltrombopag, a thrombopoietin (TPO) mimetic, is administered once daily for 6 months; its most important side effect is hepatotoxicity. The likely mechanism of action of TPO mimetics is stimulation of the hematopoietic stem cell, but iron chelation and increased regulatory T cells are also possibly beneficial effects. Eltrombopag added to first-line immunosuppression with horse ATG markedly increased overall and complete response rates, to about 80 and 50%, respectively, and triple therapy became the U.S. Food and Drug Administration (FDA)-approved standard-of-care therapy in 2018. Eltrombopag was first licensed in the refractory setting where it showed response rates of ~40%. Romiplostim, another TPO mimetic, also has been reported as effective.

Most patients with aplastic anemia lack a fully matched marrow donor, and immunosuppression is the treatment of choice. Overall survival is equivalent with transplantation and immunosuppression. However, successful transplant cures marrow failure, whereas patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Increasing age and the severity of neutropenia are the most important factors weighing in the decision between transplant and immunosuppression in adults who have a matched family donor: older patients do better with ATG and cyclosporine, whereas transplant is preferred if neutropenia is profound. Patients in whom immunosuppression has failed can be salvaged by stem cell transplant later.

ANDROGENS

The effectiveness of androgens has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. Sex hormones upregulate telomerase gene activity in vitro, which is possibly also their mechanism of action in improving marrow function. For patients with moderate disease, especially if a telomere gene defect is present, a 3- to 4-month trial may improve all blood counts **(Chap. 483)**.

SUPPORTIVE CARE

Meticulous medical attention is required so that the patient may survive to benefit from definitive therapy or, having failed treatment, to maintain a reasonable existence in the face of pancytopenia. First and most important, infection in the presence of severe neutropenia must be aggressively treated by prompt institution of parenteral, broad-spectrum antibiotics. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhlitis (necrotizing colitis) and infected lines should be sought on clinical assessment and with radiographic studies. Persistent or recrudescent fever implies fungal disease: *Candida* and *Aspergillus* are common, especially after several courses of antibacterial antibiotics. A major reason for the improved prognosis in aplastic anemia has been the development of better antifungal drugs and the timely institution of such therapy when infection is suspected. Granulocyte transfusions can be effective when bacterial or fungal infection is progressive or refractory to antibiotics. Nonabsorbed antibiotics for gut decontamination are poorly tolerated and unproven, nor does reverse isolation reduce mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization historically limited the usefulness of platelet transfusions and is now minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are usually effective in alloimmunized patients refractory to random donor products. The use of low-dose glucocorticoids to induce "vascular stability" is unproven and not recommended. With prophylactic platelet transfusions, the goal is to maintain the platelet count >10,000/μL (oozing from the gut increases sharply at counts <5000/μL). Menstruation should be suppressed either by oral estrogens or follicle-stimulating hormone/luteinizing hormone antagonists. Aspirin and other nonsteroidal anti-inflammatory agents must be avoided in the presence of thrombocytopenia.

RBCs should be transfused so as to allow patients a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelators deferoxamine and deferasirox should be added at approximately the fiftieth transfusion to avoid secondary hemochromatosis.

Hematopoietic growth factors (HGFs) such as erythropoietin (EPO) and granulocyte colony-stimulating factor (G-CSF) are not effective in aplastic anemia.

PURE RED CELL APLASIA

Other more restricted forms of marrow failure occur, in which only a single cell type is affected and the marrow shows corresponding absence or decreased numbers of specific precursor cells: aregenerative anemia as in PRCA (see below), thrombocytopenia with amegakaryocytosis **(Chap. 120)**, and neutropenia without marrow myeloid cells in agranulocytosis **(Chap. 67)**. In general, and in contrast to aplastic anemia and MDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use, either by a mechanism of direct chemical toxicity or by immune destruction. Agranulocytosis has an incidence similar to aplastic anemia (but geographically more frequent in Europe than in Asia); in contrast to aplastic anemia, agranulocytosis is more prevalent among older adults and in women. Agranulocytosis should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to a destructive immune response. In all of the single-lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

DEFINITION AND DIFFERENTIAL DIAGNOSIS

PRCA is characterized by anemia, reticulocytopenia, and absent or rare erythroid precursor cells in the bone marrow. The classification of PRCA is shown in **Table 107-4**. In adults, PRCA is usually acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment; mutations in ribosome protein genes are etiologic. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias due to acute parvovirus infection **(Chap. 202)** and in transient erythroblastopenia of childhood, which occurs in normal children.

CLINICAL ASSOCIATIONS AND ETIOLOGY

PRCA has important associations with immune system diseases. A minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or complicates chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. A ribosomal protein gene is deleted in the 5q– syndrome, such that the MDS may manifest as an acquired red cell aplasia. Occasionally (as compared to agranulocytosis), PRCA can

TABLE 107-4 Classification of Pure Red Cell Aplasia

Self-limited
Transient erythroblastopenia of childhood
Transient aplastic crisis of hemolysis (acute B19 parvovirus infection)
Fetal red blood cell aplasia
Nonimmune hydrops fetalis (in utero B19 parvovirus infection)
Constitutional pure red cell aplasia
Congenital pure red cell aplasia (Diamond-Blackfan anemia)
Acquired pure red cell aplasia
Primary immune
MDS (5q- syndrome)
Cancer
Thymoma
Lymphoid malignancies (and more rarely other hematologic diseases)
Paraneoplastic to solid tumors
Connective tissue disorders with immunologic abnormalities
Systemic lupus erythematosus, juvenile rheumatoid arthritis, rheumatoid arthritis
Multiple endocrine gland insufficiency
Viruses
Persistent B19 parvovirus, hepatitis, adult T-cell leukemia virus, Epstein-Barr virus
Pregnancy
Drugs
Especially phenytoin, azathioprine, chloramphenicol, procainamide, isoniazid
Antibodies to erythropoietin
Idiopathic (immune)

be due to an idiosyncratic drug reaction. Subcutaneous administration of EPO has provoked PRCA mediated by neutralizing antibodies to the hormone. PRCA due to antibodies to blood group antigens (isoagglutins) is a complication of allogeneic stem cell transplant. For most PRCAs, T-cell inhibition is probably the prevalent immune mechanism.

PERSISTENT PARVOVIRUS B19 INFECTION

Chronic parvovirus infection is a treatable cause of red cell aplasia. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia/arthritis syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for RBC production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In healthy individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts **(Fig. 107-2)**, which is the cytopathic sign of B19 parvovirus infection. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytotoxicity of virus causes anemia if demands on erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

TREATMENT

Pure Red Cell Aplasia

History, physical examination, and routine laboratory studies may disclose an underlying disease or a drug exposure. Thymoma should be sought by radiographic procedures; tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are

TABLE 107-5 World Health Organization (WHO) 2022 Classification of Myelodysplastic Syndromes (MDS)/Neoplasms

NAME	BLASTS	CYTOGENETICS	MUTATIONS
MDS with Defining Genetic Abnormalities			
MDS with low blasts and isolated 5q deletion (MDS-5q)	<5% BM and <2% PB	5q deletion alone, or with 1 other abnormality other than –7/7q del	
MDS with low blasts and *SF3B1* mutation (MDS-*SF3B1*)[a]	<5% BM and <2% PB	Absence of 5q–, –7, or complex karyotype	*SF3B1*
MDs with biallelic TP53 inactivation	<20% BM and PB	Usually complex	Two or more *TP53* mutations or evidence of copy number loss
MDS, Morphologically Defined			
MDS with low blasts	<5% BM and <2% PB		
MDS, hypoplastic[b]	<5% BM and <2% PB		
MDS with increased blasts-1	5–9% BM or 2–4% PB		
MDS with increased blasts-2	10–19% BM or 5–19% PB or Auer rods		
MDS with fibrosis	5–19% BM; 2–19% PB		

[a]Detection of ≥15% ring sideroblasts may substitute *SF3B1*; [b]≤25% BM cellularity.

Abbreviations: BM, bone marrow; PB, peripheral blood.

commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathic PRCA.

Red cell aplasia is compatible with long-term survival with supportive care alone: a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy. The majority of patients with acquired PRCA respond favorably to immunosuppression: glucocorticoids, cyclosporine, ATG, azathioprine, and cyclophosphamide are effective.

MYELODYSPLASTIC SYNDROMES

DEFINITION

The MDS are a heterogeneous group of hematologic disorders characterized by both (1) cytopenias due to bone marrow failure and (2) a high risk of development of AML. Anemia due to ineffective erythropoiesis, often with thrombocytopenia and neutropenia, occurs with dysmorphic (abnormal appearing) and usually a cellular bone marrow, or with specific chromosome abnormalities or acquired mutations. In patients with "low-risk" MDS, marrow failure dominates the clinical course. In other patients, myeloblasts are present at diagnosis, chromosomes are abnormal, and the "high risk" is due to leukemic progression. MDS may be fatal due, most often, to complications of pancytopenia or to progression to leukemia, but a large proportion of patients will die of concurrent disease, the comorbidities typical in an elderly population. An initial nosology of these often-confusing entities was first developed by the French-American-British Cooperative Group in 1983. Five subtypes were defined then: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). The World Health Organization (WHO) classification (2002) recognized that the distinction between RAEB-t and AML was arbitrary, grouped them together as acute leukemia, and clarified that CMML behaves as a myeloproliferative disease. Since then, classification has become more refined and now incorporates molecularly defined subtypes. Two classifications currently exist: the fifth edition of the WHO and the International Consensus Classification (ICC) **(Tables 107-5 and 107-6)**. Both classification systems incorporate morphology, cytopenias, bone marrow blasts, cytogenetics, and molecular findings. In the ICC classification, a new category has been introduced called MDS/AML, which emphasizes the disease continuum and similar outcomes between high blast count MDS and AML. In both classifications, a new molecularly defined subtype of MDS incorporating biallelic or multi-hit *TP53* has been added. In the future, MDS will become increasingly molecularly defined, as more is learned about correlation with clinical outcomes.

The diagnosis of MDS can be a challenge, even for the expert, because sometimes subtle clinical and pathologic features must be distinguished, and precise diagnostic categorization requires a hematopathologist knowledgeable in the latest classification scheme. Unfortunately, agreement among pathologists on morphologic features and classification is imperfect: changes in the appearance of megakaryocytes are more reliable than loss of granules in neutrophil precursors or dyserythropoiesis. Dysplastic changes can be observed in normal individuals, and they also can occur with vitamin deficiencies and as drug effects. Genomic testing is increasingly routine but can be difficult to interpret, as in differences between somatic and germline mutations, pathogenic mutations versus those of unknown significance (clonal hematopoiesis increases in frequency with normal aging), and clone size and changes over time. It is important that the internist and primary

TABLE 107-6 International Consensus Classification (ICC) 2022 Classification of Myelodysplastic Syndromes (MDS)/Neoplasms

NAME	BLASTS	CYTOGENETICS	MUTATIONS
MDS with 5q deletion (MDS-5q)	<5% BM and <2% PB	5q deletion alone, or with 1 other abnormality other than –7/7q del	Any, except multi-hit *TP53*
MDS with *SF3B1* mutation (MDS-*SF3B1*)	<5% BM and <2% PB	Absence of 5q–, –7, abn3q26.2, or complex karyotype	*SF3B1* (≥10% VAF), without multi-hit *TP53*, or *RUNX1*
MDS, NOS without dysplasia (no dysplastic lineages)	<5% BM and <2% PB	–7/7q del or complex	Any except multi-hit *TP53* or *SF3B1* (VAF ≥10%)
MDS, NOS with single-lineage dysplasia (1 dysplastic lineage)	<5% BM and <2% PB	Any except 5q–	Any except multi-hit *TP53* or *SF3B1* (VAF ≥10%)
MDS, NOS with multi-lineage dysplasia (≥2 dysplastic lineages)	<5% BM and <2% PB	Any except 5q–	Any except multi-hit *TP53* or *SF3B1* (VAF ≥10%)
MDS with increased blasts-1	5–9% BM or 2–9% PB	Any	Any except multi-hit *TP53*
MDS with increased blasts-2	10–19% BM or PB	Any, except AML defining	Any except *TP53, NPM1, bZIP, CEBPA*

Abbreviations: AML, acute myeloid leukemia; BM, bone marrow; NOS, not otherwise specified; PB, peripheral blood; VAF, variant allele frequency.

care physician be sufficiently familiar with MDS to expedite referral to a hematologist because many new therapies are now available to improve hematopoietic function and the judicious use of supportive care can improve the patient's quality of life.

EPIDEMIOLOGY

MDS is a disease of the elderly; the mean age at onset is older than 70 years. There is a slight male predominance. MDS is a relatively common form of bone marrow failure, with reported incidence rates of 35 to >100 per million persons in the general population and 120 to >500 per million in older adults. Estimates of incidence in the United States range from 30,000 to 40,000 new cases annually and a prevalence of 60,000–120,000 in the population. Rates of MDS have increased over time due to better recognition of the syndrome by physicians and an aging population.

MDS is rare in children, in whom it often has a constitutional genetic basis that can be identified on genomic screens of myeloid cancer predisposition panels.

Secondary or therapy-related MDS, usually related to previous iatrogenic exposure to alkylating agents and other chemotherapy or radiation, is not age related.

ETIOLOGY AND PATHOPHYSIOLOGY

MDS is associated with environmental exposures such as radiation, benzene, and smoking; other risk factors have been reported inconsistently. Secondary, therapy-related MDS occurs as a late toxicity of cancer treatment; radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5–7 years); or the DNA topoisomerase inhibitors (2-year latency). Acquired aplastic anemia, Fanconi anemia, and other constitutional marrow failure diseases can evolve into MDS; occasionally, MDS in adults is recognized as due to germline *GATA2*, *RUNX1,* or telomere gene mutations. MDS in patients <40 years of age has a high probability of being constitutional, and germline genetic screening is indicated. The typical MDS patient does not have a suggestive environmental exposure history or a preceding hematologic disease.

MDS is a clonal hematopoietic stem cell disorder characterized by disordered cell proliferation, impaired differentiation, and aberrant hematopoiesis, resulting in cytopenias and risk of progression to leukemia. MDS is a disease of older persons consistent with accumulation of mutations within a hematopoietic stem cell in an aging marrow environment. Both chromosomal and genetic instability lead to MDS; both are aging-related. Cytogenetic abnormalities are found in approximately one-half of patients, some of the same specific lesions are also seen in leukemia; aneuploidy (chromosome loss or gain) is more frequent than translocations. Accelerated telomere attrition may destabilize the genome in marrow failure and predispose to acquisition of chromosomal lesions. Cytogenetic abnormalities are not random (loss of all or part of 5, 7, and 20, trisomy of 8) and may be related to etiology (11q23 following topoisomerase II inhibitors). The type and number of cytogenetic abnormalities strongly correlate with the probability of leukemic transformation and survival.

Genomics has illuminated the role of specific mutations and distinct molecular pathways in the pathophysiology of MDS. Somatic mutations in about 100 genes, which are recurrently present in myeloid neoplasms, arise in the abnormal marrow cells (and are absent in the germline). Many of the same genes are mutated in AML and in MDS, whereas others are distinctive in subtypes of MDS. A prominent example is *SF3B1*, in which mutations strongly associate with sideroblastic anemia. Some mutations correlate with prognosis: spliceosome defects (like *SF3B1*) correlate with favorable outcome, and mutations in *EZH2, TP53, RUNX1*, and *ASXL1* correlate with poor outcome. Correlation and exclusion in the pattern of mutations indicate a functional genomic architecture. Driver genes mutated early are consistent with normal blood counts and marrow morphology, but expanded clones of mutated cells are susceptible to malignant transformation with the acquisition of additional mutations. Deep sequencing in patients whose MDS evolved to AML shows clonal succession, with founder clones acquiring additional mutations to become dominant clones. Mutations and cytogenetic abnormalities are not independent: *TP53* mutations associate with complex cytogenetic abnormalities and *TET2* mutations with normal cytogenetics. The prevalence of abnormal cells by morphology underestimates bone marrow involvement by MDS clones, as cells normal in appearance are derived from the abnormal clones. Presenting and evolving hematologic manifestations result from the accumulation of multiple genetic lesions: loss of tumor-suppressor genes, activating oncogene, epigenetic pathways that affect mRNA processing and methylation status, and other harmful alterations. Pathophysiology has been linked to mutations and chromosome abnormalities in some specific MDS syndromes. The 5q– deletion leads to heterozygous loss of a ribosomal protein gene, which mimics constitutional red cell aplasia. An immune pathophysiology may be important in lower-risk MDS, as cytopenias can respond to immunosuppressive therapy as administered for aplastic anemia. In general for MDS, our understanding remains incomplete regarding the immune system and its cells and cytokines; the role of the hematopoietic stem cell niche, the microenvironment, and cell–cell interactions; the fate of normal cells in the Darwinian competitive environment of the dysplastic marrow; and how mutant cells produce marrow failure.

CLINICAL FEATURES

Anemia dominates the early course. Most symptomatic patients complain of the gradual onset of fatigue and weakness, dyspnea, and pallor, but at least one-half of patients are asymptomatic, and their MDS is discovered only incidentally on routine blood counts. Previous chemotherapy or radiation exposure is an important historic fact. Fever and weight loss are more often features of a myeloproliferative rather than myelodysplastic process. MDS in childhood is rare and, when diagnosed, implies an underlying genetic disease. Children with Down syndrome are susceptible to MDS as well as leukemia. A family history may indicate a hereditary form of sideroblastic anemia, Fanconi anemia, or a telomeropathy. Inherited *GATA2* mutations, as in the MonoMAC syndrome (with increased susceptibility to viral, mycobacterial, and fungal infections, as well as deficient numbers of monocytes, natural killer cells, and B lymphocytes), predispose to MDS. Germline *RUNX1* mutations also confer a high risk of MDS and leukemia, often preceded by years of modest thrombocytopenia. A family history is important in all MDS patients, as constitutional mutations may not result in manifest disease until adulthood.

The physical examination in MDS is remarkable for signs of anemia; approximately 20% of patients have splenomegaly. Accompanying autoimmune syndromes are not infrequent. MDS with coexisting inflammatory disease (including Sweet's syndrome) should prompt consideration of the newly described vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic (VEXAS) syndrome, a hematopoietic cell disorder caused by somatic mutations in the *UBA1* gene. In the younger patient, stereotypical anomalies point to a constitutional syndrome (short stature, abnormal thumbs in Fanconi anemia; early graying in the telomeropathies; cutaneous warts in *GATA2* deficiency).

LABORATORY STUDIES

Blood Anemia is present in most cases, either alone or as part of bi- or pancytopenia; isolated neutropenia or thrombocytopenia is more unusual. Macrocytosis is common, as in most marrow failure disease. Platelets also are large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; contain Döhle bodies; and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantity is important for classification and prognosis. The total white blood cell (WBC) count is usually normal or low, except in CMML. As in aplastic anemia, MDS can be associated with a clonal population of PNH cells. Genetic testing is commercially available for constitutional syndromes.

Bone Marrow The bone marrow is usually normal or hypercellular, but in about 20% of cases, it is sufficiently hypocellular to be confused with aplastic anemia. No single characteristic feature of marrow

morphology distinguishes MDS, but the commonly observed are dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of or disorganized nuclei. Megaloblastic nuclei and defective hemoglobinization in the erythroid lineage are common. Prognosis strongly correlates with the proportion of marrow blasts, which should be enumerated manually on the marrow smear and by flow cytometry of the aspirate. Flow cytometry can also reveal characteristically aberrant hematopoietic differentiation. Cytogenetics and fluorescent in situ hybridization can identify chromosomal abnormalities.

DIFFERENTIAL DIAGNOSIS

Deficiencies of vitamin B_{12} or folate should be excluded by appropriate blood tests; vitamin B_6 deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Copper deficiency can lead to cytopenias and dysplastic marrows of varying cellularity. Transient marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity. Myeloid and erythroid precursor cell vacuolation is characteristic of VEXAS, though vacuolization can also occur in copper deficiency and zinc or alcohol toxicity. More difficult are the distinctions between hypocellular MDS and aplasia or between MDS with excess blasts and acute leukemia: the WHO considers 20% blasts in the marrow as the criterion that separates AML from MDS. In young patients, underlying, predisposing genetic diseases should be considered and appropriate genomic testing performed (see above).

PROGNOSIS

The median survival varies greatly from years for patients with 5q– or sideroblastic anemia to a few months in those with high-risk MDS with excess blasts. The International Prognostic Scoring System (IPSS), revised in 2012 to the IPSS-R **(Table 107-7)**, assists in making predictions. In 2022, the IPSS-M, incorporating molecular data, is now emerging as the current standard tool for risk assessment. Even "lower-risk" MDS has significant morbidity and mortality. Prognostic scoring systems can separate those with intermediate-1 risk or higher who have relatively poor prognoses. Prognostic systems have been developed based on survival from diagnosis, but prognosis changes over time, and hazard ratios for survival and leukemic transformation converge over time among risk categories, consistent with dynamic changes in clonal architecture.

Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third succumb to diseases unrelated to their MDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, increased blasts, and marrow fibrosis are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of type, is extremely poor, and most patients progress within a few months to refractory AML.

TABLE 107-7 Revised International Prognostic Scoring System (IPSS-R)

1. Marrow blast categories	≤2%, >2%–<5%, 5–10%, >10–30%
2. Refined cytogenetic abnormalities and risk groups	16 (vs 6) specific abnormalities, 5 (vs 3) subgroups[a]
3. Evaluation of depth of cytopenias[b]	Clinically and statistically relevant cut points used
4. Inclusion of differentiating features	Age, performance status, serum ferritin, LDH, β_2-microglobulin
5. Prognostic model with 5 (vs 4) risk categories	Improved predictive power

[a]Good, normal, –Y, del(5q), del (20q); poor, complex (≥3 abnormalities) or chromosome 7 abnormalities; intermediate, all other abnormalities. [b]Cytopenias at baseline, cut points: hemoglobin <80, 80–<100, or ≥100 g/L; platelet count <50, 50–100, or ≥100,000/μL, and absolute neutrophil count <800 versus ≥800/μL.

Abbreviation: LDH, lactate dehydrogenase.

TREATMENT

Myelodysplasia

Historically, therapy of MDS has been unsatisfactory, but several drugs may not only improve blood counts but also delay onset of leukemia and improve survival. The choice of therapy for an individual patient, administration of treatment, and management of toxicities are complicated and require hematologic expertise.

Only hematopoietic stem cell transplantation offers cure of MDS. The survival rate in selected patient cohorts is ~50% at 3 years but improving. Results using unrelated matched donors are similar to those with siblings, and data are emerging on the use of alternative donor transplant in MDS. Older patients can now be successfully transplanted using reduced intensive conditioning (RIC) regimens, but these regimens have a higher risk of relapse. Treatment-related mortality and morbidity increase with recipient age. The transplant conundrum is that the high-risk patient by prognostic score, for whom the procedure is most obviously indicated, has a high probability of a poor outcome from transplant-related mortality or disease relapse, whereas the low-risk patient, who is more likely to tolerate transplant, also may do well for years with less aggressive therapies. In reality, only a small proportion of MDS patients undergo transplantation.

MDS has been regarded as particularly refractory to cytotoxic chemotherapy regimens, and as in AML in the older adult, drug toxicity is frequent and often fatal, and remissions, if achieved, are brief. Low doses of cytotoxic drugs have been administered for their "differentiation" potential, and from this experience, drug therapies have emerged based on pyrimidine analogues. These drugs are classified as epigenetic modulators, believed to act through a demethylating mechanism to alter gene regulation and allow differentiation to mature blood cells from the abnormal MDS stem cell. The hypomethylating agents (HMA) azacitidine and decitabine are frequently used in MDS clinics. Azacitidine improves blood counts and survival in MDS, compared to best supportive care. Azacitidine is usually administered subcutaneously, daily for 7 days, at 4-week intervals, for at least four cycles before assessing for response. Overall, improved blood counts with a decrease in transfusion requirements occurred in ~50% of patients in published trials. Response is dependent on continued drug administration, and most patients eventually become refractory and experience recurrent cytopenias or progression to AML. Decitabine is closely related to azacitidine; 30–50% of patients show responses in blood counts, with a duration of response of almost a year. Decitabine is usually administered by continuous intravenous infusion in regimens of varying doses and durations of 3–10 days in repeating cycles. The major toxicity of azacitidine and decitabine is myelosuppression, leading to worsening blood counts. Hypomethylating agents are frequently used in the high-risk patient who is not a candidate for stem cell transplant. In the lower risk patient, they are also effective, but alternative therapies should first be considered. Decitabine-cedazuridine, an oral HMA, is FDA approved in patients with high-risk MDS.

Lenalidomide, a thalidomide derivative with a favorable toxicity profile, is particularly effective in reversing anemia in MDS patients with 5q– syndrome; not only do a high proportion of these patients become transfusion independent with normal or near-normal hemoglobin levels, but their cytogenetics also become normal. The drug has many biologic activities, and it is unclear which is critical for clinical efficacy. Lenalidomide is administered orally. Most patients will improve within 3 months of initiating therapy. Toxicities include myelosuppression (worsening thrombocytopenia and neutropenia, necessitating blood count monitoring) and an increased risk of deep vein thrombosis and pulmonary embolism.

Immunosuppression also may produce sustained independence from transfusion and improve survival. ATG, cyclosporine, and the

anti-CD52 monoclonal antibody alemtuzumab are especially effective in younger MDS patients (<60 years old) with more favorable IPSS. In a consortium retrospective review, about 50% of patients with mainly refractory anemia responded to ATG, usually combined with cyclosporine, particularly patients with hypocellular marrow.

HGFs can improve blood counts but, as in most other marrow failure states, have been most beneficial to patients with the least severe pancytopenia. EPO alone or in combination with G-CSF can improve hemoglobin levels, particularly in those with low serum EPO levels who have no or a modest need for transfusions. Survival is improved by EPO and its amelioration of anemia. G-CSF treatment alone failed to improve survival in a controlled trial. Thrombopoietin mimetics appear to improve platelet counts in some patients, but TPO agonists may increase the rate of leukemic progression in high-risk MDS. No clear evidence suggests that they increase leukemic transformation in low-risk MDS.

Luspatercept, which affects transforming growth factor β–mediated suppression of erythropoiesis, has been approved by the FDA for anemia in low-risk MDS, particularly those with *SF3B1* mutations. The FDA has approved ivosidenib, an *IDH1* inhibitor, for MDS. Venetoclax, a BCL2 inhibitor, is FDA approved for patients with AML and has been used in combination with HMA in high-risk MDS; however, it remains investigational.

Promising novel agents in trials include targeted therapies (i.e., TP53, splicing factor mutations), inflammation pathway inhibitors (including inflammasome and interleukin 1 receptor–associated kinase), and imetelstat, a telomerase inhibitor. Likely, HMA alone will be replaced with HMA combination therapies.

The same principles of supportive care described for aplastic anemia apply to MDS. Many patients will be anemic for years. RBC transfusion support should be accompanied by iron chelation to prevent secondary hemochromatosis.

MYELOPHTHISIC ANEMIAS

Fibrosis of the bone marrow (see **Fig. 65-19**), usually accompanied by a characteristic blood smear picture called *leukoerythroblastosis*, can occur as a primary hematologic disease, called *myelofibrosis* or *myeloid metaplasia* **(Chap. 108)**, and as a secondary process, called *myelophthisis*. Myelophthisis, or secondary myelofibrosis, is reactive. Fibrosis can be a response to invading tumor cells, usually an epithelial cancer of breast, lung, or prostate origin or neuroblastoma. Marrow fibrosis may occur with infection of mycobacteria (both *Mycobacterium tuberculosis* and *Mycobacterium avium*), fungi, or HIV and in sarcoidosis. Intracellular lipid deposition in Gaucher disease and obliteration of the marrow space related to absence of osteoclast remodeling in congenital osteopetrosis also can produce fibrosis. Secondary myelofibrosis is a late consequence of radiation therapy or treatment with radiomimetic drugs. Usually the infectious or malignant underlying processes are obvious. Marrow fibrosis can also be a feature of a variety of hematologic syndromes, especially chronic myeloid leukemia, multiple myeloma, lymphomas, myeloma, and hairy cell leukemia.

The pathophysiology has three distinct features: proliferation of fibroblasts in the marrow space (myelofibrosis); the extension of hematopoiesis into the long bones and into extramedullary sites, usually the spleen, liver, and lymph nodes (myeloid metaplasia); and ineffective erythropoiesis. The etiology of the fibrosis is unknown but most likely involves dysregulated production of growth factors: platelet-derived growth factor and transforming growth factor β have been implicated. Abnormal regulation of other hematopoietins would lead to localization of blood-producing cells in nonhematopoietic tissues and uncoupling of the usually balanced processes of stem cell proliferation and differentiation. Myelofibrosis is remarkable for pancytopenia despite very large numbers of circulating hematopoietic progenitor cells.

Anemia is dominant in secondary myelofibrosis, usually normocytic and normochromic. The diagnosis is suggested by the characteristic leukoerythroblastic smear. Erythrocyte morphology is highly abnormal, with circulating nucleated RBCs, teardrops, and shape distortions. WBC numbers are often elevated, sometimes mimicking a leukemoid reaction, with circulating myelocytes, promyelocytes, and myeloblasts. Platelets may be abundant and are often of giant size. Inability to aspirate the bone marrow, the characteristic "dry tap," can allow a presumptive diagnosis in the appropriate setting before the biopsy is decalcified.

The course of secondary myelofibrosis is determined by its etiology, usually a metastatic tumor or an advanced hematologic malignancy. Treatable causes must be excluded, especially tuberculosis and fungus. Transfusion support can relieve symptoms.

108 Polycythemia Vera and Other Myeloproliferative Neoplasms

Jerry L. Spivak

The World Health Organization (WHO) classification of the chronic myeloproliferative neoplasms (MPNs) includes eight disorders, some of which are rare or poorly characterized **(Table 108-1)** but all of which share an origin in a hematopoietic stem cell; overproduction of one or more of the formed elements of the blood without significant dysplasia; and a predilection to extramedullary hematopoiesis, myelofibrosis, and transformation at varying rates to acute leukemia. Within this broad

TABLE 108-1 World Health Organization Classification of Chronic Myeloproliferative Neoplasms

Chronic myeloid leukemia, *BCR-ABL*–positive
Chronic neutrophilic leukemia
Chronic eosinophilic leukemia, not otherwise specified
Polycythemia vera
Primary myelofibrosis
Essential thrombocytosis
Mastocytosis
Myeloproliferative neoplasms, unclassifiable

classification, however, significant phenotypic heterogeneity exists. Some diseases such as chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), and chronic eosinophilic leukemia (CEL) express primarily a myeloid phenotype, whereas in other diseases, such as polycythemia vera (PV), primary myelofibrosis (PMF), and essential thrombocytosis (ET), erythroid or megakaryocytic hyperplasia predominates. The latter three disorders, in contrast to the former three, also appear capable of transforming into each other.

Such phenotypic heterogeneity has a genetic basis; CML is the consequence of the balanced translocation between chromosomes 9 and 22 (t[9;22][q34;11]); CNL has been associated with a mutation of *CSF3R* and a t(15;19) translocation; and CEL occurs with a deletion or balanced translocations involving the *PDGFRα* usually with the *FIP1L1*, *PDGFRβ, FGFR1,* and *PCM1-JAK2* genes. By contrast, PV, PMF, and ET are characterized by driver mutations that directly or indirectly constitutively activate JAK2, a tyrosine kinase essential for the function of the erythropoietin and thrombopoietin receptors and also utilized by the granulocyte colony-stimulating factor receptor. This important distinction is reflected in the natural histories of CML, CNL, and CEL, which are usually measured in years, with a high rate of leukemic transformation. The natural histories of PV, PMF, and ET, by contrast, are usually measured in decades, and transformation to acute leukemia is uncommon in the absence of chemotherapy. This chapter focuses only on PV, PMF, and ET because their clinical features and driver mutation overlap are substantial, although their disease duration and clinical manifestations vary.

The other chronic MPNs will be discussed in **Chaps. 110** and **115**.

POLYCYTHEMIA VERA

PV is a clonal hematopoietic stem cell disorder in which phenotypically normal red cells, granulocytes, and platelets accumulate in the absence of a recognizable physiologic stimulus. The most common of the MPNs, PV occurs in 2.5 per 100,000 persons, sparing no adult age group and increasing with age to rates >10/100,000. Familial transmission is infrequent, and women under age 50 predominate among sporadic cases.

ETIOLOGY

Nonrandom chromosome abnormalities such as deletion 20q and deletion 13q or trisomy 9 occur in up to 30% of untreated PV patients, but unlike CML, no consistent cytogenetic abnormality has been associated with the disorder. However, a mutation in the autoinhibitory pseudokinase domain of the tyrosine kinase JAK2 that replaces valine with phenylalanine (V617F), causing constitutive kinase activation, has a central role in PV pathogenesis.

JAK2 is a member of an evolutionarily well-conserved, nonreceptor tyrosine kinase family and serves as the cognate tyrosine kinase for the erythropoietin and thrombopoietin receptors. It also functions as an obligate chaperone for these receptors in the Golgi apparatus and is responsible for their cell-surface expression. The conformational change induced in the erythropoietin and thrombopoietin receptors following binding to their respective cognate ligands, erythropoietin or thrombopoietin, leads to JAK2 autophosphorylation, receptor phosphorylation, and phosphorylation of proteins involved in cell proliferation, differentiation, and resistance to apoptosis. Transgenic animals lacking *JAK2* die as embryos from severe anemia. Constitutive activation of JAK2, on the other hand, explains the erythropoietin hypersensitivity, erythropoietin-independent erythroid colony formation, rapid terminal differentiation, increased Bcl-X_L expression, and apoptosis resistance in the absence of erythropoietin that characterize the in vitro behavior of PV erythroid progenitor cells.

More than 95% of PV patients express this mutation, as do ~50% of PMF and ET patients. Importantly, the *JAK2* gene is located on the short arm of chromosome 9, and loss of heterozygosity on chromosome 9p involving the segment containing the *JAK2* locus over time due to mitotic recombination (uniparental disomy) is the most common cytogenetic abnormality in PV. Loss of heterozygosity in this region leads to homozygosity for *JAK2* V617F and occurs in ~60% of PV patients and to a lesser extent in PMF but is rare in ET. Most PV patients who do not express *JAK2* V617F express a mutation in exon 12 of the gene and are not clinically different from those who do, with the exception of a higher frequency of isolated erythrocytosis, nor do *JAK2* V617F heterozygotes differ clinically from homozygotes. Importantly, the predisposition to acquire *JAK2* mutations appears to be associated with a specific *JAK2* gene haplotype, GGCC. *JAK2* V617F is the basis for many of the phenotypic and biochemical characteristics of PV such as increased blood cell production and increased inflammatory cytokine production; however, it cannot solely account for the entire PV phenotype and is probably not the initiating lesion in any of the MPNs. First, PV patients with the same phenotype and documented clonal disease can have mutations in *LNK*, a JAK2 inhibitor, or rarely, calreticulin (*CALR*), an ER chaperone, since MPN driver mutations are not mutually exclusive. Second, ET and PMF patients have the same mutations but different clinical phenotypes. Third, familial PV can occur without the mutation, even when other members of the same family express it. Finally, in some *JAK2* V617F–positive PV or ET patients, acute leukemia can occur in a *JAK2* V617F–negative progenitor cell, suggesting the presence of an ancestral precursor cell.

CLINICAL FEATURES

Although PV is a panmyelopathy, isolated thrombocytosis, leukocytosis, or splenomegaly can be its presenting manifestation, but most often, the disorder is first recognized by the incidental discovery of a high hemoglobin, hematocrit, or red cell count. With the exception of aquagenic pruritus or erythromelalgia, no symptoms distinguish PV from other causes of erythrocytosis.

Uncontrolled erythrocytosis causes hyperviscosity, leading to neurologic symptoms such as vertigo, tinnitus, headache, visual disturbances, and transient ischemic attacks (TIAs). Systolic hypertension is also a feature of the red cell mass elevation. In some patients, venous or arterial thrombosis may be the presenting manifestation of PV. Any vessel can be affected, but cerebral, cardiac, and mesenteric vessels are most commonly involved. Hepatic venous thrombosis (Budd-Chiari syndrome) is particularly common in young women and may be catastrophic if sudden and complete obstruction of the hepatic vein occurs; portal vein thrombosis is more common in male PV patients. Indeed, PV should be suspected in any woman who develops hepatic vein thrombosis, since this is the only type of thrombosis associated with *JAK2* V617F expression. Digital ischemia, easy bruising, epistaxis, acid-peptic disease, or gastrointestinal hemorrhage may occur due to vascular stasis or extreme thrombocytosis (>900,000/mL). In the latter instance, absorption and proteolysis of high-molecular-weight von Willebrand multimers by the large platelet mass cause acquired von Willebrand's disease. Erythema, burning, and pain in the extremities, a symptom complex known as erythromelalgia, is another complication of thrombocytosis in PV due to increased platelet stickiness. Given the large turnover of hematopoietic cells, hyperuricemia with secondary gout, uric acid stones, and symptoms due to hypermetabolism can also complicate the disorder.

DIAGNOSIS

When PV presents with erythrocytosis in combination with leukocytosis, thrombocytosis, or splenomegaly or any combination of these, the diagnosis is apparent. However, when patients present with an elevated hemoglobin, hematocrit, and red cell count alone, the diagnostic evaluation is more complex because of the many diagnostic possibilities **(Table 108-2)**. Furthermore, unless the hemoglobin level is ≥20 g/dL (hematocrit ≥60%), it is not possible to distinguish true erythrocytosis from disorders causing plasma volume contraction. This is because uniquely in PV, in contrast to other causes of true erythrocytosis, there is expansion of the plasma volume, which can mask the elevated red cell mass, particularly in women; thus, red cell mass and plasma volume determinations are necessary to establish the presence of an absolute erythrocytosis and distinguish this from relative erythrocytosis due to a reduction in plasma volume alone (also known as *stress* or *spurious erythrocytosis* or *Gaisböck's syndrome*). **Figure 66-18** illustrates a diagnostic algorithm for the evaluation of suspected erythrocytosis. While an assay for *JAK2* or rarely *LNK* mutations in the presence of a normal arterial oxygen saturation appears to provide an alternative

diagnostic approach to isolated erythrocytosis since red cell mass and plasma volume determinations are not usually available, isolated erythrocytosis is uncommon as an initial manifestation of PV, and not everyone expressing a low *JAK2* V617F quantitative mutation allele burden (variant allele frequency [VAF] ≤5%) actually has a blood disease. In addition, a normal serum erythropoietin level does not exclude the presence of PV, but an elevated erythropoietin level is most consistent with a secondary cause for the erythrocytosis.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW), particularly when the hematocrit or hemoglobin levels are <60% or 20 g/dL, respectively. Only three situations cause microcytic erythrocytosis: β-thalassemia trait, hypoxic erythrocytosis, and PV. With β-thalassemia trait, the RDW is usually normal, whereas with hypoxic erythrocytosis or PV, the RDW may be elevated due to associated iron deficiency. Today, however, the quantitative assay for *JAK2* V617F or *JAK2* exon 12 mutations using next-generation sequencing technology has superseded the other surrogate tests for establishing the diagnosis of PV.

A bone marrow aspirate and biopsy provide no specific diagnostic information because these may be normal or indistinguishable from ET or PMF. Similarly, no specific cytogenetic abnormality is associated with the disease, and the absence of a cytogenetic marker does not exclude the diagnosis.

COMPLICATIONS

Many of the clinical complications of PV relate directly to the increase in blood viscosity associated with red cell mass elevation and indirectly to the increased turnover of red cells, leukocytes, and platelets with the attendant increase in uric acid and inflammatory cytokine production. The latter also appears to be responsible for some of the constitutional symptoms in PV. Peptic ulcer disease can also be due to *Helicobacter pylori* infection, the incidence of which is increased in PV, while the pruritus associated with this disorder may be a consequence of mast cell activation by *JAK2* V617F. A sudden increase in spleen size can be associated with painful splenic infarction. Myelofibrosis appears to be part of the natural history of the disease but is a reactive, reversible process that does not itself impede hematopoiesis and by itself has no prognostic significance in PV. In ~15% of patients, however, myelofibrosis is associated with hematopoietic stem cell failure, manifested by substantial extramedullary hematopoiesis in the liver and spleen and transfusion-dependent anemia. Organomegaly can cause significant mechanical discomfort, portal hypertension, and progressive cachexia.

Although the incidence of acute myeloid leukemia is increased in PV, the incidence of acute leukemia in patients not exposed to chemotherapy or radiation therapy is very low. Interestingly, chemotherapy, including hydroxyurea, has been associated with acute leukemia in *JAK2* V617F–negative hematopoietic stem cells (HSCs) in some PV patients. *Erythromelalgia* is a curious syndrome of unknown etiology associated with thrombocytosis, primarily involving the lower extremities and usually manifested by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with PV, such as ocular migraine, appear to represent a variant of erythromelalgia.

Left uncontrolled, erythrocytosis can lead to thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation measured by the hematocrit or hemoglobin level. A "normal" hematocrit or hemoglobin level in a PV patient with massive splenomegaly should be considered indicative of an elevated red cell mass until proven otherwise.

TREATMENT

Polycythemia Vera

PV is generally an indolent disorder, the clinical course of which is measured in decades, and its management should reflect its tempo. Thrombosis due to erythrocytosis is the most significant complication and often the presenting manifestation; maintenance of the hemoglobin level at ≤140 g/L (14 g/dL; hematocrit <45%) in men and ≤120 g/L (12 g/dL; hematocrit <42%) in women is mandatory to avoid thrombotic complications. Phlebotomy serves initially to reduce hyperviscosity by reducing the red cell mass to normal while further expanding the plasma volume. Periodic phlebotomies thereafter serve to maintain the red cell mass within the normal range and induce a state of iron deficiency that prevents accelerated reexpansion of the red cell mass. In most PV patients, once an iron-deficient state is achieved, phlebotomy is usually only required at 3-month intervals. Neither phlebotomy nor iron deficiency increases the platelet count relative to the effect of the disease itself, and neither thrombocytosis nor leukocytosis is correlated with thrombosis in PV, in contrast to the strong correlation between erythrocytosis and thrombosis. The use of salicylates to prevent thrombosis in PV patients is potentially harmful not only if the red cell mass is not controlled by phlebotomy, but also due to an increased incidence of bleeding, particularly in patients over age 60.

Anticoagulation is indicated when a thrombosis has occurred, and the newer oral anticoagulants may be preferable to a vitamin K antagonist since they do not require monitoring. Asymptomatic hyperuricemia (<10 mg/dL) requires no therapy, but allopurinol should be administered to avoid further elevation of the uric acid when chemotherapy is used to reduce splenomegaly or leukocytosis or to treat pruritus. Generalized pruritus intractable to antihistamines or antidepressants such as doxepin can be a major problem in PV; the JAK1/2 inhibitor ruxolitinib, pegylated interferon α (IFN-α), psoralens with ultraviolet light in the A range (PUVA) therapy, and hydroxyurea are other methods of palliation. Asymptomatic thrombocytosis requires no therapy unless the platelet count is sufficiently high to cause bleeding due to acquired von Willebrand's disease, but bleeding in this situation is not usually spontaneous and is responsive to tranexamic acid or ε-aminocaproic acid. Symptomatic splenomegaly can be treated with either ruxolitinib or pegylated

IFN-α. Both ruxolitinib and pegylated IFN-α target the involved HSCs in PV and are not mutagenic; hydroxyurea does not target the involved HSCs in PV and is mutagenic. Furthermore, pegylated IFN-α allows only biweekly administration and produced complete hematologic and molecular remissions in ~20% of PV patients. Anagrelide, a phosphodiesterase inhibitor, can reduce the platelet count and, if tolerated, is preferable to hydroxyurea because it lacks marrow toxicity and is also protective against venous thrombosis, whereas hydroxyurea is not. However, chronic anagrelide therapy is cardiotoxic and nephrotoxic, particularly in older PV patients.

A reduction in platelet number may be necessary for the treatment of erythromelalgia or ocular migraine if salicylates are not effective or if the platelet count is sufficiently high to increase the risk of hemorrhage but only to the degree that symptoms are alleviated. Alkylating agents and radioactive sodium phosphate (^{32}P) are leukemogenic in PV, and their use should be avoided. If a cytotoxic agent must be used, hydroxyurea is preferred, but this drug does not prevent either thrombosis or myelofibrosis in PV, is itself leukemogenic, and should be considered as a short-duration therapy. Previously, PV patients with massive splenomegaly unresponsive to reduction by chemotherapy or IFN required splenectomy. However, with the introduction of the nonspecific JAK1/2 inhibitor ruxolitinib, it has been possible in the majority of patients with PV complicated by myelofibrosis and myeloid metaplasia to reduce spleen size while at the same time alleviating constitutional symptoms and pruritus due to cytokine release while reducing the phlebotomy requirement. However, in contrast to PMF, PV patients have a more chronic course; in contrast to other malignancies, PV patients have a low rate of mutation accumulation, and the acquisition of deleterious mutations such as *TP53* mutations as detected by next-generation sequencing is usually associated with leukemic transformation. Since hydroxyurea antagonizes *TP53* and also causes del17p, leading to *TP53* haploinsufficiency, its chronic use should be constrained in PV.

Ruxolitinib has also been demonstrated in a phase 3 clinical trial to be effective in PV patients without myelofibrosis who are intolerant or refractory to hydroxyurea or best available supportive therapy. Three other JAK2 inhibitors, fedratinib, pacritinib, and momelotinib, have been approved for treatment of PV patients with myelofibrosis in whom ruxolitinib treatment failed or who were intolerant to the drug. In some PV patients with end-stage disease, pulmonary hypertension may develop due to fibrosis or extramedullary hematopoiesis. A role for bone marrow transplantation, either allogeneic or haploidentical, in PV has not been defined.

Most patients with PV can live long lives without functional impairment when their red cell mass is effectively managed with phlebotomy alone. Chemotherapy is never indicated to control the red cell mass in PV, but when venous access is an issue, ruxolitinib or pegylated IFN is the preferred therapy. Interestingly, hepcidin production is suppressed, but not absent in PV, and a hepcidin agonist has been shown to reduce phlebotomy requirements in PV.

PRIMARY MYELOFIBROSIS

Chronic PMF (other designations include *idiopathic myelofibrosis*, *agnogenic myeloid metaplasia*, or *myelofibrosis with myeloid metaplasia*) is a clonal HSC disorder associated with mutations in *JAK2, MPL*, or *CALR,* and characterized by marrow fibrosis, extramedullary hematopoiesis, variable suppression of hematopoiesis, and splenomegaly. PMF is the least common MPN, and establishing its diagnosis in the absence of a specific clonal marker is difficult because myelofibrosis and splenomegaly are also features of both PV and CML. Furthermore, myelofibrosis and splenomegaly also occur in a variety of benign and malignant disorders **(Table 108-3)**, many of which are amenable to specific therapies not effective in PMF. In contrast to the other MPNs and so-called acute or malignant myelofibrosis, which can occur at any age, PMF primarily afflicts men in their sixth decade or later.

TABLE 108-3 Disorders Causing Myelofibrosis

MALIGNANT	NONMALIGNANT
Acute leukemia (lymphocytic, myelogenous, megakaryocytic)	HIV infection
Chronic myeloid leukemia	Hyperparathyroidism
Hairy cell leukemia	Renal osteodystrophy
Hodgkin's disease	Systemic lupus erythematosus
Primary myelofibrosis	Tuberculosis
Lymphoma	Vitamin D deficiency
Multiple myeloma	Thorium dioxide exposure
Myelodysplasia	Gray platelet syndrome
Metastatic carcinoma	
Polycythemia vera	
Systemic mastocytosis	

ETIOLOGY

Nonrandom chromosome abnormalities such as 9p, 20q−, 13q−, trisomy 8 or 9, or partial trisomy 1q are common in PMF, but no cytogenetic abnormality specific to the disease has been identified. *JAK2* V617F is present in ~55% of PMF patients, and mutations in the thrombopoietin receptor, *MPL*, occur in ~4%. Most of the rest have mutations in the calreticulin gene (*CALR*) that alter the carboxy-terminal portion of the protein, permitting it to bind and activate MPL while presenting it at the cell surface. The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. Fibrosis in this disorder is associated with overproduction of transforming growth factor β and tissue inhibitors of metalloproteinases and thrombopoietin, while osteosclerosis is associated with overproduction of osteoprotegerin, an osteoclast inhibitor. Marrow angiogenesis occurs due to increased production of vascular endothelial growth factor. Importantly, fibroblasts in PMF are polyclonal and not part of the neoplastic clone but can be induced by it to produce inflammatory cytokines.

CLINICAL FEATURES

No signs or symptoms are specific for PMF. Many patients are asymptomatic at presentation, and the disease is often detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. In contrast to its companion MPN, night sweats, fatigue, and weight loss are common presenting complaints. A blood smear will show the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present **(Fig. 108-1)**. Anemia, usually mild initially, is common, whereas the leukocyte and platelet counts are either normal or increased, but either can be depressed. Mild hepatomegaly may accompany splenomegaly but is unusual in its

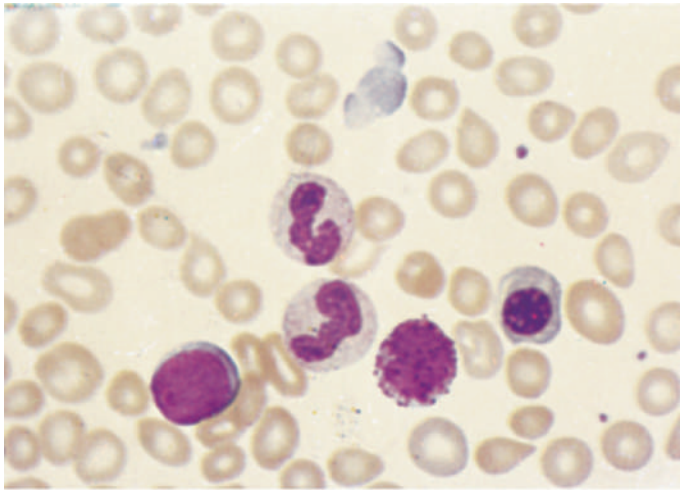

FIGURE 108-1 Teardrop-shaped red blood cells indicative of membrane damage from passage through the spleen, a nucleated red blood cell, and immature myeloid cells indicative of extramedullary hematopoiesis are noted. This peripheral blood smear is related to any cause of extramedullary hematopoiesis.

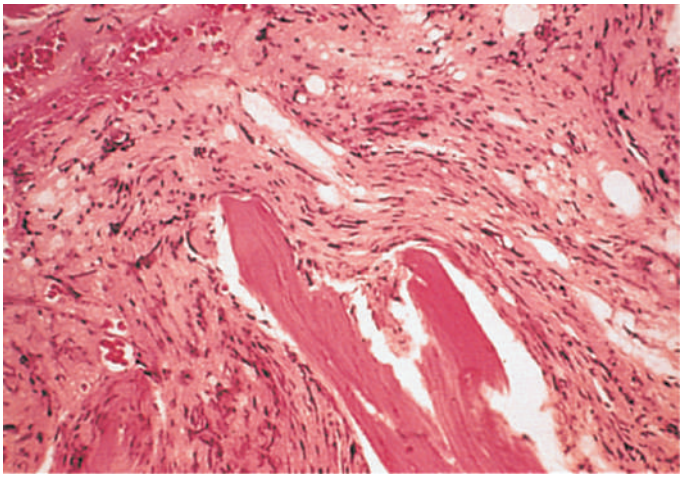

FIGURE 108-2 This marrow section shows the marrow cavity replaced by fibrous tissue composed of reticulin fibers and collagen. When this fibrosis is due to a primary hematologic process, it is called *myelofibrosis*. When fibrosis is secondary to a tumor or a granulomatous process, it is called *myelophthisis*.

absence; isolated lymphadenopathy should suggest another diagnosis. Both serum lactate dehydrogenase and alkaline phosphatase levels can be elevated. Marrow is usually inaspirable due to the myelofibrosis (Fig. 108-2), and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites; portal, pulmonary, or intracranial hypertension; intestinal or ureteral obstruction; pericardial tamponade; spinal cord compression; or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarction with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

DIAGNOSIS

While the clinical picture described above is characteristic of PMF, all of these clinical features can be observed in PV or CML. Massive splenomegaly commonly masks erythrocytosis in PV, and reports of intraabdominal thrombosis in PMF most likely represent instances of unrecognized PV. In some PMF patients, erythrocytosis has developed during the course of the disease. Importantly, because many other disorders have features that overlap with PMF but respond to distinctly different therapies, the diagnosis of PMF is one of exclusion, which requires that the disorders listed in Table 108-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes establishes the presence of extramedullary hematopoiesis, while the presence of leukocytosis, thrombocytosis with large and bizarre platelets, and circulating myelocytes suggests the presence of an MPN as opposed to a secondary form of myelofibrosis (Table 108-3). Marrow is usually inaspirable due to increased marrow reticulin, but marrow biopsy will usually reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased numbers of megakaryocytes in clusters and with large, dysplastic nuclei. A small number of PMF patients with a low *JAK2* V617F mutation allele burden (≤25%) have a faster time to anemia and leukopenia and a shortened survival. However, there are no specific bone marrow morphologic abnormalities that distinguish PMF from the other MPNs. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis dominates the clinical picture.

An intriguing feature of PMF is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs' test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of the blood is useful both to exclude CML and for prognostic purposes, because the development of complex karyotype abnormalities portends a poor prognosis in PMF. It is thought that impaired expression of the cytokine CXCL4 is responsible for the markedly increased number of circulating CD34+ cells in PMF (>15,000/μL) compared to PV patients, unless they too develop extramedullary hematopoiesis.

Importantly, ~55% of PMF patients, like patients with its companion MPNs, express the *JAK2* V617F mutation, often as homozygotes. Such patients are usually older and have higher hematocrits than patients with *MPL* (4%) or *CALR* (36%) mutations; PMF patients expressing an *MPL* mutation tend to be more anemic and have lower leukocyte counts than *JAK2* V617F–positive patients. Somatic mutations (due to deletions [type 1] or insertions [type 2]) in exon 9 of *CALR* have been found in a majority of patients with PMF who lack mutations in either *JAK2* or *MPL*. In some studies, type 1 mutations, the most common *CALR* mutation in PMF, had a survival advantage compared to *JAK2* or *MPL* mutations but not with respect to leukemic transformation. PMF patients who lack a known MPN driver mutation (triple-negative) appear to have the worst prognosis.

TABLE 108-4 Three Current Scoring Systems for Estimating Prognosis in PMF Patients

RISK FACTOR	IPSS (2009)[a]	DIPSS (2010)[b]	DIPSS PLUS (2011)[c]

Note: The Dynamic International Prognostic Scoring System (DIPSS) was developed to determine if the International Prognostic Scoring System (IPSS) risk factors identified as important for survival at the time of primary myelofibrosis (PMF) diagnosis could also be used for risk stratification following their acquisition during the course of the disease. One point is assigned to each risk factor for IPSS scoring. For DIPSS, the same is true, but anemia is assigned 2 points. The DIPSS Plus scoring system represents recognition that the addition of unfavorable karyotype, thrombocytopenia, and transfusion dependence improved the DIPSS risk stratification system for which additional points are assigned (Table 108-5). More recent studies suggest that mutational analysis of the *ASXL1, EZH2, SRSF2,* and *IDH1/2* genes further improves risk stratification for survival and leukemic transformation (Leukemia 27:1861, 2013), as can cytogenetic abnormalities (Leukemia 32:1631, 2018). These prognostic scoring systems are not accurate for risk assessment in polycythemia vera or essential thrombocytosis patients who have developed myelofibrosis (Haematologica 99:e55, 2014).

COMPLICATIONS

Survival in PMF varies according to specific risk factors at diagnosis (Tables 108-4 and 108-5) but is much shorter than in PV and ET patients. The natural history of PMF is one of increasing marrow failure with transfusion-dependent anemia and increasing organomegaly due to extramedullary hematopoiesis. As with CML, PMF can evolve from a chronic to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients spontaneously transform to an aggressive form of acute leukemia for which therapy is usually ineffective. Additional important prognostic factors for disease acceleration during the course of PMF include the presence of complex

TABLE 108-5 IPSS and DIPSS Risk Stratification Systems

	NUMBER OF RISK FACTORS		
RISK CATEGORIES[a]	IPSS	DIPSS	DIPSS PLUS
Low	0	0	0
Intermediate-1	1	1–2	1
Intermediate-2	2	3–4	2–3
High	≥3	>4	4–6

[a]The corresponding survival curves for each risk category can be found in the references cited in the footnotes of Table 108-4.

Abbreviations: DIPSS, Dynamic International Prognostic Scoring System; IPSS, International Prognostic Scoring System.

cytogenetic abnormalities, thrombocytopenia, and transfusion-dependent anemia. Mutations in the *ASXL1*, *EZH2*, *SRSF2*, and *IDH1/2* genes have been identified as risk factors for early death or transformation to acute leukemia, as have complex cytogenetic abnormalities, and have proved to be more useful for PMF risk assessment than the clinical scoring systems.

TREATMENT

Primary Myelofibrosis

No specific therapy exists for PMF. The causes for anemia are multifarious and include ineffective erythropoiesis uncompensated by splenic extramedullary hematopoiesis, hemodilution due to splenomegaly, splenic sequestration, blood loss secondary to thrombocytopenia or portal hypertension, folic acid deficiency, systemic inflammation, and autoimmune hemolysis. Neither recombinant erythropoietin nor androgens such as danazol have proven to be consistently effective as therapy for anemia. Erythropoietin may worsen splenomegaly and will be ineffective if the serum erythropoietin level is >125 mU/L. Given the inflammatory milieu that characterizes PMF, glucocorticoids can ameliorate anemia as well as constitutional symptoms such as fever, chills, night sweats, anorexia, and weight loss, and combining these with low-dose thalidomide has proved effective as well. Thrombocytopenia can be due to impaired marrow function, splenic sequestration, or autoimmune destruction and may also respond to low-dose thalidomide and prednisone.

Splenomegaly is by far the most distressing and intractable problem for PMF patients, causing abdominal pain, portal hypertension, easy satiety, and cachexia, whereas surgical removal of a massive spleen is associated with significant postoperative complications including mesenteric venous thrombosis, hemorrhage, rebound leukocytosis and thrombocytosis, and hepatic extramedullary hematopoiesis with no amelioration of either anemia or thrombocytopenia when present. For unexplained reasons, splenectomy also increases the risk of blastic transformation.

Splenic irradiation is, at best, temporarily palliative and associated with a significant risk of neutropenia, infection, and subsequent operative hemorrhage if splenectomy is attempted. Allopurinol can control significant hyperuricemia, and bone pain can be alleviated by local irradiation. Pegylated IFN-α can ameliorate fibrosis in early PMF, but in advanced disease, it may exacerbate bone marrow failure. The JAK1/2 inhibitor ruxolitinib has proved effective in reducing splenomegaly and alleviating constitutional symptoms in a majority of advanced PMF patients while possibly prolonging survival, but in some patients, ruxolitinib is associated with *RAS* mutations. Although anemia and thrombocytopenia are its major side effects, these are dose-dependent, and with time, anemia stabilizes, and thrombocytopenia may improve. Fedratinib, a new tyrosine kinase inhibitor with anti-FLT3 activity, has proved useful in patients with disease refractory to ruxolitinib. Two other JAK2 inhibitors have been approved for PMF therapy, pacritinib, which is useful when thrombocytopenia is present, and momelotinib, which may be useful in improving red cell production.

In some patients, hypomethylating agents such as azacytidine or decitabine in combination with high-dose ruxolitinib have been used to control the disease or prepare patients for bone marrow transplantation. Transformation to acute leukemia in PMF, like PV or ET, is usually refractory to treatment.

Allogeneic bone marrow transplantation is the only curative treatment for PMF and should be considered in younger patients and older patients with high-risk disease; nonmyeloablative conditioning regimens permit hematopoietic cell transplantation to be extended to older individuals.

ESSENTIAL THROMBOCYTOSIS

ET (other designations include *essential thrombocythemia*, *idiopathic thrombocytosis*, *primary thrombocytosis*, and *hemorrhagic thrombocythemia*) is a clonal hematopoietic stem cell disorder associated with mutations in *JAK2* (V617F), *MPL*, or *CALR* and manifested clinically by overproduction of platelets without a definable cause. ET has an incidence of 1–2/100,000 and a distinct female predominance. Canonical MPN driver mutations distinguish 90% of ET patients from the more common nonclonal, reactive forms of thrombocytosis **(Table 108-6)**; mutation-negative ET patients may have either uncommon *MPL* mutations, *JAK2* V617F expression limited to the platelets, or a hereditary form of thrombocytosis. Once considered a disease of the elderly and responsible for significant morbidity due to hemorrhage or thrombosis, it is now clear that ET can occur at any age in adults and often without symptoms or disturbances of hemostasis. There is an unexplained female predominance in contrast to PMF or the reactive forms of thrombocytosis where no sex difference exists. Because no specific clonal marker is available, clinical and laboratory criteria have been proposed to distinguish ET from other MPNs, which may also present initially with isolated thrombocytosis but have differing prognoses and therapies (Table 108-6). These criteria are useful in identifying disorders such as CML, PV, PMF, or myelodysplasia, which can masquerade as ET. Furthermore, as with "idiopathic" erythrocytosis, nonclonal benign forms of thrombocytosis exist (e.g., hereditary overproduction of thrombopoietin and those with noncanonical *JAK2* driver mutations) that are not widely recognized because we currently lack diagnostic assays. Approximately 50% of ET patients express *JAK2* V617F, 30% *CALR* (both type 1 and type 2), and 8% *MPL* mutations. ET patients lacking a canonical MPN driver mutation usually have a benign prognosis.

TABLE 108-6 Causes of Thrombocytosis

Tissue inflammation: collagen vascular disease, inflammatory bowel disease	Hemorrhage
Malignancy	Iron-deficiency anemia
Infection	Surgery
Myeloproliferative disorders: polycythemia vera, primary myelofibrosis, essential thrombocytosis, chronic myelogenous leukemia	Rebound: Correction of vitamin B_{12} or folate deficiency, post-ethanol abuse, postsplenectomy
Myelodysplastic disorders: 5q– syndrome, idiopathic refractory sideroblastic anemia	Hemolysis
Postsplenectomy or hyposplenism	Familial: Thrombopoietin overproduction, *JAK2, CALR*, or *MPL* mutations

ETIOLOGY

Megakaryocytopoiesis and platelet production depend on thrombopoietin and its receptor MPL. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin 3 (IL-3) and stem cell factor for optimal proliferation in addition to thrombopoietin. Their subsequent terminal development is also enhanced by the chemokine stromal cell-derived factor 1 (SDF-1). Interestingly, terminal megakaryocyte maturation and platelet production do not require thrombopoietin.

Megakaryocytes are unique among hematopoietic progenitor cells because reduplication of their genome is endomitotic rather than mitotic and promoted by thrombopoietin. Unlike erythropoietin, thrombopoietin is produced only in the liver but has important functions in the bone marrow where it functions to maintain hematopoietic stem cells quiescent in their endosteal niches; once released from their niches, thrombopoietin promotes the proliferation of these cells in the sinusoidal niches. Like plasma erythropoietin and its target erythroblasts, an inverse correlation exists between the platelet count and plasma thrombopoietin. However, unlike erythropoietin, thrombopoietin is only constitutively produced and the plasma thrombopoietin level is controlled by the size of the platelet and megakaryocyte progenitor cell pools. Also, in contrast to erythropoietin, but like its myeloid counterparts, granulocyte and granulocyte-macrophage colony-stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their end-stage product, the platelet. Paradoxically, in the three MPNs,

expression of the thrombopoietin receptor, MPL, is impaired and plasma thrombopoietin is increased despite the increased number of megakaryocytes and platelets.

The clonal nature of ET was established by analysis of glucose-6-phosphate dehydrogenase isoenzyme expression in patients hemizygous for this gene. Although thrombocytosis is its principal manifestation, like the other MPNs, the hematopoietic stem cell is involved in ET. Furthermore, a number of families have been described in which ET was inherited, in one instance as an autosomal dominant trait. In addition to ET, PMF and PV have also been observed in such kindreds.

CLINICAL FEATURES

Clinically, ET is most often identified incidentally when a platelet count is obtained during the course of a routine medical evaluation. Occasionally, review of previous blood counts will reveal that an elevated platelet count was present but overlooked for many years. No symptoms or signs are specific for ET, but these patients can have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former and microvascular occlusive events for the latter such as erythromelalgia, ocular migraine, or a TIA. Physical examination is generally unremarkable. Splenomegaly is indicative of another MPN, in particular PV, PMF, or CML.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear is most remarkable for the number of platelets present, some of which may be very large. The large mass of circulating platelets may prevent the accurate measurement of serum potassium due to release of platelet potassium upon blood clotting. This type of hyperkalemia is a test tube artifact and not associated with electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless thrombocythemic blood is collected on ice. The prothrombin and partial thromboplastin times are normal, whereas abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, despite much study, no platelet function abnormality is characteristic of ET, and no platelet function test predicts the risk of clinically significant bleeding or thrombosis.

The elevated platelet count may hinder marrow aspiration, but marrow biopsy usually reveals megakaryocyte hypertrophy and hyperplasia, as well as an overall increase in marrow cellularity. If marrow reticulin is increased, another diagnosis should be considered. The absence of stainable iron demands an explanation because iron deficiency alone can cause thrombocytosis, and absent marrow iron in the presence of marrow hypercellularity is a feature of PV.

Nonrandom cytogenetic abnormalities occur in ET but are uncommon, and no specific or consistent abnormality is notable, even those involving chromosomes 3 and 1, where the genes for thrombopoietin and its receptor, MPL, respectively, are located.

DIAGNOSIS

Thrombocytosis is encountered in a broad variety of clinical disorders (Table 108-6), in many of which inflammatory cytokine production is increased. The absolute level of the platelet count is not a useful diagnostic aid for distinguishing between benign and clonal causes of thrombocytosis. About 50% of ET patients express the *JAK2* V617F mutation. When *JAK2* V617F is absent, cytogenetic evaluation is mandatory to determine if the thrombocytosis is due to CML or a myelodysplastic disorder such as the 5q– syndrome or sideroblastic anemia. Because the *BCR-ABL* translocation can be present in the absence of the Ph chromosome, and because the *BCR-ABL* reverse transcriptase polymerase chain reaction is associated with false-positive results, fluorescence in situ hybridization (FISH) analysis for *BCR-ABL* is the preferred assay in patients with thrombocytosis in whom a cytogenetic study for the Ph chromosome is negative. *CALR* mutations (type 1 or type 2) are present in 30% and *MPL* mutations are present in 8% of ET patients who do not have a *JAK2* mutation. Anemia and ringed sideroblasts are not features of ET, but they are features of idiopathic refractory sideroblastic anemia with the *SF3B*1 mutation, and in some of these patients, thrombocytosis occurs in association with expression of *JAK2* V617F, *CALR*, or an *MPL* mutation. Significant splenomegaly should suggest the presence of another MPN such as PV or PMF, because splenomegaly can mask the presence of erythrocytosis. Importantly, what appears to be ET can evolve into PV (usually in women with *JAK2* V617F) or PMF (usually in men with type 1 *CALR* mutations) after a period of many years due to clonal evolution or succession. There is sufficient overlap of the *JAK2* V617F neutrophil allele burden between ET and PV that this test cannot be used as a distinguishing diagnostic feature with the exception that, in ET, the quantitative *JAK2* V617F neutrophil allele is never greater than 50%, and importantly in this regard, 64% of *JAK2* V617F–positive ET patients in one study actually were found to have PV when red cell mass and plasma volume determinations were performed. Claims that ET and PV form a biological continuum are unfounded as these disorders have different gene expression profiles and different natural histories.

COMPLICATIONS

Perhaps no other condition in clinical medicine has caused otherwise astute physicians to intervene inappropriately more often than thrombocytosis, particularly if the platelet count is $>1 \times 10^6/\mu L$. It is commonly believed that a high platelet count causes thrombosis; however, no controlled clinical study has ever established this association, and in patients younger than age 60 years, the incidence of thrombosis was not greater in patients with thrombocytosis than in age-matched controls, and tobacco use appears to be the most important risk factor for thrombosis in ET patients.

To the contrary, very high platelet counts are associated primarily with hemorrhage due to acquired von Willebrand's disease. This is not meant to imply that an elevated platelet count cannot cause symptoms in an ET patient, but rather that the focus should be on the patient, not the platelet count. For example, some of the most dramatic neurologic problems in ET are migraine-related and respond only to lowering of the platelet count, whereas other symptoms such as erythromelalgia respond simply to platelet cyclooxygenase-1 inhibitors such as aspirin or ibuprofen, without a reduction in platelet number. Still others may represent an interaction between an atherosclerotic vascular system and a high platelet count, and others may have no relationship to the platelet count whatsoever. Recognition that PV can present with thrombocytosis alone as well as the discovery of previously unrecognized causes of hypercoagulability **(Chaps. 121 and 122)** make the older literature on the complications of thrombocytosis unreliable.

TREATMENT

Essential Thrombocytosis

Survival of ET patients is not different than the general population regardless of their driver mutation. An elevated platelet count in an asymptomatic patient without cardiovascular risk factors or tobacco use requires no therapy. Indeed, before any therapy is initiated in a patient with thrombocytosis, the cause of symptoms must be clearly identified as due to the elevated platelet count. When the platelet count rises above $1 \times 10^6/\mu L$, a substantial quantity of high-molecular-weight von Willebrand multimers are removed from the circulation and destroyed by the enlarged platelet mass, resulting in an acquired form of von Willebrand's disease. This can be identified by a reduction in ristocetin cofactor activity. In this situation, aspirin could promote hemorrhage. Bleeding in this situation is rarely spontaneous and usually responds to tranexamic acid or ε-aminocaproic acid, which can be given prophylactically before and after elective minor surgery.

Plateletpheresis is at best a temporary and inefficient remedy that is rarely required. Importantly, ET patients treated with ^{32}P or alkylating agents are at risk of developing acute leukemia without any proof of benefit; combining either therapy with hydroxyurea increases this risk. If platelet reduction is deemed necessary on the basis of symptoms refractory to salicylates alone, pegylated IFN-α, the quinazoline derivative anagrelide, or hydroxyurea can be used to reduce the platelet count, but none of these is uniformly effective or without significant side effects. Hydroxyurea and aspirin

were more effective than anagrelide and aspirin for prevention of TIA because hydroxyurea is a nitric oxide donor, but they were not more effective for the prevention of other types of arterial thrombosis and actually less effective for venous thrombosis. The risk of gastrointestinal bleeding is also higher when aspirin is combined with anagrelide. Normalizing the platelet count does not prevent either arterial or venous thrombosis. Pegylated IFN can produce a complete molecular remission in some ET patients, but a role for it or ruxolitinib in ET management has not yet been established.

As more clinical experience is acquired, ET appears more benign than previously thought. Evolution to acute leukemia is more likely to be a consequence of therapy than of the disease itself. In managing patients with thrombocytosis, the physician's first obligation is to do no harm.

109 Acute Myeloid Leukemia

William Blum

INCIDENCE

Acute myeloid leukemia (AML) is a neoplasm characterized by infiltration of the blood, bone marrow, and other tissues by proliferative, clonal, poorly differentiated cells of the hematopoietic system. These leukemias comprise a spectrum of malignancies that untreated are uniformly fatal. In 2023, the estimated number of new AML cases in the United States was 20,380. AML is the diagnosis in 1% of all cancer cases and 31% of all new acute leukemias but causes 62% of leukemic deaths. AML is the most common acute leukemia in older patients, with a median age at diagnosis of 69 years. U.S. registry data report that only 32% of patients survive 5 years.

ETIOLOGY

Most cases of AML are idiopathic. Genetic predisposition, radiation, chemical/other occupational exposures, and drugs have been implicated in the development of AML, but AML with established etiology is relatively uncommon. No direct evidence suggests a viral etiology. Genome sequencing studies suggest that most cases of AML arise from a limited number of mutations that accumulate with advancing age. Indeed, genome sequencing provides paradigm-shifting advances in our understanding of leukemogenesis. The Cancer Genome Atlas (TCGA) and other databases demonstrate that blood cells from up to 5–6% of normal individuals aged >70 years contain potentially "premalignant" mutations that are associated with clonal expansion.

Use of the term *premalignant* to describe these lesions is not precisely accurate; rather, these mutations represent clonal hematopoiesis of *indeterminate* potential (CHIP; sometimes called age-related clonal hematopoiesis). The genes most commonly mutated in CHIP are the epigenetic regulators *DNMT3A, TET2,* and *ASXL1*. Study of CHIP is important because it has relevance not just to blood cancer evolution but also other medical conditions. Clonal expansion driven by the acquisition of new mutations is associated with a 10-fold increase in risk for developing a hematologic malignancy (compared to matched patients without CHIP), but it is clear that additional "hits" must occur to drive toward leukemia. We do not yet fully understand why or how these secondary lesions occur.

Patients with CHIP also have increased risk of cardiovascular mortality that is not fully explained. The link between these two seemingly unrelated issues (cardiovascular and hematologic malignancy) may lie in the interactions between circulating clonally expanded blood cells and vascular endothelium. A "proinflammatory" state caused by clonal, infiltrating monocytes leads to accelerated atherosclerotic plaque development and altered cardiac remodeling. Similar phenomena may occur in the marrow/blood. An altered relationship between hematopoietic stem cells and the marrow microenvironment (along with altered immune surveillance) contributes to clonal survival and expansion. These perturbations increase the likelihood that a clone with somatic mutations may survive, acquire additional mutations, and then further expand eventually to leukemia. Whether early identification of CHIP in patients will provide therapeutic opportunities for patients remains to be seen. Certainly, modifying cardiovascular risk in patients with CHIP seems prudent, but development of mutation-directed therapy designed to eliminate a problematic clone and prevent future leukemia is likely to be more elusive.

Genetic Predisposition Myeloid neoplasms occur sporadically in adults; inherited predisposition is uncommon. Yet, it is clear that myeloid neoplasms with germline predisposition represent an important and growing subset of disease. Germline mutations associated with increased risk of developing a myeloid neoplasm include *CEBPA*, *DDX41*, *TP53*, *RUNX1*, *ANKRD26*, *ETV6*, and *GATA2,* and others (Table 109-1). Myeloid neoplasms with germline predisposition are

TABLE 109-1 World Health Organization 2022, Subtypes of Myeloid Neoplasms Associated with Germline Predisposition

Myeloid neoplasms with germline predisposition without a preexisting platelet disorder or organ dysfunction

- Germline *CEBPA* P/LP variant (CEBPA-associated familial AML)
- Germline *DDX41* P/LP variant[a]
- Germline *TP53* P/LP variant[a] (Li-Fraumeni syndrome)

Myeloid neoplasms with germline predisposition and preexisting platelet disorder

- Germline *RUNX1* P/LP variant[a] (familial platelet disorder with associated myeloid malignancy [FPD-MM])
- Germline *ANKRD26* P/LP variant[a] (thrombocytopenia 2)
- Germline *ETV6* P/LP variant[a] (thrombocytopenia 5)

Myeloid neoplasms with germline predisposition and potential organ dysfunction

- Germline *GATA2* P/LP variant (GATA2 deficiency)
- Bone marrow failure syndromes
  - Severe congenital neutropenia (SCN)
  - Shwachman-Diamond syndrome (SDS)
  - Fanconi anemia (FA)
- Telomere biology disorders
- RASopathies (neurofibromatosis type 1, CBL syndrome, Noonan syndrome or Noonan syndrome-like disorders[a])
- Down syndrome[a]
- Germline *SAMD9* P/LP variant (MIRAGE syndrome)
- Germline *SAMD9L* P/LP variant (SAMD9L-related ataxia pancytopenia syndrome)[b]
- Biallelic germline *BLM* P/LP variant (Bloom syndrome)

[a]Lymphoid neoplasms can also occur. [b]Ataxia is not always present.

Abbreviations: LP, likely pathogenic; P, pathogenic.

Source: Modified from JD Khoury et al: The 5th edition of the World Health Organization Classification of Haematolymphoid Tumours: Myeloid and histiocytic/dendritic neoplasms. Leukemia 36:1703, 2022.

a feature of several well-described clinical syndromes, including bone marrow failure disorders (e.g., Fanconi anemia, Shwachman-Diamond syndrome, Diamond-Blackfan anemia) and telomere biology disorders (e.g., dyskeratosis congenita). As new mutations and associations are added to a rapidly growing list, it is clear that genetic predisposition plays a larger role than has been previously understood.

Several genetic syndromes with somatic cell chromosome aneuploidy, such as Down syndrome with trisomy 21, are associated with an increased incidence of AML. Down syndrome–associated AML in young children (<4 years) is typically of megakaryocytic differentiation and is associated with mutation in the *GATA1* gene. Such patients have excellent clinical outcomes but require dose modification of chemotherapy due to high treatment-related toxicities. Inherited diseases with defective DNA repair (e.g., Fanconi anemia, Bloom syndrome, and ataxia-telangiectasia) are also associated with AML. Each syndrome is associated with unique clinical features and atypical toxicities with chemotherapy, requiring expert care. Congenital neutropenia (Kostmann syndrome), due to mutations in the genes encoding the granulocyte colony-stimulating factor receptor and neutrophil elastase, is another disorder that may evolve into AML.

Chemical, Radiation, and Other Exposures Anticancer drugs are the leading cause of therapy-associated AML. AML post chemotherapy (AML-pCT) with alkylating agents occurs 4–6 years after exposure; affected individuals often have multilineage dysplasia, monosomy/aberrations in chromosomes 5 and 7, mutations of *TP53*, and poor prognosis. AML-pCT with topoisomerase II inhibitors occurs 1–3 years after exposure; affected individuals often have AML with monocytic features and aberrations involving chromosome 11q23 (involved gene previously called *MLL*, now *KMT2A*). The risk of acute leukemia is much higher after combined-modality therapy with alkylating agent–based chemotherapy plus external beam radiation therapy. Exposure to ionizing radiation, benzene, chloramphenicol, phenylbutazone, and other drugs can result in bone marrow failure that may evolve into AML.

CLASSIFICATION

Historically, marrow (or blood) myeloid blast count of ≥20% established the diagnosis of AML. However, biologically distinct groups are now primarily classified based on genetic aberrations, in addition to clinical features and light microscopy. It is increasingly understood that genetic aberrations drive clinical presentation and clinical course, and thus, in 2022, the World Health Organization (WHO) eliminated the blast percent requirement among cases with specific, defined genetic aberrations **(Table 109-2)**. In the WHO system referenced here, genetic aberrations are notated by the gene mutation or fusion involved; learners may find clarity by also reviewing the European LeukemiaNet (ELN) risk classification **(Table 109-3)**, which lists associated cytogenetic abnormalities alongside the gene fusions. Dueling classification systems of the WHO and the International Consensus Classification (ICC) assign AML diagnosis inconsistently with regard to blast percent, but the differences are semantic. Cases with <20% blasts that are still classified as AML have recurrent genetic abnormalities including t(15;17), t(8;21), inv(16), t(16;16), rearrangements involving *KMT2A* (with many different fusion partners), mutations in *NPM1* (nucleophosmin), and other defined genetic aberrations. The emergence of novel targeted treatment options for specific aberrations, such as menin inhibitors for patients with *KMT2A* rearrangement, *NPM1* mutation, or (possibly) *NUP98* rearrangement, suggests that a practical approach to classification based on the presence of a specific aberration regardless of blast count may indeed be most appropriate. All AML cells contain genetic mutations, most of which are recurring; in 2024, the majority of AML patients will have a genetic lesion that can be specifically targeted with a novel drug.

Genetic Findings Subtypes of AML are recognized due to the presence or absence of specific, recurrent cytogenetic, and/or genetic abnormalities. For example, the diagnosis of *acute promyelocytic leukemia* (APL) is based on the presence of the t(15;17)(q22;q12) cytogenetic rearrangement or the *PML-RARA* fusion. Similarly, core binding factor (CBF) AML is designated based on the presence of t(8;21)(q22;q22), inv(16)(p13.1q22), or t(16;16)(p13.1;q22) or the respective fusion products *RUNX1-RUNX1T1* and *CBFB-MYH11*. Each of these three groups identifies patients with favorable clinical outcomes when appropriately treated.

Many genetic AML subtypes are associated with a specific morphologic appearance such as a complex karyotype (and/or mutation of *TP53*) and dysplastic morphology in AML, myelodysplasia-related (AML-MR). One abnormality is invariably associated with a specific morphologic feature: t(15;17)(q22;q12) or the molecular fusion *PML-RARA* with APL. Further examples include inv(16)(p13.1q22) with AML and abnormal bone marrow eosinophils; t(8;21)(q22;q22) and slender Auer rods, expression of CD19, and increased normal eosinophils; and rearrangements involving *KMT2A* with monocytic features. AML with mutation of *NPM1*, especially when co-occurring with mutation of *FLT3* (fms-related tyrosine kinase 3), often presents with blasts having "cup-shaped" nuclear morphology. Recurring genetic aberrations in AML may also be loosely associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(15;17), and with older age are del(5q), del(7q), and mutated *TP53*. Myeloid sarcomas are associated with t(8;21); disseminated intravascular coagulation (DIC) is associated with t(15;17). *KMT2A* aberrations and monocytic leukemia are associated with extramedullary sites of involvement at presentation, especially gingival hypertrophy. High leukocyte count is commonly observed with *NPM1* and/or *FLT3* mutation. Many other cytogenetic and genetic findings commonly, but not always, are associated with a morphologic description, highlighting the necessity of genetic and cytogenetic testing for precise diagnosis.

TABLE 109-2 World Health Organization 2022 Classification of Acute Myeloid Leukemia

Acute myeloid leukemia with defining genetic abnormalities
Acute promyelocytic leukemia with *PML*::*RARA* fusion
Acute myeloid leukemia with *RUNX1*::*RUNX1T1* fusion
Acute myeloid leukemia with *CBFB*::*MYH11* fusion
Acute myeloid leukemia with *DEK*::*NUP214* fusion

TABLE 109-3 2022 European LeukemiaNet Risk Classification of Acute Myeloid Leukemia (AML) by Genetics at Initial Diagnosis[a]

RISK CATEGORY	GENETIC ABNORMALITY
Favorable	• t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1*[b,c] • inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*[b,c] • Mutated *NPM1*[b,d] without *FLT3*-ITD • bZIP in-frame mutated *CEBPA*[e]
Intermediate	• Mutated *NPM1*[b,d] with *FLT3*-ITD • Wild-type *NPM1* with *FLT3*-ITD (without adverse-risk genetic lesions) • t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*[b,f] • Cytogenetic and/or molecular abnormalities not classified as favorable or adverse
Adverse	• t(6;9)(p23.3;q34.1)/*DEK*::*NUP214* • t(v;11q23.3)/*KMT2A*-rearranged[g] • t(9;22)(q34.1;q11.2)/*BCR*::*ABL1* • t(8;16)(p11.2;p13.3)/*KAT6A*::*CREBBP* • inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2, MECOM(EVI1)* • t(3q26.2;v)/*MECOM*(*EVI1*)-rearranged • –5 or del(5q); –7; –17/abn(17p) • Complex karyotype,[h] monosomal karyotype[i] • Mutated *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1*, and/or *ZRSR2*[j] • Mutated *TP53*[k]

[a]Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated. Acute promyelocytic leukemia is excluded from this table. [b]Mainly based on results observed in intensively treated patients. Initial risk assignment may change during the treatment course based on the results from analyses of measurable residual disease. [c]Concurrent *KIT* and/or *FLT3* gene mutation does not alter risk categorization. [d]AMLs with *NPM1* mutation and adverse-risk cytogenetic abnormalities are categorized as adverse risk. [e]Only in-frame mutations affecting the basic leucine zipper (bZIP) region of *CEBPA*, irrespective of whether they occur as monoallelic or biallelic mutations, have been associated with favorable outcome. [f]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations. [g]Excluding *KMT2A* partial tandem duplication (PTD). [h]Complex karyotype: three or more unrelated chromosome abnormalities in the absence of other class-defining recurring genetic abnormalities; excludes hyperdiploid karyotypes with three or more trisomies (or polysomies) without structural abnormalities. [i]Monosomal karyotype: presence of two or more distinct monosomies (excluding loss of X or Y), or one single autosomal monosomy in combination with at least one structural chromosome abnormality (excluding core-binding factor AML). [j]For the time being, these markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes. [k]*TP53* mutation at a variant allele fraction of at least 10%, irrespective of the *TP53* allelic status (mono- or biallelic mutation); *TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

Source: Reproduced with permission from H Döhner et al: Diagnosis and management of AML in adults: 2022 recommendations from an international expert panel on behalf of the ELN. Blood 140:1345, 2022.

WHO classification incorporates molecular abnormalities by recognizing fusion genes or specific genetic mutations with a role in leukemogenesis. As a classic example, t(15;17) results in the fusion gene *PML-RARA* that encodes a chimeric protein, promyelocytic leukemia (Pml)–retinoic acid receptor α (Rarα), which is formed by the fusion of the retinoic acid receptor α (*RARA*) gene from chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. Unique clinical therapy with retinoic acid and arsenic trioxide has revolutionized the care of APL patients (see "Treatment of Acute Promyelocytic Leukemia" section). Similar examples of molecular subtypes included in the category of AML with recurrent genetic abnormalities are those characterized by the leukemogenic fusion genes *RUNX1-RUNX1T1* and *CBFB-MYH11* and the so-called CBF AML subtypes noted cytogenetically as t(8;21), inv(16), or t(16;16). Additional examples of fusions are *MLLT3-KMT2A* and *DEK-NUP214*, resulting from t(9;11) and t(6;9)(p23;q34). Mutated genes are also critical elements of AML classification. The most common is AML with mutated *NPM1*, a mutation seen in 30% of AML patients and in 60% of those with cytogenetically normal AML (CN-AML). Another subtype is AML with mutated *CEBPA* (specifically in-frame bZIP mutation). Both are associated with more favorable clinical outcomes, though the presence of coexisting mutation in *FLT3* negatively affects *NPM1* prognostic impact. Activating mutations of *FLT3* are present in ~30% of adult AML patients, primarily due to internal tandem duplications (ITDs) in the juxtamembrane domain that have negative prognostic impact. In contrast, point mutations of the activating loop of the kinase, called tyrosine kinase domain (TKD) mutations, have uncertain prognostic impact. Aberrant activation of the *FLT3*-encoded protein provides increased proliferation and antiapoptotic signals to the myeloid progenitor cell. *FLT3*-ITD, the most common of the *FLT3* mutations, also occurs preferentially in patients with CN-AML. The importance of identifying *FLT3*-ITD at diagnosis relates to the fact that it is not only useful as a negative prognosticator but also predicts response to specific treatment such as a tyrosine kinase inhibitor (TKI). Several TKIs targeting FLT3 are either approved for AML (e.g., midostaurin or quizartinib, only in first-line therapy in combination with chemotherapy; gilteritinib, in relapse as monotherapy) or currently in clinical investigation.

Immunophenotypic Findings The immunophenotype of human leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. This can be important in quickly distinguishing AML from acute lymphoblastic leukemia and for identifying some subtypes of AML. For example, AML with minimal differentiation, characterized by immature morphology and no lineage-specific cytochemical reactions, may be diagnosed by flow-cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 and/or 117. Similarly, acute megakaryoblastic leukemia can often be diagnosed only by expression of the platelet-specific antigens CD41 and/or CD61. Although flow cytometry is widely used, and in some cases essential for the diagnosis of AML, it has only a supportive role in establishing the different subtypes of AML through the WHO classification given the paramount importance of genetics. Increasingly, multiparameter flow cytometry is used for the measurement of measurable residual disease (MRD) after remission is achieved.

PROGNOSTIC FACTORS

Several factors predict outcome of AML patients treated with chemotherapy; they should be used for risk stratification and treatment guidance.

Chromosome and molecular investigations performed at diagnosis provide the most important prognostic information. Patients with t(15;17) have a very good prognosis (~85% cured), and those with t(8;21) and inv(16) have a good prognosis (~55% cured), whereas those with no cytogenetic abnormality have an intermediate outcome risk (~40% cured). Patients with *NPM1* mutation without a *FLT3*-ITD also have favorable risk and high cure rate; conversely, those with *TP53* mutation, complex karyotype, t(6;9), inv(3), or –7 have adverse risk and very poor clinical outcomes with virtually no chance for cure without transplantation.

For patients lacking prognostic cytogenetic abnormalities, i.e., those with CN-AML, testing for several mutated genes can help to risk-stratify. In addition to *NPM1* mutation and *FLT3*-ITD as described above, in-frame bZIP *CEBPA* mutation has favorable prognosis. Given the proven prognostic importance of *NPM1*, *FLT3*, and *CEBPA*, molecular assessment of these genes and others at diagnosis has been incorporated into AML management guidelines by the National Comprehensive Cancer Network (NCCN) and the ELN. The same markers help to define genetic groups in the ELN standardized reporting system, which is based on both cytogenetic and molecular abnormalities and is used for comparing clinical features/treatment response among subsets of patients reported across different clinical studies (Table 109-3). These genetic groups should be used for risk stratification and treatment guidance (note that APL is excluded from the table).

In addition to *NPM1, FLT3, CEBPA*, and *TP53* mutations, molecular aberrations in other genes are routinely used for prognostication. Among these mutated genes are those encoding receptor tyrosine kinases, transcription factors (*RUNX1* and *WT1*), and epigenetic

modifiers (*ASXL1*, *DNMT3A*, isocitrate dehydrogenase 1 [*IDH1*], *IDH2*, and *TET2*). Among an expanding panel of mutated genes associated with adverse risk (at least when not coexisting with favorable aberrations) are *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1, ZRSR2,* and *TP53*. Because prognostic molecular markers in AML are not mutually exclusive and often occur concurrently (>80% patients have at least two or more prognostic gene mutations), distinct marker combinations will certainly be part of continued evolution of AML classification, prognosis, and treatment.

Novel drugs that inhibit/modulate cellular pathways activated by genetic aberrations (especially *FLT3*, *IDH1*, *IDH2*, and *NPM1*/*KMT2A*/*NUP98*) have been remarkably effective in subsets of disease (see section on treatment of AML). Epigenetic changes (e.g., DNA methylation and/or posttranslational histone modification) and microRNAs are often involved in deregulation of genes involved in hematopoiesis, contribute to leukemogenesis, and may associate with the previously discussed prognostic gene mutations. These changes have been shown to provide biologic insights into leukemogenic mechanisms and provide independent prognostic information. Therapeutic progress based on advances in understanding the role of epigenetic changes in AML over the last decade has been tremendous. For example, in patients with mutations of *IDH1* or *IDH2*, novel enzymes produced from these respective mutations have aberrant activity and "hijack" the citric acid cycle. These mutations lead to production of a novel "oncometabolite," 2-hydroxyglutarate, which disrupts a myriad of epigenetic processes. Pharmacologic inhibition of these aberrant enzymes can reverse these leukemogenic activities and restore normal marrow function (though monotherapy is not typically curative).

In addition to cytogenetic and molecular aberrations, several clinical factors are associated with outcome in AML. Age at diagnosis is the most important. Advancing age is associated with a poor prognosis for two reasons: (1) its influence on the ability to survive induction therapy due to coexisting medical comorbidities, and (2) with each successive decade of age, a greater proportion of patients have intrinsically more resistant disease/adverse genetic risk. Next, a prolonged symptomatic interval with cytopenias preceding AML diagnosis, or a history of antecedent hematologic disorders including myelodysplastic syndrome (MDS) or myeloproliferative neoplasm, is often found in older patients. Preexisting cytopenia is a clinical feature associated with a lower complete remission (CR) rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >3 months before the diagnosis of AML when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder increases. Likewise, AML-pCT, typically developing after treatment with cytotoxic agents for other malignancies, is often resistant to treatment given its association with adverse genetic features. In general, older patients less frequently harbor favorable genetic aberrations (e.g., t[8;21], inv[16], and t[16;16], *NPM1* mutation) and more frequently harbor adverse genetic aberrations (e.g., complex karyotypes, mutations in *ASXL1*, *TP53*).

Other factors independently associated with worse outcome are poor performance status, which influences ability to survive induction therapy, and a high presenting leukocyte count that in some series is an adverse prognostic factor for attaining a CR. Among patients with hyperleukocytosis (>100,000/μL), early central nervous system bleeding and pulmonary leukostasis contribute to poor outcomes.

Following administration of therapy, achievement of CR is associated with better outcome and longer survival, of course. CR is defined after examination of both blood and bone marrow and essentially represents eradication of detectable leukemia *and* restoration of normal hematopoiesis. The blood neutrophil count must be ≥1000/μL and the platelet count ≥100,000/μL for formal criteria; CR with incomplete recovery of counts is a lesser but still meaningful response. Hemoglobin concentration is not considered in determining CR. Circulating blasts should be absent. Although rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. At CR, the bone marrow should contain <5% blasts, and extramedullary leukemia should not be present.

CLINICAL PRESENTATION

Symptoms Patients with AML usually present with nonspecific symptoms that begin gradually, though sometimes abruptly, and are the consequence of anemia, leukocytosis, leukopenia/leukocyte dysfunction, or thrombocytopenia. Nearly half have symptoms for ≤3 months before the leukemia is diagnosed.

Fatigue is a frequent first symptom among AML patients. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are common. Bone pain, lymphadenopathy, nonspecific cough, headache, or diaphoresis may also occur.

Rarely, patients may present with symptoms from a myeloid sarcoma (a tumor mass consisting of myeloid blasts occurring at anatomic sites other than bone marrow). Sites involved are most commonly the skin, lymph node, gastrointestinal tract, soft tissue, and testis. This may precede or coincide with blood and/or marrow involvement by AML. Patients who present with isolated myeloid sarcoma typically develop blood and/or marrow involvement quickly thereafter and cannot be cured with local therapy (radiation or surgery) alone.

Physical Findings Fever, infection, and hemorrhage are often found at the time of diagnosis; splenomegaly, hepatomegaly, lymphadenopathy, and "bone pain" may also be present but less commonly. Hemorrhagic complications are most commonly and, classically, found in APL. APL patients often present with DIC-associated minor hemorrhage but may have significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage. Counterintuitively, thrombosis while less frequent is another well recognized clinical feature of DIC in APL. Complications associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other morphologic subtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingiva, skin, soft tissues, or meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes and those with *KMT2A* chromosomal abnormalities.

Hematologic Findings Anemia is usually present at diagnosis, although it is not typically severe. The anemia is usually normocytic normochromic. Decreased erythropoiesis in the setting of AML often results in a reduced reticulocyte count, and red blood cell (RBC) survival is decreased by accelerated destruction. Active blood loss may rarely contribute to the anemia.

The median presenting leukocyte count for new AML cases is ~15,000/μL. Lower presenting leukocyte counts are more typical of older patients and those with antecedent hematologic disorders. Between 25 and 40% of patients have counts <5000/μL, and 20% have counts >100,000/μL. Fewer than 5% have no detectable leukemic cells in the blood. In AML blasts, the cytoplasm often contains primary (nonspecific) granules, and the nucleus shows fine, lacy chromatin with one or more nucleoli characteristic of immature cells. Abnormal rod-shaped granules called Auer rods are not uniformly present, but when they are, AML (and not acute lymphocytic leukemia) is certain **(Fig. 109-1)**.

Platelet counts <100,000/μL are found at diagnosis in ~75% of patients, and ~25% have counts <25,000/μL. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation Once the diagnosis of AML is suspected, thorough evaluation and initiation of appropriate therapy should follow. In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and renal systems **(Table 109-4)**. Factors that have prognostic significance, either for achieving CR or for CR duration, should also be assessed before initiating treatment including cytogenetics and molecular markers. Leukemic

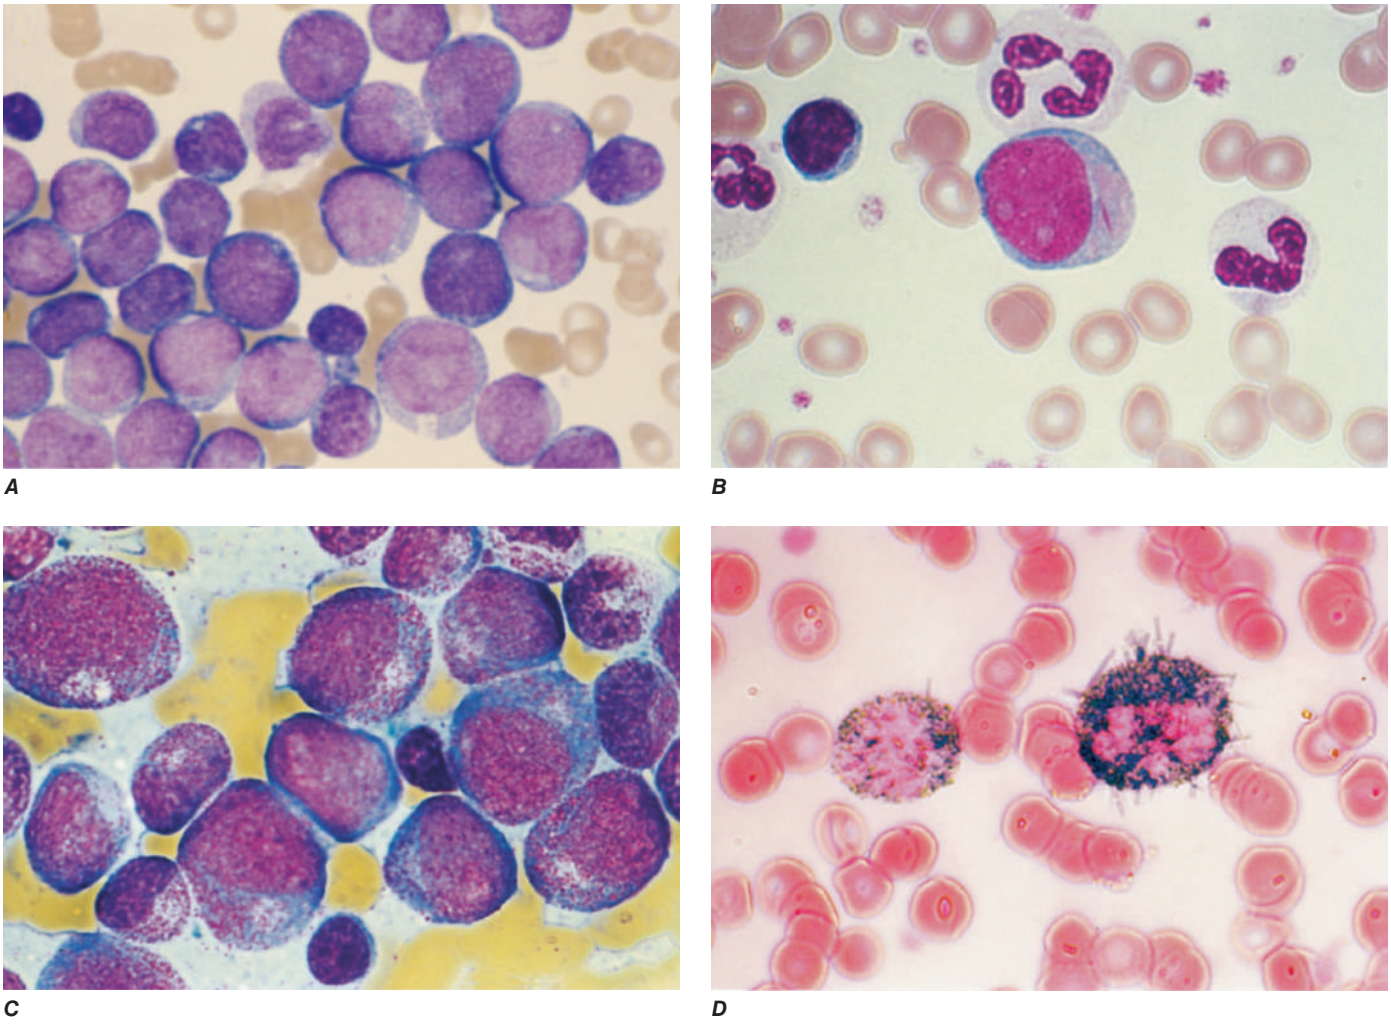

FIGURE 109-1 Morphology of acute myeloid leukemia (AML) cells. ***A.*** Uniform population of primitive myeloblasts with immature chromatin, nucleoli in some cells, and primary cytoplasmic granules. ***B.*** Leukemic myeloblast containing an Auer rod. ***C.*** Promyelocytic leukemia cells with prominent cytoplasmic primary granules. ***D.*** Peroxidase stain shows dark blue color characteristic of peroxidase in granules in AML.

cells should be obtained from all consenting patients and cryopreserved for future investigational testing as well as potential use as new diagnostics and therapeutics become available. All patients should be evaluated for infection. Patients with respiratory symptoms should undergo testing for the presence of the novel coronavirus, SARS-CoV-2, and other viruses before initiation of chemotherapy.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion even if the platelet count is only moderately decreased.

About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually started immediately on allopurinol and hydration at diagnosis. Rasburicase (recombinant uric oxidase) is also useful for treating uric acid nephropathy and often can normalize the serum uric acid level within hours with a single dose of treatment, although its expense suggests that limiting its use to patients with severe hyperuricemia and/or kidney injury may be prudent (and it should be avoided in setting of glucose-6-phosphate dehydrogenase deficiency). The presence of high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction for a minority of patients.

TREATMENT

Acute Myeloid Leukemia

Treatment of the newly diagnosed patient with AML is usually divided into two phases, induction and postremission management (consolidation) (Fig. 109-2). The initial goal is to induce CR. Once CR is obtained, further therapy must be given to prolong survival and achieve cure. The initial induction treatment and subsequent postremission therapy are chosen based on the patient's age, overall fitness, and cytogenetic/molecular risk. Intensive therapy with cytarabine and anthracycline in younger patients (<60 years) increases the cure rate of AML. In older patients, the benefit of intensive therapy is controversial in all but favorable-risk patients; novel approaches for selecting patients predicted to be responsive to treatment and new therapies are being pursued. Importantly, even infirm older patients should be considered for therapy; treatment is better than supportive care for all candidates. Improved options have emerged for older AML patients such as the addition of the BCL2 antagonist venetoclax to one of several low-intensity chemotherapies. Venetoclax is currently in testing in combination with intensive chemotherapies as well. Likewise, novel oral drugs targeting IDH1/IDH2, alone (IDH1) or in combination (IDH1 and IDH2) with low-intensity chemotherapy, may be considered as initial therapy for unfit older patients who have mutations in those respective pathways.

TABLE 109-4 Initial Diagnostic Evaluation and Management of Adult Patients with AML

History
Increasing fatigue or decreased exercise tolerance (anemia)
Excess bleeding or bleeding from unusual sites (DIC, thrombocytopenia)
Fevers or recurrent infections (neutropenia)
Headache, vision changes, nonfocal neurologic abnormalities (CNS leukemia or bleed)
Early satiety (splenomegaly)
Family history of AML (Fanconi, Bloom, or Kostmann syndromes or ataxia-telangiectasia)
History of cancer (exposure to alkylating agents, radiation, topoisomerase II inhibitors)
Occupational exposures (radiation, benzene, petroleum products, paint, smoking, pesticides)
Physical Examination
Performance status (prognostic factor)
Ecchymosis and oozing from IV sites (DIC, possible acute promyelocytic leukemia)
Fever and tachycardia (signs of infection)
Papilledema, retinal infiltrates, cranial nerve abnormalities (CNS leukemia)
Poor dentition, dental abscesses
Gum hypertrophy (leukemic infiltration, most common in monocytic leukemia)
Skin infiltration or nodules (leukemia infiltration, most common in monocytic leukemia)
Lymphadenopathy, splenomegaly, hepatomegaly
Back pain, lower extremity weakness (spinal granulocytic sarcoma, most likely in t[8;21] patients)
Laboratory and Radiologic Studies
CBC with manual differential cell count
Chemistry tests (electrolytes, creatinine, BUN, calcium, phosphorus, uric acid, hepatic enzymes, bilirubin, LDH, amylase, lipase)
Clotting studies (prothrombin time, partial thromboplastin time, fibrinogen, D-dimer)
Viral serologies (CMV, HSV-1, varicella-zoster)
RBC type and screen
HLA typing for potential allogeneic HCT
Bone marrow aspirate and biopsy (morphology, cytogenetics, flow cytometry, molecular studies)
Cryopreservation of viable leukemia cells
Myocardial function (echocardiogram or MUGA scan)
PA and lateral chest radiograph
Placement of central venous access device
Interventions for Specific Patients
Dental evaluation (for those with poor dentition)
Lumbar puncture (for those with symptoms of CNS involvement)
Screening spine MRI (for patients with back pain, lower extremity weakness, paresthesias)
Social work referral for patient and family psychosocial support
Counseling for All Patients
Provide patients with information regarding their disease and genetic risks, sperm banking or menstrual suppression, financial counseling, support group contact, and consent for tissue banking of leukemic cells

Abbreviations: AML, acute myeloid leukemia; BUN, blood urea nitrogen; CBC, complete blood count; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HLA, human leukocyte antigen; HCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; IV, intravenous; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MUGA, multigated acquisition; PA, posteroanterior; RBC, red blood (cell) count.

INDUCTION CHEMOTHERAPY

The most commonly used induction regimens (for patients other than those with APL) consist of combination chemotherapy with cytarabine and an anthracycline (e.g., daunorubicin, idarubicin). Cytarabine is a cell cycle S-phase–specific antimetabolite that becomes phosphorylated intracellularly to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalators. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks.

In adults, cytarabine used at standard dose (100–200 mg/m^2) is administered as a continuous intravenous infusion for 7 days. With cytarabine, anthracycline therapy generally consists of daunorubicin (60–90 mg/m^2) or idarubicin (12 mg/m^2) intravenously on days 1, 2, and 3 (the 7+3 regimen). Other agents can be added (e.g., gemtuzumab ozogamicin) when 60 mg/m^2 of daunorubicin is used. Patients failing remission after one induction are offered reinduction with the same (or slightly modified) therapy. The CD33-targeting immunoconjugate gemtuzumab ozogamicin may be added to induction therapy for subsets of patients, especially those with CBF AML. Many alternative intensive approaches other than 7+3 chemotherapy exist and are commonly used.

In older patients (age ≥60–65 years), the outcome with conventional intensive therapy is generally poor due to a higher frequency of resistant disease and increased rate of treatment-related morbidity and mortality. Patients still fare far better with treatment than with supportive care only. Conventional therapy for fit older patients is similar to that for younger patients: the 7+3 regimen with standard-dose cytarabine and idarubicin (12 mg/m^2) or daunorubicin (60 mg/m^2). For patients aged >65 years, high-dose daunorubicin (90 mg/m^2) has increased toxicity and is not recommended. A liposomal preparation of cytarabine and daunorubicin in a fixed molar ratio may instead be administered, especially to fit patients with AML-MR. Patients over 75 years and those unable to receive intensive therapy due to medical comorbidity may receive repetitive cycles of lower intensity therapy with a hypomethylating agent (HMA; decitabine or azacitidine) or low-dose cytarabine in combination with daily venetoclax (BCL2 antagonist). As noted, targeted IDH1- or IDH2-directed therapy is another consideration for particularly infirm patients. All patients should be considered for clinical trials.

With the 7+3 regimen (or other similar approaches), 60–80% of younger and 33–60% of older patients (among those who are candidates for intensive therapy) with primary AML achieve CR. Response rates around 60% in first line have been similarly reported with the combination of HMA plus venetoclax in older or infirm patient groups. Induction death is more frequent with advancing age and medical comorbidity, but the most common reason for treatment failure is lack of remission. Patients with refractory disease after inductions should be considered for salvage treatments, preferably on clinical trials. Planning for the possibility of allogeneic hematopoietic stem cell transplantation (HCT) for all eligible patients under age 75 years is part of optimal initial AML care. Typically, allogeneic HCT is performed only for patients who are in CR but at risk for relapse, but fit younger patients with primary refractory disease (not in remission after initial induction) have ~15–20% cure rates with allogeneic HCT after myeloablative conditioning. For this reason, early planning for possible future allogeneic HCT (including human leukocyte antigen [HLA] typing, donor search, etc.) should be part of the initial approach for most AML patients.

POSTREMISSION THERAPY

Induction of a durable first CR (CR1) is critical to long-term survival in AML. However, without further therapy, virtually all CR patients will eventually relapse. Thus, postremission therapy is designed to eradicate residual (typically undetectable) leukemic cells to prevent relapse and prolong survival. As with induction, the type of postremission therapy in AML is selected for each individual patient based on age, fitness, and cytogenetic/molecular risk.

The choice between consolidation with chemotherapy or with transplantation is complex and based on age, risk, and practical considerations. In younger patients receiving chemotherapy, postremission therapy with intermediate- or high-dose cytarabine for two to four cycles is standard practice. Higher doses of cytarabine during postremission therapy appear more effective than

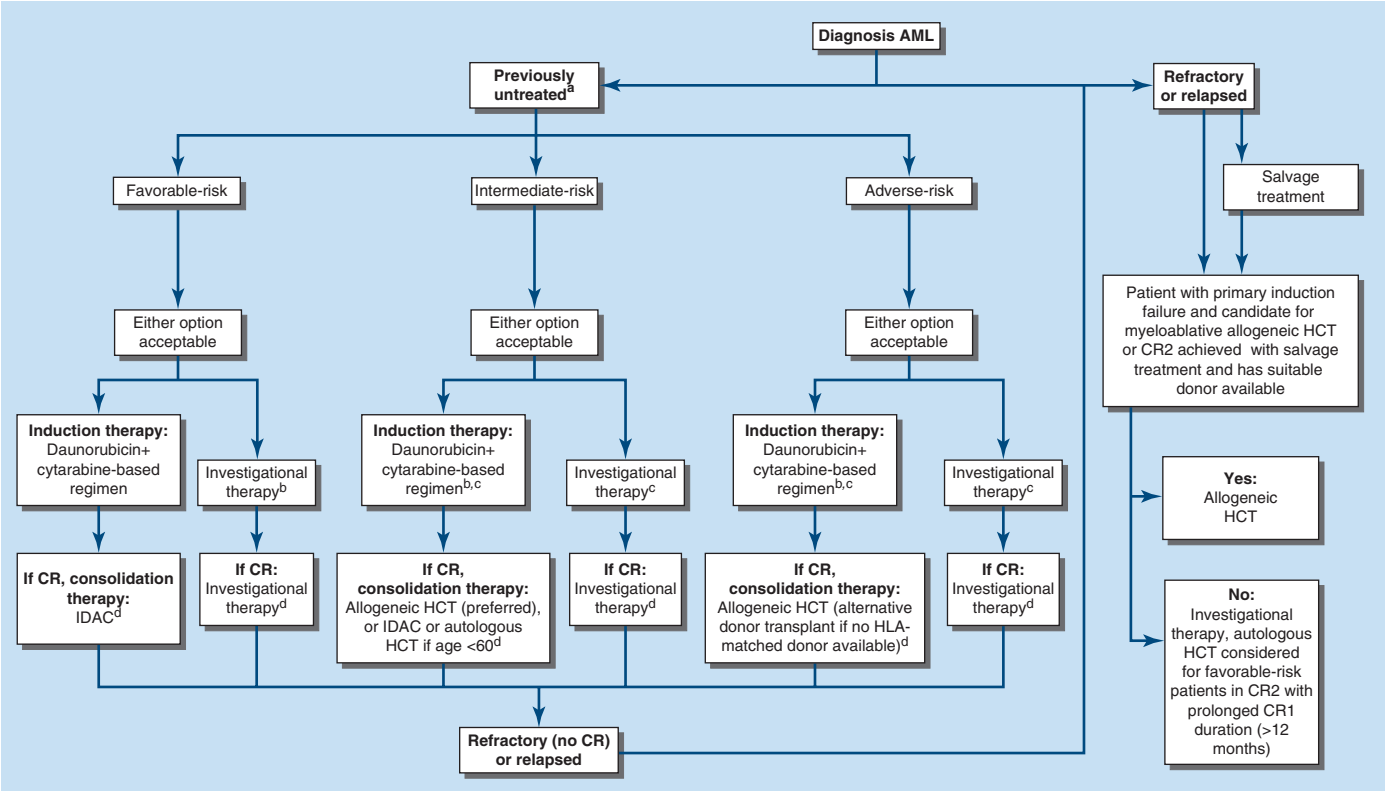

FIGURE 109-2 Algorithm for the therapy of newly diagnosed acute myeloid leukemia (AML). [a]Risk stratification according to the European LeukemiaNet (see Table 109-3). [b]Younger patients (<60–65 years) should routinely be offered investigational therapy on a backbone of standard intensive chemotherapy for induction and consolidation. [c]Older patients, especially those >65 years or with adverse risk disease, or those who are unfit for intensive anthracycline + cytarabine regimens, may be considered for investigational therapy alone or in combination or lower intensity chemotherapy plus venetoclax. Whether venetoclax-containing regimens will be effective in younger, fit patients when compared to intensive chemotherapy is an important question. [d]Novel allogeneic transplantation approaches are preferred for nonfavorable risk when available; other investigational therapy or oral azacitidine (approved in nonfavorable risk) as maintenance should be considered following consolidation.

Allogeneic hematopoietic cell transplantation (HCT) is a consideration for all eligible patients in first complete remission (CR) with non–favorable-risk disease and highly recommended for all older patients (60–75 years) and those with adverse risk.

For all forms of AML in fit patients, except acute promyelocytic leukemia (APL), standard induction therapy includes a regimen based on a 7-day continuous infusion of cytarabine (100–200 mg/m^2/d) and a 3-day course of daunorubicin (60–90 mg/m^2/d) with or without additional drugs. Idarubicin (12 mg/m^2/d) can be used in place of daunorubicin (not shown). The value of postremission/consolidation therapy for older patients (>60 years) who do not have favorable-risk disease is uncertain. Patients who achieve CR undergo postremission consolidation therapy, including sequential courses of intermediate-dose cytarabine, allogeneic HCT, autologous HCT, or novel therapies, based on their predicted risk of relapse (i.e., risk-stratified therapy). Patients receiving induction of lower intensity chemotherapy with venetoclax (or investigational therapy) typically receive repetitive cycles of same on an attenuated schedule, if necessary due to myelotoxicity, after achieving remission. Patients with APL (see text for treatment) usually receive tretinoin and arsenic trioxide–based regimens with or without anthracycline-based chemotherapy and possibly maintenance with tretinoin. HLA, human leukocyte antigen; IDAC, intermediate-dose cytarabine.

standard doses (such as are used in induction) for those who do not have adverse-risk genetics. Studies have shown that the long-standing practice of high-dose cytarabine (3 g/m^2, every 12 h on days 1, 3, and 5) may not improve survival over intermediate-dose cytarabine (IDAC; 1–1.5 g/m^2) for such patients. Thus, the ELN has recommended IDAC at 1–1.5 g/m^2, every 12 h, on days 1–3, as the optimal postremission chemotherapy approach for favorable- and intermediate-risk younger patients, for two to four cycles. While high-dose cytarabine may not be necessary, it is important to note that younger, favorable-risk patients have worse outcomes when doses <1 g/m^2 are used. In contrast to favorable-risk patients, intermediate- or adverse-risk patients should proceed with allogeneic HCT in CR1 when feasible (see transplant discussion below). Because older patients have increased toxicities with higher doses of cytarabine, ELN recommends relatively attenuated cytarabine doses (0.5–1 g/m^2, every 12 h, on days 1–3) in favorable-risk older patients. There is no clear value for intensive postremission therapy in non–favorable-risk older patients; allogeneic HCT in CR1 (up to age 75 years) or investigational postremission therapy is recommended. Indeed, postremission therapy is an appropriate setting for introduction of new agents in both older and younger patients. For older patients (with nonfavorable cytogenetic risk) in CR after intensive therapy who have no transplantation option, maintenance treatment with prolonged low-dose oral azacitidine improves survival.

For patients treated initially with lower intensity regimens that include venetoclax, the current practice is to continue repetitive cycles of the same combination of agents after remission until disease progression. Therapy often must be abbreviated over time due to cumulative myelotoxicity. In the largest published trial with azacitidine and venetoclax in older AML, patients had median survival of <15 months; survival depended on genetic risk. The median duration of remission (including those with incomplete count recovery) was 17.5 months.

Allogeneic HCT is the best relapse-prevention strategy currently available for AML. Allogeneic HCT is best understood as an opportunity for immunotherapy; residual leukemia cells potentially elicit an immunologic response from donor immune cells, the so-called graft-versus-leukemia (GVL) effect. The benefit of GVL in relapse risk reduction unfortunately is offset somewhat by increased morbidity and mortality from complications of HCT including graft-versus-host disease (GVHD). Given that relapsed AML is typically resistant to chemotherapy, allogeneic HCT in CR1 (i.e., before relapse ever occurs) is a favored strategy. We have often explained to patients that transplant can effectively "eliminate the needle in a haystack, but not a stack of needles." Transplant is recommended for patients age <75 years who do not have favorable-risk disease and who have an available HLA-compatible donor (related or unrelated). We recommend allogeneic HCT in CR1 for patients

with intermediate-risk disease (Table 109-3). However, considerable debate exists regarding whether allogeneic HCT in CR1 is a requirement for younger patients with intermediate-risk AML, as one large series from the Medical Research Council reported that such patients have similar outcomes if transplanted only after relapse (and achievement of CR2), sparing some the long-term morbidity of transplantation. That said, allogeneic HCT is generally recommended as soon as possible after CR1 is achieved unless the patient is in a favorable-risk group. Patients without HLA-matched donors are considered for alternative donor transplants (e.g., HLA-mismatched unrelated, haploidentical related, and umbilical cord blood) even in CR1. More effective and safe methods of in vivo T-cell depletion (e.g., posttransplant cyclophosphamide following mismatched transplantation or use of abatacept) have broadened the availability of potential allogeneic HCT donors. Now, virtually any patient with a healthy parent or child has an available donor suitable for allogeneic HCT if desired. Long-term outcomes with conventional chemotherapy for older patients are dismal; transplantation for such patients is expanding and improving outcomes.

Trials comparing allogeneic HCT with intensive chemotherapy or autologous HCT have shown improved duration of remission with allogeneic HCT. The relapse risk reduction observed with allogeneic HCT, however, is partially offset by the increase in fatal treatment-related toxicity (GVHD, organ toxicity). Despite this, there is no debate that patients with adverse-risk AML have improved long-term survival with early allogeneic HCT. For rare patients with no allogeneic donor option, high-dose chemotherapy with autologous HCT rescue is another postremission approach in non–adverse-risk subsets. Autologous HCT patients receive their own stem cells (collected during remission and cryopreserved), following administration of myeloablative chemotherapy. The toxicity is relatively low with autologous HCT (5% mortality rate), but the relapse rate is higher than with allogeneic HCT due to the absence of the GVL effect. Favorable- and intermediate-risk patients may benefit from autologous HCT; it is not recommended in adverse-risk patients. Practically speaking, autologous HCT in AML patients is less frequently employed currently due to enhanced relapse risk reduction seen with allogeneic HCT and the growing availability of HLA-mismatched donors (and novel transplantation approaches).

Prognostic factors help to select the appropriate postremission therapy in patients in CR1. Our approach includes allogeneic HCT in CR1 for patients without favorable cytogenetics or genotype. Patients with adverse-risk disease should proceed to allogeneic HCT at CR1 if possible. The decision for allogeneic HCT for younger intermediate-risk patients is complex and individualized as described above; we recommend it. Subsets of patients may benefit from targeted therapy given during remission; emerging data demonstrate survival benefit from incorporation of the FLT3 inhibitors midostaurin or quizartinib, for example, into induction and postremission therapies for patients with *FLT3*-mutated AML. Allogeneic transplantation in CR1 is still recommended for most of these patients.

For patients in morphologic CR, measurement of MRD remains a very important and challenging research area. Cytogenetics are a mainstay of disease assessment, and persistence of abnormal karyotype (despite morphologic CR) is clearly associated with poor clinical outcomes. Immunophenotyping (flow cytometry) to detect minute populations of blasts and/or sensitive molecular assays such as quantitative reverse transcriptase polymerase chain reaction (RT-PCR) to detect AML-associated molecular abnormalities when present (e.g., *NPM1*, *RUNX1/RUNX1T1* and *CBFB/MYH11* transcripts, *PML/RARA*) can be performed to assess MRD at sequential time points during or after treatment. We know that continued detection of MRD after therapy is unfavorable. Whether emerging next-generation sequencing or serial quantitative assessment using flow or PCR, performed during remission, can effectively direct subsequent therapy and improve clinical outcome remains to be determined for most subtypes. Currently, no consensus exists for the optimal MRD measurement technique or its application, although testing is increasingly employed in clinical practice. Data suggest that MRD measurement can in some settings be a reliable discriminator between patients who will continue in CR or relapse, but whether subsequent therapy (i.e., allogeneic HCT or additional therapy) can effectively eradicate disease in such patients is not yet clear. For patients with *NPM1* mutation, MRD-negative status by *NPM1* PCR after two courses of chemotherapy predicts favorable outcome without transplantation (even for patients with coexisting *FLT3* mutation); emerging data demonstrate that transplantation of MRD-positive patients does indeed improve outcome (rather than just predict they will do poorly irrespective of subsequent therapy given). In the subset of patients with APL, serial PCR (for the *PML/RARA* transcript) is a very useful and reliable tool to detect early relapse and to direct initiation of reinduction therapy prior to onset of overt relapse. Critical in the general understanding of MRD in all disease subsets is the recognition that even patients with undetectable levels of MRD remain at risk for leukemic relapse.

SUPPORTIVE CARE

Measures geared to supporting patients through several weeks of neutropenia and thrombocytopenia are critical to successful AML therapy. Patients with AML should be treated in centers expert in providing supportive care. Multi-lumen central venous catheters should be inserted as soon as newly diagnosed AML patients have been stabilized. They should be used thereafter for administration of intravenous medications/chemotherapy and transfusions, as well as for blood drawing instead of venipuncture during prolonged periods of myelosuppression.

Adequate and prompt blood bank support is critical to therapy of AML. Platelet transfusions should be given as needed to maintain a platelet count ≥10,000/μL. The platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding or DIC. Patients with poor posttransfusion platelet count increments may benefit from administration of ABO-matched platelets or platelets from HLA-matched donors. RBC transfusions should be considered to keep the hemoglobin level >70–80 g/L (7–8 g/dL) in the absence of active bleeding, DIC, or congestive heart failure, which may require higher hemoglobin levels. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products may also be irradiated to prevent transfusion-associated GVHD.

Neutropenia (neutrophils <500/μL or <1000/μL and predicted to decline to <500/μL over the next 48 h) can be part of the initial presentation and/or a side effect of the chemotherapy treatment in AML patients. Thus, infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy for AML. Antibacterial (e.g., quinolones) and antifungal (e.g., posaconazole) prophylaxis, especially in conjunction with regimens that cause mucositis, is beneficial. For patients who are herpes simplex virus or varicella-zoster seropositive, antiviral prophylaxis should be initiated (e.g., acyclovir, valacyclovir).

Fever develops in most patients with AML, but infections are documented in only half of febrile patients. Empiric initiation of empirical broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications **(Chap. 79)**. An antibiotic regimen adequate to treat gram-negative organisms should be instituted at the onset of fever in a neutropenic patient after clinical evaluation, including a detailed physical examination with inspection of the indwelling catheter exit site and a perirectal examination (for perirectal abscess), as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on institutional antibiotic sensitivity data obtained from where the patient is being treated. Acceptable regimens for empiric antibiotic therapy include monotherapy with imipenem-cilastatin, meropenem, piperacillin/tazobactam, or an extended-spectrum antipseudomonal cephalosporin (cefepime or ceftazidime). The combination of an aminoglycoside with an antipseudomonal penicillin (e.g., piperacillin) or an aminoglycoside in combination with

an extended-spectrum antipseudomonal cephalosporin should be considered in complicated or resistant cases. Aminoglycosides should be avoided, if possible, in patients with renal insufficiency. Empirical vancomycin should be added in neutropenic patients with catheter-related infections, blood cultures positive for gram-positive bacteria before final identification and susceptibility testing, hypotension or shock, or known colonization with penicillin/cephalosporin-resistant pneumococci or methicillin-resistant *Staphylococcus aureus*. In special situations where decreased susceptibility to vancomycin, vancomycin-resistant organisms, or vancomycin toxicity is documented, other options including linezolid and daptomycin need to be considered.

Caspofungin (or a similar echinocandin), voriconazole, isavuconazonium, or liposomal amphotericin B should be considered for antifungal treatment if fever persists for 4–7 days following initiation of empiric antibiotic therapy. Although liposomal formulations of amphotericin B have improved the toxicity profile of this agent, use has been limited to situations with high risk of or documented mold infections, especially in those in whom an azole fails. Caspofungin has been approved for empiric antifungal treatment. Voriconazole has also been shown to be equivalent in efficacy and less toxic than amphotericin B; isavuconazonium may also be effective with fewer drug-drug interactions. Unfortunately, use of prophylactic or empiric antibiotics contributes to the development of resistance and increased incidence of nosocomial infections such as *Clostridium difficile* colitis, so hospital-wide antibiotic surveillance and isolation strategies should be employed to reduce these complications. Recombinant hematopoietic growth factors have a limited role in AML; myeloid growth factors may be useful in the postremission setting but are not recommended in induction or for "palliative" care for patients not in remission.

TREATMENT FOR REFRACTORY OR RELAPSED AML

In patients who relapse after achieving CR, the length of first CR is predictive of response to salvage chemotherapy treatment; patients with longer first CR (>12 months) generally relapse with drug-sensitive disease and have a higher chance of attaining a CR, even with the same chemotherapeutic agents used for first remission induction. Patients with short prior CR duration are at high risk for treatment failure. Similar to patients with refractory disease, patients with relapsed disease are rarely, if ever, cured by salvage chemotherapy treatments alone. Therefore, patients who eventually achieve a second CR and are eligible for allogeneic HCT should be transplanted. For patients who relapse after allogeneic HCT, no consensus for best therapy exists; outcomes in this setting are very poor.

Because achievement of a second CR with routine salvage therapies is relatively uncommon, especially in patients who relapse rapidly after achievement of first CR (<12 months), these patients and those lacking HLA-compatible donors or who are not candidates for allogeneic HCT should be considered for innovative approaches on clinical trials. Many new agents are in current testing **(Table 109-5)**. The discovery of novel gene mutations and mechanisms of leukemogenesis that might represent actionable therapeutic targets has prompted the development of many new targeting agents. In addition to kinase inhibitors for *FLT3*-mutated AML, other compounds targeting the aberrant activity of mutant proteins (e.g., IDH1/2 inhibitors) and numerous other biologic mechanisms are either approved by the Food and Drug Administration (FDA) or being tested in clinical trials. Inhibitors of FLT3 (gilteritinib, quizartinib), IDH1 (ivosidenib, olutasidenib), or IDH2 (enasidenib) are approved in AML. Exciting early clinical data with menin inhibitors in AML with *KMT2A* rearrangement, *NPM1* mutation, or other genetic aberrations with shared biology of *HOXA* cluster gene upregulation are likely to result in FDA approval of the first agent in this pathway during 2024. Furthermore, approaches with antibodies targeting markers commonly expressed on leukemia blasts (e.g., CD33) or leukemia-initiating cells (e.g., CD123) are also under investigation. Next-generation immune compounds such as bispecific or trispecific antibodies are promising and under study. Investigation of these in combination with other molecular targeting compounds and/or chemotherapy should be pursued.

TABLE 109-5 Novel Therapies in Clinical Development in Acute Myeloid Leukemia (AML)

	UNDER INVESTIGATION	APPROVED BY FOOD AND DRUG ADMINISTRATION SINCE 2017
Kinase inhibitors/ cell signaling	FLT3 inhibitors IRAK-4 inhibitors KIT inhibitors PI3K/AKT/mTOR inhibitors Aurora and polo-like kinase inhibitors, CDK4/6 inhibitors, CDK9 inhibitors, CHK1, WEE1, CSFR1, and MPS1 inhibitors SRC and HCK inhibitors Syk inhibitors	Midostaurin (FLT3) Gilteritinib (FLT3) Quizartinib (FLT3) Pemigatinib (FGFR1)
Epigenetic modulators	Menin inhibitors, other spliceosome modulators DNA methyltransferase inhibitors Histone methylation or acetylation modulators Other spliceosome modulators IDH1 and IDH2 inhibitors DOT1L inhibitors BET-bromodomain inhibitors	Revumenib (menin inhibitor; FDA review pending, 2024) Enasidenib (IDH2) Ivosidenib (IDH1) Olutasidenib (IDH1)
Chemotherapeutic agents	Liposomal preparations Nucleoside analogues	CPX-351 (liposomal cytarabine and daunorubicin) Oral azacitidine
Mitochondrial inhibitors	BH3 mimetics; Bcl-2, Bcl-xL, and Mcl-1 inhibitors Caseinolytic protease inhibitors	Venetoclax (BCL2)
Therapies targeting oncogenic proteins	Fusion transcript targeting EVI1 targeting NPM1 targeting Hedgehog inhibitors	Glasdegib (hedgehog)
Antibodies and immunotherapies	Monoclonal antibodies against CD33, CD44, CD47, CD123, CLEC12A Immunoconjugates Bispecific T-cell engagers (BiTEs) and dual-affinity retargeting molecules (DARTs) for CD33, CD123, others Trispecific T-cell or NK-cell engagers Chimeric antigen receptor (CAR) T cells, genetically engineered T-cell receptor (TCR) T cells, CAR-NK cells Immune checkpoint inhibitors (PD-1/PD-L1, CTLA-4, LAG-3, LILRB4) Vaccines	Gemtuzumab ozogamicin (CD33-toxin)
Therapies targeting AML environment	CXCR4 and CXCL12 antagonists Antiangiogenic therapies

TREATMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

APL is a highly curable AML subtype, and ~85% of these patients achieve long-term survival with current approaches. APL has long been shown to be responsive to cytarabine and daunorubicin. However, in the past, patients who were treated with these drugs

alone frequently died from DIC induced by the release of granule components by the chemotherapy-treated leukemia cells. The prognosis of APL patients changed dramatically first with the introduction of tretinoin (all-*trans*-retinoic acid [ATRA]) and then with combined ATRA and arsenic trioxide (ATO). ATRA is an oral drug that induces the differentiation of leukemic cells bearing the t(15;17), which disrupts the *RARA* gene encoding retinoid acid receptor. ATRA decreases the frequency of DIC but often produces another complication called the APL (differentiation) syndrome. Occurring within the first 3 weeks of treatment, it is characterized by fever, fluid retention, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxemia. The syndrome is related to adhesion of differentiated neoplastic cells to the pulmonary vasculature endothelium. Glucocorticoids, chemotherapy for cytoreduction, and/or supportive measures can be effective for management of the APL syndrome. Temporary discontinuation of ATRA is necessary in cases of severe APL syndrome (i.e., patients developing renal failure or requiring admission to the intensive care unit due to respiratory distress). The mortality rate of this syndrome is ~10% if unrecognized. APL syndrome may also occur, less commonly, with ATO.

In adults with low-risk APL (low leukocyte count at presentation), ATRA (45 mg/m^2/d) plus ATO (0.15 mg/kg/d) was compared to ATRA plus concurrent idarubicin chemotherapy. ATRA/ATO was superior and is the new standard of care for such patients. CR rates in low-risk disease approach 100%, with excellent long-term survival. Notably, patients with high-risk APL (defined as leukocyte count >10,000/μL) must be uniquely treated, as they require immediate cytoreduction with chemotherapy due to life-threatening APL syndrome and rapidly rising leukocyte count after initiation of ATRA. High-risk patients are at increased risk for induction death due to this syndrome as well as increased frequency of hemorrhagic complications (related to DIC).

Assessment of residual disease by PCR amplification of the t(15;17) chimeric gene product *PML-RARA* following the final cycle of treatment is important. Disappearance of the signal is associated with long-term disease-free survival; its persistence or reemergence invariably predicts relapse. Sequential monitoring by PCR for *PML-RARA* is now considered standard for postremission monitoring of APL, at least in high-risk patients.

110 Chronic Myeloid Leukemia

Hagop Kantarjian, Elias Jabbour

Chronic myeloid leukemia (CML) is a clonal hematopoietic myeloproliferative stem cell neoplasm. The disease is driven by the *BCR::ABL1* chimeric gene that codes for a constitutively active tyrosine kinase, resulting from a reciprocal balanced translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34.1;q11.2), known as the Philadelphia chromosome (Ph) **(Fig. 110-1)**. Untreated, the course of CML is typically biphasic or triphasic, with an early indolent or chronic phase, followed often by an accelerated phase and a terminal blastic phase. Before the era of BCR::ABL1 tyrosine kinase inhibitors (TKIs), the median survival in CML was 3–7 years, and the 10-year survival rate was 30% or less. Introduced into standard CML therapy in 2000, TKIs have revolutionized the treatment, natural history, and prognosis of CML. Today, the estimated 10-year survival rate with imatinib mesylate, the first BCR::ABL1 TKI approved, is >85% and approaches that of a normal age-matched population. Allogeneic hematopoietic stem cell transplantation (HSCT), a curative approach but one that involves more risks, is now offered as later-line therapy after failure of TKIs.

INCIDENCE AND EPIDEMIOLOGY

CML accounts for ~15% of all cases of leukemia. There is a slight male predominance (male-to-female ratio 1.6:1). The median age at diagnosis is 55–65 years. It is uncommon in children; only 3% of patients with CML are younger than 20 years, although in recent years, a higher proportion of young patients have been diagnosed. The incidence of CML increases gradually with age, with a steeper increase after the age of 40–50 years. The annual incidence of CML is 2 cases per 100,000 individuals. In the United States, this translates into about 9000 new cases per year. The incidence of CML has not changed over several decades. By extrapolation, the worldwide annual incidence of CML is about 250,000 cases. With a median survival of 3–6 years before 2000, the disease prevalence in the United States was ~30,000 cases. With TKI therapy, the annual mortality has been reduced from 10–20% to about 1–2%. Therefore, the prevalence of CML is expected to continue to increase. Based on these estimates (incidence of 9000 cases, annual mortality of 2%), the plateau prevalence of CML is estimated to be reached at ~450,000 in the United Stated (9000 × 100/2) by about 2040, with full TKI optimal treatment penetration. The worldwide prevalence will depend on the treatment penetration of TKIs and their effect on reduction of worldwide annual mortality. Ideally, with full TKI treatment penetration, the worldwide prevalence should plateau at 35 times the incidence, or ~9–10 million patients. These estimates are based on extrapolations from the incidence and prevalence of CML in the United States, as well as an estimated annual mortality of 2% with modern TKI therapy; they could vary considerably if the estimates were to change.

ETIOLOGY

There are no familial associations in CML. The risk of developing CML is not increased in monozygotic twins or in relatives of patients with CML. No etiologic agents are incriminated, and no associations exist with exposures to benzene or other toxins, fertilizers, insecticides, or viruses. CML is not a frequent secondary leukemia following therapy of other cancers with alkylating agents and/or radiation. Exposure to ionizing radiation (e.g., nuclear accidents, higher doses of radiation treatment) has increased the risk of CML, which peaks at 5–10 years after exposure and is dose-related. The median time to development of CML among atomic bomb survivors was 6.3 years. Following the Chernobyl accident, no increase in the incidence of CML was reported, suggesting that larger dose exposures of radiation are required to cause CML. Because of adequate protection, the risk of CML has not

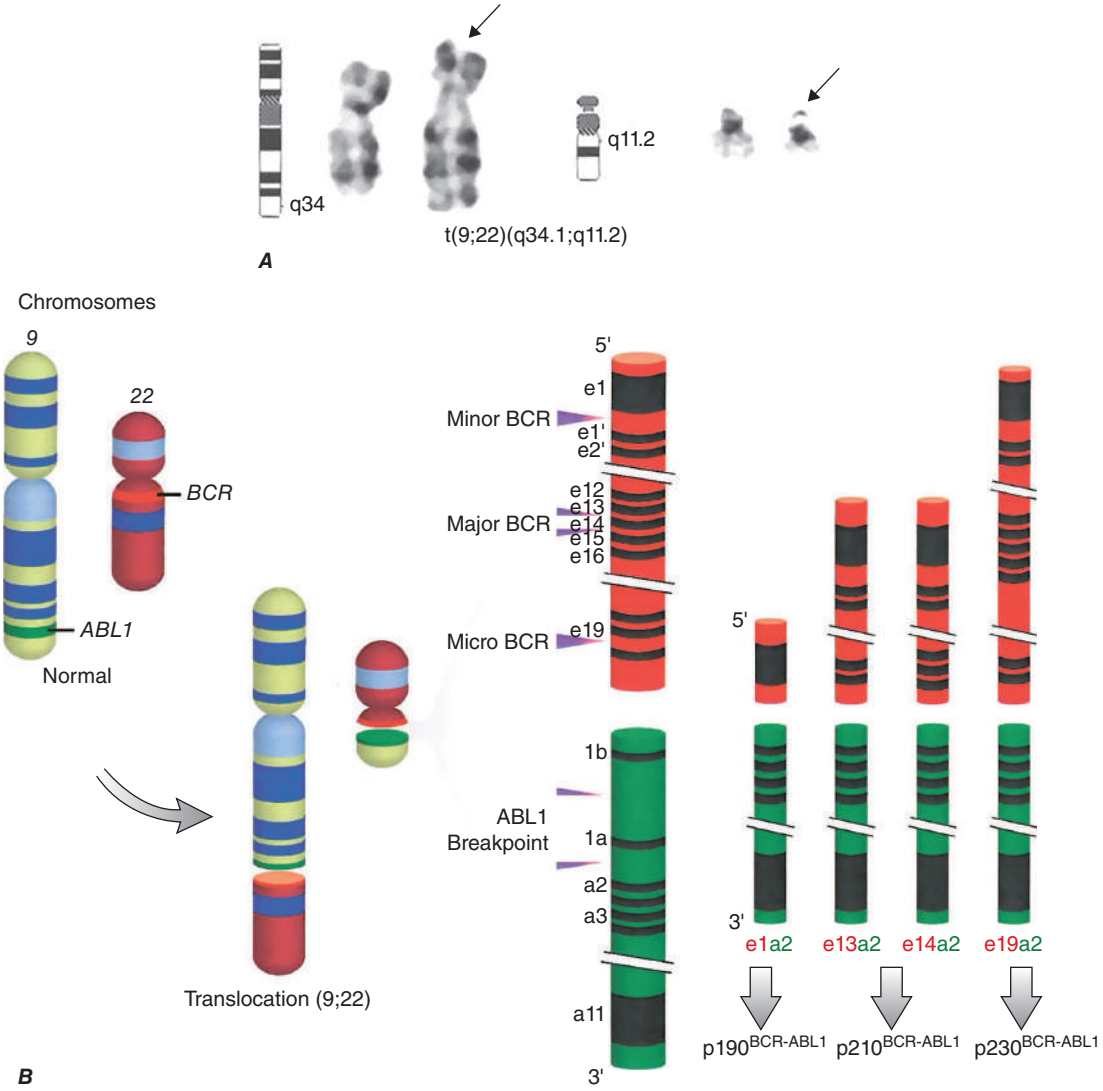

FIGURE 110-1 ***A.*** The Philadelphia (Ph) chromosome cytogenetic abnormality. ***B.*** Breakpoints in the long arms of chromosome 9 (*ABL1* locus) and chromosome 22 (*BCR* regions) result in at least three different BCR::ABL1 oncoprotein messages, $p210^{BCR::ABL1}$ (most common message in chronic myeloid leukemia [CML]), $p190^{BCR::ABL1}$ (present in two-thirds of patients with Ph-positive acute lymphoblastic leukemia; rare in CML), and $p230^{BCR::ABL1}$ (rare in CML and associated with an indolent course). Other rearrangements (e.g., e14a3, e14a3) are less common. *(© 2013 The University of Texas MD Anderson Cancer Center.)*

increased among individuals working in the nuclear industry or among radiologists.

PATHOPHYSIOLOGY

The t(9;22)(q34.1;q11.2) is present in >90% of classical CML cases. It results from a balanced reciprocal translocation between the long arms of chromosomes 9 and 22. It is present in hematopoietic cells (myeloid, erythroid, megakaryocytes, and monocytes; less often mature B lymphocytes; rarely mature T lymphocytes, but not stromal cells), but not in other cells in the human body. As a result of the genetic translocation, DNA sequences from the cellular *ABL* proto-oncogene 1 (*ABL1*) are juxtaposed to the major breakpoint cluster region (*BCR*) gene on chromosome 22, generating a hybrid *BCR::ABL1* oncogene. Depending on the breakpoint site in the major *BCR* region on chromosome 22 (e13 or e14), two main messenger RNA transcripts occur, e13a2 (previously b2a2) and e14a2 (previously b3a2). Both transcripts encode for a novel oncoprotein of molecular weight 210 kDa, referred to as $p210^{BCR::ABL1}$ (**Fig. 110-1*B***). This oncoprotein exhibits constitutive kinase activity that leads to increased proliferation and reduced apoptosis of CML cells, endowing them with a growth advantage over their normal counterparts. Over time, normal hematopoiesis is suppressed, but normal stem cells can persist and reemerge following effective anti-CML therapy, for example with TKIs. In two-thirds of patients with Ph-positive acute lymphoblastic leukemia (ALL) and in rare cases of CML, the breakpoint in *BCR* is more centromeric, in a region called the minor *BCR* region (*mBCR*). As a result, a shorter sequence of *BCR* is fused to *ABL1*, with a consequent e1a2 transcript and a smaller BCR::ABL1 oncoprotein, $p190^{BCR::ABL1}$. When occurring in Ph-positive CML, this translocation is associated with a worse outcome. A rarer breakpoint in *BCR* occurs telomeric to the major *BCR* region in the *micro-BCR* (μ-BCR) region. It juxtaposes a larger fragment of the *BCR* gene to *ABL1* and produces an e19a2 transcript and a larger $p230^{BCR::ABL1}$ oncoprotein (associated with a more indolent CML course). Other rearrangements (based on different breakpoints in the *ABL* region), such as e13a3 or e14a3 (also resulting in a $p210^{BCR::ABL1}$ oncoprotein), occur much less frequently. These are not readily identifiable nor quantifiable with the routine polymerase chain reaction (PCR) probes, thus producing falsely negative PCR levels on follow-up studies if not tested at diagnosis.

The constitutive activation of *BCR::ABL1* results in autophosphorylation and activation of multiple downstream pathways that affect gene transcription, apoptosis, stromal adherence, skeletal organization, and degradation of inhibitory proteins. These transduction pathways involve RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol-3-kinase (PI3k), MYC, and others. These interactions are mostly

mediated through tyrosine phosphorylation and require binding of BCR::ABL1 to adapter proteins such as GRB-2, CRK, CRK-like (CRK-L) protein, and Src homology containing proteins (SHC). Most BCR::ABL1 TKIs (imatinib, dasatinib, bosutinib, nilotinib, ponatinib) bind to the BCR::ABL1 ATP-binding domain, inhibiting its kinase activity, preventing the activation of transformation pathways, and inhibiting downstream signaling. As a result, proliferation of CML cells is inhibited and apoptosis induced, allowing the reemergence of normal hematopoiesis. An additional layer of complexity in CML is related to differences in signal transduction between CML-differentiated cells and early progenitors. Beta-catenin, Wnt1, Foxo3a, transforming growth factor β, interleukin 6, PP2A, SIRT1, and others have been implicated in CML stem cell survival. ABL1 also has a myristoyl site that functions as a negative regulator of its kinase activity. This site and its negative regulatory activity are lost upon fusion with BCR. Asciminib, a novel "third-generation" TKI (third generation refers to novel TKIs that inhibit the *ABL1*-T315I-mutated CML disease, such as ponatinib), is the first-in-class TKI that works through a novel mechanism that specifically targets the ABL1 myristoyl pocket (STAMP is an acronym for specifically targets the ABL1 myristoyl pocket). Asciminib binds this myristoyl site and restores the lost inhibitory activity. Mutations in other cancer-associated genes may also occur at diagnosis, most frequently in *ASXL1*, *IKZF1*, and *RUNX1*. Their significance is being clarified. Some reports suggest that their presence may be associated with worse response to TKI therapy and a higher risk of transformation to blastic phase. An *ASXL1* mutation is often associated with a higher incidence of recurrent cytopenias on TKI therapy, resulting in frequent treatment interruptions, TKI dose reductions, failure to achieve optimal therapeutic milestones, and the need to proceed to allogeneic HSCT.

Experimental models have established the causal relationship between the *BCR::ABL1* rearrangement and the development of CML. In animal models, expression of *BCR::ABL1* in normal hematopoietic cells produced CML-like disorders or lymphoid leukemia, demonstrating the leukemogenic potential of *BCR::ABL1* as a single oncogenic abnormality. Other models, however, suggest the need for a "second hit."

The cause of the *BCR::ABL1* rearrangement is unknown. Molecular techniques that detect *BCR::ABL1* at a level of 1 in 10^8 cells identify this molecular abnormality in the blood of up to 25% of normal adults and 5% of infants, but 0% of cord blood samples. This suggests that *BCR::ABL1* is not sufficient to cause overt CML in the overwhelming majority of individuals in whom it occurs. Because CML develops in only 2 of 100,000 individuals annually, additional molecular events or poor immune recognition of the rearranged cells may contribute to overt CML.

CML is defined by the presence of the *BCR::ABL1* fusion gene in a patient with a myeloproliferative neoplasm. In some patients with a typical morphologic picture of CML, the Ph chromosome is not detectable by standard G-banding karyotype, but fluorescence in situ hybridization (FISH) and/or molecular studies (PCR) detect *BCR::ABL1*. These patients have a course similar to patients with Ph-positive CML and respond to TKI therapy. Many of the remaining patients have atypical morphologic or clinical features and have other diseases, such as atypical CML, chronic myelomonocytic leukemia, and myelodysplastic syndrome/myeloproliferative neoplasms (MDS/MPN). These individuals do not respond to TKI therapy and usually have a poor prognosis with a median survival of ~2–3 years. Detection of mutations in the granulocyte colony-stimulating factor receptor (*CSF3R*) in chronic neutrophilic leukemia (80% of cases) and in some cases of atypical CML (5–10% of cases), mutations in *SETBP1* in atypical CML (25% of cases), and mutations in *SF3B1* in MDS/MPN with ringed sideroblasts and marked thrombocytosis (MDS/MPN-RS-T; 50–70% of cases, associated with longer median survival of 7 years vs 3.3 years with wild-type *SF3B1*) supports the notion that these are distinct molecular and biologic entities. Patients with chronic neutrophilic leukemia or atypical CML whose disease is associated with *CSF3R* mutation may respond to ruxolitinib (a JAK2 inhibitor) therapy (complete response rate 50–60%).

The events associated with the transition of CML from a chronic to the accelerated-blastic phase are poorly understood. Characteristic chromosomal abnormalities such as a double Ph, trisomy 8, isochromosome 17 or deletion of 17p (loss of *TP53*), 20q–, translocations involving 3q26, and others may be noted with disease acceleration. Molecular events associated with transformation include mutations in *TP53*, retinoblastoma 1 (*RB1*), myeloid transcriptions factors like *RUNX1*, and cell cycle regulators like *p16*. A plethora of other mutations or functional abnormalities have been implicated in blastic transformation, but no unifying theme has emerged other than the fact that *BCR::ABL1* itself induces genetic instability that favors the acquisition of additional molecular defects and eventually results in blastic transformation. One critical effect of TKIs is to stabilize the CML genome, leading to a reduced transformation rate. In particular, the previously observed sudden blastic transformations (i.e., abrupt transformation to blastic phase in a patient who had been in cytogenetic response) have become uncommon, occurring rarely in younger patients in the first 1–2 years of TKI therapy (usually sudden lymphoid blastic transformation). Sudden blastic transformations beyond the third year of TKI therapy are rare in patients who continue on TKI therapy. The incidence of any CML blastic transformation is now reduced to 5–6% at 10 years. Moreover, the course of CML is now frequently more indolent in patients treated with TKI, even without cytogenetic response, compared to previous experience with hydroxyurea/busulfan, suggesting a definite clinical benefit of continued inhibition of the kinase activity.

Among patients developing resistance to TKIs, several resistance mechanisms have been observed. The most clinically relevant one is the development of *ABL1* kinase domain mutations that may prevent the binding of TKIs to the catalytic site (ATP-binding site) of the kinase or maintain the kinase activity despite the presence of a TKI. More than 100 *ABL1* kinase domain mutations have now been described, many of which confer relative or absolute resistance to imatinib. Consequently, second-generation (i.e., dasatinib, nilotinib, bosutinib) and third-generation TKIs (ponatinib, asciminib, olverembatinib [approved in China; ongoing trials worldwide since 2023]) were developed. All three third-generation TKIs demonstrate significant efficacy against T315I, a "gatekeeper" mutation that prevents binding of, and causes resistance to, imatinib and the second-generation TKIs (dasatinib, bosutinib, nilotinib).

CLINICAL PRESENTATION

The presenting signs and symptoms in CML depend on the availability of and access to health care, including physical examinations and screening tests. In developed countries, because of the wider access to health care screening and physical examinations, 50–60% of patients are diagnosed on routine blood tests and have minimal symptoms at presentation, such as fatigue. In geographic locations where access to health care is more limited, patients often present with high CML disease burden including splenomegaly, anemia, and related symptoms (abdominal pain, weight loss, fatigue), associated with a higher frequency of high-risk CML. Presenting findings in patients diagnosed in the United States are shown in **Table 110-1**.

Symptoms Most patients with CML (90%) present in the indolent or chronic phase. Depending on the timing of diagnosis, patients are often asymptomatic (if the diagnosis is discovered during health care screening tests). Common symptoms, when present, are manifestations of anemia and splenomegaly. These include fatigue, malaise, weight loss (if high leukemia burden), or early satiety and left upper quadrant pain or masses (from splenomegaly). Less common presenting findings include thrombotic or hyperviscosity-related events from severe leukocytosis or thrombocytosis. These include priapism, cardiovascular complications, myocardial infarction, venous thrombosis, visual disturbances, dyspnea and pulmonary insufficiency, drowsiness, loss of coordination, confusion, or cerebrovascular accidents. Manifestations of bleeding diatheses include retinal hemorrhages, gastrointestinal bleeding, and others. Patients who present with, or progress to, the accelerated or blastic phases frequently have additional symptoms including unexplained fever, significant weight loss, severe fatigue, bone and joint pain, bleeding and thrombotic events, and infections.

TABLE 110-1 Presenting Signs and Symptoms of Newly Diagnosed Philadelphia Chromosome–Positive Chronic Myeloid Leukemia in Chronic Phase

PARAMETER	PERCENTAGE
Age ≥60 years (median)	40–50 (55–65)
Female gender	35–45
Splenomegaly	30
Hepatomegaly	5–10
Lymphadenopathy	5
Other extramedullary disease	2
Hemoglobin <10 g/dL	10–15
Platelets	
>450 × 10^9 cells/L	30–35
<100 × 10^9 cells/L	3–5
White blood cells ≥50 × 10^9 cells/L	35–40
Marrow	
≥5% blasts	5
≥5% basophils	10–15
Peripheral blood	
≥3% blasts	8–10
≥7% basophils	10
Additional chromosomal abnormalities (other than the Philadelphia chromosome)	4–5
Sokal risk	
Low	60–65
Intermediate	25–30
High	10

Physical Findings Splenomegaly is the most common physical finding, occurring in 20–70% of patients depending on health care screening frequency. Less common findings include hepatomegaly (5–10%), lymphadenopathy (5%), and extramedullary disease (skin or subcutaneous lesions). The latter indicates CML transformation if a biopsy confirms predominance of blasts. Other physical findings are manifestations of complications of high tumor burden described earlier (e.g., cardiovascular, cerebrovascular, bleeding). High basophil counts may be associated with histamine overproduction causing pruritus, diarrhea, flushing, and even gastrointestinal ulcers.

Hematologic and Marrow Findings In untreated CML, leukocytosis ranging from 10–500 × 10^9/L is common. The peripheral blood differential shows left-shifted hematopoiesis with predominance of neutrophils and the presence of bands, myelocytes, metamyelocytes, promyelocytes, and blasts (usually ≤5%). Basophils and/or eosinophils are frequently increased. Thrombocytosis is common, but thrombocytopenia is rare and, when present, suggests a worse prognosis, disease acceleration, or an unrelated etiology. Anemia is present in one-third of patients. Cyclic oscillations of counts are noted in 10–20% of patients without treatment. Biochemical abnormalities include a low leukocyte alkaline phosphatase score and high levels of vitamin B_{12}, uric acid, lactic dehydrogenase, and lysozyme. The presence of unexplained and sustained leukocytosis, with or without splenomegaly, should lead to a marrow examination and cytogenetic analysis.

The bone marrow is hypercellular with marked myeloid hyperplasia and a high myeloid-to-erythroid ratio of 15–20:1. Marrow blasts are typically 5% or less; when higher, they carry a worse prognosis or represent transformation to accelerated phase (if they are ≥15%). Increased reticulin fibrosis (detected with silver stain) is common, with 30–40% of patients demonstrating grade 3–4 reticulin fibrosis. This was considered adverse in the pre-TKI era. With TKI therapy, reticulin fibrosis resolves in most patients and is not an indicator of poor prognosis. Collagen fibrosis (Wright-Giemsa stain) is rare at diagnosis. Disease progression with a "spent phase" of myelofibrosis (myelophthisis, or burnt-out marrow) was a common end-stage CML condition with busulfan therapy (20–30%); it is extremely rare now with TKI therapy.

Cytogenetic and Molecular Findings The diagnosis of CML is straightforward and depends on documenting the translocation t(9;22)(q34.1;q11.2), which is identified by G-banding in 90% of cases. This is known as the Philadelphia chromosome (initially identified in Philadelphia as a minute chromosome; later identified to be chromosome 22) (Fig. 110-1). Some patients (~10%) may have complex translocations (complex variant Ph) involving three or more chromosomes including chromosomes 9 and 22 and one or more additional chromosomes. Others may have a "masked Ph," involving translocations between chromosome 9 and a chromosome other than 22 (but molecularly showing the *ABL1* rearrangement; known as simple variant Ph). The prognosis of these patients and their response to TKI therapy are like those in patients with Ph. Translocation (9;22)(q34;p13)/*ETV6*::*ABL1* is now classified as a myeloproliferative neoplasm-eosinophilia and may respond better to second-generation TKIs. About 5–10% of patients may have additional chromosomal abnormalities (ACAs) in the Ph-positive cells at diagnosis. These usually involve trisomy 8, a double Ph, isochromosome 17 or 17p deletion, 20q–, or others. This was historically a sign of adverse prognosis, particularly when trisomy 8, double Ph, or chromosome 17 abnormalities were noted. A less common abnormality involving chromosome 3q26.2 occurs with disease progression and carries a poor prognosis.

Techniques such as FISH and PCR are now used to aid in the diagnosis of CML. They are more sensitive to estimate the CML burden in patients on TKI therapy. They can be done on peripheral blood and thus are more convenient to patients. Patients with CML at diagnosis should have a FISH analysis to quantify the percentage of Ph-positive cells, if FISH is used to replace marrow cytogenetic analysis in monitoring response to therapy. FISH will not detect additional chromosomal abnormalities; thus, a cytogenetic analysis is recommended at the time of diagnosis. In addition, 10–15% of patients may develop chromosomal abnormalities in Ph-negative metaphases after responding to TKIs. These abnormalities may carry a worse prognosis but are not detected by FISH unless already identified and FISH is used to follow them. Molecular studies at diagnosis are important to document the type and presence of *BCR*::*ABL1* transcripts to avoid spurious "undetectable" *BCR*::*ABL1* transcripts on follow-up studies, with the false impression of a complete molecular response. The presence of the Philadelphia chromosome with "negative" PCR with standard methodology should prompt investigation of atypical transcripts (e13a3, e14a3, e19a2, others).

Both FISH and PCR studies can be falsely positive at low levels or falsely negative because of technical issues. Therefore, a diagnosis of CML must always rely on a marrow analysis with routine cytogenetics. The diagnostic bone marrow confirms the presence of the Ph chromosome, detects additional chromosomal abnormalities, and quantifies the percentage of marrow blasts and basophils. In 10% of patients, the percentage of marrow blasts and basophils can be significantly higher than in the peripheral blood, conferring poorer prognosis or even representing disease transformation.

Monitoring patients on TKI therapy by cytogenetics, FISH, and PCR has become an important standard practice to assess response to therapy, emphasize compliance, evaluate possible treatment resistance, identify the need to change TKI therapy, and determine the need to assess for kinase domain mutations. Because of the decreasing reliance of bone marrow aspirations to monitor response, equivalence has been established to correlate cytogenetic results with PCR values. These are not absolute correlations but provide adequate guidance. A partial cytogenetic response is defined as the presence of 35% or less Ph-positive metaphases by routine cytogenetic analysis. This is roughly equivalent to *BCR*::*ABL1* transcripts on the International Scale (IS) of 10% or less. A complete cytogenetic response refers to the absence of Ph-positive metaphases (0% Ph positivity). This is approximately equivalent to *BCR*::*ABL1* transcripts (IS) ≤1% (MR2). A major molecular response (MMR or MR3) refers to *BCR*::*ABL1* transcripts (IS) ≤0.1%, or roughly a 3-log or greater reduction of *BCR*::*ABL1* transcripts from

a standardized baseline. MR4 (deep molecular response; DMR) refers to *BCR::ABL1* transcripts (IS) ≤0.01%, and MR4.5 refers to *BCR::ABL1* transcripts (IS) ≤0.0032%, roughly equivalent to a 4.5-log reduction or greater of transcripts.

Findings in CML Transformation Progression of CML is usually associated with leukocytosis resistant to therapy, increasing anemia, fever and constitutional symptoms, and increased blasts and basophils in the peripheral blood or marrow. Criteria of accelerated-phase CML, historically associated with median survival of <2 years, include the presence of 15% or more peripheral blasts, 30% or more peripheral blasts plus promyelocytes, 20% or more peripheral basophils, cytogenetic clonal evolution (presence of additional chromosomal abnormalities other than Ph), and thrombocytopenia <100 × 10^9/L (unrelated to therapy). About 5–10% of patients present with de novo accelerated phase or blastic phase. The prognosis of de novo accelerated phase with TKI therapy has improved, with an estimated 8-year survival rate of 60–70%. The median survival of accelerated phase evolving from chronic phase has also improved from a historical median survival of 18 months to an estimated 3-year survival rate of 50% on TKI therapy. Therefore, the criteria for accelerated-phase CML should be revisited because most clinical criteria defining accelerated phase have lost much of their prognostic significance. The newest World Health Organization (WHO) classification suggested eliminating accelerated-phase CML as an entity and classifying such patients as high-risk CML. However, the survival of patients with both de novo and evolved accelerated-phase CML is significantly worse than in high-risk CML. The accelerated-phase definition should be maintained in order to recognize such patients and treat them differently than chronic-phase CML, either with existing standards of care (combinations of TKIs with other agents, allogeneic HSCT) or on investigational trials of novel TKIs or other modalities. Blastic-phase CML is defined by the presence of 30% or more peripheral or marrow blasts or the presence of sheets of blasts in extramedullary disease (usually skin, soft tissues, or lytic bone lesions). Blastic-phase CML is commonly myeloid (60%) but can present uncommonly as erythroid, promyelocytic, monocytic, or megakaryocytic. Lymphoid blastic phase occurs in about 25% of patients. Lymphoblasts are terminal deoxynucleotide transferase positive and peroxidase negative (although occasionally with low positivity up to 3–5%) and express lymphoid markers (CD10, CD19, CD20, CD22). They also often express myeloid markers (50–80%), resulting in diagnostic challenges. Proper immunophenotypic diagnosis is important because lymphoid blastic-phase CML is responsive to anti-ALL-type chemotherapy (e.g., hyper-CVAD [cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) in combination with TKIs and immunotherapies (complete response rate 70%; median survival 3 years; high rates of bridging to allogeneic HSCT and possible cure).

PROGNOSIS AND CML COURSE

Before the TKI era, the annual mortality in CML was 10% in the first 2 years and 15–20% thereafter. The median survival in CML was 3–7 years (with hydroxyurea-busulfan and interferon α). Without a curative option of allogeneic HSCT, the course of CML was toward transformation to, and death from, accelerated or blastic phases for most patients. Even disease stability was unpredictable, with some patients demonstrating sudden transformation to a blastic phase. With imatinib therapy, the annual mortality rate in CML has decreased to 1–2% in the first 20 years of observation. The 10-year survival rate is about 85%, the 10-year CML-specific survival rate is 90%, and CML-specific mortality rate is 10%; the 10-year incidence of blastic transformation is 5–6%. More than half of the deaths are from conditions other than CML, such as old age, comorbidities, accidents, suicides, other cancers, and other medical conditions (e.g., infections, surgical procedures) **(Fig. 110-2)**. The course of CML has also become quite predictable. In the first 2 years of TKI therapy, rare sudden transformations are still reported (1–2%), usually lymphoid blastic transformations that respond to combinations of chemotherapy and TKIs followed by allogeneic HSCT. These may be explained by the intrinsic mechanisms of sudden transformation already existing in the CML clones before the start of therapy that were not amenable to TKI inhibition, in particular imatinib. Second-generation TKIs (nilotinib, dasatinib, bosutinib) used as frontline therapy have reduced the incidence of transformation in the first 2–3 years from 4–6% with imatinib to 1–2% with second-generation TKIs. Disease transformation to accelerated or blastic phase is rare with continued TKI therapy, estimated at <1% annually in years 4–10 of follow-up. Patients usually develop resistance in the form of cytogenetic relapse, followed by hematologic relapse and subsequent transformation, rather than the previously feared sudden transformation without the warning signals of cytogenetic-hematologic relapse.

Before the imatinib era, several pretreatment prognostic factors predicted for worse outcome in CML and have been incorporated into prognostic models and staging systems. These have included older age, significant splenomegaly, anemia, thrombocytopenia or thrombocytosis, high percentages of blasts and basophils (and/or eosinophils), marrow fibrosis, additional chromosomal abnormalities, and others. The introduction of TKIs into CML therapy has decreased or eliminated the prognostic impact of these prognostic factors and the significance of the CML models (e.g., Sokal, Hasford, European Treatment and Outcome Study [EUTOS]). Treatment-related prognostic factors have emerged as the most important prognostic factors in the era of imatinib therapy. Achievement of complete cytogenetic response (MR2) has become the major therapeutic endpoint and is the only endpoint associated with improvement in survival. Achievement of MMR (MR3) is associated with decreased risk of events (relapse) and CML transformation but not with survival prolongation among patients with complete cytogenetic response. This may be due to the efficacy of salvage TKI therapies, which are implemented at the first evidence of cytogenetic relapse. Achievement of durable DMR (MR4/MR4.5) may offer the possibility of treatment-free remission (TFR). A durable DMR for 2+ years is associated with a TFR rate of 50%; a durable DMR for 5+ years is associated with a TFR rate of 80%+. A TFR may allow a temporary TKI therapy interruption in women pursuing pregnancy. The lack of achievement of MMR or DMR should not be considered as "failure" of a particular TKI therapy and/or an indication to change the TKI or to consider allogeneic HSCT.

Long-term updates of randomized trials suggest that second-generation TKIs and imatinib are similarly effective in lower-risk CML; second-generation TKIs may offer a therapeutic advantage in high-risk CML and when TFR is an important treatment endpoint (younger patients).

TREATMENT

Chronic Phase Chronic Myeloid Leukemia

Since 2001, six oral BCR::ABL1 TKIs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of CML. These include imatinib (Gleevec, Glivec), nilotinib (Tasigna), dasatinib (Sprycel), bosutinib (Bosulif), ponatinib (Iclusig), and asciminib (Scemblix). Dasatinib, nilotinib, and bosutinib are referred to as second-generation TKIs; ponatinib and asciminib are referred to as third-generation TKIs, a term also used generally for the more recently developed TKIs that are active against T315I-mutated CML (asciminib is also referred to as a STAMP inhibitor because of its different mechanism of action). Nilotinib is similar in structure to imatinib but 30 times more potent. Dasatinib and bosutinib inhibit the *SRC* family of kinases in addition to *ABL1*, with dasatinib reported to be 300 times more potent and bosutinib 30–50 times more potent than imatinib **(Table 110-2)**. Ponatinib inhibits vascular endothelial growth factor receptor (VEGFR), which may be partly responsible for the high incidence of hypertension observed with this agent (Table 110-2).

ESTABLISHED AND EVOLVING THERAPEUTIC CONCEPTS IN CML

In the early days of TKI development, the primary aim in CML therapy was to improve survival, as the therapeutic miracle of

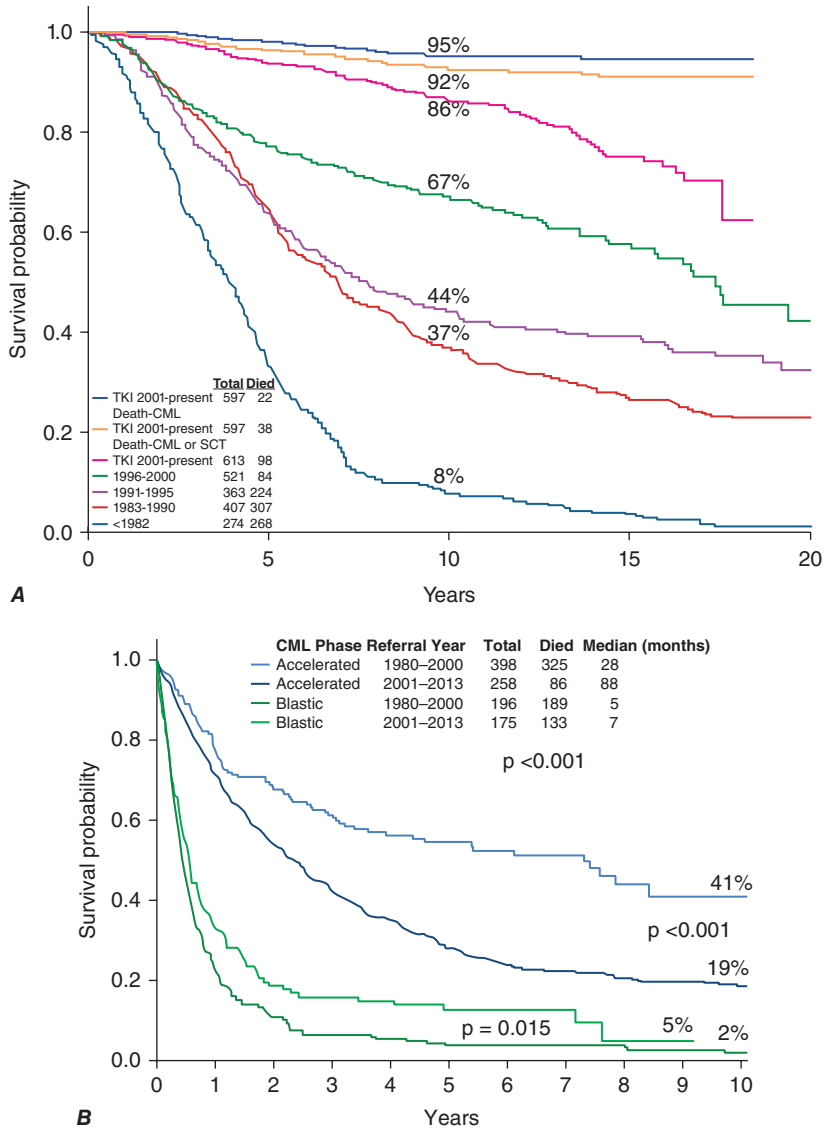

FIGURE 110-2 ***A.*** Survival in newly diagnosed chronic-phase chronic myeloid leukemia (CML) by era of therapy (MD Anderson Cancer Center experience from 1965 to present). Top blue curve is survival with tyrosine kinase inhibitors (TKIs), accounting for only CML-related deaths. The orange curve (second from top) accounts for deaths related to CML or CML treatment complications (e.g., deaths following allogeneic hematopoietic stem cell transplant [HSCT]). The red curve (third from top) is survival including all deaths regardless of causality (old age, car accidents, suicide, gun shots, second cancers, complications of unrelated surgeries, infections, others). The difference in the denominators, 613 minus 597 cases, is because 16 deaths were from unknown/undocumented causes (outside MD Anderson and no good tracking for cause of death). ***B.*** Survival in patients with accelerated- and blastic-phase CML referred to MD Anderson Cancer Center by era of therapy, demonstrating the significant survival benefit in the TKI era in accelerated-phase CML but the modest benefit in blastic-phase CML. Referred cases included de novo and post-chronic-phase transformations.

TABLE 110-2 Medical Therapeutic Options in Chronic Myeloid Leukemia

AGENT (BRAND NAME)	APPROVED INDICATIONS	DOSE SCHEDULE	NOTABLE TOXICITIES
Imatinib mesylate (Gleevec)	All phases	400 mg daily	See text
Dasatinib (Sprycel)	All phases	First-line: 100 mg daily Salvage: 100 mg daily in chronic phase; 140 mg daily in transformation	Myelosuppression; pleural and pericardial effusions; pulmonary hypertension
Nilotinib (Tasigna)	All phases except blastic phase	First-line: 300 mg twice daily Salvage: 400 mg twice daily	Diabetes; arterio-occlusive events; pancreatitis
Bosutinib (Bosulif)	All phases	First line: 400 mg daily Salvage: 500 mg daily	Diarrhea; liver toxicity; renal dysfunction
Ponatinib (Iclusig)	T315I mutation; failure of ≥2 tyrosine kinase inhibitors	45 mg daily (may consider lower starting doses, e.g., 30 mg daily; lower the dose to 15 mg daily once a complete cytogenetic response is achieved)	Skin rashes (10–20%); pancreatitis (5%); arterio-occlusive events (10–20%); systemic hypertension (10–15%)
Asciminib (Scemblix)	Third-line therapy; T315I mutation	40 mg twice daily or 80 mg daily; T315I: 200 mg twice daily	Arterial occlusive events; hypertension; (others?)
Omacetaxine mepesuccinate (Synribo)	Failure ≥2 tyrosine kinase inhibitors	1.25 mg/m^2 subcutaneously twice daily for 14 days of induction; 7 days of maintenance every month (consider shorter dose schedules, 7 days of induction, 2–5 days of maintenance)	Myelosuppression

near-normal survival with TKI therapy was never anticipated. It was thought that CML cells would develop resistance mechanisms after a period of TKI exposure. This happened, as CML was the first tumor demonstrating the development of mutations in the ABL1 kinase domain that prevented the binding of the TKIs. However, the true resistance rate was only 10% after 10 years of imatinib exposure. The TKIs were developed at a dose level below the maximum tolerated dose (MTD; traditional development of chemotherapy agents in cancer), based on the toxicities noted in the first one to two courses or few months of therapy. As the success of therapy required treatment continuation for years, or even a patient's lifetime, additional unanticipated toxicities were observed with long-term exposures. This shifted the concept to develop these targeted therapies in CML (and in other cancers) at an "optimal biologic dose" (OBD; a dose that presumably maintains the same efficacy but reduces toxicities). Such OBDs were derived initially from clinical experience in CML, although ongoing trials are basing them on translational studies of the drug exposure and target modulation, compared with preclinical research findings. This led, in CML, to study dasatinib 50 mg daily as frontline therapy, which proved to be as effective and less toxic than 100 mg daily. Similar results were reported with other TKIs where dose adjustments after achieving a good molecular response maintained efficacy. Other early concepts included the following: (1) changing a TKI if evidence of toxicity (rather than lowering the TKI dose, with the concern being that lowering the TKI dose will compromise efficacy and cause resistance); (2) changing a TKI if the National Comprehensive Cancer Network (NCCN)/European Leukemia Network (ELN) landmark-defined milestones of "failure" or "warning" were noted; and (3) changing TKI therapy in a responding patient (MMR or even MR4), in order to achieve a complete molecular response and aim for a TFR status. As experience matured, it was noted that such strategies may be harmful, as they increased the cost of therapy and increased the risk of potential additional side effects, without benefiting patients. At present, therapy of CML may consider lower-dose schedules of TKIs as frontline or later-line therapy; reducing the TKI dose once a good molecular response (≥MR2) is achieved; not changing TKI therapy in patients in good molecular response; and perhaps not changing TKI therapy based on the NCCN/ELN milestones (as the long-term follow-up data showed survival to be favorable even among patients who did not achieve these molecular milestones). These concepts will be discussed further.

At the beginning of the TKI experience, survival prolongation was the primary goal of therapy, but once near-normal survival was accomplished, investigators started addressing additional treatment endpoints. Thus, a second treatment goal was whether CML is curable (defined, as in other cancers, as the ability to stop TKI therapy without disease recurrence after several years of observation). This led to studies aimed at stopping TKI therapy after 2–5 years of durable DMR and achieving a TFR status. The third treatment goal is to make TKI therapies available and affordable to all patients (rather than the few who can afford them), a problem addressed with the availability of generic TKIs. The fourth treatment goal is to minimize the early and long-term toxicities (currently addressed with studies investigating the OBDs of TKIs).

Frontline Therapy of CML Imatinib, dasatinib, bosutinib, and nilotinib are all acceptable frontline therapies in CML. The long-term results of imatinib are very favorable. The 10-year cumulative rate of MMR is 90%, and of DMR 80%. The 10-year survival rate was 82%, and 10-year relative (compared with age-matched population) survival rate 92%. About 25% had to change to second-generation TKIs, 10% because of resistance to imatinib and 15% for other reasons (adverse events). The 10-year incidence of blastic-phase CML was 5.8%. In multiple randomized studies, (e.g., ENESTnd, DASISION, BFORE), the second-generation TKIs resulted in better outcomes in early surrogate endpoints (higher rates of MMR and MR4.5; lower rates of blastic transformation). However, none showed survival benefit. This may be because the rate of complete cytogenetic response (MR2) was ultimately similarly high with imatinib versus second-generation TKIs and because later-line salvage TKI therapy (following close observation and treatment change at progression) provided highly effective therapy; this ensured adequate long-term outcome despite resistance or intolerance to initial imatinib therapy.

The choice of TKI frontline CML therapy depends on several factors: (1) the treatment aims (survival, TFR), which are tightly linked to age; (2) the TKI cost and affordability (generic vs patented TKIs); and (3) the patient comorbidities (e.g., avoid dasatinib if history of lung injury or chronic lung disease; avoid nilotinib if history of pancreatitis, diabetes mellitus, or arterio-/veno-occlusive spastic events; avoid bosutinib if history of liver or renal dysfunction of gastrointestinal problems [colitis, diverticulitis]). In general, if survival is the treatment aim in CML, all four TKIs achieve similar outcomes. However, if TFR is the treatment aim, then second-generation TKIs may be preferred. Second-generation TKIs may also be preferred in high-risk chronic-phase CML. Two additional important aims include the comparative long-term toxicities and the TKI treatment value.

The frontline TKI dose schedules are as follows: imatinib 400 mg orally daily; dasatinib 100 mg orally daily; bosutinib 400 mg orally daily (use dose escalation of 100–200 mg daily for 1–2 weeks, 300 mg daily for 2 weeks, then 400 mg daily to avoid the early self-limited gastrointestinal toxicity [diarrhea, nausea, and vomiting]); and nilotinib 300 mg orally twice a day (on an empty stomach). Dasatinib 50 mg orally daily is as effective in frontline therapy as 100 mg daily and significantly less toxic.

A recent randomized trial compared asciminib to investigator's TKI of choice in frontline CML therapy. The 12-month MMR was significantly higher with asciminib versus other TKIs (68% vs 49%; p<.001) and with asciminib versus imatinib (69% vs 40%); p<.001), but not with asciminib versus second-generation TKIs (66% vs 58%). Whether the higher MMR rate will translate into better long-term survival or TFR rates, lower long-term side-effects, or better treatment value is an open question.

Management of TKI Toxicities In the first 10–15 years of the TKI experience, it was common practice to change TKI therapy when toxicities occurred because of the erroneous assumption that reducing the TKI dose may reduce efficacy. This was not borne out in the long-term experience, particularly in patients who are in good molecular response. Among such patients, the TKI dose can be reduced for mild-moderate or even severe reversible toxicities. Imatinib can be reduced to 100–300 mg daily, dasatinib to 20–50 mg daily, nilotinib to 200 mg daily or 150 mg twice daily, bosutinib to 100–300 mg daily, and ponatinib to 15–30 mg daily, depending on the toxicities and molecular response.

Side effects of TKIs are generally mild to moderate, although with long-term TKI therapy, they could affect the patient's quality of life. Serious side effects occur in <5–10% of patients. With imatinib therapy, common mild to moderate side effects include fluid retention, weight gain, nausea, diarrhea, skin rashes, periorbital edema, bone or muscle aches, fatigue, and others (rates of 10–20%). In general, second-generation TKIs are associated with lower rates of these bothersome adverse events. However, dasatinib 100 mg daily is associated with higher rates of myelosuppression (20–30%), particularly thrombocytopenia; pleural (10–25%) or pericardial effusions (≤5%); and pulmonary hypertension (<5%). A lower dose of dasatinib (50 mg daily instead of 100 mg daily) used in frontline CML therapy resulted in similar efficacy and a lower incidence of serious side effects (pleural effusions <5%, myelosuppression <10%). Nilotinib is associated with higher rates of hyperglycemia (10–20%), pruritus and skin rashes, hyperbilirubinemia (typically among patients with Gilbert's syndrome and mostly of no clinical consequences), and headaches. Nilotinib is also associated with occasional instances of pancreatitis (<5%). Nilotinib 300–400 mg

twice daily is associated with a 10-year cumulative incidence of cardiovascular complications of 25–35%. Bosutinib is associated with higher rates of liver toxicity, renal dysfunction, and early and self-limited gastrointestinal adverse events, particularly diarrhea. Occasionally, the gastrointestinal symptoms mimic chronic severe enterocolitis, which reverses with treatment discontinuation. Ponatinib 45 mg daily is associated with higher rates of serious skin rashes (10–15%), pancreatitis (10%), elevations of amylase/lipase (10%), and systemic hypertension (50–60%; severe in 20%). Arterio-occlusive events (cardiovascular, cerebrovascular, and peripheral arterial) have been reported with most TKIs. The incidence appears to be highest with ponatinib, but both nilotinib and dasatinib are associated with these events at an incidence significantly higher than imatinib or bosutinib. Among the TKIs, imatinib and bosutinib are associated with the lowest incidence of cardiovascular events.

With long-term follow-up, rare but clinically relevant serious toxicities are emerging. Renal dysfunction and occasionally renal failure (creatinine elevations >2–3 mg/dL) are observed in 2–3% of patients, more frequently with imatinib and bosutinib than other TKIs, and usually reverse with TKI discontinuation and/or dose reduction. Rarely, patients may develop TKI-related peripheral neuropathy or even central neurotoxicities that are misdiagnosed as dementia or Alzheimer's disease; these may reverse slowly after TKI discontinuation.

Some toxicities are prohibitive and require a change of TKI therapy: recurrent pleural effusions (most commonly with dasatinib; least with imatinib and nilotinib; responsive to a short course of steroids); vasospastic or vaso-occlusive events (cerebrovascular accidents, myocardial infarction or unstable angina; more common with ponatinib and nilotinib; least with imatinib and bosutinib); pulmonary hypertension (1–2% with dasatinib, but can occur with other TKIs; slowly reversible with a short course of steroids and sildenafil citrate), pancreatitis (2% with nilotinib, 2–4% with ponatinib); neurologic problems (dementia-like, parkinsonism; rare and slowly reversible with TKI discontinuation); immune-mediated events (pneumonitis, myocarditis, pericarditis, hepatitis, nephritis; usually reversible with TKI discontinuation and a short course of high-dose steroids [e.g., methylprednisolone 50 mg twice daily for 3–5 days]); and severe colitis (bosutinib; reversible with discontinuation).

When switching TKI therapy for prohibitive toxicity, the dose of the new TKI does not have to be the dose recommended for "failure" (a term that historically encompassed resistance and intolerance). Many of these patients are already in good molecular response, and the dose of the new TKI used for previous TKI intolerance can be lower, particularly if the patient is already in ≥MR2: dasatinib 20–50 mg daily; bosutinib 100–300 mg daily; nilotinib 200 mg daily or 150 mg twice a day; ponatinib 15–30 mg daily.

TKI cross-intolerance may be more common than previously thought. Because the TKIs have different chemical structures, cross-intolerance was thought to be uncommon. With experience, it appears that patients who have intolerance to one TKI may more often have intolerance to others, with the intolerance/side effect manifesting as the same or as a different one.

Discontinuation of TKIs and TFR Several studies have confirmed that TKI discontinuation among patients who achieve DMR (MR4) for longer than 2–3 years can result in TFR rates of 40–60%. Discontinuation of TKI therapy after 5+ years of DMR is associated with TFR rates of 80%+. Since the incidence of durable MR4 is 60–80%, ~30–60% of all patients with CML on TKI therapy may potentially achieve TFR with optimization of the current TKI strategies. Suggested conditions to attempt TFR include low or intermediate Sokal risk CML in first chronic phase (no evidence or history of transformation); quantifiable *BCR::ABL1* transcripts (e13a2, e14a2); long-term TKI therapy (5+ years); and documented DMR for >2–5 years. Once TFR is attempted, patients should be monitored molecularly every 1.5–2 months in the first 6–12 months, every 2–3 months in the second year, and then every 3–6 months in subsequent years (perhaps for up to 6–8 years of TFR status). TKIs should not be restarted unless the *BCR::ABL1* transcripts (IS) increase to >0.1% (documented at least twice).

Management of TKI Resistance Resistance to a TKI refers today to *BCR::ABL1* transcripts (IS) >10% after 6 months of TKI frontline therapy or *BCR::ABL1* transcripts (IS) >1% after 12+ months of frontline TKI therapy. The NCCN and ELN updates of the criteria for resistance and suboptimal response have evolved over time, settling on more conservative criteria to change TKI therapy. The long-term follow-up studies have shown that patients who previously met suboptimal or resistance criteria still had excellent long-term survival without changing TKI therapy. For example, older patients with persistent *BCR::ABL1* transcripts (IS) 1–10% at 2 years of imatinib therapy still had 10-year survival rates similar to those with transcripts <1%.

Before switching TKI therapy for resistance, it is important to check for BCR::ABL1 kinase domain mutations. About 50% of patients with TKI resistance have BCR::ABL1 mutations that may selectively respond to particular TKIs. For example, mutations involving Y253H, E255K/V, and F359V/C/I respond better to dasatinib or bosutinib. Mutations involving V299L, T315A, and F317L/F/I/C respond better to nilotinib. T315I mutations require therapy with ponatinib or asciminib and serious consideration of allogeneic HSCT.

Dasatinib, bosutinib, nilotinib, ponatinib, and asciminib are approved for CML salvage therapy. The second-generation TKIs are excellent second-line therapies after imatinib frontline resistance. In patients with resistance to one second-generation TKI, switching to another second-generation TKI yields poor results (MR2 rate 10–20%; unless specific guiding mutations), and switching to ponatinib is indicated. Ponatinib is a very potent TKI with high activity in T315I-mutated CML and in CML after two TKI exposures (particularly if there is resistance to a second-generation TKI). In third-line therapy, ponatinib produces high molecular response rates and improves survival compared with second-generation TKIs. Asciminib is approved as third-line therapy and for T315I-mutated disease.

The TKI dose schedule in later-line therapy for CML resistance is as follows: dasatinib 100 mg daily; nilotinib 400 mg twice daily; bosutinib 500 mg daily; ponatinib 45 mg daily; and asciminib 40 mg twice daily or 80 mg once daily or 200 mg twice daily in T315I-mutated CML. Because ponatinib 45 mg daily may be associated with serious side effects, a response-directed dose-adjusted regimen (starting dose of 45 mg and reduction to 15 mg once MR2 is achieved) was investigated and resulted in a lower incidence of arterio-occlusive events.

TKI later-line therapy in chronic-phase CML with dasatinib, nilotinib, bosutinib, ponatinib, or asciminib is associated with MR2 rates of 30–80%, depending on the line of therapy (second vs later), CML status (cytogenetic/molecular relapse vs hematologic relapse), prior response to other TKIs, number of prior TKIs used, and the mutations at the time of relapse. The estimated 6- to 8-year survival rates with second-generation TKIs as second-line therapy are 65–75% (compared with <30–40% before their availability). Ponatinib third-line therapy resulted in an MR2 rate of 50–60%, MMR rate of 40%, and a 5-year overall survival rate of 70–75%. Its results appear even surprisingly better in real-word data: MR2 rate 80%, MMR rate 70–75%, and MR4 rate 40%.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT

Allogeneic HSCT, a curative modality in CML, is associated with long-term survival rates of 50–70% when implemented in chronic phase. It carries the risk of complications related to myelosuppression, infections, and graft-versus-host disease (GVHD). Consequently, the early (1-year) mortality rate is 5–30%, and 10–15% of

patients die in the subsequent 1–2 decades from long-term complications of the transplant (rather than from CML relapse). These are related to GVHD, organ dysfunction, development of second cancers, occasional late relapses, and hazard ratios for mortality higher than in the normal population. Other significant morbidities include infertility, chronic immune-mediated complications, cataracts, hip necrosis, and other morbidities affecting quality of life. The cure and early mortality rates in chronic-phase CML are also associated with several factors: patient age, duration of chronic phase, whether the donor is related or unrelated, degree of matching, preparative regimen, and others. In accelerated-phase CML, the cure rates with allogeneic HSCT are 30–50%, depending on the definition of accelerated disease. Patients with clonal evolution as the only criterion have cure rates of 40–50%. Patients undergoing allogeneic HSCT in second chronic phase have cure rates of 40–50%. The cure rates with allogeneic HSCT in blastic-phase CML are ≤20%. Post–allogeneic HSCT strategies in the setting of molecular or cytogenetic relapse include the use of TKIs for prevention or treatment of relapse, donor lymphocyte infusions, and second allogeneic HSCTs, among others. TKIs are successful at reinducing cytogenetic/molecular remissions in the setting of cytogenetic or molecular relapse after allogeneic HSCT.

Choice and Timing of Allogeneic HSCT Allogeneic HSCT was considered first-line CML therapy before 2000. The positive experience with TKIs has now relegated its use as a later-line approach. It should be considered in any patient in chronic-phase CML who develops resistance to a second-generation TKI or with a T315I-mutated disease. Relying on third-generation TKIs in these settings as long-term therapy can be very expensive ($250,000 to $1.5 million per year) and may be associated with serious toxicities. Among patients who present with or evolve to blastic phase, combinations of chemotherapy and TKIs should be used to induce remission, followed by allogeneic HSCT as soon as possible. The same applies to patients who evolve from chronic to accelerated phase. Patients with de novo accelerated-phase CML may do well with long-term TKI therapy (estimated 8-year survival rate 75%). Older patients with CML (age 65–70 years or older) have a reasonable CML-specific 10-year overall survival rate even with persistent molecular disease after 2 years of TKI therapy, with *BCR::ABL1* transcripts (IS) 1–10%, or even > 10%. Such patients may opt to continue on daily TKI therapy alone or with the addition of other agents (hydroxyurea, decitabine, low-dose cytarabine). They can then remain in chronic-phase CML disease without MR2 and avoid the adverse events and poorer quality of life associated with allogeneic HSCT.

MONITORING THERAPY IN CML

Achievement of complete cytogenetic response by 12 months of imatinib therapy and its persistence later, the only consistent prognostic factor associated with prolonged survival, is now the main therapeutic endpoint in CML. Failure to achieve a complete cytogenetic response by 12 months or occurrence of later cytogenetic or hematologic relapse is considered as treatment failure and an indication to change therapy. Because later-line TKI therapy may re-establish good outcome, it is important to ensure patient compliance to continued TKI therapy and change therapy when cytogenetic relapse is confirmed unless this is related to nonadherence. Patients on frontline imatinib therapy should be closely monitored until documentation of complete cytogenetic response, at which time they can be monitored every 6 months with peripheral blood PCR or more frequently (e.g., every 3 months) if there are concerns about changes in *BCR::ABL1* transcripts. Cytogenetic relapse on imatinib is an indication of treatment failure and need to change TKI therapy. Mutational analysis in this instance helps in the selection of the next TKI and identifies mutations in 30–50% of patients. Mutational studies by standard Sanger sequencing (which is the technique currently available in most clinical laboratories) in patients in complete cytogenetic response (in whom there may be concerns of increasing *BCR::ABL1* transcripts) identify mutations in ≤5% and are therefore not indicated.

Changes of TKI therapy for patients with "slow" molecular response have not been proven to be of long-term benefit compared to changes when more obvious signs of resistance appear.

TREATMENT OF ACCELERATED AND BLASTIC PHASES

Patients in accelerated or blastic phase may receive therapy with TKIs, preferably second- or third-generation TKIs (dasatinib, nilotinib, bosutinib, ponatinib), alone or in combination with chemotherapy, to reduce the CML burden, before undergoing allogeneic HSCT. Response rates (major hematologic) with single-agent TKIs range from 30 to 50% in accelerated phase and from 20 to 30% in blastic phase. Cytogenetic responses, particularly complete cytogenetic responses, are uncommon (10–30%) and transient in blastic phase. Studies of TKIs in combination with chemotherapy show that combined TKI-chemotherapy strategies increase the response rates and their durability and improve survival. This is particularly true in CML lymphoid blastic phase, where the combination of anti-ALL chemotherapy with TKIs results in complete response rates of 70% and median survival times of 3 years (compared with historical response rates of 40–50% and median survival times of 12–18 months). This allows many patients to undergo allogeneic HSCT in a state of minimal CML burden or second chronic phase, which are associated with higher probability of long-term survival. In CML nonlymphoid blastic phase, anti–acute myeloid leukemia chemotherapy combined with TKIs results in complete remission rates of 30–50% and median survival times of 12 months (compared with historical response rates of 20–30% and median survival times of 3–5 months). In accelerated phase, response to single TKIs is significant in conditions where "softer" accelerated phase criteria are considered (e.g., clonal evolution alone, thrombocytosis alone, significant splenomegaly or resistance to hydroxyurea, but without evidence of high blast and basophil percentages). In accelerated phase, combinations frequently include TKIs with low-intensity chemotherapy such as low-dose cytarabine, decitabine, interferon α, hydroxyurea, or others.

OTHER TREATMENTS AND SPECIAL THERAPEUTIC CONSIDERATIONS

Interferon α Interferon α is considered in combination with TKIs (an investigational approach) and occasionally in patients during pregnancy.

Chemotherapeutic Agents Hydroxyurea remains a safe and effective agent (at daily doses of 0.5–10 g) to reduce initial CML burden, as a temporary measure in between definitive therapies, or in combination with TKIs to sustain complete hematologic or cytogenetic responses. Busulfan is often used in allogeneic HSCT preparative regimens. Because of its side effects (delayed myelosuppression, Addison-like disease, pulmonary and cardiac fibrosis, myelofibrosis), it is now rarely used in the chronic management of CML. Omacetaxine, low-dose cytarabine, decitabine, 6-mercaptopurine, 6-thioguanine, thiotepa, anagrelide, and other agents are sometimes useful in different CML settings to control the disease burden, usually in combination with a daily TKI.

Others Leukapheresis is occasionally used in patients presenting with extreme leukocytosis and leukostatic complications. Single doses of high-dose cytarabine or high doses of hydroxyurea, with tumor lysis management, may be as effective and less cumbersome.

Pregnancy and CML TKI therapy in the first trimester of pregnancy is associated with fetal malformations (2–10%). Women with CML who become pregnant should discontinue TKI therapy immediately. Among 125 babies delivered to women with CML who discontinued imatinib therapy as soon as the pregnancy was known, three babies were born with neurologic, skeletal, and renal malformations, suggesting the teratogenicity of imatinib known from animal studies. A similar experience has been reported with

dasatinib, where the incidence of malformations was reported to be higher, 10–12%. Data are scant with other TKIs. Control of CML during pregnancy can be managed with leukapheresis for severe symptomatic leukocytosis in the first trimester and with hydroxyurea subsequently until delivery. TKI therapy with imatinib (but not dasatinib; scant data with nilotinib or bosutinib), if indicated, may be safe after 20 weeks of gestation and in the third trimester. There are reports of successful pregnancies and deliveries of normal babies with interferon α therapy and registry studies in essential thrombocytosis, but interferon α has side effects that may be troublesome during pregnancy, can be antiangiogenic, and may increase the risk of spontaneous abortions.

Cytogenetic Abnormalities in Ph-Negative Cells; Mutations and CML Approximately 5% of patients on TKI therapy and in cytogenetic/molecular response may develop chromosomal abnormalities in the Ph-negative cells. These may involve loss of chromosome Y, trisomy 8, 20q−, chromosome 5 or 7 abnormalities, and others. Most chromosomal abnormalities disappear spontaneously and may be indicative of the genetic instability of the hematopoietic stem cells that predisposes the patient to develop CML in the first place. Rarely (in <1% of instances), abnormalities involving chromosomes 5 or 7 may be truly clonal and evolve into myelodysplastic syndrome, acute myeloid leukemia, or myeloproliferative neoplasms. This is thought to be part of the natural course of patients in whom CML was suppressed and who live long enough to develop other hematologic malignancies. The presence of mutations (*ASXL1, DNMT3A, RUNX1, TET2, EZH2, IDH1/2*) at diagnosis or later during CML was discussed earlier.

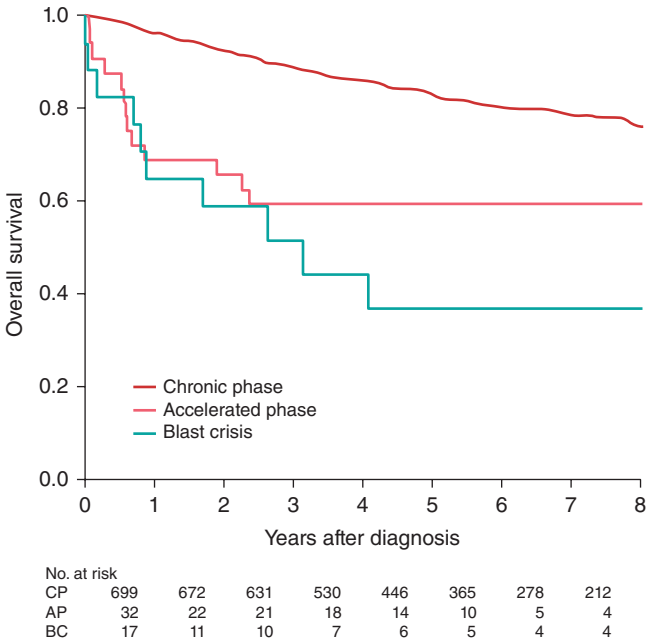

FIGURE 110-3 Survival in chronic (CP), accelerated (AP), and blastic phase (BP) phases of chronic myeloid leukemia (CML) in the population-based Swedish national registry study. The accelerated- and blastic-phase cases are de novo presentations. The favorable outcome with de novo blastic phase may be due to use of 20% blasts or more to define blastic phase. *(From Dr. Martin Hoglund, Swedish CML Registry, 2013.)*

GLOBAL ASPECTS OF CML

Routine physical examinations and blood tests in the United States and advanced countries result in early detection of CML in most patients. About 50–70% of patients with CML are diagnosed incidentally, and high-risk CML as defined by prognostic models (e.g., Sokal risk groups) is found in only 10% of patients. This is different in emerging nations where most patients are diagnosed following evaluation for symptoms and many present with high tumor burden, such as massive splenomegaly, and advanced phases of CML (high-risk CML documented in 20–30%). Therefore, the prognosis of such patients on TKI therapy may be worse than the published experience.

The high cost of TKI therapies (annual costs of $120,000–270,000 in the United States; lower but variable in the rest of the world) makes the general affordability of such treatments difficult. Fortunately, in 2024, some imatinib generic formulations cost about $500/year in the United States and worldwide. Generic dasatinib is also available in many geographies, and generic formulations of bosutinib, nilotinib, and ponatinib may become available by 2027. Therefore, in frontline CML therapy, if survival is the treatment endpoint, generic imatinib is a good choice. If TFR is the endpoint, generic dasatinib (50 or 100 mg daily) is a good choice. Although TKI treatment penetration is high in nations with universal health care and where cost of therapy is not an issue (e.g., Europe, Canada, Australia, United Kingdom), it may be less so in other nations, even in advanced ones like the United States, where out-of-pocket expenses may be prohibitive to a subset of patients. The estimated 10-year survival rate in CML is >85% in single-institution or national studies in countries with TKI affordability (Sweden) (**Figs.** 110-2 and **110-3**), whereas the estimated 10-year survival rate worldwide is likely to be <50%. The Surveillance, Epidemiology, and End Results (SEER) data from the United States report an estimated 5-year survival rate of 70% in the era of TKIs. It appears that the treatment penetration of imatinib and other TKIs into CML therapy worldwide is still not optimal.

The current high cost of TKI therapies, particularly in later-line therapy, encouraged considering allogeneic HSCT as third-line therapy (one-time cost of $20,000–500,000) despite the associated mortality and morbidities. Safe and effective generic TKIs should be preferred frontline and second-line therapies in CML, precluding the necessity of an allogeneic HSCT until evidence of resistance to generic second-generation TKIs.
