Aspergillosis is a model for invasive mold infections that have a propensity to invade blood vessels and tissue. Antifungal therapy should be initiated rapidly and aggressively (**Table 78-8**) in conjunction with the removal or reversal of immunosuppression if possible. Definite or probable invasive aspergillosis should be treated with voriconazole, isavuconazole, or lipid amphotericin B formulation (ie, liposomal AmB 3–5 mg/kg/day), or combination therapy.[171–173] In a recent European Organization for Research and Treatment of Cancer (EORTC)/Mycoses Study Group (MSG) trial performed in patients with probable or proven aspergillosis, a combination therapy with voriconazole plus anidulafungin for at least 2 weeks was associated with an 8% reduction in 6-week all-cause mortality versus voriconazole monotherapy alone, although this difference was not statistically different in the context of the design of the clinical trial.[174] Therefore, the optimal approach for using combination therapy in invasive aspergillosis remains unresolved. Despite early and intensive therapy, mortality from invasive aspergillosis can be >50%.[175] In unresponsive patients, a lipid AmB formulation in combination therapy or possibly triazole should be considered.[171–177] Importantly, some less common molds intrinsically resistant to several antifungal classes (ie, Mucorales, *Fusarium* spp., *Scedosporium* spp.) occasionally present as infections or

breakthrough infections that may be indistinguishable from invasive aspergillosis.

Table 78-8
Therapeutic Options for Treatment of Aspergillosis

Disease	Primary	Secondary
Hyalohyphomycetes		
Aspergillosis		
Allergic bronchopulmonary	Prednisone 1 mg/kg/day followed by 0.5 mg/kg/day or every other day × 3–6 months; no antifungal therapy	ITZ 200 mg bid × 4 months[a]
Aspergilloma	Observation	Surgery[b]
Systemic (invasive)	Isavuconazole 300 mg IV three times daily for 48 hours LD, then 300 mg daily	Amphotericin B lipid formulation[c], or Posaconazole 300 mg twice-daily LD, then 300 mg daily or/and Combination therapy with an echinocandin[d]

AmB, amphotericin B; bid, twice daily; ITZ, itraconazole; LD, loading dose; tid, three times daily.

[a]Treatment should be continued until the patient is symptom-free and culture-negative for 3 months. Noted durations or total doses should be used only as a compass to help guide therapy.

[b]Indicated only for serious symptoms (eg, hemoptysis).

[c]Lipid formulations of amphotericin B should be utilized preferentially in these patients.

[d]Anidulafungin (AFG) 200 mg parenterally; caspofungin (CFG) 70 (50) mg parenterally on day 1 (2–14); micafungin (MFG) 70 mg parenterally; flucytosine (5FC) 150 mg/day parenterally.

Patients with mild-to-moderate *Aspergillus* should be treated with voriconazole or isavuconazole.[166] Clinical and microbiologic cure

rates of 50% to 71% have been reported for voriconazole- or isavuconazole-treated invasive aspergillosis. In a comparative trial of voriconazole versus isavuconazole for patients with proven or probable aspergillosis, patients randomized to receive isavuconazole had similar clinical response and mortality rates as voriconazole-treated patients with lower rates of ocular, hepatic, and cutaneous adverse reactions.[178],[179]

Cryptococcosis

CASE 78-9

Question 1: D.W., a 48-year-old male, was hospitalized with fever and severe headache. His history was significant for Hodgkin lymphoma, which is in remission. Lumbar puncture revealed the following:

Opening pressure of 280 mm Hg (normal, 10 mm Hg)
WBC count, 50 leukocytes/μL (normal, 0 leukocytes/μL)
Positive India ink preparation
Cryptococcal antigen titer, 1:4096
Serology for HIV infection was negative. Culture of the CSF eventually grew *C. neoformans*. The presumptive diagnosis is cryptococcal meningitis.

What are the treatment options for D.W.?

Currently, only two therapeutic options exist for meningeal cryptococcal disease: an AmB formulation with or without flucytosine and fluconazole. Flucytosine cannot be used alone for therapy or prophylaxis because of the rapid development of resistance. This yeast is also resistant to echinocandins. Patients, whether infected with HIV or not, have improved treatment outcomes when the combination of AmB and flucytosine is used.[180],[181] Furthermore, when flucytosine (100–150 mg/kg/day divided into four daily doses) is used in combination therapy, the dose of AmB may be reduced to 0.3 to 0.6 mg/kg/day, which decreases the frequency of dose-related AmB toxicity. In patients who cannot be treated with flucytosine, the dosage of AmB must be increased to more than 0.6 mg/kg/day. AmB 1 mg/kg/day is more rapidly fungicidal than 0.7 mg/kg/day when

used with 5FC. Liposomal AmB 3 mg/kg/day can and probably should be used instead of the nonlipid formulations in this disease owing to presumed increase in safety.[182]

Fluconazole is an alternative to AmB in patients infected with HIV with cryptococcal meningitis. It is important to be mindful of the following caveats, however: Sterilization of the CSF occurs more rapidly, and mortality is lower during the first 2 weeks of therapy in patients treated with AmB as compared with fluconazole.[182] Early mortality was especially high in fluconazole-treated patients who presented with altered mental status.[183–185] Thus, initial therapy of cryptococcal meningitis in patients with mental status changes should be initiated with AmB for at least 2 weeks or until the patient has stabilized clinically.

A landmark study on patients with cryptococcal meningitis compared patients randomized to receive either amphotericin B 1 mg/kg/day for 4 weeks or a 2-week induction regimen of amphotericin B 1 mg/kg/day plus flucytosine (1 mg/kg/day) or fluconazole (400 mg twice daily).[185] At day 70 after randomization, significantly fewer deaths were observed in patients receiving amphotericin B plus flucytosine versus patients receiving amphotericin B alone (hazard ratio: 0.61, 95% CI, 0.39–0.97, P = .04). Combination therapy with fluconazole did not significantly impact survival over amphotericin B monotherapy. Notably, the amphotericin B-flucytosine combination was associated with more rapid clearance of yeast from the CSF versus other regimens. Rates of adverse effects were similar in all groups even though neutropenia was slightly more common in patients receiving amphotericin B-flucytosine or amphotericin B-fluconazole combinations versus amphotericin B monotherapy (34% and 32% vs 19%, P = .04).

Fluconazole 400 mg/day may be an acceptable option in patients with less severe disease in all other patients. Another alternative may include liposomal AmB 4 to 6 mg/kg/day for 21 days. Until larger clinical studies have been completed, however, this regimen cannot be recommended over generic AmB (see Chapter 77, Opportunistic Infections in Patients Living With HIV).[181]

In D.W., initial treatment should focus on the elimination of all factors leading to immunosuppression. Antifungal therapy should be initiated immediately with AmB 0.3 to 0.6 mg/kg/day plus flucytosine 100 to 150 mg/kg/for a minimum of 6 weeks to optimize the chance of a cure, especially in transplant recipients.[185] In addition, CSF hypertension, usually presenting as headache, should be resolved through therapeutic spinal tap. Acetazolamide should be avoided in these cases.[186] An unfortunate consequence of eliminating immune suppression is immune reconstitution syndrome (IRIS). This syndrome is most commonly observed in patients infected with HIV started on antiretrovirals who experience complications secondary to new onset inflammatory reactions from replenished leukocytes. IRIS may make it appear these patients are failing antifungal therapy.

Case 78-9, Question 2: What parameters should be monitored while D.W. is treated with flucytosine?

The most common side effect of flucytosine is GI distress (eg, nausea, vomiting, and diarrhea). Although flucytosine is not metabolized per se by mammalian cells, gut flora may be responsible for metabolism of flucytosine to fluorouracil. This toxic metabolite has been speculated to account, in part, for the GI distress and bone marrow toxicity associated with flucytosine therapy.[187] Other flucytosine adverse effects include leukopenia, thrombocytopenia, and hepatotoxicity. Dose-dependent bone marrow suppression, which can be fatal, generally is seen in patients whose serum concentration of flucytosine is >100 µg/mL. Thus, it is important to monitor blood concentrations and maintain concentrations below this level.[181],[183] If assays for flucytosine serum concentrations are unavailable, signs and symptoms of bone marrow suppression or worsening renal function should result in a dosage reduction or discontinuation of the drug. Flucytosine is eliminated by glomerular filtration, with 80% to 95% of the dose excreted unchanged in the urine. Renal excretion of flucytosine is directly related to creatinine clearance, and dosages should be adjusted

based on creatinine clearance to prevent the accumulation of toxic concentrations in patients with renal impairment.[101] Patients with creatinine clearances of 10 to 40 mL/minute should have the dosage of flucytosine reduced by 50% (usual dose, 37.5 mg/kg every 12 hours). For patients with creatinine clearance <10 mL/minute, dosing should be initiated at 37.5 mg/kg/day, with frequent monitoring of flucytosine serum concentrations. Dosage adjustment and close monitoring also are required for patients receiving hemodialysis, and it is recommended that the dose be given postdialysis.

Case 78-9, Question 3: When is combination antifungal therapy indicated?

In vitro results of antifungal combinations against many common mycotic pathogens have been variable. These incomplete and inconsistent findings have been attributed to variable incubation times, variable concentrations of antifungal agents, and the sequence of antifungal addition. As a result, clinical decisions about combination therapy should be based on patient-specific in vivo evaluations. Because of the limited clinical data, combination antifungal therapy should be initiated cautiously. Except for the treatment of cryptococcal meningitis and disseminated aspergillosis, combination therapy should be reserved for cases of treatment failure (disseminated candidiasis) with no other established pharmacologic options for therapy or mold infections with high mortality rates.

Viral Infections

Sandra Benavides, Neeta Bahal O'Mara, and Milap C. Nahata

CORE PRINCIPLES		CHAPTER CASES
1	Herpes simplex virus (HSV) encephalitis is associated with significant morbidity and mortality. Intravenous acyclovir for a 21-day period is the therapy of choice.	**Case 79-1 (Questions 1–4)**
2	Neonatal herpes can present with mucocutaneous and ocular infection, as well as encephalitis and disseminated HSV infection. Transmission can be acquired during the first trimester of pregnancy or during vaginal delivery in an infected mother.	**Case 79-2 (Questions 1–3)**
3	Herpes labialis is the most common oral–facial HSV infection and is usually self-limiting in an immunocompetent host. Patients who are immunocompromised must be treated	**Case 79-3 (Question 1)** **Case 79-4 (Questions 1, 2)** **Case 79-5 (Question 1)**

	with antiviral therapy, primarily oral or intravenous acyclovir or oral valacyclovir.	
4	Individuals with progressive varicella, those with extracutaneous complications, or those at high risk for developing complications to varicella infection benefit from antiviral therapy.	**Case 79-6 (Question 1)** **Case 79-7 (Questions 1, 2)**
5	The goal of pharmacotherapy of herpes zoster is to reduce pain and duration of rash and to prevent the development of postherpetic neuralgia (PHN). These outcomes can be accomplished with the use of oral acyclovir, famciclovir, or valacyclovir. For the treatment of PHN, topical capsaicin gels, creams and patches, topical lidocaine patches, and oral gabapentin and pregabalin are efficacious.	**Case 79-8 (Questions 1–3)** **Case 79-9 (Question 1, 2)**
6	Neuraminidase inhibitors, such as zanamivir, oseltamivir, and peramivir, are indicated for the treatment of influenza if used within 48 hours of the onset of symptoms.	**Case 79-10 (Question 1, 2)** **Case 79-11 (Question 1)**
7	Influenza vaccination is the most effective mechanism to prevent the flu. However, certain high-risk populations may require additional prophylaxis with oseltamivir or zanamivir.	**Case 79-11 (Question 2)** **Case 79-12 (Questions 1–3)**
8	Infants at high risk for severe disease caused by respiratory syncytial virus (RSV) should receive monthly	**Case 79-13 (Questions 1, 2)**

	intramuscular injections of palivizumab for a total of five doses during the RSV season.	
9	West Nile virus can cause disease ranging from a febrile infection to encephalitis. Treatment is supportive; however, ribavirin and interferon-α-2b have been tried in this patient population.	**Case 79-14 (Questions 1, 2)**
10	Severe acute respiratory syndrome coronavirus (SARS-CoV-2) is a highly transmissible virus that causes COVID-19. Patients can be asymptomatic or have viral pneumonia with multisystem organ dysfunction. Preventive and treatment strategies continue to be developed.	**Case 79-15 (Questions 1–3)**
11	The common cold is the most prevalent viral infection. Numerous pathogens can cause this respiratory infection, including rhinovirus, coronavirus, parainfluenza, RSV, adenovirus, and enterovirus. There are currently no products that have been conclusively shown to prevent or treat the common cold.	**Case 79-16 (Question 1)**

INTRODUCTION

Viral infections are common causes of human disease. An estimated 60% of illnesses in developed countries result from viruses,

compared with only 15% from bacteria. These include the common cold, chickenpox, measles, mumps, influenza, bronchitis, gastroenteritis, hepatitis, poliomyelitis, rabies, and numerous diseases caused by the herpesviruses. Upper respiratory tract infections, such as the common cold or influenza, are among the most common reasons for visits to a health care professional.[1] Most of these patients have a self-limiting illness; however, certain viral infections, such as influenza, can cause significant mortality, particularly in the elderly. During the worldwide Spanish influenza epidemic of 1918 to 1920, 50 to 100 million people died.[2] At the writing of this chapter, the world is enduring a pandemic caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which has caused millions of deaths worldwide and unknown long-lasting health consequences. Although influenza and SARS-CoV-2 vaccines reduce the morbidity and mortality associated with these diseases, for many other potentially severe viral infections, including herpes encephalitis and neonatal herpes, no vaccine is available.

Substantial progress has been made in antiviral chemotherapy as a result of advances in molecular virology and genetic engineering. Antiviral agents can be designed to inhibit functions specific to viruses, which maximize their therapeutic benefits and minimize adverse effects.

Current technology also permits rapid diagnosis of viral diseases. It is now possible to make a specific diagnosis of several viral illnesses within hours to a few days; previously, a specific diagnosis often took days to months. These improved diagnostics have facilitated rapid selection of an appropriate antiviral drug.

This chapter describes the etiology, pathogenesis, and treatment of common viral infections. Specific case presentations illustrate the optimal use of antiviral drugs in patients with viral infections.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes viruses are responsible for a broad spectrum of diseases including acute life-threatening illness (herpes encephalitis and neonatal herpes), as well as more chronic, recurrent infection (genital herpes). Antivirals significantly decrease the morbidity and mortality in most of these infections.[3]

Herpes Encephalitis

Herpes simplex virus (HSV) encephalitis is the most common sporadic viral infection of the central nervous system (CNS). HSV encephalitis occurs in up to 500,000 people yearly, although this may be an underestimate owing to difficulties in diagnosis. It typically occurs in two populations, those ages 6 months to 20 years and those older than 50 years. It is characterized by the acute onset of fever, headache, decreased consciousness, and seizures. Any child with fever and altered behavior should be evaluated for HSV encephalitis. Without treatment, mortality approaches 70% and some morbidity is evident in up to 90% of survivors. Only 2.5% of patients recover to baseline neurologic function.[4]

Herpes simplex virus type 1 (HSV-1) is the etiologic agent in most patients with herpes encephalitis, but herpes simplex virus type 2 (HSV-2) is more common in newborns. The infection may be localized to the brain or involve cutaneous and mucous membranes. Although any area of the brain can be involved, the orbital region of the frontal lobes and the temporal lobes are most often affected.[5]

Herpes encephalitis is often difficult to diagnose. A magnetic resonance imaging (MRI) can identify brain abnormalities in 80% to 100% of patients with herpes encephalitis.[6] If an MRI is unavailable, a computed tomography (CT) scan can be used to rule out other conditions such as brain abscess or other space-occupying lesions.

Cerebrospinal fluid (CSF) examination usually reveals pleocytosis (predominately lymphocytes) with 50 to 2000 white blood cells (WBCs)/μL. Polymorphonuclear leukocytosis and red blood cells (RBCs) may also be seen. Many patients have an elevated protein

level in the CSF (median, 80 mg/dL; normal values differ per age, eg, if 6 months or older, 15–45 mg/dL).

The electroencephalogram (EEG) is the most sensitive but least specific test. There are usually CT or brain scan abnormalities, but these may take a day or two longer to appear. The EEG, MRI, CT, and brain scan findings compatible with HSV encephalitis can be mimicked by other conditions, and a brain biopsy is required to clearly establish the diagnosis. Rapid diagnosis of herpes encephalitis by a polymerase chain reaction (PCR) assay of HSV DNA in the CSF is available at most medical centers. This is a highly sensitive, specific, and rapid method for diagnosing herpes encephalitis.[7]

CLINICAL PRESENTATION

CASE 79-1

Question 1: R.F., a 7-year-old male weighing 44.09 pounds (20 kg), was seen in the emergency department (ED) after a seizure. For the previous 3 days, R.F. had decreased appetite, headache, fever of 101 to 102 °F (38.33–38.89 °C), and was lethargic and disoriented. His leukocyte count was 13,000/μL with a shift to the left. Ceftriaxone (50 mg/kg intravenously [IV] every 12 hours) and dexamethasone (0.15 mg/kg IV every 6 hours) were initiated for presumed bacterial meningitis. Levetiracetam (10 mg/kg IV every 12 hours) was given for seizure control. The CSF finding was normal, and no bacteria could be cultured. Acyclovir 20 mg/kg IV every 8 hours was started immediately. A PCR analysis of HSV-1 returned a positive result.

What findings in R.F. are consistent with the diagnosis of herpes encephalitis?

Fever, headache, lethargy, and disorientation are common features of herpes encephalitis. As illustrated by R.F., the CSF examination can be normal in some patients. A negative CSF culture result suggests the absence of a bacterial infection.[8] However, the positive HSV-1 DNA finding by PCR analysis confirms the diagnosis of herpes encephalitis.

TREATMENT: ACYCLOVIR

Case 79-1, Question 2: What is the treatment of choice for R.F.'s herpes encephalitis?

Two studies comparing acyclovir and vidarabine (no longer marketed in the United States) have demonstrated that IV acyclovir (10 mg/kg every 8 hours for 10 days) is the treatment of choice in patients with herpes encephalitis.[9,10] The 12-month all-cause mortality was 25% in the acyclovir-treated group and 59% in the vidarabine-treated group. Notably, nearly one-third of the patients treated with acyclovir returned to normal life, compared with only 12% of those treated with vidarabine.[11]

Acyclovir is the treatment of choice for R.F. because it has been shown to decrease morbidity in patients with herpes encephalitis. Acyclovir should be started as soon as HSV encephalitis is suspected because early initiation of therapy is associated with improved outcome. Therapy should be continued for 14 to 21 days.[12,13] The role of corticosteroids in the treatment of herpes encephalitis is not well defined. One small, nonrandomized trial found that corticosteroid therapy, in combination with IV acyclovir, was associated with an improved outcome.[14] However, prospective, randomized trials are needed before routine use of corticosteroids can be recommended.[15] Acyclovir-resistant herpes is not an important consideration in the management of herpes encephalitis in most patients.

Adverse effects

Case 79-1, Question 3: What adverse effects can occur with IV acyclovir therapy in R.F.? How should these be monitored, and how can they be minimized?

Acyclovir is a relatively safe drug, but renal toxicity associated with IV acyclovir is well described (**Table 79-1**). Blood urea nitrogen (BUN) and serum creatinine (SCr) levels can increase in 5% to 10% of patients; however, these changes are generally reversible.

Acyclovir is relatively insoluble: maximal urine solubility at 98.6 °F (37 °C) is 1.3 mg/mL. Consequently, the mechanism of acyclovir-associated renal disease is a transient crystal nephropathy, which may occur at high acyclovir concentrations.[11]

Table 79-1
Adverse Effects of U.S. Food and Drug Administration–Indicated Drugs for Various Viral Infections

Drug	Adverse Effects
Acyclovir[11]	Local irritation, phlebitis; increased SCr, BUN; nausea, vomiting; itching, rash; increased liver transaminases; CNS toxicity; hematologic abnormalities
Baloxivir[85]	Facial swelling, dysphonia, angioedema, anaphylaxis reactions; rash, urticaria, erythema multiforme, vomiting, bloody diarrhea, melena, colitis, delirium, abnormal behavior, hallucination
Cidofovir[185]	Nephrotoxicity; neutropenia; rash; headache; alopecia; anemia; abdominal pain; fever; infection; ocular hypotonia; nausea, vomiting; asthenia; diarrhea
Famciclovir[42]	Headache; nausea; diarrhea
Foscarnet[186]	Fever, nausea, vomiting; renal dysfunction; anemia; diarrhea; headache; electrolyte abnormalities; bone marrow suppression; seizure; anorexia; abdominal pain; mental status changes; paresthesia, peripheral neuropathy; cough, dyspnea; rash; first-degree AV block, ECG changes
Ganciclovir[187]	Increased SCr; anemia; neutropenia, pancytopenia, thrombocytopenia; abdominal pain, anorexia; diarrhea; nausea, vomiting; retinal detachment, vitreous hemorrhage, cataracts, corneal opacification; neuropathy; rash
Oseltamivir[84]	Nausea, vomiting; diarrhea; abdominal pain; dizziness, vertigo, insomnia; self-injury and psychosis
Peramivir[86]	Diarrhea, constipation, insomnia, AST elevation, hypertension, hyperglycemia, elevated CPK, elevated neutrophils, anaphylaxis, Stevens–Johnson syndrome, behavioral abnormalities
Ribavirin[110]	Worsening of respiratory status, bacterial pneumonia, pneumothorax, apnea, ventilator dependence; cardiac arrest, hypotension; rash; conjunctivitis

Remdesivir[188]	Hypersensitivity reactions (ie, infusion related, anaphylaxis), elevated AST and ALT, seizure (<2%), rash (<2%)
Trifluridine[189]	Burning or stinging on instillation (4.6%); palpebral edema (2.8%); keratopathy; hypersensitivity reaction; stromal edema; hyperemia; increased intraocular pressure
Valacyclovir[41]	Headache (14%); nausea (15%); vomiting (6%); dizziness (3%); abdominal pain (3%)
Valganciclovir[190]	Neutropenia; thrombocytopenia; diarrhea; nausea, vomiting; abdominal pain; increased SCr; insomnia; peripheral neuropathy; paresthesias; CNS (ataxia, dizziness, seizures, psychosis, hallucinations, confusion, drowsiness); retinal detachment (during treatment of CMV retinitis); hypersensitivity
Zanamivir[83]	Bronchospasm; decline in respiratory function, especially if underlying respiratory disease; nasal or throat irritation or congestion; headache; cough; diarrhea; nausea, vomiting

ALT, alanine transaminase; AST, aspartate transaminase; AV, atrioventricular; BUN, blood urea nitrogen; CMV, cytomegalovirus; CNS, central nervous system; CPK, creatine phosphokinase; ECG, electrocardiogram; SCr, serum creatinine.

Other common adverse effects include gastrointestinal (GI) problems, such as nausea and vomiting and, less commonly, neurologic disturbances, including lethargy, tremors, confusion, hallucinations, and seizures.[11,16] Neurotoxicity appears to be more common in patients with impaired renal function and is reversible. Finally, IV acyclovir can cause phlebitis and pain at the injection site.[11,16] This complication can be minimized by administering acyclovir at a concentration of 5 mg/mL (maximum, 7 mg/mL).[16]

Renal function tests, including BUN, SCr, and urine output, should be monitored in R.F. To minimize the risk of acyclovir nephrotoxicity, R.F. should be well hydrated, and each acyclovir dose should be infused for 1 hour. In addition, the IV infusion site should be inspected for inflammation and pain, and R.F. should be asked about pain at the infusion site.

Conversion to oral therapy

Case 79-1, Question 4: After 7 days of IV acyclovir, R.F. is alert, responsive, actively moving about, and eating a normal diet. The intern suggests switching him to oral acyclovir and discontinuing IV therapy. Is this appropriate?

Oral acyclovir therapy is inappropriate for R.F. On the basis of studies in adults, the absorption of acyclovir after oral administration is variable, slow, and incomplete. The relative bioavailability (*F*) of acyclovir is low (*F* = 0.1–0.2) and decreases with increasing doses.[17] The mean peak plasma concentration has ranged from only 0.83 to 1.61 μg/mL after multiple acyclovir doses of 200 to 800 mg.[18] Thus, with only ~50% of acyclovir penetrating the blood–brain barrier, the concentrations of acyclovir in the CSF may be inadequate for R.F. There is only very limited information regarding the use of oral valacyclovir for therapy. A small pharmacokinetic trial of oral valacyclovir in patients with HSV encephalitis found that while therapeutic CSF concentrations of valacyclovir were achieved, CSF concentrations dropped over time, likely because of resolution of inflammation of the blood–brain barrier.[18] Consequently, switching to oral therapy cannot be recommended at this time and therapy with IV acyclovir should be continued to complete a 14- to 21-day course (**Table 79-2**).[12,13]

Table 79-2
Food and Drug Administration–Indicated Drugs for Various Viral Infections

Disease	Drug	Dosage (Age Group)	Route	Duration
COVID-19	Remdesivir (Veklury®)	≥12 years and &88.18 [wunds (40 Kg): 200 mg on day 1, followed by 100 mg daily	IV	3 days for nonhospiralized patients; 5 days for patlents not requiring invasive mechanfcal ventllation and/or FCMO: 10 days if patient does not exhiblt clinical Improvement at day 5
Herpes encephalltis	Acyclovir (Zovirax*)*	>12 years: 10 mg/kg every 8 hours	IV	14–21 days
		3 months–12 years: 20 mg/kg every 8 hours	IV	14–21 days
Neonatal herpes	Acyclovir (Zovirax")	Birth–3 months. 10–20 mg/kg every 8 hours"	IV	14–21 days
Oral-facial herpes (for treatment of recurrent Infection)	Acyclovir (Zovirax")	Adults: 400 mg five times per day	PO	5 days
	Famclclovir (Famvir*)	Adults: 1500 mg	PO	One dose
	Valacyclovit (Valtrex®)	Adults: 2000 rng bid	PO	1 day
Oral-faoal herpes[1,2] (immunocompromised patlents)	Acyclovir (Zovirax*)	>12 years: 5 mg/kg every 8 hours	IV	7 days
		<12 years: 10 mg/kg every 8 hours	IV	7 days
	Famctclovir (Famvir*)	Adults: 500 mg bld	PO	7 days
Herpes zoster" (tmmunocompetem patients)	Acyclovir (Zovirax®)	Adults: 800 mg Five urnes per day	PO	7–10 days
	Famciclovtr (Famvir*)	Adult: 500 mg every 8 hours	PO	7 days
	Valacyclovir (Valtrex*)	Adult; 1000 mg every 8 hours	PO	7 days
Herpes zoster*[1] (immunocompromised patients)	Acyclovir (Zovirax*)	>12 years: 10 mg/kg every 8 hours	IV	7 days
		<12 years: 20 mg/kg every 8 hours	IV	7 days
Varicella (immunocompetent patient)	Acyclovir (Zovirax*)	>88 18 pounds (40 kg): SOOmgqid	PO	5 days
		>2 years and <88.18 pounds (40 kg): 20 mg/kg (max 800 mg) qid	PO	5–10 days
Varicella (immunocompromised patiems)	Acyclovir (Zovirax*)	<12 years: 10 mg/kg every 8 hours	IV	7–10 days
		>12 years: 500 mg/m' every 8 hours	IV	7–10 days
Cytomegalovirus retinltls (immunocompromised patients)	Gancldovlr (Cytovene®)	5 mg/kg every 12 hours: then 5 mg/kg/day, 1 days a week or 6 mg/kg/day, 5 days a week	IV	14–21 days for inductlon; maintenance
	Odofovlr (Vistide*)	5 mg/kg every week for 2 weeks, then every 2 weeks	IV	Maintenance
	Foscarnet (Foscavir®)	90 mg/kg every 12 hours, then 90 mg/kg every day	IV	Inductlon for 2 weeks, maintenance
	Valganciciovir (Vaicyte*)	900 mg bid: 900 mg every day	PO	Induction for 21 days: maintenance
Influenza A and B	Baloxavir (Xofluza*)	88.18 pounds (40 kg) to <176 37 pounds (80 kg): 40 mg once	PO	Single dose
		sti 76 37 pounds (80 kg): 80 mg once	PO	Single dose
	Oseltamivir (Tamiflu*)	>13 years (or >88 18 pounds [40 kgl): 75 mg bid	PO	5 days (treatment)
		>13 years (or >88 18 pounds [40 kgl): 75 mg every day	PO	10 days (prophylaxis)
				Up to 6 weeks (community outbreaks)
		52.91–88 18 pounds (24–40 kg): 60 mg bld	PO	5 days (treatment)
		35.27–50.71 pounds (16–23 kg): 45 mg bid		

Disease	Drug	Dosage (Age Group)	Route	Duration
		>1 year (33.07 pounds 115 kg): ≤15–30 kg bid		
		52.91–88.18 pounds (24–40 kg): 60 mg every day	PO	10 days (prophylaxis)
		2 weeks to 1 year: 3 mg/kg bid	PO	5 days
		35.27–50.71 pounds (16–23 kg): 45 mg every day		
		>1 year–33.07 pounds (15 kg): 30 mg every day		
	Peramivir (Rapivab®)	2–12 years: 12 mg/kg (maximum 600 mg)	IV	Single dose
		213 years: 600 mg	IV	Single dose
	Zanamivir (Relenza*)	>7 years: 10 mg (two inhalatlons) bid	Inhaiation	5 days (treatment)
		Adolescent and adult: 10 mg (two inhalations) every day	Inhaiation	10 days (prophylaxis) 28 days (community outbreak)
		>5 years: 10 mg (two inhalations) every day	Inhaiation	10 days (prophylaxis)
Respiratory syncytial virus	Ribavirin (Virazole®)	6 g In 300 mL for 12–18 hour/day	Inhaiation	3–7 days

ECMO, extracorporeal membrane oxygenation; bid, two times day; IV, intravenously; PO, orally; qid, four times a day.

[a]FDA-approved dose is 10 mg/kg. Although doses of 15 to 20 mg/kg have been used, safety has not been established at these doses.

[b]Foscarnet 40 mg/kg IV every 8 hours is recommended for acyclovir-resistant herpes simplex virus or varicella zoster virus.

Neonatal Herpes

Most neonates acquire herpes from the infected genital secretions of the mother at delivery, and most can be caused by HSV-1 or HSV-2 virus.[19] In the United States, there are ~1500 cases annually.[19] The infection can present in one of three forms: localized to the skin, eye, and mouth (SEM) (45%); encephalitis (30%); or disseminated disease (25%).[19] The effects of neonatal herpes can be devastating, and severe disabilities persist in many afflicted children.[20] With currently available antivirals, the mortality has ranged from 4% in those with CNS involvement to 29% in those with other disseminated disease.[20] Neonatal HSV-1 infections may also be acquired after birth through contact with family members with symptomatic or asymptomatic oral–labial HSV-1 infection or from nosocomial transmission. When the virus is transmitted from the mother, clinical

evidence of infection in the neonate usually is present 5 to 17 days after birth. Although skin vesicles are the hallmark of infection, up to 40% of neonates never have skin lesions.[20] In 70% of patients, the disease may progress from isolated skin lesions to involve other organs, including the lungs, liver, spleen, CNS, and eyes.

Diagnosis can be made by direct fluorescent antibody examination of epithelial cells from the infant or the mother. Examination of the base of a vesicular lesion may show giant cells and intranuclear inclusions, which are characteristic of HSV infections. Serologic test results can support a diagnosis of neonatal herpes.

RISK FACTORS

CASE 79-2

Question 1: S.P., an 18-year-old pregnant female, was admitted to labor and delivery with premature rupture of the membranes. Four hours later, S.P. vaginally delivered a 5.51-pound (2.5-kg) infant, R.P., who had an estimated gestational age of 33 weeks. Twenty-four hours after delivery, S.P. reported the onset of vesicles in the genital area; she had a history of previous episodes of genital herpes. The last infection was during her first trimester of pregnancy.

Is R.P. at risk for developing herpes infection?

R.P. is at risk for acquiring herpes infection because the mother had genital herpes during the first trimester and because he was delivered vaginally rather than by cesarean section.[20] The risk of a newborn acquiring the disease from an infected mother with primary disease is about 35%; that from a mother who has reactivation of disease is 3%.[20]

TREATMENT: ACYCLOVIR

Case 79-2, Question 2: Ten days after birth, R.P. exhibited poor feeding patterns, irritability, and respiratory distress. Three days later, skin lesions appeared. How should R.P. be treated?

R.P. is manifesting signs of HSV infection and should be treated with antiviral therapy (see Table 79-2). The drug of choice for neonatal HSV infections is IV acyclovir.[19,20] Vidarabine was the first antiviral agent used in the treatment of neonatal HSV. Because of the drastic reduction in morbidity, it became the standard of therapy to which other antiviral agents were compared. In clinical trials comparing vidarabine with acyclovir, acyclovir was shown to be as effective as vidarabine in infants with SEM involvement, encephalitis, and disseminated HSV infection.[21] Although both agents were equally effective, acyclovir was safer and easier to administer, making it the standard of care for neonatal HSV.

Acyclovir administration

Case 79-2, Question 3: What dosage of acyclovir should R.P. receive?

Although an IV dosage of 30 mg/kg given in three divided doses has been shown to be effective in the treatment of neonatal herpes, the use of 60 mg/kg given in three divided doses is superior in decreasing morbidity and mortality. The higher dose of acyclovir is associated with a higher frequency of hematologic abnormalities, especially neutropenia.[11,16,20] The minimum duration of therapy should be 14 days for neonates with only SEM involvement, whereas longer courses (eg, 21 days) are indicated in infants with CNS involvement or disseminated disease.[19,20]

The role of prolonged oral suppressive therapy in newborns with SEM involvement has been investigated.[22–24] Acyclovir, given orally (PO) at 300 mg/m^2 per dose three times a day (tid), resulted in a reduction in the recurrences of lesions and improved neurodevelopmental outcomes. The demonstrated improvement in neurodevelopmental outcomes supports the use of suppressive acyclovir for 6 months. Owing to the high incidence of neutropenia in infants on suppressive treatment, monitoring of the absolute neutrophil counts (ANCs) is recommended at 2 weeks, 4 weeks, and

monthly after the initiation of treatment.[19] It is important to adjust the dose as the infant gains weight.

Oral–Facial Herpes (Herpes Labialis)

Both primary and recurrent oral–facial HSV-1 infections can be asymptomatic. Gingivostomatitis and pharyngitis are the most common clinical manifestations of a first episode of HSV-1 infection, and recurrent herpes labialis is most commonly caused by reactivated HSV infection. Clinical features include fever, malaise, myalgia, inability to eat, and irritability. Immunocompromised patients with oral–facial herpes have severe pain, extensive lesions, and prolonged viral shedding; thus, they are candidates for antiviral therapy.

Herpes labialis (cold sores) is the most common oral–facial HSV infection. Clinical features include pain or paresthesia and erythematous or papular lesions followed by vesiculation and swelling. These lesions usually crust and heal in a few days. Viral culture results generally are positive within 2 to 3 days. Rapid diagnosis can be made by visualizing viral particles in vesicular fluid with electron microscopy or fluorescent antibody staining of cells from vesicles.

INDICATIONS FOR ANTIVIRAL TREATMENT

CASE 79-3

Question 1: M.K., a 26-year-old male, experienced pain and erythematous skin lesions on his face and around his mouth during a 2-day period after contact with a person with active herpetic lesions. For the next 2 days, significant swelling was noted. He remembers similar episodes in the past. M.K. has no previous history of any other illness.

Should he be treated with antiviral drugs?

Most patients with herpes labialis have a self-limiting benign course and the lesions heal within 10 days. Antiviral drugs (eg,

acyclovir, valacyclovir, famciclovir) are indicated when the patient has a primary infection, an underlying illness, or a compromised immune system that may lead to prolonged illness, dissemination, or recurrent infections.[25] In patients with severe disease, such as those undergoing a solid organ transplant, IV therapy may be necessary.[26]

M.K. should not receive antiviral therapy. However, acetaminophen or nonsteroidal anti-inflammatory agents (NSAIDs) can be considered for symptomatic relief. Although ice, ether, lysine, silver nitrate, and smallpox vaccine have been used to treat cold sores, no data support their efficacy.

CASE 79-4

Question 1: P.L., a 16-year-old male diagnosed with acute lymphocytic leukemia 8 months ago, is now admitted for a bone marrow transplant. Admission laboratory tests reveal that he has antibodies against HSV-1 and that 4 months ago, during a course of chemotherapy, he developed an oral–facial herpes infection.

What is the significance of these findings for P.L., who is about to undergo a bone marrow transplant?

Immunosuppressed patients have more frequent and severe mucocutaneous HSV infections. Therefore, IV acyclovir should be considered to suppress the reactivation of oral–facial HSV infections.[26] Oral therapy with famciclovir is approved for use in patients with human immunodeficiency virus (HIV) infection,[27] but efficacy in other immunocompromised patients is not yet established.

Antiviral treatment

Case 79-4, Question 2: P.L. did not receive antiviral therapy. Two weeks later, he developed malaise and painful oral mucosal and skin lesions on his face. HSV was identified from the lesion by immunofluorescence. What is the treatment of choice for P.L.?

Acyclovir should be administered IV at 5 mg/kg every 8 hours for 7 days[11] or until the lesions are healed, followed by oral acyclovir 200

mg tid.[26] For patients with bothersome or multiple recurrences, the daily use of antiviral therapy is recommended to suppress the infection until the immunosuppression can be decreased.[27] In patients with marrow transplants and culture-proven recurrent mucocutaneous herpes simplex, oral acyclovir (400 mg five times daily for 10 days) is significantly more effective than is placebo in reducing pain, virus shedding, new lesion formation, and lesion healing time.[28] Valacyclovir and famciclovir have also been used in the transplant population.[29]

CASE 79-5

QUESTION 1: N.B., a 43-year-old female, experiences 8 to 10 cold sores a year. These are typically preceded by "colds" or sun exposure. She requests a prescription for acyclovir to prevent cold sores when she feels one coming on.

What is the role of antiviral medications in the acute treatment and prevention in immunocompetent patients with recurrent herpes labialis?

Topical agents approved by the U.S. Food and Drug Administration (FDA) for the treatment of recurrent herpes labialis in immunocompetent patients include acyclovir 5% cream (Zovirax®), acyclovir 5% and hydrocortisone 1% cream (Xerese®), docosanol 10% cream (Abreva®), and penciclovir 1% cream (Denavir®). Clinical trials demonstrate that each agent modestly decreases the healing time of herpes lesions when started at the first sign or symptom of a cold sore.[30–36] Although penciclovir cream may be more effective than is acyclovir cream, the benefit is small.[33,34] An advantage of docosanol cream compared with the other agents is its availability without a prescription. Topical acyclovir and docosanol require administration five times a day, whereas penciclovir must be applied within 1 hour of the first sign or symptom of a cold sore and then every 2 hours for 4 days while awake.

Studies evaluating the use of oral antiviral agents have produced conflicting results. In some studies, oral antiviral medications have shown to decrease the duration of pain and healing time in immunocompetent patients. One study demonstrated that oral

acyclovir 200 mg five times daily for 5 days had no benefit.[37] However, 400 mg five times daily for 5 days started within 1 hour of the development of a cold sore significantly decreased duration of pain and healing time in immunocompetent patients.[38] Valacyclovir 2 g at the first signs of a cold sore followed by 2 g 12 hours later, and famciclovir 1500 mg as a single dose showed similar clinical efficacy.[39],[40] No studies have directly compared the efficacy of the different oral antiviral medications.[40] Frequency of dosing and cost should be considered when choosing a particular agent.[17],[41],[42]

Daily suppressive therapy may be recommended in patients with six or more recurrences per year, in patients with frequent infection who do not experience a prodrome, or in patients with severe episodes. In immunocompetent patients with six or more episodes of herpes labialis, oral acyclovir 400 mg twice a day (bid) for 4 months was more effective than was placebo in decreasing the number of recurrences.[43] Oral valacyclovir, 500 or 1000 mg once daily, is efficacious in decreasing the number of recurrences.[44] Controlled trials of famciclovir for chronic suppressive therapy of herpes labialis have not been performed.

N.B. should be treated with either a topical antiviral medication or an oral antiviral for the acute episode of herpes labialis. She should be instructed to start treatment as soon as the first sign or symptom of the cold sore appears. If suppressive therapy is desired, N.B. should be treated with oral acyclovir or valacyclovir.

RESISTANCE

The incidence of acyclovir-resistant herpes in patients with herpes labialis is greater in immunocompromised patients compared with immunocompetent patients. Current estimates of HSV resistance in the immunocompromised population are about 6.4%; some populations, such as bone marrow transplant patients, have a resistance rate of 34%.[45] IV foscarnet 40 mg/kg every 8 hours is more effective and less toxic than is IV vidarabine 15 mg/kg/day in patients with acquired immunodeficiency syndrome (AIDS) and mucocutaneous herpetic lesions unresponsive to IV acyclovir.[46] More

concerning, however, are the reports of foscarnet-resistant HSV, particularly in the bone marrow transplant population.[45,47] Cidofovir has been used with moderate success in such cases. In patients with recurrent acyclovir-resistant genital herpes, limited evidence suggests that topical imiquimod 5% cream may be effective.[48]

VARICELLA ZOSTER INFECTIONS

Chickenpox

Chickenpox used to be a common childhood infection; however, its incidence has decreased by up to 81% and by 92% in patients receiving one or two doses of the varicella zoster virus (VZV) vaccine, respectively.[49] This vaccine is now considered a routine childhood vaccine by the American Academy of Pediatrics. Unimmunized adolescents and adults who have not had chickenpox should also be vaccinated. Before the vaccine was available, ~4 million cases occurred per year in the United States: 90% of cases occurred in children and adolescents younger than age 15 years, with the majority of cases occurring between ages 1 and 4 years.[50,51] In addition to a decline in cases of chickenpox, complications and mortality have also declined.[50,51] The population at risk for complications such as pneumonia and encephalitis, because of VZV, include immunocompromised individuals and pregnant females. Children with HIV are at an increased risk for mortality from VZV.[51]

Chickenpox is a contagious disease; the average incubation period is 14 to 16 days. Children are considered contagious from 1 to 2 days before the onset of rash until all vesicles have crusted (usually 4–6 days after the onset of rash).[51]

After household exposure, >90% of susceptible individuals become infected. Thus, a history of exposure is useful in making a diagnosis. A smear of cells scraped from the lesions will show multinucleated giant cells. Viruses also can be identified in vesicular

lesions by electron microscopy, or antigen can be detected by countercurrent immunoelectrophoresis. Chickenpox is a primary varicella zoster infection, whereas herpes zoster (shingles) is caused by reactivation of VZV.[52]

CLINICAL PRESENTATION

CASE 79-6

QUESTION 1: A.V., a 10-year-old male, was admitted to the hospital for evaluation and treatment of possible recurrent chickenpox. According to his mother and his physician, he had a mild case of chickenpox at age 4 years and has not received the vaccine. At admission, A.V. had a 10-day history of progressive vesicular and pustular lesions that began on his neck and spread to his back, trunk, extremities, and face. Although he had been febrile (up to 104.9 ° F [40.5 °C] orally) for the past 3 days, his temperature on admission was 98.6 ° F (37 °C). A.V. had episodes of vomiting during the 4 days before admission. On admission, he was alert, cooperative, and well oriented but had overt ataxia with abnormal cerebellar signs. Lesions consistent with VZV infection were extensive and confluent over the face, neck, chest, and back. Stages of lesions varied from tiny thin-walled vesicles with an erythematous base to umbilicated vesicles. Few crusted lesions were present. Blood analysis revealed the following results:

BUN, 9 mg/dL (normal, 5–18 mg/dL; 1.8–6.4 mmol/L)
SCr, 0.2 mg/dL (normal, 0.5–0.8 mg/dL; 44–71 μmol/L)
Serum aspartate aminotransferase, 65 IU/L (normal, 0–34 units/L)
Serum alanine aminotransferase 122 IU/L (normal, 0–34 units/L)

Because of the possibility of cerebellar involvement with VZV infection, therapy with acyclovir 550 mg IV every 8 hours (1500 mg/m^2/day) was instituted. Oral diphenhydramine was also prescribed for itching, but A.V. required only two doses on the first hospital day.

New lesions were noted on the second day of acyclovir therapy, but by the third day no new lesions appeared and previous lesions were healing. The ataxia improved daily. He was discharged on day 7 with no further nausea and vomiting. Follow-up serologic evaluation demonstrated a fourfold rise in the optical density for the VZV enzyme-linked immunosorbent assay (ELISA) from day 20 to day 60 after the onset of infection. These results suggested primary VZV infection.

Why is the use of acyclovir in A.V. appropriate?

ANTIVIRAL TREATMENT

Neonates, adults, immunocompromised hosts, patients with progressive varicella, and those with extracutaneous complications benefit from acyclovir therapy. Acyclovir is effective in preventing dissemination of VZV infection, accelerating cutaneous healing, and reducing mortality.[53] A.V. had a prolonged progressive course of varicella and demonstrated an extracutaneous manifestation of varicella infection (eg, ataxia with abnormal cerebellar signs). Because of the concern of possible cerebellar involvement, the use of IV acyclovir was appropriate in A.V.

CASE 79-7

QUESTION 1: C.J., an 8-year-old male, developed a case of chickenpox and was kept home from school. Four days later, his 15-year-old brother, K.J., began to exhibit similar symptoms.

What is the role of acyclovir in immunocompetent patients with chickenpox? Should C.J. or K.J. be treated with acyclovir?

Three studies in children (2–18 years old) have shown that oral acyclovir 20 mg/kg (when initiated within 24 hours of disease onset) four times a day (qid) for 5 to 10 days accelerates healing and decreases the formation of new lesions, fever, and itching. However, the benefit is modest (usually healing 1 day sooner than does placebo) and does not reduce the complications of varicella.[53] Thus, the American Academy of Pediatrics does not consider routine use of acyclovir in healthy children justified, and it is not indicated for C.J.[54]

Adolescents and adults are more likely to develop complications (eg, pneumonia, encephalitis) than do children. Others at higher risk for developing complications include those with chronic cutaneous or pulmonary disease, patients receiving chronic salicylate therapy, and patients receiving short, intermittent, or aerosolized corticosteroid therapy.[54] In these patients, acyclovir therapy may be warranted. Acyclovir 800 mg PO qid for 5 days in adolescents and adults (initiated within 24 hours of disease onset) decreases the number of

lesions and reduces time for healing, fever, and itching. The effect of acyclovir on prevention of severe complications is unknown.[55–57] Thus, acyclovir therapy should be considered in those at increased risk for severe chickenpox, for example, those similar to K.J. who are older than 14 years or those with chronic respiratory or skin disease.[55] There are no published clinical trials to support the use of famciclovir and valacyclovir in the treatment of chickenpox. However, valacyclovir or famciclovir may be preferred because of the need for less frequent administration for adolescents and adults at risk for moderate-to-severe complications.

SUPPORTIVE TREATMENT

Case 79-7, Question 2: What is the role of supportive treatment in C.J. and K.J.?

Cool baths and application of calamine or other topical antipruritic agents may decrease itching. Fingernails should be trimmed to avoid scratching and secondary bacterial infections. In severe cases, a systemic antipruritic and antihistamine preparation may be useful because some degree of sedation may be desired. In C.J. and K.J., aspirin should not be used because Reye syndrome has been associated with the use of salicylates in chickenpox or flu-like illness (see Chapter 102, Pediatric Pharmacotherapy).

Shingles (Herpes Zoster)

Herpes zoster infections are caused by the reactivation of dormant VZV in the sensory neurons. Reactivation is believed to occur because of waning immunity. The incidence of herpes zoster is higher in immunocompromised patients (eg, those with HIV or cancer or those receiving immunosuppressive medications), and the incidence of zoster increases with age. It tends to be more severe in the elderly.[58]

Acute herpes zoster infection is characterized by pain, which is described as a deep aching or burning pain. It may be accompanied by excessive sensitivity to touch. Many patients exhibit a rash that presents initially as erythematous patches and progresses to vesicles that crust in 7 to 10 days. By 1 month, the rash is usually gone, but scarring can occur.[58]

Postherpetic neuralgia (PHN) is the most common complication of acute herpes zoster characterized by pain that continues for >1 month after the onset of the rash. It is estimated that 20% of patients experience PHN, although the incidence can be as high as 90% in individuals older than age 50 years.[58] Prevention is important because PHN pain is difficult to treat.

The goal of pharmacotherapy in acute herpes zoster is to inhibit viral replication, to reduce the pain and duration of the rash. Ultimately, by inhibiting the virus, nerve damage can be prevented and the incidence and severity of PHN can be decreased. Unfortunately, no therapy can prevent all cases of PHN.

The herpes zoster vaccines (Shingrix® and Zostavax®) significantly reduce the incidence of herpes zoster and the associated resulting PHN (see Chapter 64, Vaccinations).

ANTIVIRAL THERAPY IN IMMUNOCOMPETENT PATIENTS

CASE 79-8

QUESTION 1: E.O. is a 72-year-old, previously healthy male who reports a burning pain under his left arm for the past 2 days. The pain radiates across his chest. The pain is worse when the area is touched. This morning, he noticed a rash that starts under his arm and continues to his midline. Pertinent laboratory findings include BUN of 15 mg/dL (normal, 8–18) and SCr of 2.0 mg/dL (normal, 0.6–1.2). He has not received the herpes zoster vaccine. A diagnosis of herpes zoster is made.

What therapy should be initiated?

Acyclovir is the standard antiviral agent against which new VZV therapies are compared. In immunocompetent patients, oral acyclovir 800 mg five times daily for 10 days is moderately beneficial

in reducing acute pain during the first 28 days. Acyclovir therapy should be initiated within 72 hours of the onset of the rash. The benefit of acyclovir in reducing PHN and chronic pain is modest at best. Although a number of trials showed no benefit from acyclovir in reducing PHN, a meta-analysis of acyclovir treatment in herpes zoster concluded that acyclovir was effective, but that 6.3 patients would need to be treated to prevent one patient from having PHN 6 months after the outbreak of VZV.[59]

Famciclovir (Famvir®) is approved for the treatment of acute herpes zoster infection. Famciclovir is a prodrug and is rapidly absorbed and converted to the active drug penciclovir in the intestine. The bioavailability of famciclovir is greater than that of acyclovir, resulting in higher concentrations of active drug in the infected cells. In addition, the intracellular half-life (10 hours) of penciclovir allows for less frequent administration.[60] Famciclovir 500 mg tid is as effective as acyclovir 800 mg five times a day in reducing the duration of acute pain and healing of the rash.[61] Although famciclovir does not decrease the incidence of PHN, it may reduce the duration of PHN.[62]

To overcome the poor oral bioavailability of acyclovir, valacyclovir (Valtrex®), a prodrug of acyclovir, was developed. Valacyclovir is rapidly and extensively absorbed and converted to acyclovir after oral administration. Valacyclovir 1 g tid is as effective as acyclovir 800 mg five times a day in terms of reducing rash progression and time to rash healing, and valacyclovir is more effective than is acyclovir in relieving zoster-associated pain.[63] Valacyclovir is comparable to famciclovir with respect to decreasing the duration of acute zoster-associated pain and PHN.[64]

E.O. should be started on acyclovir, famciclovir, or valacyclovir. Famciclovir or valacyclovir may be preferred because adherence with a tid regimen will likely be better than with acyclovir, which must be administered five times a day. Therapy should be initiated within 72 hours of the rash onset and continued for 10 days; the duration of therapy for famciclovir and valacyclovir is 7 days. Although therapy may not prevent PHN, it may decrease the duration of pain. Because

these agents are renally eliminated, the dosage should be adjusted based on E.O.'s reduced creatinine clearance (**Table 79-3**).

Table 79-3
Clinical Pharmacokinetics of Antiviral Drugs

Drug	Type of Patient	Peak Serum Concentration (μg/mL)	VD	Elimination: % Recovered Unchanged in Urine	Elimination: Total Clearance	Elimination: Half-Life (hours)	Comments
Acyclovir[11,16,17,191–194]	Adults	3.4–22.9 (based on a dose of 2.5–10 mg/kg IV) 0.83–1.61 (based on a dose of 200–800 mg PO)	59 L/1.73 m^2	69–91	327 mL/minute/1.73 m^2	2.5–3.3	Use 100% of recommended dose, but extend dosage interval to 12 and 24 hours if CrCl ranges from 25 to 50 and 10 to 25 mL/minute/1.73 m^2, respectively; use 50% of recommended dose every 24 hours if ClCr ranges from 0 to 10 mL/minute/1.73 m^2
	Neonates	N/A	24–30 L/1.73 m^2	N/A	98–122 mL/minute/1.73 m^2	3.2–4.1	
Baloxivir[85,195]	Adolescents and adults	0.0491 fasting (based on a dose of 20 mg)	1180 L	3.3%	4.38 L/hour	79.1	
Famciclovir[41,196,197]	Adults	0.8–6.6 (based on a dose of 125–1000 mg PO)	1.1 L/kg	73–94[a]	0.37–0.48 L/hour/kg	2.2–3.0	Use 100% of recommended dose, but extend dosage interval to 12 and 24 hours if ClCr ranges from 40 to 59 and 20 to 39 mL/minute, respectively; use 250 mg every 24 hours if ClCr >20 mL/minute
Oseltamivir[84,198–200]	Adults	0.6–3.5[b] (based on a dose of 75 mg PO)	23–26 L	99[b]	18.8 L/hour	6.0–10	Use 75 mg/day in patients if ClCr 10–30 mL/minute. The effect of hepatic impairment has not been determined.
	Pediatrics (1–12 years)	0.06–0.8[b] (based on a dose of 2 mg/kg PO)	N/A	N/A	0.63 L/hour/kg	3.2–7.8	Dosage recommendations are based on body weight and age.
	Adolescents	N/A	N/A	N/A	0.32 L/hour/kg	8.1	
Peramivir[86,201]	Adults	0.0468 μg/mL after a single 600-mg dose	12.56 L	90	6.19–7.58 L/hour/kg	20	In adolescents 13 years and older and adults, use 200 mg if ClCr is 30–49 mL/minute and 100 mg if ClCr is 10–29 mL/minute. In pediatric patients ages 2–12 years, use 4 mg/kg if ClCr is 30–49 mL/minute and 2 mg/kg if the ClCr is 10–29 mL/minute.
Remdesivir[188,202]	Adults	2.23 (based on multiple doses of 100 mg IV)	85.5 L (based on multiple doses of 150 mg/day for 7–14 days)	10%	N/A	1 hour	In patients with an eGFR <30 mL/minute, remdesivir is not recommended.
Valacyclovir[42,203] (see Acyclovir [prodrug of acyclovir])	Adults	5.7–6.7[c] (based on a dose of 1000 mg PO)	N/A	46–80[c]	N/A	2.5–3.3[c]	Use 100% of recommended dose, but extend dosage interval to 12 and 24 hours if ClCr ranges from 30 to 49 and 10 to 29 mL/minute, respectively; use 500 mg every 24 hours if ClCr >10 mL/minute.
Zanamivir[83,204,205]	Adults	0.02–0.1 (based on a dose of 10 mg INH)	15.9 L	7–17	2.5–10.9 L/hour	2.5–5.1	4%–17% of inhaled dose systemically absorbed. Although only limited studies with renal or hepatic impairment, dosing adjustment likely unnecessary

bid, twice a day; ClCr, creatinine clearance; eGFR, estimated glomerular filtration rate; INH, inhalation; IV, intravenously; N/A, not available; PO, orally; VD, volume of distribution.

[a]Pharmacokinetic properties of active metabolite penciclovir.

[b]Active metabolite oseltamivir carboxylate.

[c]Pharmacokinetic properties of active metabolite acyclovir.

For acute illness, E.O. may require pain control with medications such as nonsteroidal anti-inflammatory agents, opioids, topical lidocaine, or tramadol.[47] In addition, E.O. should be counseled to

keep the area of the rash clean and dry and to avoid topical antibiotics. If the rash worsens or fever develops, he should contact his health care professional.

Case 79-8, Question 2: Should E.O. receive a corticosteroid to treat or prevent the pain associated with herpes zoster?

The decision to use corticosteroids, such as prednisone or prednisolone, remains controversial.[65] A number of studies have examined the effect of steroids on pain during acute neuralgia and on the development of PHN. Early studies revealed that steroids are effective for both acute pain and PHN, but these studies were small and uncontrolled, and used various corticosteroid regimens. Most studies suggest relief of the acute pain but no decrease in PHN.[66–68] Because of recent studies demonstrating a lack of benefit in preventing PHN, the theoretical concerns of herpes zoster dissemination, the development of secondary bacterial infections, and the beneficial effects of antiviral agents such as acyclovir, famciclovir, and valacyclovir for acute pain, corticosteroids should not be used in E.O.

Case 79-8, Question 3: Two months after the onset of the rash, E.O. continues to report pain. A diagnosis of PHN is made. What FDA-approved treatments for PHN should be prescribed for E.O.?

Although many different agents have been studied, the only FDA-approved treatments for PHN are topical capsaicin cream or gel, capsaicin patch 8% (Qutenza®), topical lidocaine 5% patches (Lidoderm®), and oral gabapentin (Neurontin®) and pregabalin (Lyrica®). Capsaicin depletes substance P, a mediator that transmits pain from the periphery to the CNS. The largest double-blind, placebo-controlled trial of capsaicin evaluated 143 patients with PHN for at least 6 months.[68] After 6 weeks of treatment with capsaicin 0.075% cream, pain scores were reduced in 21% and 6% of the capsaicin and placebo groups, respectively. After the double-blind

phase of the study ended, a subset of patients continued to use capsaicin cream for up to 2 years, and most patients experienced prolonged pain relief.[68] Capsaicin should be applied three or four times per day. Qutenza® is a capsaicin patch that is applied by a health care professional. The patch is applied for 1 hour and cannot be repeated more frequently than every 3 months. Lidocaine 5% patches have only been compared with placebo and have been shown to relieve pain for 4 to 12 hours after administration. Currently, an over-the-counter lidocaine 4% patch is the only available product. Either capsaicin cream or gel or lidocaine patches can be considered as a first-line option for E.O. A common adverse effect is a burning sensation after application of capsaicin, which is intolerable in up to one-third of patients. The burning sensation usually lessens with continued use.

If lidocaine patches are prescribed, E.O. should be instructed to apply up to three patches to the painful area. Patients should be instructed to wear the patches for a maximum of 12 hours a day, and proper disposal of used patches should be emphasized. Even a used patch contains a large amount of lidocaine, and small children or pets could suffer serious consequences from chewing or swallowing a used patch.[69]

Gabapentin at doses >1200 mg/day has demonstrated up to a 50% decrease in PHN compared to placebo.[70] However, adverse effects limit the ability for patients to reach this dose. Pregabalin is approved for the treatment of PHN, but it is associated with a greater risk of adverse effects. Pregabalin binds to a subunit of calcium channels, thereby decreasing calcium influx at nerve terminals and reducing the release of several neurotransmitters, including glutamate, norepinephrine, and substance P.[71] In clinical trials, dizziness was experienced by 29% of patients treated with pregabalin compared with 9% of placebo-treated patients; somnolence was noted in 22% of patients who received pregabalin compared with 8% of placebo-treated patients. Dizziness and somnolence usually occur soon after the pregabalin is started and is dose dependent.[71]

Other agents that have been used in the treatment of PHN include tricyclic antidepressants (eg, amitriptyline, desipramine) and opioids.[47]

ANTIVIRAL THERAPY IN IMMUNOCOMPROMISED PATIENTS

CASE 79-9

QUESTION 1: R.F. is a 68-year-old female with vesicles on her face associated with severe pain. She has a history of polymyalgia rheumatica and possible temporal arteritis with headaches that are responsive to steroids. She had been having increasing headaches on the right side of her forehead 5 days before admission. Two days before admission, her family physician increased the dosage of prednisone from 30 to 60 mg/day. Vesicles developed on her face 1 day before admission. She was admitted for pain control and diagnosed with herpes zoster infection. Six hours after admission, R.F. began having visual hallucinations, hearing noises, and talking to herself. A lumbar puncture was performed with the following results:

WBCs, three (two lymphocytes and one monocyte)
RBCs, three
Protein, 84 mg/dL
Glucose, 86 mg/dL
VZV was isolated from the CSF and IV acyclovir was started at a dosage of 10 mg/kg every 8 hours.

Why is antiviral therapy indicated in R.F.? Should her prednisone be continued or discontinued?

Antiviral therapy is indicated for R.F. Acyclovir may halt the progression of acute herpes zoster infection in immunocompromised hosts such as R.F., who has been taking large doses of corticosteroids.[72]

IV acyclovir 10 mg/kg every 8 hours is effective in severely immunocompromised patients. Alternatively, in less severely immunocompromised patients, oral therapy with acyclovir 800 mg five times a day, valacyclovir 1000 mg tid, or famciclovir 500 mg tid, along with close monitoring, can be used.[73] Antiviral therapy is associated with more rapid clearance of the herpes zoster virus from the vesicles. Acyclovir has little to no benefit in resolution of pain or

prevention of PHN.[74] Initial data indicate that famciclovir or valacyclovir are effective in severe herpes zoster infection in an immunocompromised host.[74,75]

Systemic corticosteroids are of unproven usefulness and may slow the healing of lesions. Therefore, if possible, R.F.'s prednisone should be slowly tapered.

Acyclovir toxicity

Case 79-9, Question 2: On the fourth day of acyclovir therapy, R.F. developed severe nausea and vomited three times. The laboratory data showed a BUN of 45 mg/dL and SCr of 3.2 mg/dL (baseline BUN, 10 mg/dL and SCr, 1.0 mg/dL). Why must R.F.'s acyclovir dosage be altered?

Nausea and vomiting have been reported with acyclovir therapy in patients with herpes zoster infections.[11] Similarly, elevations of SCr and BUN can occur in association with acyclovir therapy. This may be secondary to acyclovir crystallization in the renal tubules, particularly when fluid intake is inadequate (see Table 79-1). Because R.F.'s creatinine clearance is between 10 and 25 mL/minute/1.73 m^2, the acyclovir dosage interval should be extended to 24 hours. Every effort should be made to maintain adequate hydration for the duration of acyclovir therapy. (See Table 79-3 and Chapter 2, Interpretation of Clinical Laboratory Tests, for creatinine clearance calculation.)

INFLUENZA

Influenza is an acute infection caused by the virus of the Orthomyxoviridae family. Epidemics of influenza are usually caused by the type A virus; type B virus is generally associated with more sporadic infection. Infection is transmitted by the inhalation of virus-containing droplets ejected from the respiratory tract of a person with influenza. Influenza can be spread by direct contact, large droplets,

or items recently contaminated by nasopharyngeal secretions. The incubation period is typically 2 days (range, 1–4 days).

Influenza A viruses are classified into subtypes of hemagglutinin (H) and neuraminidase (N) surface antigens. Three subtypes of hemagglutinin (H1, H2, H3) and two subtypes of neuraminidase (N1, N2) have caused influenza in humans. Infection with a virus of one subtype may confer little or no protection against viruses of other subtypes. In addition, significant antigenic variation (antigenic drift) within a subtype may occur with time. Thus, infection or vaccination with one strain may not protect against a distantly related strain of the same subtype. This is why major epidemics of influenza continue to occur, and influenza vaccines must be reformulated each year with the most likely viral strains to maximize vaccine benefit.[76]

The influenza vaccine is indicated for all individuals ages 6 months and older. However, there are a number of populations for which vaccination is vital. Persons at highest risk for influenza infection (**Table 79-4**) should receive the influenza vaccine each year. The majority of influenza vaccine products are the quadrivalent vaccines that contain two strains of type A and type B.[77] In addition, there are a number of influenza virus vaccine products available that are indicated for patients 65 years or older, a population known to have a suboptimal response to the standard-dose influenza vaccine. These vaccine formulations contain either a higher dose of antigen or have a different adjuvant and are designed to produce a stronger immune response than do standard influenza vaccines. For example, a high-dose vaccine product contains four times the amount of antigen relative to other influenza vaccine products. Early trials with the higher strength vaccine found the high-dose vaccine was 24.2% more effective in preventing influenza in adults ages 65 years and older relative to a standard-dose vaccine.[78] The high-dose and adjuvanted flu vaccines may result in more of the temporary, mild adverse effects that occur with standard-dose influenza vaccines. Adverse effects can include pain, redness, or swelling at the injection site; headache; muscle ache; and malaise, and typically resolve within 1 to 3 days.[76]

Table 79-4

Persons Who Should Receive the Influenza Vaccine

Groups in which the influenza vaccine is indicated in:

- All persons ages 6 months and older

Individuals for which the influenza vaccine is vital for:

- All persons ages 50 years or older
- Nursing home or chronic care facility residents
- Adults and children who have chronic pulmonary (eg, asthma) or cardiovascular (excluding isolated hypertension), renal, hepatic, neurologic, hematologic, or metabolic disorders (including diabetes)
- People who are immunocompromised because of any condition including HIV infection or those taking medications that cause immunosuppression
- Children (6 months–18 years) receiving long-term aspirin therapy or salicylate-containing medications
- Females who will be pregnant during influenza season
- American Indians/Alaska Natives
- Persons who are extremely obese (BMI ≥40 for adults)
- Health care workers
- Persons who take care of people at high risk for influenza-related complications including health care workers and household contacts and caregivers of these individuals.

BMI, body mass index; HIV, human immunodeficiency virus.

Source: Grohskopf LA, Alyanak E, Ferdinands JM, et al. Prevention and control of seasonal influenza with vaccines: recommendations of the advisory committee on immunization practices (ACIP)—United States, 2021–22 influenza season. *MMWR Morb Mortal Wkly Rep*. 2021;70:1–28.

The efficacy of the influenza vaccine depends on the similarity of the components of the vaccine to the circulating viruses that year and the immunocompetence of the host. If there is a good match with the circulating viruses, the inactivated injectable influenza vaccines can prevent illness in ~60% of healthy adults and children, can prevent 50% to 60% of hospitalization among elderly persons, and prevent 80% of deaths among the elderly.[76] Despite the lower efficacy, vaccination is still associated with less severe illness and fewer complications in vaccinated individuals.

Individuals at high risk for transmission to patients include health care personnel in the hospital and ambulatory settings; employees of nursing homes and chronic care facilities; providers of home care services; and household members, including children. It is vital that all these individuals should be vaccinated annually. In addition, considering the morbidity and mortality associated with influenza, all individuals older than 6 months of age should receive an annual influenza vaccination.

The optimal time for vaccine administration is between mid-October and mid-November because influenza activity peaks between late December and early March in the United States. Vaccinating an individual too early in the season could result in waning antibody concentrations before the influenza season is over. However, influenza vaccine should be offered throughout the influenza season, even if outbreaks of influenza have already been documented in the community.[77]

Because the parenteral influenza vaccine is an inactivated vaccine and contains no infectious viruses, it cannot cause influenza. The most common adverse effect is soreness at the administration site lasting for up to 2 days.[79] Fever, malaise, myalgia, and other systemic reactions occur infrequently; these may develop within 6 to 12 hours of the vaccine being given and persist for 1 to 3 days.[79,80] Immediate hypersensitivity to egg protein (hives, angioedema, allergic asthma, or systemic anaphylaxis) rarely occurs. However, there are influenza vaccine products that are not manufactured in embryonated eggs and use of these vaccines should be considered in those with a history of egg allergy. Minor illnesses with or without fever are not contraindications to the influenza vaccine, particularly in children with a mild upper respiratory tract infection or allergic rhinitis. When the vaccine is contraindicated, an oral antiviral agent should be used for prophylaxis.[77] Amantadine and rimantadine are no longer recommended for prophylaxis of influenza because of widespread resistance in the United States.[77]

Clinically, it is impossible to differentiate between influenza A and B. Definitive diagnosis can be made by isolating the virus from throat

washings or sputum and by a significant increase in antibody titers during the convalescent period.

Clinical Presentation

CASE 79-10

QUESTION 1: K.B., a 40-year-old female, comes into the pharmacy claiming she has "the flu." She recently started a new job and is afraid she will lose her job if she misses too many days from work.

What questions would you ask her to differentiate the common cold from an influenza infection?

Although it can be difficult to differentiate the common cold from influenza, there are some clues that may suggest one viral infection from the other. Influenza infections typically occur from December through March in the United States. Patients with influenza generally experience more systemic symptoms, such as fever >102 °F (38.89 °C), headache, myalgia, and cough. Rhinorrhea, nasal congestion, and sneezing are more pronounced in patients with the common cold. Sore throat can occur with both a cold and the flu. Bacterial sore throat (eg, strep throat) is somewhat differentiated from a viral sore throat in that a viral sore throat usually has a slower onset and the throat pain is less severe. Lymph nodes are only slightly enlarged and not tender in a viral sore throat, whereas with a bacterial sore throat, lymph nodes are large and tender.[81]

K.B. should be questioned about her symptoms and exposure to ill contacts, and investigation into whether influenza has been documented in the community should be performed to help differentiate an influenza infection from the common cold.

Treatment

CASE 79-10, QUESTION 2: K.B. describes symptoms consistent with an influenza infection for the past 24 hours. What treatment options exist for the

treatment of influenza? Why is she a candidate for an antiviral agent?

Persons with suspected or confirmed influenza virus infection who are at high risk for developing complications (eg, those with preexisting cardiac or pulmonary disease, unvaccinated infants and children, elderly, immunocompromised) may benefit from antiviral therapy. Treatment is recommended regardless of influenza vaccination status and severity of illness in all patients who develop symptoms of influenza and who require hospitalization.[82] Antiviral therapy should also be used in outpatients with severe or progressive illness, those at high risk for complications, children younger than age 2 years and adults ages 65 years and older, and in outpatient females who are pregnant or within 2 weeks' postpartum.[82] Treatment can be considered in outpatients within 48 hours of onset of symptoms, symptomatic outpatients who are household contacts of people who are at high risk for complications, and symptomatic health care providers who care for patients who are at high risk for complications of influenza infection.[82] Therapy will shorten the duration of illness and decrease the risk of transmission to others in close contact with persons at high risk for complications secondary to influenza infection. The benefits are less clear in patients who have had symptoms >48 hours.[82]

The neuraminidase inhibitors, zanamivir (Relenza®), oseltamivir (Tamiflu®), and peramivir (Rapivab®), and the polymerase acidic endonuclease inhibitor baloxavir marboxil (Xofluza®) are the currently available agents that are active against influenza A and B. Neuraminidase inhibitor agents work by selectively inhibiting the enzyme neuraminidase, an enzyme necessary for viral replication and spread. Baloxavir inhibits the endonuclease activity of the polymerase acidic protein, an influenza virus–specific enzyme necessary for virus replication. Oral oseltamivir is currently indicated for the prevention and treatment of influenza in patients ages 1 year and older; oral zanamivir is indicated for the prevention of influenza in patients ages 7 years and older and for the treatment of influenza in patients ages 5 years and older; and baloxavir is indicated for the

treatment of influenza in patients ages 12 years and older who have been symptomatic for no more than 48 hours.[83–85] Peramivir, a parenteral formulation, is indicated in adults older than ages 18 years and in patients who cannot tolerate or absorb orally administered oseltamivir or inhaled zanamivir.[86]

Zanamivir is available as an oral powder for inhalation. For the treatment of influenza infection in adults, 10 mg (two inhalations) bid for 5 days should be used. Patients should inhale two doses, separated by at least 2 hours, on the first day and then two doses, separated by 12 hours, on days 2 through 5.[83] Bronchospasm after use can occur, and if bronchodilators are also prescribed, the bronchodilator should be used before zanamivir.[83] Proper use of the delivery system (Rotadisk®/Diskhaler®) is important, and thus patients should be instructed by the pharmacist on proper delivery technique, with a demonstration device.

Oseltamivir is pharmacologically related to zanamivir but has significantly better oral bioavailability, allowing oral dosing. It is approved for children older than age 1 year and for adults. The dosage of oseltamivir for the treatment of influenza in adults is 75 mg bid for 5 days.[84] Oseltamivir is available as a suspension with pediatric dosing recommendations. As with zanamivir, treatment with oseltamivir must be started within 48 hours of the onset of symptoms. Common side effects include nausea, vomiting, and headache.[84] Of concern is that oseltamivir-resistant influenza has been reported.[87] In addition, there are reports, predominantly in children, of self-injury and delirium after the administration of oseltamivir.[76]

Baloxavir, the newest antiviral approved for the treatment of influenza infection, is administered as a single oral dose within 48 hours of symptom onset, with or without food. The dose varies with weight: 40 mg (two 20-mg tablets) for patients weighing between 88.18 pounds (40 kg) and <176.37 pounds (80 kg) and 80 mg (two 40-mg tablets) for those weighing at least 176.37 pounds (80 kg). Coadministration with dairy products, calcium-fortified beverages, polyvalent cation–containing laxatives, antacids, or oral supplements (eg, calcium, iron, magnesium, selenium, or zinc) should be avoided

because of chelation leading to decreased baloxavir absorption. The most commonly noted adverse effects include diarrhea and nausea.[85]

Peramivir is dosed at 600 mg once and is administered intramuscularly (IM) or IV as an infusion over 15 to 30 minutes. As the agent was primarily studied in patients with influenza A and moderate disease, efficacy is unknown for patients infected with influenza B or patients with severe infection requiring hospitalization. The most common side effect is diarrhea; however, severe dermatologic reactions and abnormal behaviors have been reported with its use.[86]

Resistance to amantadine and rimantadine has increased dramatically in recent years; consequently, these agents are no longer recommended for the routine prevention or treatment of influenza infections.[88]

When administered within 48 hours of onset of illness, zanamivir, oseltamivir, and baloxavir reduce influenza symptoms by ~1 day.[85,89–91] Information regarding the effectiveness of the neuraminidase inhibitors in preventing serious complications of influenza, such as pneumonia or worsening of chronic diseases, is limited.[77] Considering the causative agent is unknown and symptoms have been present for only 24 hours, K.B. may benefit from an antiviral agent. Oral oseltamivir or oral baloxavir is easier to administer than is inhaled zanamivir, and the patient has no reason to not tolerate this drug. Although no antiviral agent will cure influenza, these medications may reduce the severity and duration of symptoms by about 1 day. She should be treated with a 5-day course of oseltamivir or a single dose of baloxavir.

CASE 79-11

QUESTION 1: J.T., a 74-year-old male, is brought to the ED from a nursing home with fever (103 °F [39.44 °C]), shaking chills, cough, headache, malaise, anorexia, and photophobia. He has been ill for the past 48 hours but is much worse this evening. On physical examination, he appeared flushed, his skin was hot and moist, and he was having difficulty breathing. Vital signs included blood pressure, 150/90 mm Hg; pulse, 108 beats/minute; respiratory rate (RR), 22

breaths/minute; and temperature, 103 °F (39.44 °C). Rales were audible on auscultation of both lungs. A chest roentgenogram showed bilateral infiltrates but no consolidation. His viral respiratory panel finding was positive for influenza A. Results of blood gas studies showed significant hypoxia, with a partial pressure of oxygen (Pa_{O_2}) of 50 mm Hg and a partial pressure of carbon dioxide (Pa_{CO_2}) of 50 mm Hg. J.T.'s medical history was significant for chronic bronchitis and a stroke 16 months ago. Blood, sputum, and urine cultures were obtained, and J.T. was started on antibiotics (ceftriaxone 1 g IV every 24 hours and azithromycin 500 mg IV every 24 hours). Gram stain of the sputum sample showed many WBCs but no bacteria. He was started on oxygen therapy at 4 L/minute via nasal cannula. Twenty-four hours later, his respiratory symptoms worsened, and his arterial blood gases deteriorated slightly (Pa_{O_2}, 40 mm Hg; Pa_{CO_2}, 55 mm Hg) and J.T. was intubated. Blood, urine, and sputum culture results were all negative for bacterial pathogens.

Why is this presentation consistent with influenza infection? Is antiviral treatment appropriate in J.T.?

Although symptoms of influenza may vary depending on age, most patients with influenza A have an abrupt onset of fever, chills, cough, and headache. In elderly patients such as J.T. and those with underlying diseases, the course of influenza can worsen quickly, and patients are more likely to require hospitalization.

Antiviral therapy in J.T. is inappropriate. None of the antiviral agents has been studied in patients presenting with symptoms after 48 hours of onset. In addition, the antiviral agents have shown efficacy only in uncomplicated influenza.[92] However, owing to the severity of his illness, the administration of peramivir should be prescribed.[92]

Prevention

INFLUENZA VACCINES

Case 79-11, Question 2: During the next 3 weeks, two other nursing home patients develop influenza A infections. What measures should be taken to prevent a further outbreak of influenza among other residents?

The nursing home residents and staff should receive influenza vaccine plus chemoprophylaxis with oseltamivir or zanamivir. The Centers for Disease Control and Prevention (CDC) recommends immunization of all individuals 6 months of age or older, and especially those in high-risk groups, primarily all individuals who are at high risk for influenza-related complications and their household contacts (Table 79-4).[77] Second in priority are otherwise healthy adults ages 50 years and older and children with chronic metabolic diseases severe enough to warrant regular follow-up during the preceding year. Any child younger than age 9 years in whom the vaccine is indicated requires two doses of the vaccine for optimal effectiveness in the first year the vaccine is administered. The first dose should be administered as soon as the vaccine becomes available, if possible by October, and the second dose is given before influenza infection is present in the community. Vaccination should continue throughout the season and can be given as late as February or March, depending on the duration of the influenza season. However, the efficacy of the influenza vaccine is incomplete (70%).[91] Therefore, an oral antiviral agent should be considered for pre- and postexposure prophylaxis in high-risk individuals who may not develop an adequate antibody response (eg, patients with advanced HIV infection, residents of nursing homes) to supplement the protection by vaccine.[82],[88],[93]

A live, attenuated influenza vaccine (FluMist®) is an option for healthy, individuals between ages 2 and 49 years. In clinical studies with matched influenza strains, live, attenuated influenza vaccine was ~87% effective in preventing influenza in children and provided 85% efficacy in adults.[91],[94] Advantages of the intranasal route of administration include ease of administration and patient acceptability of an intranasal preparation compared with an IM injection. However, because the vaccine is live, viral shedding can occur for ≥2 days after vaccination. Consequently, patients who are immunosuppressed and close contacts of patients who are severely immunocompromised (including health care workers who care for them) should not receive the live vaccine. Others who should not receive the live vaccine include patients with asthma or other chronic

disorders of the pulmonary or cardiovascular systems, those with chronic metabolic diseases such as diabetes, renal dysfunction, or hemoglobinopathies, and children or adolescents who are receiving aspirin or other salicylates.[76]

OSELTAMIVIR, ZANAMIVIR, AND BALOXAVIR

Analysis of clinical trials of oseltamivir in the prevention of influenza showed a decreased incidence of laboratory-confirmed influenza: 4.8% in the placebo group and 1.2% in the treatment group.[95] The incidence of influenza in a skilled nursing facility was 4.4% in the placebo group and 0.4% in the oseltamivir group. In addition, oseltamivir lowered the rate of infection in patients exposed to influenza at home from 12% to 1%. Baloxavir has been shown to have efficacy similar to that of oseltamivir in high-risk outpatients.[96] Zanamivir has also been found to be effective in preventing infection.[97],[98]

Comparative studies between oral antiviral agents have not been published. Considering that oseltamivir and baloxavir are available in oral formulations and are easier to administer in patients in nursing homes compared with zanamivir, which requires proper use of the delivery device and a coordinated inspiratory effort, these agents may be preferred.

RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

Respiratory syncytial virus (RSV) causes bronchiolitis and bronchopneumonia in infants younger than age 2 years. More than one-half of affected infants are infected in the first 2 years of life. Of these infants, ~1% to 2% will require hospitalization.[99] Children who are severely premature, immunocompromised, or with underlying congenital heart disease or lung disease may be at increased risk for mortality because of RSV.[100] Patients with RSV infection before 3

years of age are at increased risk for wheezing and asthma during childhood.[101]

RSV infections usually occur in the winter. The chest radiograph and blood gas findings are often abnormal, and the virus can be isolated in the nasopharyngeal secretions.

Clinical Presentation and Ribavirin Therapy

CASE 79-12

QUESTION 1: J.R., a 6-month-old male infant who is lethargic, tachypneic, and cyanotic, is brought to the ED. J.R.'s medical history is significant for congenital HIV. He has a fever (102 °F [38.89 °C]), his breathing is labored, and wheezing is audible on expiration. The chest roentgenograms reveal a flattened diaphragm and hyperinflated lung parenchyma. Because of hypoxemia and hypercarbia, J.R. is placed on ambient oxygen to maintain the alveolar oxygen pressure at >60 mm Hg. RSV is identified in the viral respiratory panel collected in the ED.

What therapy is indicated for J.R.?

The goal of RSV therapy is to increase oxygen saturation and decrease airway resistance in patients such as J.R.[102] Treatment of RSV is highly individualized, depending on the presenting signs and symptoms and associated comorbidities. Oxygen is first-line therapy. Although decreases in airway resistance are often achieved with the use of bronchodilators or corticosteroids in other conditions, such as asthma, they have not proved to be effective in the treatment of bronchiolitis.[103],[104] Hypertonic saline, administered as a nebulized solution, is beneficial in increasing mucociliary clearance.[105] Adverse reactions of hypertonic saline include wheezing and excessive secretions.

Ribavirin (Virazole®) is active against many DNA and RNA viruses, including RSV. However, its clinical benefit remains controversial. Early studies with ribavirin showed significant clinical improvement compared with placebo in both healthy children and those with underlying disease.[106] These studies reported benefit in terms of clinical recovery and improvement in arterial oxygenation.

Subsequent studies found ribavirin to be ineffective in patients with a variety of risk factors.[107],[108] Consequently, the routine use in previously healthy infants and children has not been clearly established. Whether ribavirin decreases the long-term sequelae and severity of illness in high-risk groups (including premature infants, patients with bronchopulmonary dysplasia, congenital heart disease, cystic fibrosis, and immunodeficiency) has not been determined.[109] Current recommendations include consideration for use of ribavirin in infants at risk for severe life-threatening infection.[106] Because J.R. has an underlying immunodeficiency, ribavirin may be considered if J.R.'s condition worsens.

ADMINISTRATION OF RIBAVIRIN

Case 79-12, Question 2: How is ribavirin administered, and what precautions should be taken during drug administration in J.R.?

Ribavirin is administered as an aerosol through a collision generator that generates particles small enough (1–2 μm wide) to reach the lower respiratory tract. The concentration of the ribavirin solution in the reservoir is 20 mg/mL (6 g in 300 mL of sterile water). The dose is administered over the course of 12 to 18 hours, although in nonventilated patients, 2 g during 2 hours tid (using a 60-mg/mL solution) has been successfully used.[106] Ribavirin therapy is continued for 3 to 7 days.[110]

Ribavirin is approved for use in patients requiring mechanical ventilation. However, ribavirin is hygroscopic, and aerosol particles can deposit in the tubing and around the expiratory valve of a ventilator. The precipitated drug can obstruct the expiratory valve and alter the peak end-expiratory pressure.[110] Ribavirin has been safely used in such patients,[111],[112] but close monitoring of respiratory therapy is advised to prevent this problem. In addition to the inspection of the tubing, modifications of standard ventilatory circuits have been suggested.[110]

ADVERSE EFFECTS

CASE 79-12, QUESTION 3: What are the important adverse effects of ribavirin?

The most common adverse effects of ribavirin are rash, initial mild bronchospasm, and reversible skin irritation.[113] Although long-term follow-up data are limited, a study evaluating the effects of ribavirin in patients 1 year after administration showed a reduction in the incidence and severity of reactive airway disease, as well as in hospitalizations related to respiratory illness.[114] Further long-term evaluation is still necessary.

Ribavirin is contraindicated in females who are or may become pregnant during exposure to the drug. Although there are no human data, ribavirin has been found to be teratogenic or lethal to embryos in nearly all animal species in which it has been tested. Teratogenesis was evident after a single oral dose of 2.5 mg/kg in hamsters and after daily oral doses of 10 mg/kg in rats. Malformation of the skull, palate, eye, jaw, skeleton, and GI tract have been documented in animals. Ribavirin has reduced the survival of fetuses and offspring of animals tested. It is lethal to rabbit embryos in daily oral doses as small as 1 mg/kg. There are no studies that address teratogenicity in humans, but hospital personnel who are pregnant or may become pregnant should avoid exposure to this drug.[111]

It is important to consider the environmental effects of ribavirin on the personnel involved with its administration. One study found no detectable plasma or urine concentrations of ribavirin in 19 nurses, whereas another reported its presence in the RBCs of a nurse caring for a patient who received ribavirin via oxygen tent.[115] The ribavirin concentration in the air was highest when it was administered via oxygen tent, followed by mist mask, and was lowest after administration via endotracheal tubes of mechanically ventilated patients. This has led to several recommendations: (a) Ribavirin aerosol should be administered solely via endotracheal tube of mechanically ventilated patients in a closed filtered system[99]; (b) children receiving ribavirin should be placed in a containment

chamber equipped with a high-efficiency particulate air filter exhaust in an isolation room with negative air pressure[110]; (c) disposable full-body coverings and either a powered air-purifying respirator or disposable particulate respirator should be made available to all health care personnel[115]; and (d) males and females planning to have children should not care for patients receiving ribavirin via oxygen tents.[115] The manufacturer provides an aerosol delivery system for oxygen and ribavirin that decreases the liberation of ribavirin into the environment.[110]

Prevention

CASE 79-13

QUESTION 1: S.N. is a 7-month-old male born prematurely at 27 weeks' gestation. He has chronic lung disease (CLD) of prematurity and uses oxygen at home. RSV season will begin next month.

What treatments to prevent RSV infection are available? Why is S.N. a candidate for such treatment?

Palivizumab (Synagis®), a humanized monoclonal antibody made from recombinant DNA, is active against RSV and is indicated for children at risk for severe RSV respiratory tract infections (eg, infants with CLD or a history of premature birth before 29 weeks' gestation). The efficacy of palivizumab has been demonstrated in children with a history of prematurity or CLD.[116] Children receiving monthly IM injections of palivizumab for 5 months during RSV season had a reduction in hospitalizations and intensive care admissions for RSV disease. Palivizumab has replaced the use of RSV immunoglobulins (Igs) in infants because it is easier to administer (IM vs IV), does not interfere with the response of live vaccines such as measles–mumps–rubella or varicella vaccine, and is not likely to transmit blood-borne diseases because it is a synthetic product rather than one derived from human blood.[117]

Based on S.N.'s age and his CLD, he is a candidate for palivizumab therapy.[116]

PALIVIZUMAB DOSAGE AND ADMINISTRATION

CASE 79-13, QUESTION 2: How are the doses of palivizumab calculated, and how should it be administered?

The dose of palivizumab is 15 mg/kg given IM. The first dose is given before the start of the RSV season, and then monthly doses are given for a total of 5 months. In the Northern Hemisphere, the RSV season is typically November through April.

HANTAVIRUS

Infections

Rodents are the primary reservoir hosts of *Hantavirus*, and in the United States the deer mouse (*Peromyscus maniculatus*) is the main reservoir. These viruses apparently do not cause illness in the reservoir hosts, but infection in humans occurs when infected saliva, urine, and feces produced by the rodent are inhaled as aerosols. Most patients recall exposure to rodents or rodent feces within 6 weeks of the onset of illness.[118] Person-to-person transmission has not been documented.

The case definition includes clinical evidence of (a) febrile illness characterized by unexplained acute respiratory distress syndrome (ARDS) or acute bilateral pulmonary interstitial infiltrates, or (b) an autopsy finding of noncardiogenic pulmonary edema, resulting from an unexplained respiratory illness. In addition, laboratory evidence consists of (a) a positive serology (ie, presence of hantavirus-specific IgM or rising titers of IgG), (b) positive immunohistochemistry for hantavirus antigen in a tissue specimen, or (c) positive PCR for hantavirus RNA in a tissue specimen.[119] Hantavirus infection can cause three different clinical diseases: hemorrhagic fever with renal syndrome, nephropathia epidemica, and hantavirus pulmonary

syndrome (HPS). Hemorrhagic fever with renal syndrome and nephropathia epidemica occur in Asian and European countries. HPS occurs only in the Western Hemisphere, including North America.[118] From 1993 to 2018, 797 cases of HPS were reported in the United States, leading to 32% mortality rate.[120] Most cases have occurred in the southwestern United States during spring and summer.

Clinical Presentation

The clinical features of patients with HPS include fever, myalgia, headache, chills, dizziness, and nonproductive cough. Abdominal pain, nausea, or vomiting may also be present. The physical examination has been unreliable. Laboratory abnormalities may include leukocytosis, thrombocytopenia, and hypoalbuminemia. The chest radiograph may initially be normal, but rapid disease progress may show bilateral infiltrates and ARDS. Other viral pneumonias do not typically progress to ARDS as rapidly as hantavirus infections. Because of the nonspecific signs and symptoms, some patients may be misdiagnosed as having influenza.[121]

Treatment

Supportive treatment is important. Oxygen therapy and mechanical ventilation may be necessary. Hypotension can be treated with vasopressor agents and judicious use of IV crystalloids (ie, 0.9% NaCl) to prevent worsening of pulmonary edema. Universal precautions and respiratory isolation should be instituted.[118]

There is no FDA-approved drug to treat hantavirus infections. Based on one study in 242 patients, IV ribavirin was more effective than was placebo in reducing morbidity (oliguria and hemorrhage) and mortality. IV ribavirin was given as a loading dose of 33 mg/kg, followed by 16 mg/kg every 6 hours for 4 days, and 8 mg/kg every 8 hours for the next 3 days.[122]

Two other clinical trials, however, did not show similar clinical efficacy in the treatment of HPS. One open-label trial conducted by the CDC showed a mortality rate of 47% in patients who received ribavirin compared with 50% in those who did not.[123] In addition, a small trial conducted at the National Institutes of Health could not demonstrate any benefit from ribavirin.[124]

WEST NILE VIRUS

West Nile virus (WNV) was first identified in the United States in 1999 in New York City. Since then, the virus has had rapid geographic expansion and has infected individuals in all states in the continental United States and Puerto Rico.[125] Although WNV normally occurs in tropical climates, the increase in international travel and changes in weather patterns have led to its spread.

WNV is a member of the Flaviviridae family. Culicine mosquitoes (including *Culex pipiens*, *C. restuans*, and *C. quinquefasciatus*) are the vectors, and they infect both birds and humans.[126] Infection with the virus involves direct inoculation by the infecting mosquito. Birds are reservoir hosts. WNV can infect a number of vertebrates, including horses. Transmission usually occurs from a mosquito bite; however, reports indicate that transmission of the infection has occurred through transfusions, organ transplantation, placental transfer, and via breast milk.[126] Because of the seasonal variations in the life cycle of the mosquito, cases are most commonly seen during the summer and early fall.

Diagnosis is usually made by high clinical suspicion and laboratory tests. WNV can cause a wide range of illness, from an asymptomatic disease to West Nile fever to encephalitis or meningitis. Mortality is low except in the neuroinvasive forms of the infection. Mortality rates in the elderly, particularly those older than 70 years, can be nine times higher than that in the general population.[126] The CDC laboratory criteria for diagnosis of WNV include (a) isolation of the WNV antigen or genomic sequence from a tissue, blood, CSF, or

other body fluids; (b) WNV IgM antibody in a CSF sample; (c) a fourfold rise in the antibody titer to WNV; and (d) demonstration of an IgM or rising titers of IgG to WNV in a single serum sample.[127]

Clinical Presentation

CASE 79-14

Question 1: A.G. is an 84-year-old female. She is very active and runs the yearly flower festival in the community. She was brought to the ED by her granddaughter, who found her at home, confused and with a headache, fatigue, and increasing muscle weakness. She has a temperature of 103 °F (39.44 °C), and her Mini-Mental Status Examination score is 21 of 30. She has decreasing muscle strength and an erythematous, macular, papular rash on her arms and legs. The complete blood count and electrolytes are normal, with the exception of slightly decreased sodium. The CSF reveals increased WBCs, increased protein, normal glucose, and positive IgM antibody to WNV. A CT scan shows no abnormalities.

What signs and symptoms are indicative of WNV encephalitis?

Acute signs and symptoms of WNV include sudden onset of fever, anorexia, weakness, nausea, vomiting, eye pain, headache, altered mental status, and stiff neck. A rash may be present on the arms, legs, neck, and trunk. The rash is typically erythematous, macular, and papular with or without morbilliform eruption.[126] Laboratory parameters may show normal or elevated WBC counts. Low serum sodium concentrations may be seen in patients with encephalitis. CSF usually shows pleocytosis, mostly with an elevation of lymphocytes, elevated protein levels, and normal glucose levels.[126] MRI shows some enhancement of the leptomeninges or the periventricular areas in approximately one-third of patients, but no other abnormalities or evidence of acute disease are present on either CT or MRI examination.[126]

With disease progression, further muscle weakness and hyporeflexia may be observed. Patients may progress to a diffuse, flaccid paralysis similar to that of Guillain–Barré syndrome. Ataxia,

extrapyramidal symptoms, cranial nerve abnormalities, myelitis, optic neuritis, and seizures may be seen.

Treatment

Case 79-14, Question 2: What treatment options are available to A.G.?

Currently, treatment of WNV infection is supportive. Patients with febrile infection usually have a self-limiting course. In severe cases, patients with muscle weakness and signs of encephalitis will require admission to an intensive care unit (ICU), and many will need mechanical ventilation. The available antiviral medications do not have any activity against WNV in vivo, although ribavirin inhibits replication in vitro.[126] Combination therapy of high-dose ribavirin and interferon-α-2b has been used in patients with severe disease with limited success. Although optimal doses have not been established, the doses needed to inhibit the virus were 2 to 3 million units of interferon and 2400 mg of ribavirin daily.[128–130]

SEVERE ACUTE RESPIRATORY SYNDROME

Severe acute respiratory syndrome (SARS), a highly transmissible infectious disease caused by a SARS-associated coronavirus, was first identified in China in early 2003. During the 2003 outbreak, ~8000 cases were reported, with a case fatality rate of about 10%.[131],[132] No cases of SARS were reported worldwide after this outbreak was contained in 2004. In 2012, an outbreak of another severe respiratory illness caused by a coronavirus was identified in Saudi Arabia. As of December 2021, a total of 2583 cases with Middle East respiratory syndrome (MERS) have been reported, with a case fatality rate of 37.1%.[133] In December 2019 in Wuhan, China, an alarming number of patients presented with symptoms of viral pneumonia, with the initial 27 cases presumably associated with a

seafood market in downtown Wuhan. Since the initial identification of this novel coronavirus, named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus has spread to all countries in the world and been declared a pandemic by the World Health Organization on March 11, 2020.[134] The number of cases and deaths reported worldwide exceed 430 million and 5.9 million, respectively, as of March 1, 2022. In the United States, 78 million infections and 939,950 deaths have been reported as of March 1, 2022.[135]

Infection with SARS-CoV-2 is generally caused by exposure to airborne droplets from a symptomatic patient. Patients who are asymptomatic or presymptomatic may also transmit the virus, with estimates of at least 50% of infected individuals contracting the infection from an asymptomatic or presymptomatic individual.[136] Because the virus is easily transmitted by airborne microdroplets, precautions such as wearing a face mask, maintaining a distance of at least 72 inches (182.88 cm) from others and frequent handwashing can decrease the risk of infection. In December 2020, the first vaccine was granted Emergency Use Authorization (EUA) in the United States for protection against SARS-CoV-2.

SARS-CoV, responsible for the 2003 outbreak, was isolated from patients and identified as the causative agent of SARS. Although the natural reservoir of SARS-CoV has not been identified, the virus has been detected in the Himalayan masked palm civet, the Chinese ferret badger, and the raccoon dog. SARS-CoV-2 was isolated from bronchoalveolar lavage fluid samples in patients initially infected in Wuhan. The sequence of SARS-CoV-2 shares 79% of genome sequencing with SARS-CoV and 50% with Middle East Respiratory Syndrome coronavirus (MERS-CoV).[137] It is thought that the virus originated from the *Rhinolophus malayanus* bat indigenous in the Yunnan province in China. Bats are natural hosts to alphacoronaviruses and betacoronavirus, two of which (RaRTG13 and RmYN02) have been identified as sharing >90% of the genomic sequencing as the SARS-CoV-2. Viruses similar to SARS-CoV-2 have also been identified in pangolins that were smuggled from Southeast Asia into southern China.[137]

Clinical Presentation

CASE 79-15

Question 1: S.R. is a 75-year-old Black male. His past medical history is unremarkable except for hypertension controlled by lisinopril 20 mg daily. He is retired but spends many hours outdoors and at his church. S.R. enjoys the company of many of his fellow churchgoers who would visit his home frequently without masks or social distancing. S.R. does not have a history of smoking and does not drink alcohol. S.R. has not received a vaccine for COVID-19.

S.R. experienced a cough, headache, myalgia, and fever 2 days before his presentation to the ED. He began experiencing shortness of breath and weakness that prompted a visit to the ED. Upon arrival, his heart rate was 76 beats/minute, blood pressure 142/88, temperature 103.2 °F (39.56 °C), RR of 32 breaths/minute, and oxygen saturation of 92% on room air. His chest radiograph revealed ground glass opacities bilaterally in the middle and lower lung. The ED physician immediately quarantined S.R., started supplemental oxygen via nasal cannula, and obtained a nasopharyngeal swab to test for SARS-CoV-2. S.R. was admitted to the hospital.

What signs and symptoms are consistent with COVID-19? What severity of COVID-19 does S.R. present with?

The 2021 case definition of COVID-19 established by the CDC as of August 2021 includes clinical, laboratory, and epidemiologic criteria.[138] **Table 79-5** describes the symptoms required for diagnosis of COVID-19 named for coronavirus disease first identified in 2019 and caused by SARS-CoV-2. S.R. exhibits symptoms consistent with COVID-19, including cough, fever, headaches, myalgia, shortness of breath, and weakness. His oxygen saturation and chest radiograph are indicative of COVID-19. Based on his clinical presentation, he meets the clinical criteria for a probable infection. Despite not having known contact with someone infected with SARS-CoV-2, his lack of wearing a mask and social distancing may have increased his risk of contact. The reverse transcriptase polymerase chain reaction (RT-PCR) test will confirm the diagnosis of COVID-19 if the result is positive.

Table 79-5

2021 Case Definition for Diagnosis of Coronavirus Disease 2019

Case Classification

Suspect:

- Meets supportive laboratory evidence with no prior history of being a confirmed or probable case

Probable:

- Meets clinical criteria *and* epidemiologic linkage with no confirmation or presumptive laboratory evidence for SARS-CoV-2
- Meets presumptive laboratory evidence
- Meets vital records criteria with no confirmatory laboratory evidence for SARS-CoV-2

Confirmed:

Meets confirmatory laboratory evidence

Clinical Criteria	Laboratory Criteria	Epidemiologic Linkage
In the absence of a more likely diagnosis, acute onset or worsening of at least two of the following: ▪ Fever (measured or subjective) ▪ Chills ▪ Rigors ▪ Myalgia ▪ Headache ▪ Sore throat ▪ Nausea/vomiting ▪ Diarrhea ▪ Fatigue ▪ Congestion or rhinorrhea *or* *Acute onset or worsening of any one of the following:* ▪ Cough	*Confirmatory* ▪ Detection of SARS-CoV-2 RNA in a postmortem respiratory swab or clinical specimen using a diagnostic molecular amplification test *or* ▪ Detection of SARS-CoV-2 by genomic sequencing *Presumptive* ▪ Detection of SARS-CoV-2–specific antigen in a postmortem-obtained respiratory swab or clinical specimen using a diagnostic test *Supportive* ▪ Detection of antibody in serum, plasma, or whole blood specific to natural infection with SARS-CoV-2 ▪ Detection of SARS-CoV-2–specific antigen by immunocytochemistry in an autopsy specimen	*One or more of the following exposures in the prior 14 days:* ▪ Close contact with a confirmed or probable case of COVID-19 disease[a] ▪ Member of an exposed risk cohort as defined by public health authorities during an outbreak or a high community transmission

▪ Shortness of breath ▪ Difficulty breathing ▪ Olfactory disorder ▪ Taste disorder ▪ Confusion or change in mental status ▪ Persistent pain or pressure in chest ▪ Pale, gray, or blue-colored skin, lips, or nail beds, depending on skin tone ▪ Inability to wake or stay awake *or* *Severe respiratory illness with at least one of the following:* ▪ Clinical or radiographic evidence of pneumonia ▪ ARDS	*or* ▪ Detection of SARS-CoV-2 RNA or specific antigen	

ARDS, acute respiratory distress syndrome; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

[a]Close contact defined by being within 72 inches (182.22 cm) for at least 15 minutes (cumulative over a 24-hour period).

Source: Centers for Disease Control and Prevention. Coronavirus disease 2019 (COVID-19) 2021 case definition. Updated August 24, 2021. Accessed October 29, 2020. https://ndc.services.cdc.gov/case-definitions/coronavirus-disease-2019-2021/.

Virologic (ie, molecular and antigen) testing is available for patients suspected of having COVID-19 infection or for those at high-risk for contracting SARS-CoV-2. Treatment guidelines recommend a virologic test preferably from a nasopharyngeal, nasal, or an oropharyngeal sample for diagnostic purposes. A swab of the

nasopharynx has a higher yield, but concerns regarding aerosolization of the virus may limit this method in some settings; therefore, nasal or oropharyngeal samples are acceptable.[139] RT-PCR is the gold standard for detecting SARS-CoV-2 infection. Sensitivity varies, depending on time of symptom onset, collection of sample, and the sample tested for SARS-CoV-2.[140–142] A meta-analysis that determined the highest sensitivity for RT-PCR was obtained from the sputum (97.2%, 95% confidence interval [CI] 90.3%–99.7%), nasopharyngeal aspirate/swab or throat swab (73.3%, 95% CI 68.1%–78.0%) and saliva (62.3%, 95% CI 54.5%–69.6%).[142] Rapid, point-of-care antigen testing varies in sensitivity and specificity. A meta-analysis evaluated 18 cohorts utilizing rapid point-of care testing from North America (10), Europe (4), South America (2), China (1), and one conducted in several countries.[143] Average sensitivity for antigen point-of-care tests was 56.2% (95% CI 29.5%–79.8%) and specificity was 99.5% (95% CI 98.1%–99.9%). Patients with symptoms of COVID-19 who have a negative point-of-care test result should have an RT-PCR test for confirmation.

Probable or likely exposure to SARS-CoV-2 through a close contact or as a member of a high-risk cohort during an outbreak is a critical component of the SARS case definition.[138] A close contact is defined as being within 6 feet for at least 15 minutes at one time or cumulatively over a 24-hour period.

COVID-19 can present and progress to varying degrees of severity.[139] Patients can remain asymptomatic throughout infection or develop critical illness involving respiratory failure, shock, and multiple organ dysfunction resulting in death.[139] **Table 79-6** outlines the categories of severity based on the clinical guidelines developed by the National Institutes of Health. Patients considered to be at higher risk for developing severe disease include those older than age 65 years, underlying cardiovascular disease or CLD, sickle cell disease, diabetes, cancer, obesity, chronic kidney disease, being pregnant, being a cigarette smoker, being a transplant recipient, or an individual on immunosuppressant therapy.[139] Once a patient recovers from COVID-19, symptoms may persist. Although the

sequelae of the disease have not been clearly elucidated, reports have included fatigue, joint pain, chest pain, palpitations, shortness of breath, cognitive impairments, and worsened quality of life.[139] The CDC defines the syndrome of persistent symptoms (commonly referred to as "long COVID") with sequelae that extend beyond 4 weeks after initial infection.[144] These may persist for at least 3 months, although long-term follow-up is still required to determine the associated COVID-19 morbidity. S.R. presents with severe illness based on his respiratory rate, oxygen saturation, and chest radiograph findings.

Table 79-6

Severity Categories for Adults Diagnosed With SARS-CoV-2

Category	Criteria
Asymptomatic or presymptomatic infection	Individuals whose test result is positive for SARS-CoV-2 using a virologic test (ie, a nucleic acid amplification test or an antigen test), but who have no symptoms that are consistent with COVID-19
Mild illness	Individuals who have any of the various signs and symptoms of COVID-19 (eg, fever, cough, sore throat, malaise, headache, muscle pain, nausea, vomiting, diarrhea, loss of taste and smell) but who do not have shortness of breath, dyspnea, or abnormal chest imaging
Moderate illness	Individuals who show evidence of lower respiratory disease during clinical assessment or imaging and who have an oxygen saturation (Spo_2) ≥94% on room air at sea level
Severe illness	Individuals who have Spo_2 <94% on room air, a ratio of arterial partial pressure of oxygen to fraction of inspired oxygen (Pao_2/Fio_2) <300 mm Hg, respiratory frequency >30 breaths/minute, or lung infiltrates >50%
Critical illness	Individuals who have respiratory failure, septic shock, and/or multiple organ dysfunction

SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

Treatment

Case 79-15, Question 2: What treatment is indicated for S.R. at this time?

Patients presenting with mild-to-moderate COVID-19 disease may be managed on an ambulatory basis with symptomatic treatment. Patients not hospitalized or not requiring oxygenation should not receive any specific antiviral, corticosteroid, or immunomodulatory therapy because clinical trials with these treatments have not found any benefit from antiviral therapy.[139] Antiviral therapies are available for patients at high risk for progression to severe COVID-19. The therapies (in order of preference based on efficacy and convenience of administration per guidelines) are ritonavir-boosted nirmatrelvir, sotrovimab, remdesivir, and molnupiravir.

Ritonavir-boosted nirmatrelvir (Paxlovid®) is an oral inhibitor against the SARS-CoV-2 main protease (M^{pro}) with activity against coronaviruses known to infect humans. It is boosted with ritonavir, a potent CYP3A4 inhibitor, to decrease its metabolism and thus increase concentrations of nirmatrelvir at the site of action. Clinical studies demonstrate an 87.8% ($P < 0.001$) reduced risk of hospitalization or death when administered within 3 days of symptom onset compared to placebo in patients at high risk for severe COVID-19 disease.[145] Use of ritonavir-boosted nirmatrelvir has resulted in rebound of COVID-19.Ritonavir-boosted nirmatrelvir is administered at a dose of 300 mg of nirmatrelvir and 100 mg of ritonavir every 12 hours for 5 days. Adverse effects attributed to nirmatrelvir included taste disturbances, diarrhea, and vomiting.[145] Owing to the ritonavir component in the therapy, a review of current medications the patient is taking is required to minimize drug–drug interactions. Dose reductions are required in patients with an estimated glomerular filtration rate (eGFR) between 30 and 60 mL/minute. Ritonavir-boosted nirmatrelvir is not recommended for use in patients with an eGFR <30 mL/minute or severe hepatic impairment (Child–Pugh class C). EUA for ritonavir-boosted nirmatrelvir was granted for

children 12 years old with a weight of at least 88.18 pounds (40 kg) and adults in December 2021.[146]

Sotrovimab is an IV therapy of anti-SARS-CoV-2 monoclonal antibodies approved for nonhospitalized patients with mild-to-moderate COVID-19 at risk for progression to severe disease.[139] Clinical trials demonstrated an 85% relative risk reduction (95% CI, 44%–96%) in risk of hospitalization or death in adult patients who received sotrovimab 500 mg IV within 5 days of symptom onset.[147] Sotrovimab received EUA for adults and children age older than 12 years and weighing >88.18 pounds (40 kg). Owing to the risk of hypersensitivity reactions, sotrovimab must be administered in a health care setting where a patient can be monitored during and for 1 hour after the infusion. Diarrhea was reported more frequently in patients receiving sotrovimab compared to placebo. Although the patients were treated within 5 days of symptom onset in the clinical trial, EUA is approved for up to 10 days of symptom onset.[148]

Remdesivir was the first antiviral granted FDA authorization for use in hospitalized patients with COVID-19. A clinical trial evaluated the efficacy of remdesivir in nonhospitalized patients (12 years or older) at high risk for progression to severe disease presenting within 7 days of symptom onset. The study found those randomized to receive IV remdesivir for 3 days had an 87% lower risk of COVID-19–related death or hospitalization (hazard ratio, 0.13; 95% CI 0.03%–0.59%; P = 0.008).[149] The most common adverse effects were nausea, headache, and cough. The dose of remdesivir is 200 mg IV on day 1, followed by 100 mg on days 2 and 3 for adults and pediatric patients older than 12 years and weighing >88.18 pounds (40 kg). EUA has been granted for nonhospitalized children younger than 12 years weighing at least 7.72 pounds (3.5 kg), but not ≥88.18 pounds (40 kg), at risk for progression to severe COVID-19.[150] For these patients, the dose is 5 mg/kg IV on day 1, followed by 2.5 mg/kg IV on day 2. Similar to sotrovimab, administration must occur in a health care setting to monitor and manage hypersensitivity reactions. The use of remdesivir is not recommended for patients with an eGFR <30 mL/minute.

Molnupiravir is a prodrug that is metabolized to its triphosphate form, subsequently serving as a substrate for RNA polymerases. Molnupiravir increases mutations in various viruses, including SARS-CoV-2, which results in nonfunctional viral genomes.[151] Owing to the mechanism of action, concern regarding genotoxicity in humans has been evaluated. Based on data and the short duration of treatment, the risk of genotoxicity is thought to be low. However, concern exists regarding the risk of molnupiravir on SARS-CoV-2 mutation rates. Although the manufacturer is mandated to monitor genomic databases for mutations of the virus, the use of molnupiravir is recommended only when no other therapies are available for prevention of severe disease in high-risk patients. A randomized controlled trial evaluated the efficacy of molnupiravir 800 mg orally twice daily for 5 days versus placebo on rates of hospitalization or death. The study was stopped early because it met the primary outcome at the interim analysis. Molnupiravir was found to decrease rate of hospitalization by 31% (hazard ratio, 0.69; 95% CI, 0.48–1.01) compared to placebo.[152] Molnupiravir has EUA for adults within 5 days of symptom onset.[153] Common adverse effects include diarrhea, nausea, and dizziness. No dose adjustments are recommended for patients with renal or hepatic dysfunction.

Patients with moderate-to-severe disease admitted to an acute care setting require aggressive management from an interprofessional health care team. Patients presenting with oxygenation saturation levels <94% on room air require supplemental oxygen. Current clinical guidelines recommend the use of remdesivir in patients requiring supplemental oxygen.[139] The Adaptive COVID-19 Treatment Trial evaluated 1062 patients older than 18 years treated with remdesivir at 200 mg IV on day 1, followed by 100 mg IV daily until day 10 or discharge. Patients treated with remdesivir had a recovery time of 10 days (95% CI, 9–11) in the treatment group compared to 15 days (95% CI, 13–19) in the placebo group. Patients randomized to remdesivir also had an improved clinical outcome compared to those in the placebo group.[154] The most common adverse events reported in the remdesivir group included anemia, acute kidney injury,

hyperglycemia, and increases in aminotransferase levels.[154] Another study evaluated the duration of therapy with remdesivir in patients 12 years or older.[155] Patients were randomized in this open-label trial to 5 or 10 days of treatment. Patients in the 10-day group, at baseline, were more critically ill than were those in the 5-day group. After adjusting for baseline clinical status, there was no difference in the length of hospitalization, or time to clinical improvement.[155] Patients on the 10-day course had a higher incidence of adverse events, including elevated liver enzymes, and decreased renal and hepatic function. In addition, 10% of the patients on the 10-day course discontinued treatment because of adverse events compared to 4% in the 5-day course.[155] Because the study did not demonstrate a difference in clinical outcomes with a 5-day course in patients who did not require mechanical ventilation at initiation of the study, the recommended treatment duration for nonintubated patients is 5 days.[155] For those who do not demonstrate clinical improvement after 5 days, the treatment may be extended to 10 days.[139] In addition, any patient progressing to administration of high-flow oxygen, noninvasive or mechanical ventilation, or extracorporeal membrane oxygenation should complete a 10-day course of remdesivir. Remdesivir was approved by the FDA on October 22, 2020.

Dexamethasone is recommended in patients requiring supplemental oxygen.[139] The randomised evaluation of COVID-19 therapy (RECOVERY) trial was a controlled, open-label multicenter trial evaluating the dexamethasone in hospitalized patients with COVID-19.[156] Patients randomized to dexamethasone received 6 mg IV or PO for 10 days or until discharge. The preliminary findings reported an improved survival benefit for patients requiring supplemental oxygen treated with dexamethasone compared to standard of care (22.9% vs 25.7% deaths at 28 days, rate ratio 0.83 [95% CI, 0.75–0.93] P <.001). In a subgroup analysis, patients not on supplemental oxygen did not appear to have a survival benefit (14.0% vs 17.8%), whereas patients on invasive mechanical ventilation had an improved survival benefit (41.4% vs 29.3%) compared to standard of care.[156] For this reason, dexamethasone, or

other corticosteroids if dexamethasone is unavailable, is recommended for patients on supplemental oxygen.[139]

S.R. is a candidate for remdesivir because his oxygen saturation is <94% and he is receiving supplemental oxygen. He should receive a 200 mg IV dose as soon as he is admitted, followed by 4 additional days of 100 mg IV every 24 hours. If he does not demonstrate clinical improvement in 5 days, a 10-day course of remdesivir is warranted. S.R. should also receive dexamethasone for 10 days or until discharge.

Case 79-15, Question 3: S.R. is on day 7 of remdesivir therapy. He is now intubated, with increasing oxygen demands. Which therapy could be considered in addition to remdesivir and dexamethasone?

Patients who are critically ill requiring rapidly increasing oxygen supplementation may benefit from an interleukin (IL)-6 inhibitor or Janus kinase (JAK) inhibitors. However, owing to lack of data on efficacy, the selection of an additional immunomodulator must be made on an individual basis. The addition of either baricitinib or tocilizumab to a regimen including corticosteroids may depend on the availability of the medication and the patient's comorbidities. It is not recommended to use baricitinib and tocilizumab together because of the risk of immunosuppression. If baricitinib is unavailable, clinicians may consider using tofacitinib. Similarly, if tocilizumab is unavailable, sarilumab may be considered. The use of corticosteroids and an IL-6 or JAK inhibitor, may potentially increase the risk of opportunistic infections regardless of the treatment duration.[139] Because S.R. requires increased oxygen, he may be a candidate for the addition of baricitinib or tocilizumab.

Patients with COVID-19 require management of other complications because of associations with bacterial pulmonary superinfections, septic shock secondary to cytokine storm, thromboembolic events, cardiac dysfunction, and renal or hepatic dysfunction. A critical aspect in managing patients with COVID-19 is prevention or treatment of thromboembolic events.

COVID-19 IN PEDIATRIC PATIENTS

Infection rates and disease severity due to SARS-CoV-2 appear to be lower in pediatric patients compared to that in the adult population. Initial reports of children infected with SARS-CoV-2 in China indicated that 2% of infections were in individuals younger than 19 years.[158] As of February 22, 2022, in the United States, over 10 million cases have been reported in individuals younger than 18 years. Of these, 1346 have died of COVID-19.[157] One epidemiologic study determined the highest hospitalization rates of COVID-19 between March 1, 2020 and August 14, 2021 were in children younger than 2 years (69.2 hospitalizations per 100,000 children and adolescents). An analysis of pediatric patients with or without a vaccine against SARS-CoV-2 found a hospitalization rate of 0.8 per 100,000 person-weeks (95% CI, 0.6–0.9) in unvaccinated children and adolescents compared to 0.1 per 100,000 person-weeks (95% CI, 3.7–27.9) in fully vaccinated children and adolescents.[158] Children at risk for severe disease include those with a history of concurrent medical conditions (eg, genetic disorders, neurologic impairment), obesity, chronic pulmonary or cardiac disease, or those who are immunocompromised.[159] Adolescents and non-White children also are at increased risk.

Children may be asymptomatic or have milder symptoms than do adults. Symptoms in pediatric patients are similar to that in adults (Table 79-6), with the most common symptoms being fever and cough.[160] Children may also present with only GI symptoms.[160] Fever, nausea/vomiting, cough, shortness of breath, and upper respiratory symptoms are the more common signs and symptoms in pediatric patients who are hospitalized.[139] Diagnostic tests in children are the same as that in adults.

Clinical guidelines have been published to provide recommendations for use of pharmacologic agents in the treatment of COVID-19 in pediatric patients.[139] Supportive care remains the main treatment for COVID-19 infection in pediatric patients because most children will not progress to severe disease. Although the recent clinical guidelines do not outline specific recommendations for

nonhospitalized children with COVID-19 at high risk for severe disease, ritonavir-boosted nirmatrelvir, sotrovimab, and remdesivir have received EUA for children and adolescents older than 12 years weighing ≥88.18 pounds (40 kg). In addition, remdesivir received EUA in January 2022 for children at least 7.72 pounds (3.5 kg) but not more than 88.18 pounds (40 kg) who do not require hospitalization but are at risk for progression of COVID-19.[150] The use of these agents must be considered on an individual basis given underlying risks in the child.[139]

For pediatric patients requiring hospitalization, guidelines recommend remdesivir in those 12 years or older with worsening respiratory disease requiring increased oxygen support and risk factors for severe disease. For children 16 years or older, remdesivir is recommended for all patients with an increased requirement of oxygen support, regardless of risk factors. In consultation with an infectious disease team, all children (regardless of age and risk factors) with worsening severity of COVID-19 can be considered for treatment with remdesivir.[139] Dosing for remdesivir for patients <88.18 pounds (40 kg) is 5 mg/kg IV on day 1 followed by 2.5 mg/kg IV every 24 hours. For patients >88.18 pounds (40 kg), the dose is 10 mg/kg IV on day 1 followed by 5 mg/kg IV every 24 hours. The duration of therapy is 5 to 10 days, with 10 days indicated for patients not improving at day 5.[161]

Corticosteroids are recommended for use in pediatric patients who are hospitalized and require high-flow oxygen, noninvasive ventilation, invasive ventilation, or extracorporeal membrane oxygenation.[139] If available, dexamethasone is recommended at 0.15 mg/kg/dose (maximum 6 mg) once daily for 10 days. Prednisone, methylprednisolone, and hydrocortisone (at equivalent doses) can be used should dexamethasone be unavailable. Caution is warranted in immunocompromised patients. The guidelines do not recommend for or against the use of baricitinib or tocilizumab. However, the guidelines do not recommend the use of sarilumab or convalescent plasma in pediatric patients.

The guidelines also recommend enrolling children and adolescent patients in clinical trials when possible to expand the data on the

efficacy and safety of these agents in pediatric patients. Medical care for complications related to COVID-19 (eg, renal dysfunction, thromboembolic events) is necessary.

Another manifestation of SARS-CoV-2 in children and adolescents presents as hyperinflammatory shock with clinical characteristics similar to Kawasaki disease.[162] The multisystem inflammatory syndrome in children was described in children from Europe and appeared to be associated with SARS-CoV-2 but presenting 2 to 4 weeks after an acute infection. Patients presented with fever, rash, conjunctivitis, peripheral edema, GI symptoms, shock, and cardiac damage. Patients also presented with increased inflammatory markers and positive serology for SARS-CoV-2. Cases in the United States were first recognized in New York in May 2020.[162] As of January 31, 2022, 6851 cases have been reported in the United States, with 59 associated deaths.[163] The syndrome is referred to as pediatric multisystem inflammatory syndrome temporally related to SARS CoV-2 (PMIS-TS) or multisystem inflammatory syndrome in children (MISC-C).

The case definition for MISC-C includes (a) an individual younger than 21 years with fever, laboratory evidence of inflammation (eg, CRP, erythrocyte sedimentation rate [ESR], fibrinogen, D-dimer), and evidence of clinically severe illness requiring hospitalization with two or more organs involved, (b) no alternative plausible diagnosis, and (c) positive result for current or recent SARS-CoV-2 infection by RT-PCR, serology, or antigen test or COVID-19 exposure within the 4 weeks of the onset of symptoms. Fever is defined as a temperature ≥100.4 °F (38 °C) or a subjective fever for at least 24 hours.[164]

In the first 570 cases of MISC-C in the United States, 86.5% presented with some form of cardiac involvement including shock, increased cardiac enzymes, myocarditis, and cardiac dysfunction.[162] Patients will require intensive care with cardiac monitoring. In addition, 60.4% presented with elevated D-dimers, indicating an existing coagulopathy. Patients presenting with an elevated D-dimer may require anticoagulation for prevention or treatment of thromboembolism.[165]

Treatment for patients presenting with MIS-C includes supportive care and immunotherapy directed at antibodies responsible for the inflammatory response. Recommended treatment is IVIG (1–2 g/kg [not to exceed 100 g] over 12 hours) in combination with a moderate-dose corticosteroid such as methylprednisolone 1 to 2 mg/kg/day.[139] Data from nonrandomized clinical trials found that this combination improves recovery of cardiac function, shorter ICU stay, less treatment failure, and decreased need for escalation compared to IVIG alone.[139] However, no randomized clinical trials have been conducted for safety and efficacy of these agents. Other immunotherapies such as infliximab, anakinra, or tocilizumab have been used in patients with treatment failure to IVIG and corticosteroid therapy. Treatment failure is defined as persistent fever, ongoing organ dysfunction, and increasing levels of inflammatory markers. These patients may require intensification therapy with anakinra at a dose of 5 to 10 mg/kg/day, infliximab at a dose of 5 to 10 mg/kg/day, or higher dose corticosteroids (eg, methylprednisolone 10–30 mg/kg/day). A second dose of IVIG for intensification is not recommended.[139]

Because patients with MIS-C are not in an acute phase of an infection, remdesivir is not indicated. Most patients with MIS-C recover; however, long-term effects are currently unknown.

PREVENTION OF SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2

Prevention against infection with SARS-CoV-2 includes avoiding contact with infected individuals and vaccination against SARS-CoV-2. If the infected person is in the same household, it is recommended to maintain at least 72 inches (182.22 cm) between the infected person and others and limiting time to 15 minutes cumulatively. Avoid poorly ventilated areas and crowds when possible. A mask can prevent spreading infection to others and should be worn in public settings. Handwashing with soap and water for at least 20 seconds is recommended after sneezing or coughing. In the event soap and water are not available, hand sanitizer is a suitable

alternative. Surfaces that are touched daily (eg, tables, doorknobs, light switches, phones) should be disinfected daily with a household disinfectant. It is also important to monitor health daily for symptoms of COVID-19. It is important to monitor for signs and symptoms of COVID-19 and test if symptoms of COVID-19 occur after a close contact.[166]

As of February 2022, three vaccines are available in the United States to protect against COVID-19. The mRNA vaccines, Spikevax® (manufactured by ModernaTX, Inc.) and Comirnaty® (manufactured by BioNTech Manufacturing GmbH and Pfizer, Inc.) are recommended for primary and booster immunization over the COVID-19 vaccine (manufactured by Janssen Biotech Inc.) owing to improved effectiveness against severe COVID-19 requiring hospitalization and lower risk of serious adverse effects.[167] The primary series of the vaccine is recommended for everyone age 5 years and older and requires administration of two doses for the mRNA vaccines. Children 12 years and older should receive a booster of an mRNA vaccine 5 months after the completion of the primary series. Individuals who are immunocompromised may require an additional booster (fourth dose) 3 months after the first booster. The efficacy of the vaccines depends on the number of boosters an individual receives and the circulating variant. The CDC updates the risk of testing positive and risk of dying from COVID-19 based on vaccine status. The most recent data reported on January 22, 2022 indicated unvaccinated adults had 2.6 times the risk of testing positive for COVID-19 and 14 times the risk of dying from COVID-19 compared to fully vaccinated adults.[168] In the same time frame, compared to fully vaccinated adults with booster doses, unvaccinated adults had a 3.2 times greater risk of testing positive for COVID-19 and a 41 times greater risk of dying from COVID-19.

Adverse reactions to the vaccines range from mild to moderate in severity. Common side effects include pain, swelling and redness at the site of injection, fever, headache, fatigue, myalgia, chills, and nausea. More severe, rare adverse effects include anaphylaxis. An increased risk of thrombosis with thrombocytopenia syndrome (TTS) has been reported with all three vaccines but more often with the

Johnson & Johnson/Jansen vaccine. Females between ages 30 and 49 years may be at increased risk for TTS, which causes blood clots in large blood vessels and thrombocytopenia.[167] Cases of myocarditis and pericarditis have been reported after administration of the mRNA vaccines. The reported cases were mild and self-limiting, with more occurrences in male adolescents and young adults.[139]

Although vaccines are the most effective way to prevent COVID-19, people who have had a severe reaction to a vaccine or are unable to mount an adequate immune response (eg, immunocompromised) may require pre-exposure prophylaxis with anti-SARS-CoV-2 monoclonal antibodies tixagevimab plus cilgavimab (Evusheld®). Tixagevimab 150 mg with cilgavimab 150 mg administered as two IM injections can offer protection against COVID-19 for up to 6 months. Although no data are available on the use of repeated doses every 6 months, it is recommended that individuals meeting criteria for administration receive the monoclonal antibodies every 6 months. These monoclonal antibodies are not recommended for individuals able to receive vaccines safely but rather for individuals with a severe reaction to a vaccine or are severely immunocompromised.[139] Data demonstrated a 77% reduction in infection in patients receiving tixagevimab and cilgavimab compared to placebo (95% CI, 46%–90%; $P < 0.001$).[139] For patients who receive a COVID-19 vaccine, it is recommended to wait 2 weeks before administration of tixagevimab and cilgavimab. Serious adverse effects reported included anaphylaxis and rare serious cardiac events including myocardial infarction, cardiac failure, and arrhythmia. The cardiac events occurred in participants with underlying heart disease or risk factors for heart disease. Less serious reported adverse reactions included headache and fatigue.[169]

It is important to reference the most recent clinical guidelines by the National Institutes of Health and the CDC for updated prevention and treatment recommendations. The COVID-19 pandemic is continuing to evolve with the possibility of new variants. The Omicron variant spread quickly around the world and became the dominant

strain, replacing the Delta variant. Soon, data emerged on the effectiveness of diagnostic tests, vaccines, and treatments for the new variant. For example, during the Delta wave, monoclonal antibodies for postexposure prophylaxis, bamlanivimab plus etesevimab and casirivimab plus imdevimab received EUA for individuals at risk for progression to severe disease. However, when Omicron became the dominant variant, it was determined that these monoclonal antibodies were no longer effective against the new variant. As such, they are no longer available in the United States. Thus, preferred treatment would depend on the efficacy and safety of various medications for a specific COVID variant and should be based on the most recent evidence-based guidelines for the optimal management of patients.

MIDDLE EAST RESPIRATORY SYNDROME

MERS was first reported in 2012 in Saudi Arabia. As of January 2020, a total of 2519 cases have been reported with a case fatality rate of 34.3%, primarily in the Arabian Peninsula.[170] To date, only two cases have been reported in the United States, both in health care workers who lived in Saudi Arabia and traveled to the United States. Both received supportive care at a hospital and were discharged.[170]

The causative organism of MERS is the MERS-CoV. Symptoms of MERS include fever, cough, chills/rigors, lethargy, myalgia, headache, confusion, and shortness of breath. In some patients, GI symptoms such as nausea, diarrhea, and vomiting have been reported. The infection progresses to complications including progressive pneumonitis, respiratory failure, acute respiratory distress syndrome, septic shock, and multiorgan failure. Those at greatest risk for death are those older than 60 years and those with comorbid conditions, such as diabetes, cancer, lung disease, or chronic kidney disease. Individuals older than 60 years with a history of smoking, preexisting pneumonia, abnormal renal function, and comorbidities are at greatest risk for death.[171]

MERS-CoV appears to be transmitted through close contact with an infected individual, likely through respiratory droplets. Most infections reported have occurred in hospitals or in individuals caring for or living with an infected individual.[171] Treatment of MERS is directed as supportive care and management of symptoms and complications.

COMMON COLD

The most prevalent viral infection is the common cold. In the United States, ~62 million cases of the common cold occur annually.[172] An estimated 20 million and 22 million days of absence from work and school, respectively, occur. The frequency of the occurrence of a cold is greater in younger children and decreases with increasing age. Although the common cold is self-limiting, otitis media occurs in ~20% of children after infection.[173]

Many viruses have been isolated from patients with respiratory infections, but rhinovirus is the most common viral pathogen.[174] Rhinovirus accounts for 30% to 50% of all respiratory illnesses. More than 100 different serotypes of rhinovirus exist, and the prevalence of each varies with time and geography. Other pathogens include coronavirus, parainfluenza, RSV, adenovirus, and enterovirus. Because of the number of pathogens known to cause the common cold, development of an effective vaccine remains difficult.

Treatment for the common cold is directed at pharmacologic treatment of symptoms. Nonsteroidal anti-inflammatory drugs, oral or intranasal decongestants, antihistamines, and antitussives may be used. However, these products provide minimal relief of symptoms and do not shorten the natural course of infection.[175–177] In pediatric patients younger than 4 years, the use of cough and cold medications is not recommended by the FDA because of the lack of evidence for efficacy and deaths associated with their use.[178–180] Currently, there are no specific antiviral treatments for the common cold.

Prevention

CASE 79-16

QUESTION 1: J.C. comes into the pharmacy asking for an herbal product that will help him prevent colds this upcoming cold season. He states that last year he had three colds and his neighbor had none. His neighbor had mentioned an herbal product he had been taking. J.C. cannot remember the name of the product but wonders whether there are any products that may be helpful.

What can you recommend for J.C.?

ZINC

Zinc, a dietary supplement, has been studied in both the prevention and treatment of the common cold. The proposed mechanism of action is that the rhinovirus 3C protease is inhibited by zinc, and the inhibition of this enzyme prevents viral replication. In vitro, zinc has been shown to have antiviral activity. Several trials conducted in the past several decades have produced conflicting results on the benefits of zinc in decreasing symptom severity or duration. If started within 24 hours of symptom onset, zinc may shorten symptoms but not severity of the cold. Zinc lozenges, dosed at a minimum of 75 mg/day for the duration of cold symptoms, is recommended.[181] Patients who took zinc lozenges for the common cold reported mouth irritation, unpleasant taste, feeling sick, and diarrhea. Daily administration of zinc is not currently recommended for prophylaxis of the common cold.

ECHINACEA

Echinacea is an herbal product extracted from the *Echinacea* plant, which belongs to the Compositae family. Echinacea is believed to stimulate the immune system, specifically phagocytosis. Some clinical trials using echinacea have shown positive results in decreasing the incidence of infection when compared with placebo, but the data remain inconclusive.[182] One study showed no benefit of echinacea versus placebo but did show an increased incidence of rash in the treatment group.[183] Because the current data are

inconclusive for efficacy and owing to the variability of echinacea concentrations in the available products and their association with adverse effects, use of echinacea in the prevention and treatment of the common cold is not recommended.[182–184]

Viral Hepatitis

Jerika T. Lam and Amy Kang

CORE PRINCIPLES		CHAPTER CASES
1	Hepatitis A virus (HAV) is a worldwide, acute self-limiting disease transmitted via the fecal–oral route. Hepatocyte injury is caused by a cytopathic and immunologic response, which can result in jaundice and increased liver function tests. Treatment measures are usually supportive and aimed toward prevention (pre-exposure and postexposure) through vaccination.	**Case 80-1 (Questions 1–3)** **Case 80-2 (Question 1)** **Case 80-3 (Question 1)**
2	Hepatitis B virus (HBV) is a bloodborne pathogen that is transmitted through percutaneous or perinatal exposure, blood products, or sexual contact. HBV has an acute phase with resolution and a chronic phase. Over the course of decades, the chronic phase can lead to	**Case 80-4 (Questions 1–4)** **Case 80-5 (Questions 1, 2)** **Case 80-6 (Questions 1–3)** **Case 80-7 (Question 1)**

	complications of the liver, hepatic cirrhosis, and death. Patients with chronic infection require treatment with pegylated interferon and nucleoside and nucleotide reverse transcriptase (RT) inhibitors. Several effective prophylactic strategies (immunizations and nucleoside or nucleotide RT inhibitors) are used to prevent HBV infection.	**Case 80-8 (Question 1)** **Case 80-9 (Question 1)** **Case 80-10 (Questions 1, 2)** **Case 80-11 (Question 1)** **Case 80-12 (Questions 1–14)**
3	Hepatitis C virus (HCV) is a bloodborne pathogen that is transmitted primarily through percutaneous exposure, blood products, or sexual contact. HCV has an acute and a chronic phase. The chronic phase can lead to cirrhosis, decompensated liver disease, hepatocellular carcinoma, and death. Acute clinical manifestations are similar to those for HAV and HBV. Current effective treatment of chronic HCV infection (genotypes 1–6) is with direct-acting antivirals (DAAs).	**Case 80-13 (Question 1)** **Case 80-14 (Questions 1–3)** **Case 80-15 (Questions 1–4)** **Case 80-16 (Questions 1–5)**
4	Hepatitis D virus (HDV) is a small RNA virus that requires coinfection with HBV for replication. HDV transmission is most likely associated with percutaneous exposure. HDV, in combination with HBV, leads to a much higher risk of acute liver failure. Prevention strategies rely on successful immunization of HBV. Pegylated interferon is the only medication used to treat HDV infection. An investigational	**No cases**

	injectable antiviral agent is under investigation to treat HDV infection.	
5	Hepatitis E virus is similar to HAV and is transmitted via the fecal–oral route, especially through contaminated water, which is found to be more common in developing countries. Recovery from acute illness usually occurs.	**No cases**
6	Immunizations for persons with viral hepatitis infections, specifically against HAV, HBV, and pneumococcal disease, are highly recommended.	**No cases**

INTRODUCTION

There are five distinctly separate hepatitis viruses that cause liver disease. A sixth virus also has been identified but has yet to be implicated in liver disease. Four of these viruses are RNA viruses, and one is a DNA virus.[1] The individual virus types can be distinguished by serologic assays and, in some instances, by genotyping. Although progress in the area of disease prevention has improved, advances in treatment of certain viral infections have been limited because of the large concentration of viruses produced and their rapid mutation. For instance, the hepatitis C virus (HCV) replicates ~1 trillion virus particles (virions) daily, compared with 100 billion hepatitis B virus (HBV) virions daily and 10 billion human immunodeficiency virus (HIV) virions daily.[1,2] This chapter reviews the virology, epidemiology, pathogenesis, natural history, diagnosis, clinical manifestations, prevention, and treatment strategies for viral hepatitis A through E.

CAUSATIVE AGENTS AND CHARACTERISTICS

Viral hepatitis is a major cause of morbidity and mortality in the United States.[1–3] At least five distinct pathogens are responsible for viral hepatitis. These hepatotropic viruses are identified by the letters A through E, as follows: (a) type A hepatitis caused by hepatitis A virus (HAV), (b) type B hepatitis caused by hepatitis B virus (HBV), (c) type C hepatitis caused by HCV, (d) type D or delta hepatitis caused by the HBV-associated hepatitis D virus (HDV), and (e) type E hepatitis caused by the hepatitis E virus (HEV). Hepatitis A through E viruses differ in their immunologic characteristics and epidemiologic patterns (**Table 80-1**).[4,5] Fecal–oral transmission is the primary mode of infection for HAV and HEV, whereas parenteral and sexual transmission are characteristic of HBV, HCV, and HDV infections.[1–3] Several other viruses primarily affect nonhepatic organ systems and may secondarily induce a hepatitis-like syndrome. These include the Epstein–Barr virus (infectious mononucleosis), cytomegalovirus, herpes simplex viruses, varicella zoster virus, and rubella, rubeola, and mumps viruses.

Table 80-1

Characteristics of Hepatitis Viruses

Virus	Nucleic Acid	Routes of Transmission	Risk of Chronic Illness	Mortality
HAV	Nonenveloped SS RNA	Fecal–oral	None	Low
HBV	Enveloped DS DNA	Parenteral (sex, perinatal)	High	Moderate–high
HCV	Enveloped SS RNA	Parenteral (sex, perinatal)	High	Moderate–high
HDV	Enveloped SS RNA	Parenteral (sex, perinatal)	High	High
HEV	Nonenveloped SS RNA	Fecal–oral	None	Low–moderate

DNA, deoxyribonucleic acid; DS, double-stranded; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; RNA, ribonucleic acid; SS, single-stranded.

Definitions of Acute and Chronic Hepatitis

Viral hepatitis can present as either an acute or a chronic illness. Acute hepatitis is defined as an illness with a discrete date of onset with jaundice or increased serum aminotransferase concentrations >10 times the upper limit of normal (ULN)[1–3,5] and does not exceed 6 months. Chronic hepatitis is a prolonged inflammatory condition of the liver that involves ongoing hepatocellular necrosis for ≥6 months beyond the onset of acute illness.[4,5] The most common causes of chronic viral hepatitis are HBV and HCV.[3] Drug-induced and autoimmune chronic hepatitis occur less frequently; metabolic disorders and HDV chronic hepatitis are relatively uncommon in the United States.[6,7] HAV and HEV are self-limiting infections that rarely progress to chronic hepatitis.

Serologic Evaluation in Presumed Chronic Hepatitis

Serologies are useful in diagnosing viral hepatitis. Antibodies against HAV (anti-HAV), HBV (anti-HBs or HBsAb), and HCV (anti-HCV) are useful diagnostic markers. A diagnosis of acute HAV infection includes the presence of immune globulin (Ig) M anti-HAV. If HBsAb is present, further testing for hepatitis B surface antigen (HBsAg), hepatitis B envelope antigen (HBeAg), and HBV DNA confirm the presence of active viral replication and viral load, respectively. Testing for HDV antibody (anti-HDV) should also be performed in patients with HBV infection to evaluate the possibility of coinfection or superinfection. If the serology result is negative, rare but treatable causes of chronic active hepatitis should be further ruled out. These could include alcoholic liver disease, α-1-antitrypsin deficiency, and drug-induced hepatitis. Commonly reported drugs associated with reversible hepatitis syndrome include anticonvulsants, methyldopa,[8] nitrofurantoin,[9] isoniazid,[10] and, rarely, sulfonamides,[11] and propylthiouracil.[12]

HEPATITIS A VIRUS

Virology and Epidemiology

HAV is an icosahedral, nonenveloped virus measuring 28 nm in diameter. It is a single-stranded, positive-sense, linear RNA enterovirus of the *Picornaviridae* family in the *Hepatovirus* genus (Table 80-1).[2,4,5] HAV has a worldwide distribution.[13,14] The prevalence of infection is linked to the quality of the water supply, level of sanitation, and age.[14,15] Incidence data are unreliable because the disease is frequently mild and often unrecognized, resulting in underreporting. The primary mode of transmission is from person to person via the fecal–oral route.[15,16] The virus is sturdy and resists degradation by drying, environmental conditions (temperatures as high as 56 °C and as low as −20 °C), gastric acid (pH 3.0), and digestive enzymes in the upper gastrointestinal (GI) tract. Therefore, HAV is easily spread within a population. Direct contact with fecally contaminated water or food is a significant mode of transmission.[16,17] Children are considered a relatively common reservoir, but rarely exhibit clinical symptoms.[17,18]

In 2019, the estimated number of infections had increased to 5.6 times, or an estimated 37,000 infections in the United States.[19] The incidence of new HAV infections is mainly attributed to hepatitis A outbreaks among people who inject drugs (PWID) or are homeless. HAV infection could also occur from common-source outbreaks of fecally contaminated food or water, as well as uncooked HAV-contaminated foods. In developed countries with well-maintained sanitation and water supplies, waterborne outbreaks of HAV are uncommon.[19] Originally, HAV vaccination was recommended for persons at high risk for infection and children living in communities at high risk. However, owing to the significant number of cases of HAV disease still occurring in the United States, HAV vaccination recommendations have expanded. In 2020, the Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination

for all children and adolescents ages 2 to 18 years in the United States.[20]

Exceedingly rare causes of HAV include transfusion of blood or blood products collected from donors during the viremic phase of their infection and from contact with experimentally infected nonhuman primates.[16,21] Percutaneous transmission is rare because no asymptomatic carrier state for HAV exists and the incubation period is brief.[16] Occupations at risk for HAV infection include sewage workers, hospital cleaning personnel, day care staff, and pediatric nurses.[18,19] HAV is the most common preventable (eg, vaccination) infection in travelers visiting locations with poor hygienic conditions.[22]

Transmission

Before HAV vaccination prevalence and availability, asymptomatic children, as HAV carriers shedding viral contents, were thought to be one of the main sources of transmission primarily infecting via the fecal–oral route from direct person-to-person contact or from contaminated food or water. After the universal vaccination implementation in the United States, transmission of HAV predominantly occurs via susceptible adults who are unvaccinated, partially vaccinated, or nonresponders to vaccines.[20] HAV has been also detected in saliva, but data evaluating the transmissibility of saliva with HAV is lacking at this time.[23]

Pathogenesis

Although the exact mechanism of injury is unknown,[17,18] viral replication occurs within the liver or hepatocytes. Subsequent hepatocyte death results in viral elimination and eventual resolution of the clinical illness.[18]

Natural History

After exposure to HAV, usually via ingestion of HAV from material contaminated with feces, the virus resides and replicates in the hepatocytes within hours and days of infection. Following the translational and replication processes, HAV is released into the bile canaliculi and is transported to the intestine, where it is excreted in the feces at concentrations ranging up to 10^9 infectious virions per gram of feces.[17] This occurs during the subclinical stage (incubation period) or anicteric prodromal period (14–21 days) of the infection before alanine aminotransferase (ALT) levels become elevated and clinical symptoms or jaundice occur.[18]

The contagiousness of the infection is highest during this period and is significantly reduced following the onset of symptoms or jaundice. HAV infection could occur in two clinical courses, varying from subclinical hepatitis (asymptomatic), usually observed in children, to anicteric hepatitis (symptoms without jaundice) or icteric hepatitis that occurs in adults and could result in fulminant hepatitis and death, especially among adults older than 50 years.[18] Chronic HAV infection usually does not manifest because of the robust humoral and cellular immune responses, particularly natural killer cells, $CD4^+$ and $CD8^+$ cytotoxic T cells.[18] More importantly, humoral immunity plays a pivotal role in viral clearance, leading to viremia declines after the presence of neutralizing antibodies.[24] Typically, the course of HAV includes an incubation phase, an acute hepatitis phase, and a convalescent phase. Complete clinical recovery is usually seen in all patients within 6 months of HAV infection.

Clinical Manifestations

CASE 80-1

Question 1: E.T., a 34-year-old medical sales representative, presents to the emergency department (ED) with acute onset of jaundice and “dark urine.” He was in good health until 2 weeks ago, when he noted feeling fatigued and weak, which he attributed to his demanding work schedule. He also recalled having a mild headache, loss of appetite, muscle pain, diarrhea, and low-grade fevers from 99 °F (37.22 °C) to 101 °F (38.33 °C). He attributed these symptoms to the

flu and took acetaminophen with plenty of fluids. His symptoms persisted until yesterday when they resolved unexplainably. He then noticed his urine was cola colored. This morning, he noted jaundice of his eyes and skin and sought medical attention.

E.T.'s medical history includes a recent respiratory tract infection, treated successfully with levofloxacin. His social history is significant for frequenting the local oyster bar, where he regularly ingests raw oysters. He denies smoking and recent travel outside the United States but admits to occasional alcohol consumption. E.T. has no history of sexual exposure, needle use, or transfusions. His current medications include oral diazepam 5 mg at bedtime as needed for "muscle spasms," but he has not taken diazepam for "several months." He also has a seizure disorder sustained after a motorcycle accident 2 years before admission, for which he takes phenytoin 400 mg orally (PO) at bedtime.

Physical examination is significant for a well-developed, well-nourished male in no acute distress. He is alert and oriented, with a temperature of 99 °F (37.22 °C). His sclerae and skin are icteric, and his abdomen is positive for a tender, enlarged liver and right upper quadrant pain. Laboratory test results reveal the following values:

Hemoglobin (Hgb): 16 g/dL
Hematocrit (Hct): 44%
White blood cell (WBC) count: 5500 cells/μL
Aspartate transaminase (AST): 120 units/L
ALT: 240 units/L
Alkaline phosphatase: 86 units/L
Total bilirubin: 3.2 mg/dL
Direct bilirubin: 1.5 mg/dL
Phenytoin concentration: 12 mg/L (normal: 10–20 mg/L)

The albumin, prothrombin time (PT), blood glucose, and electrolytes are all within normal (WNL) limits. E.T.'s test result is negative for anti-HCV, HBeAg, HBsAg, and hepatitis B core antibody (anti-HBc), but is positive for anti-HBs and IgM anti-HAV.

What clinical features and serologic markers are consistent with viral hepatitis in E.T.?

The incubation period for HAV is 15 to 50 days (average 28 days) after inoculation. The host is usually asymptomatic during this stage of the infection; thus, E.T. is beyond the inoculation phase of the disease. Because HAV titers are highest in the acute-phase fecal samples, the period of infectivity is 14 and 21 days before the onset of jaundice to 7 or 8 days after jaundice. Therefore, E.T. should be considered infectious at this time. In HAV infections, acute-phase

serum and saliva are less infectious than are fecal samples, whereas urine and semen samples are not infectious. Family members and persons recently in immediate contact with E.T. should be notified.[25]

The symptoms of acute viral hepatitis caused by HAV, HBV, HCV, HDV, and HEV are similar. The onset of symptoms in HAV infection, however, is less insidious than those seen with HBV and HCV infection.[5] Generally, symptoms of HAV infection present a week or more before the onset of jaundice. The likelihood of having symptoms is related to age. In children younger than age 6 years, 70% of infections are asymptomatic, whereas older children and adults have symptomatic disease with jaundice occurring in >70% of cases.[18] E.T. has signs and symptoms of acute HAV infection, including the nonspecific prodromal symptoms of fatigue, weakness, anorexia, nausea, and vomiting. Abdominal pain and hepatomegaly are common. Less common symptoms include fever, headache, arthralgias, myalgias, and diarrhea. Within 1 to 2 weeks of the onset of prodromal symptoms, patients may enter an icteric phase with symptoms, including clay-colored stools, dark urine, scleral icterus, and jaundice. The dark urine is caused by bilirubin (bilirubinuria), generally occurring shortly before the onset of jaundice. E.T. should be questioned about the presence of pale stools (light gray or yellow color), which usually is observed during the icteric phase. His scleral icterus is strongly suggestive of viral hepatitis. Icteric infections usually occur in adults and are 3.5 times more common than is the anicteric presentation that is seen in children.[16,25]

The results of E.T.'s liver function tests (eg, elevations in AST, ALT, and total bilirubin) also are consistent with viral hepatitis. Serum transaminase concentrations increase during the prodromal phase (usually ALT > AST) of HAV infection, peaking before the onset of jaundice. These concentrations are often >500 units/L and decline at an initial rate of 75%/week, followed by a slower rate of decline thereafter. Serum bilirubin peaks after aminotransferase activity and rarely exceeds 10 mg/dL. Total bilirubin levels decline more slowly than do aminotransferases and generally normalize within 3 months. Right upper quadrant tenderness, mild liver enlargement, and

splenomegaly may also be present in patients with acute HAV infection.[5,25]

Extrahepatic Manifestations

Case 80-1, Question 2: Are there any additional complications that E.T. could experience from his acute HAV infection?

With the appearance of jaundice, prodromal pruritus and extrahepatic manifestations can occur, usually in patients with a more protracted illness. E.T. should be monitored for additional manifestations of HAV infection, including immune complex–associated rash, leukocytoclastic vasculitis, glomerulonephritis, cryoglobulinemia (less likely than with HCV), and arthritis.[25]

Diagnosis and Serology

Diagnostic methods for detecting HAV antigen and anti-HAV are listed in **Figure 80-1**. Detection of IgM antibodies to HAV in a patient who presents with clinical characteristics of hepatitis, or in an asymptomatic patient with elevated transaminases, is consistent with acute HAV infection. HAV IgG appears after IgM and is indicative of previous exposure and immunity to HAV, whereas a rising IgG is consistent with recent exposure.[5,25] Anti-HAV IgM is commonly present throughout the disease course (16–40 weeks), usually peaking early and declining to undetectable levels 3 to 4 months after the initial infection.[25] One-quarter of patients infected with HAV have IgM present for up to 6 months and occasionally longer. HAV IgG appears early in the convalescent phase and is detectable for decades after the acute infection resolves, with a slowly declining titer.[16,25] Both enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay methods of antibody detection are sensitive, specific, and reliable to diagnose acute HAV infection. E.T. has a positive IgM anti-HAV, consistent with acute HAV infection. He has a negative IgM anti-HBc test, ruling out acute HBV infection.[16,25]

Treatment

GENERAL MEASURES

HAV infection is usually a self-limiting disease and rarely leads to serious complications including fulminant liver failure and death. Management involves supportive care and medical treatment of serious complications. Intravenous (IV) fluid and electrolyte replacement, nutritional support, and the use of antiemetics may be necessary for some patients. Antipyretics (acetaminophen) should

not be used because the risk of fulminant hepatic failure (FHF) could increase. Considering that hemolysis or acute kidney injury is possible, a regular assessment of renal function with a complete blood count (CBC) should be performed. Patients should abstain from alcohol during the acute phase of the disease. After resolution of symptoms and serum biochemical abnormalities, moderate alcohol intake is no longer contraindicated. In general, prognosis after HAV infection is very good. Long-term immunity accompanies HAV infection, and recurrence or chronic hepatitis usually does not occur.

Adjustment of Medication Doses

Case 80-1, Question 3: Should E.T.'s medications be adjusted during the acute phase of HAV infection?

Dosage adjustments for hepatically eliminated drugs in the setting of liver disease are difficult to predict. This is because hepatic metabolism is complex, involving numerous oxidative and conjugative pathways that are variably affected in hepatic disease. In renal disease, creatinine serves as an endogenous marker to predict the clearance of renally eliminated drugs. In hepatic disease, however, no reliable endogenous biomarkers exist to predict drug hepatic clearance. Laboratory tests that approximate the synthetic function of the liver (eg, albumin, PT) and biliary clearance (bilirubin) are used to estimate the degree of hepatic impairment, but these tests are not dependable in predicting alterations in pharmacokinetic parameters for hepatically metabolized drugs. Unnecessary and potentially hepatotoxic medications should be avoided during the acute phase of the illness. When drug therapy is indicated with agents that undergo hepatic elimination, it is prudent to use the lowest doses possible to achieve the desired therapeutic effect.

E.T. should be advised to discontinue diazepam because this medication undergoes extensive hepatic biotransformation and limited data suggest this agent accumulates in the setting of acute

viral hepatitis.[26] If E.T. should require drug therapy for muscle spasms, he should either decrease the diazepam dose or consider using an alternative agent (eg, lorazepam) that does not accumulate in acute viral hepatitis.[27] Patients with acute viral hepatitis do not require phenytoin dosage adjustments.[28] Because E.T.'s plasma phenytoin concentration is within the desired therapeutic range, no dosage adjustment is needed.

Prevention of Hepatitis A

Prevention of hepatitis A infection can be achieved through immunoprophylactic measures. Immunoprophylaxis may be passive, active, or a combination of both. In passive immunization, temporary protective antibody in the form of Ig is administered. In active immunization, a vaccine is administered to induce the formation of long-term protective antibodies.[20],[29] Prophylaxis can be administered before (pre-exposure prophylaxis) or after exposure (postexposure prophylaxis).

Pre-exposure Prophylaxis

CASE 80-2

QUESTION 1: M.D., a 22-year-old student, is preparing for a 2-week vacation to Thailand. He plans to travel 3 months from now.

Should he receive prophylaxis for HAV?

IMMUNE GLOBULIN

Before hepatitis A vaccine was available, the only therapy for pre-exposure prophylaxis of hepatitis A infection was Ig, which is a concentrated solution of antibodies prepared from pooled human plasma. Although passive immunization with Ig alone is highly effective in preventing HAV infection,[20] the duration of protection is short. For these reasons, hepatitis A vaccine is generally preferred to Ig for pre-exposure prophylaxis. However, when Ig is used for pre-

exposure prophylaxis in specific circumstances (eg, travelers who are allergic to a vaccine component decide against vaccination, or age younger than 1 year), a single dose of 0.1 mL/kg of Ig administered intramuscularly (IM) confers protection for up to 1 month of travel, and an IM dose of 0.2 mL/kg confers protection for up to 2 months, with a repeat dose every 2 months if >2 months of travel will occur.[19,20,25,30]

For selected populations, including those traveling in <2 weeks to intermediate-to-high HAV endemic countries, of older age (older than 40 years), have underlying immunocompromised conditions and chronic liver diseases, they may receive Ig in addition to hepatitis A vaccine administered at a separate anatomic site.

VACCINE

Active immunization with hepatitis A vaccine has largely supplanted the use of Ig for pre-exposure prophylaxis of infection caused by HAV. Two types of the inactivated, monovalent hepatitis A vaccines are available in the United States and globally: Havrix® and Vaqta®. Both vaccines are formalin-inactivated preparations of attenuated HAV strains.[31] The manufacturers use differing units to express antigen content of their respective vaccines. Havrix® dosages are expressed in ELISA units, and Vaqta® dosages are expressed as units of hepatitis A antigen. These vaccines are developed to provide long-term immunity. They contain an aluminum adjuvant, are free of thimerosal and mercury preservatives, and are safe and effective for children and adults.[32]

DOSING REGIMEN

Havrix® is available in two formulations that differ according to age: for persons 12 months to 18 years old, 720 ELISA units (0.5 mL) per dose in a two-dose schedule; and for persons 19 years and older, 1440 ELISA units (1.0 mL) per dose in a two-dose schedule (**Table 80-2**).[27,31,32] Havrix® is injected IM into the deltoid muscle, with a second dose administered 6 to 12 months later. The pediatric Havrix® formulation (three-dose schedule) is no longer available.

Vaqta® is available in two formulations that differ according to the person's age: for persons 12 months to 18 years old, 25 units (0.5 mL) per dose in a two-dose schedule; and for persons 19 years and older, 50 units (1.0 mL) per dose in a two-dose schedule (Table 80-2).[29,31,33] Likewise, this vaccine is injected IM into the deltoid muscle, with a second dose administered 6 to 18 months later.[20,29,31]

Table 80-2
Recommended Doses of Hepatitis A Vaccines

Age at Vaccination	Dose (Volume)[a]	Schedule (Months)[b]
Havrix®		
Children 12 months–18 years	720 ELISA units (0.5 mL)	0, 6–12
Adults >19 years	1440 ELISA units (1.0 mL)	0, 6–12
Vaqta®		
Children 12 months–18 years	25 units (0.5 mL)	0, 6–18
Adults >19 years	50 units (1.0 mL)	0, 6

[a]Enzyme-linked immunosorbent assay (ELISA) units.

[b]Zero months represent timing of the initial dose; subsequent numbers represent months after the initial dose.

Prevention of hepatitis A with the hepatitis A vaccine. *N Engl J Med*. 2004;350:476–481.

COMBINATION VACCINE

The U.S. Food and Drug Administration (FDA) has also licensed a combined HAV and HBV vaccine (Twinrix®) for use in persons ages 18 years and older. Twinrix® is composed of the same antigenic components used in Havrix® and Engerix-B®. Each dose of Twinrix® contains at least 720 ELISA units of inactivated HAV (half of the Havrix® adult dose) and 20 µg of recombinant HBsAg protein (same as the Engerix-B® adult dose).[34,35] Twinrix® does not contain

thimerosal and mercury as preservatives and is safe and effective for adults.[32]

Primary immunization consists of a series of three doses, given on a 0-, 1-, and 6-month schedule, the same that is used for single-antigen hepatitis B vaccine.[34],[35] Any person 18 years and older having an indication for both hepatitis A and hepatitis B vaccine can receive Twinrix®, including persons with chronic liver disease, PWID, men who have sex with men (MSM), persons who have occupational risk for infection (eg, who work with HAV-infected primates), and persons with clotting factor disorders who receive therapeutic blood products.[34],[35] For international travel, hepatitis A vaccine is recommended; hepatitis B vaccine is recommended for travelers to areas of high or intermediate hepatitis B endemicity who plan to stay for >6 months and have frequent close contact with the local population.[36]

EFFICACY, SAFETY, AND DURATION OF RESPONSE

The efficacy of the hepatitis A vaccine is well established, with a protective efficacy of 94% to 100%.[33],[34] The vaccine is well tolerated, with soreness at the injection site, headache, myalgias, and malaise as the most commonly reported adverse effects.

The duration of protection from the vaccines has not been studied extensively. However, protective levels of antibody to HAV could be present for at least 14 to 20 years in children and for at least 25 years in adults.[31],[34] The ACIP has no recommendations regarding the need for booster doses for healthy populations who completed the vaccination series at this time. The safety data of the HAV vaccine during pregnancy are limited. However, because the vaccine is produced from inactivated HAV, the theoretic risk to the developing fetus is low. The benefits versus risks associated with vaccination for HAV in females who might be at high risk for exposure to the infection should be discussed with her primary care physician and obstetrician.[19]

INDICATIONS

Universal HAV vaccination is recommended for all children and adolescents ranging from 2 to 18 years old if previously unvaccinated. In addition to universal recommendations, ACIP also recommends HAV vaccination for several high-risk groups, including HIV-infected populations if age 1 year or older, pregnant patients at risk for HAV infection (illicit drug users regardless of injection or noninjection, international travelers, close contact with an international adoptee, homelessness), 6- to 11-month-old infants traveling outside the United States, older adults (older than 40 years), immunocompromised conditions, travelers to countries with high endemicity of infection (South and Central America, Africa, South and Southeast Asia, Caribbean, and the Middle East),[37–39] travelers to countries with intermediate endemicity of infection (Eastern and Southern Europe and Russia), anyone age 1 year old or older during HAV outbreaks at risk for HAV infection (MSM, persons living with HIV), or living in communities with high rates of hepatitis A infection or periodic hepatitis A outbreaks (Alaskan Native villages, American Indian reservations), health care workers or settings providing services to those who are at risk for HAV infection, group homes, day care facilities for people with developmental disabilities, prisoners, and persons with chronic liver disease who are at increased risk for fulminant hepatitis A.[20,29,31,33]

Thus, M.D. should receive either Havrix® 1440 ELISA units or Vaqta® 50 units. This initial injection dose will provide adequate protection from HAV infection during his travel, and he can receive the second dose upon his return, at least 6 months after the first dose. If M.D. decides to travel within the next 2 weeks, he should receive both vaccination and Ig before departure.[36]

Postexposure Prophylaxis

CASE 80-3

Question 1: L.W., a 26-year-old male, was recently diagnosed with HAV infection. He attends college and works part-time as a retail clerk. He lives with his healthy, 25-year-old wife and 10-month-old infant daughter.

Which of L.W.'s contacts require postexposure prophylaxis for HAV?

Although Ig has been recommended in the past for unvaccinated people recently exposed to HAV, hepatitis A vaccines (Havrix® and Vaqta®) are effective in preventing secondary HAV infection in healthy people. Twinrix® is not recommended for postexposure prophylaxis because there are no data available for its use in this setting.[19] A vaccine, Ig, or both should be administered for people who have been exposed to HAV within the past 2 weeks and have not been vaccinated, particularly those age older than 1 year with immunocompromised condition or chronic liver disease.[20],[29],[36] For infants age younger than 1 year old, Ig should be administered instead of the vaccine. Of note, if Ig is administered, the measles, mumps, rubella (MMR) vaccination should be delayed until after a minimum of 6 months have passed owing to the concerns that Ig may interfere with live vaccines such as MMR.[30],[34] In addition, Ig of 0.1 mL/kg should be used for populations with existing contraindications for hepatitis A vaccines within 2 weeks of exposure.[20]

Therefore, L.W.'s wife should receive prophylactic administration of the HAV vaccine, and his 10-month-old infected daughter should receive hepatitis A Ig at a dose of 0.1 mL/kg IM as soon as possible but no later than 2 weeks after exposure. Contacts who have received a dose of hepatitis A vaccine at least 1 month before exposure do not need Ig because protective antibody titers are achieved in >95% of patients 1 month after vaccination.[20] Prophylaxis is not recommended for casual contacts at work or school.

Administration of Ig within 2 weeks of exposure to HAV is 80% to 90% effective in preventing acute HAV infection.[20],[25] In most cases, when given early, Ig prevents both clinical and subclinical HAV illness. Protection after Ig administration is immediate and complete, but a short-lived one. Other situations in which Ig administration may be indicated include hepatitis A infection in day care centers and in settings with infected persons who prepare and serve food. Ig is

recommended for all staff and children in day care settings when a case of HAV infection is confirmed among employees or attendees.[15,19,20] When a food handler is diagnosed with hepatitis A, Ig is recommended for other food handlers at the same location. Given the improbability of disease transmission to persons consuming food prepared or served by workers infected with hepatitis A, the routine administration of Ig in this setting is not recommended.[15,20]

When Ig is required for infants or pregnant patients, preparations free of thimerosal should be used.[15] Although Ig does not impede the immune response to inactivated vaccines, oral poliovirus vaccine or yellow fever vaccine, it may interfere with the response to live attenuated vaccines such as the MMR and varicella vaccines. Therefore, MMR and varicella vaccines should be delayed for at least 3 months after administration of Ig for HAV prophylaxis. Ig should not be given within 2 weeks of the administration of MMR or varicella vaccine. Finally, if Ig is administered within 2 weeks of MMR, the person requires revaccination, but not sooner than 3 months after the Ig administration for MMR.[15,19,20] Serologic tests for varicella vaccination should be performed 3 months after Ig administration to determine whether revaccination is required.

HEPATITIS B VIRUS

Virology

HBV is an icosahedral, enveloped, and encapsulated virus measuring 40 to 42 nm in diameter and belongs to the *Hepadnaviridae* family of viruses.[35–38] The viral genome is a partially double-stranded, circular DNA linked to a DNA polymerase. Unlike HAV, HBV carries various antigenic components, including HBsAg, hepatitis B core antigen (HBcAg), and HBeAg, potentially causing acute illness with or without a chronic disease state. HBV infection

can produce either asymptomatic or symptomatic infection. The average incubation period is 90 days (range: 60–150 days) from exposure to the onset of jaundice and 60 days (range: 40–90 days) from exposure to the onset of abnormal serum ALT levels because the liver is the primary site utilized for HBV replication.[37,38]

The life cycle of HBV is described in **Figure 80-2**. Elucidation of the HBV life cycle has resulted in opportunities for drug development. Of special importance, the viral DNA polymerase functions as both a reverse transcriptase (RT) for synthesis of the negative DNA strand from genomic RNA and as an endogenous DNA polymerase. Because the HBV polymerase is remotely related to the RT enzymes of retroviruses (eg, HIV), some inhibitors of HIV polymerase or RT also have activity against the HBV polymerase. Thus, several RT inhibitors (nucleosides and nucleotides) have been evaluated for treating and preventing HBV; however, rapid emergence of resistance occurs with many of these agents.

Figure 80-2 Life cycle of hepatitis B virus in the hepatocyte. cccDNA, covalently closed circular DNA; ER, endoplasmic reticulum; HBeAg, hepatitis B envelope antigen; HBsAg, hepatitis B surface antigen; hNTCP, human sodium taurocholate cotransporting polypeptide; IFN, interferon; NL, natural killer cell; pgRNA, progenomic RNA. Epidemiology

Globally, ~2 billion persons are infected with HBV, and between 350 and 400 million persons are living with chronic hepatitis B virus (CHB) infection.[39,40] HBV disease causes ~1 million deaths from cirrhosis, liver failure, and hepatocellular carcinoma (HCC).[41–43] In 2002, >600,000 persons died of HBV-associated acute and chronic liver disease.[39,40] In the United States, an estimated 2.2 million persons are living with chronic HBV infection and ~5500 died annually from CHB-related complications and HCC.[42,43]

Acute HBV infection is usually asymptomatic in infants and children younger than 5 years old compared to 30% to 50% of children older than 5 years and adults who could develop clinical signs and symptoms.[44] Clinical signs and symptoms can include anorexia, nausea, vomiting, abdominal pain, malaise, and jaundice. Extrahepatic manifestations of CHB disease may include skin rashes, arthralgias, and arthritis.[35] Approximately 95% of primary infections in immunocompetent adults are self-limiting, with elimination of the virus from the blood and subsequent lasting immunity to reinfection. Progression from acute to CHB infection is influenced by the person's age at acquisition of the virus. CHB infection occurs in ~30% of infected children younger than 5 years old, and <5% of infected persons older than 5 years.[44] Persons who are HBV infected and are at risk for developing CHB disease include immunosuppressed persons (eg, persons with diabetes, HIV, or on hemodialysis).[35]

With respect to HBV infection in certain parts of the world, it is commonly acquired perinatally in Asia. The cellular immune responses to hepatocyte-membrane HBV proteins that are associated with acute hepatitis do not occur, and chronic, lifelong infection is established in >90% of persons infected in Asia.[45] On the

other hand, most acute HBV infections that occur in the West are reported during adolescence and early adulthood because of behaviors and environments that favor the transmission of bloodborne infections, such as sexual activity, injection drug use, and occupational exposure. There are no specific treatments for acute HBV, and supportive care is the mainstay of therapy.[45,46]

Similar to HAV infection, CHB infection is defined as persons positive for HBsAg for >6 months (**Fig. 80-3**). The incidence of acute HBV infection has declined in the United States by ~82% since 1991.[40,46–48] This reduction in infection occurs in all age, racial, ethnic, and high-risk groups, particularly among children and health care workers, the groups with the highest rate of vaccination. Less high-risk behaviors also have led to decreased transmission of infection. High-risk groups in the United States for acquiring HBV infection include certain ethnic groups (eg, Alaskan Eskimos, Asian Pacific Islanders), first-generation immigrants from regions of high endemicity (eg, India, Central and Southeast Asia), PWID, MSM, African Americans, and males (more than females).[46–48] The most prominent risk factors associated with acute HBV infection include heterosexual contact (42%), MSM (15%), and injection drug use (21%).[46–48] HBV vaccination opportunities include clinics for sexually transmitted infections (STIs), correctional facilities, and holding centers for incarceration.

Figure 80-3 Acute hepatitis B virus infection. HbeAg, hepatitis B envelope antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus. (AASLD/IDSA Guidelines.)

Transmission

HBV is known to be highly infectious and can be transmitted even when the presence of blood is invisible. Of note, the virus can live on an environmental surface for a minimum of 7 days.[47,49,50] The transmission of HBV is from exposure to blood, semen, and other body fluids infected with HBV. Furthermore, HBV transmission could occur among unvaccinated adults with risky behaviors, including sexual contact, and percutaneous or perinatal exposure to infectious blood or body fluids. HBV is most highly concentrated in serum with lower concentrations in semen, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid, all of which can potentially transmit the virus if contacted through percutaneous, mucosal, or nonintact skin.[44] Other body fluids, such as sweat, urine, fecal matter, sputum, breast milk, bile, and

nasopharyngeal washing, are unlikely to transmit HBV owing to low quantities of HBV unless they also contain blood.[51] The modes of HBV transmission include sexual, percutaneous, and perinatal routes, which are summarized in the following sections.

SEXUAL TRANSMISSION

Sexual activity, especially unprotected sex and having multiple sexual partners, is the most significant mode of HBV transmission worldwide, including North America where the prevalence of infection is low compared to Southeast Asia, Africa, and Europe.[46–48] Heterosexual intercourse accounts for the majority of U.S. infections (26%). In heterosexual persons, factors associated with an enhanced risk of HBV infection include duration of sexual activity, number of sexual partners, and history of STI. Sexual partners of PWID, sex workers, and clients of sex workers are at a very high risk for infection. Sexual partners of infected individuals are at high risk for infection, even in the absence of high-risk behavior. Because most patients with CHB infection are unaware of their infection and are “silent carriers,” sexual transmission is a significant mode of transmission. Many of the HBV infections could have been prevented through universal vaccination. Furthermore, the use of condoms could reduce the risk of sexual transmission.[46–48]

From 1980 to 1985, a very high rate of HBV infection was observed in MSM, accounting for 20% of all reported cases of infection.[46–48] Having multiple sexual partners, anal-receptive intercourse, and duration of sexual activity were the most common factors associated with HBV acquisition in the MSM population. Fortunately, the current rates of HBV infection in the MSM population have fallen and are estimated to be about 8%, possibly as a result of modifications of sexual behavior in response to HIV transmission. Similar to heterosexuals, the use of condoms in the MSM population has also reduced the risk of sexual transmission of HBV.

PERCUTANEOUS TRANSMISSION

Another common mode of HBV transmission among adults is via the percutaneous route, primarily from injection drug use. Recreational and illicit drug use in the United States and globally is a significant mode of HBV transmission, accounting for ~23% of all patients.[46–48] The risk increases with the duration of injection drug use; thus, serologic markers of ongoing or prior HBV infection are usually positive after 5 years of drug use. In addition, use of contaminated needles including acupuncture, tattoo procedures, or needlestick injuries in health care settings can lead to HBV transmission.

PERINATAL TRANSMISSION

Early childhood exposure and perinatal exposure are additional modes of transmission of HBV infection. High serum concentrations of virus have been linked to increased risk of transmission by vertical routes and needlestick exposure. Infants born to HBeAg-positive mothers with high viral replication (>80 pg/mL) have a 70% to 90% risk of perinatal HBV acquisition compared with a 10% to 40% risk in infants born to mothers infected with HBV who are HBeAg negative.[46–48] Infection generally occurs via inoculation of the infant at the time of birth or soon thereafter; and even with active and passive immunization, 10% to 15% of infants acquire HBV infection at birth.

In developing countries with high prevalence rates and in regions of the United States with high endemicity, children born to HBsAg-positive mothers are at risk for acquiring HBV infection in the perinatal period, with infection rates reported to be between 7% and 13%.[35],[43],[44] In addition, children of HBsAg-positive mothers who are not infected at birth remain at very high risk for early childhood infection, with 60% of those born to HBsAg-positive mothers becoming infected by the age of 5 years. The mechanism of the later infection, which is neither perinatal nor sexual, is not known. Although HBsAg is detectable in breast milk, breast-feeding is not believed to be a primary mode of HBV transmission. HBV antibody treatment criteria and recommended agents to prevent perinatal

transmission in pregnant patients are discussed later in the section under management of HBV in pregnancy.

OTHER MODES OF TRANSMISSION

Other risk factors for transmission of HBV include personal contact, such as sharing a toothbrush or razor, exudates from skin lesions, or contact with HBV-contaminated surfaces. Dialysis, organ transplantation, traveling to regions of the world endemic for HBV infection, and living in correctional facilities or prisons can also serve as a possible source of transmission.[46–48] Sporadic cases of HBV transmission have been attributed to nonpercutaneous transmission by way of small breaks in the skin, biting, or mucous membranes. Transfusion-associated HBV infection is rare with the screening of blood (tests for HBsAg and anti-HBc), the exclusion of donors who engage in high-risk activities, and viral inactivation process before the transfusion. It is estimated that 1 of 50,000 transfused units could transmit HBV infection. Although HBsAg is found in bodily fluids (eg, saliva, tears, sweat, semen, vaginal secretions, breast milk, cerebrospinal fluid, ascites, pleural fluid, synovial fluid, gastric juice, and urine), only semen, saliva, and serum actually contain infectious HBV.[49–54]

Pathogenesis

Similar to HAV infection, clinical observations suggest that host immune responses are more important than are virologic factors in the pathogenesis of liver injury. Host cellular and humoral immune responses are linked to T lymphocytes, which enhance viral clearance from hepatocytes and cause liver injury.[49,52]

Diagnosis

The presence of HBsAg in serum is diagnostic for HBV infection. In 5% to 10% of acute cases in which the HBsAg levels fall below sensitivity thresholds of current assays, the presence of IgM anti-

HBc in serum confirms a recent acute HBV infection. Another highly reliable marker of active HBV replication and diagnosis is the presence of HBV DNA in serum through qualitative or quantitative assays, detectable early during the course of acute HBV infection.[53–55] Persistent levels of HBV DNA indicate ongoing infection and a high degree of active viral replication and infectivity.

Serology

Antigens and antibodies associated with HBV infection include HBsAg and surface antibody to hepatitis B (anti-HBs or HBsAb), HBcAg, anti-HBc, HBeAg, and antibody to hepatitis B envelope (anti-HBe). The serologic markers that differentiate between acute, resolving, and chronic infection are HBsAg, anti-HBc, and anti-HBs. HBeAg and anti-HBe screenings are used for the management of patients with chronic infection and used as markers for how infectious the person with HBV is.[44,56]

Serologic patterns, general definitions, and diagnostic criteria of HBV infection are depicted in **Table 80-3**. Within the first several weeks of exposure (range: 2–10 weeks), HBsAg appears in the blood and is present for several weeks before serum concentrations of aminotransferases increase and symptoms occur (**Fig. 80-4**).[53,54] Clinical illness usually follows HBV exposure by 1 to 3 months. HBsAg can be detected in serum until the clinical illness resolves and usually becomes undetectable after 4 to 6 months. Persistence of HBsAg beyond 6 months implies progression to CHB infection. The anti-HBs often appear after a short “window” period during which neither HBsAg nor anti-HBs are detectable. Therefore, screening should be performed using both HBsAg and anti-HBs. In most patients, anti-HBs persist for years after HBV infection, conferring immunity to reinfection (see Fig. 80-4).

Table 80-3

Hepatitis B Virus: Laboratory Markers and Interpretations

Laboratory Marker	Interpretation

Hepatitis B surface antigen (HBsAg)	Marker of infection; presence indicates person is infectious.
Hepatitis B surface antibody (HBsAb or anti-HBs)	Past infection, or person has been vaccinated.
Hepatitis B core antibody (anti-HBc)	Marker of previous or ongoing infection
IgM antibody to hepatitis B core antigen (IgM anti-HBc)	Indicates acute infection; first reaction of the body's immune response to HBV
Hepatitis B e antigen (HBeAg)	Marker of active replication of virus and infectiveness
Hepatitis B e antibody (HBeAb or anti-HBe)	Virus is no longer replicating; predictor of long-term clearance of HBV in patients undergoing antiviral therapy
Hepatitis B virus DNA (HBV DNA)	Indicates active replication of virus; more accurate than is HBeAg; used mainly for monitoring response to therapy

Interpretation of serologic markers is described in **Table 80-4**. A soluble viral protein, HBeAg, is detectable early during the acute phase of the disease and persists in chronic CHB infection. HBeAg is a marker of active HBV replication, and its presence correlates with circulating HBV particles. The presence of both HBeAg and HBsAg indicates high levels of viral replication and infectivity and a

need for antiviral therapy. Generally, seroconversion from HBeAg to hepatitis B envelope antibody (anti-HBe) results in a reduction in HBV DNA and suggests resolution of HBV infection. Some patients may, however, continue to have active liver disease and detectable serum HBV DNA levels as a result of the presence of wild-type virus or the presence of precore or promoter mutations that impair HBeAg secretion (patients who are HBeAg negative).

Table 80-4

Hepatitis B Virus: Interpretations of Laboratory Results

Laboratory Markers	Laboratory Results	Clinical Interpretation
HBsAg Anti-HBc Anti-HBs	Negative Negative Negative	Susceptible
HBsAg Anti-HBc Anti-HBs	Negative Positive Positive	Immune because of natural infection
HBsAg Anti-HBc Anti-HBs	Negative Negative Positive	Immune because of hepatitis B vaccination
HBsAg Anti-HBc IgM anti-HBc Anti-HBs	Positive Positive Positive Negative	Acute infection
HBsAg Anti-HBc Anti-HBs	Negative Positive Negative	Interpretation unclear; four possibilities: 1. Resolved infection (most common) 2. False-positive anti-HBc, thus susceptible 3. “Low-level” chronic infection 4. Resolving acute infection

Source: Dienstag JL. Hepatitis B virus infection. *N Engl J Med.* 2008;359:1486–1500.

HBcAg does not circulate freely in the bloodstream and is not measured. Anti-HBc, the antibody directed against HBcAg, is usually detected 1 to 2 weeks after the appearance of HBsAg and just

before the onset of clinical symptoms; and it persists for life. The detection of IgM anti-HBc is the most sensitive diagnostic test for acute HBV infection or recent infection with HBV ≤6 months. During the recovery phase of infection, the predominant form of anti-HBc is in the IgG class. The presence of this antibody suggests prior or ongoing infection with HBV. Furthermore, in areas where HBV is not endemic, isolated detection of anti-HBc in a patient's serum may correlate with low levels of HBV DNA. The presence of HBV DNA may enhance the risk of transmission of HBV and progression to cirrhosis and HCC. Patients immunized against HBV do not develop anti-HBc; therefore, the presence of this antibody differentiates successful vaccination from actual HBV infection. Previous testing modalities such as anti-HBc enzyme immunoassay and radioimmunoassay tests had limited specificity leading to frequent false-positive results, but newer tests have improved specificity for anti-HBc.

Natural History

Of those patients with acute HBV infection, only 1% develops FHF with associated coagulopathy, encephalopathy, and cerebral edema.[57],[58] The cause of fulminant infection is a heightened immune response to the virus, in the absence of HDV or HCV coinfection. Patients with acute liver failure (ALF) often have early clearance of HBsAg, which may complicate the diagnosis, but a positive IgM antibody to HBcAg generally confirms the diagnosis.

Four phases of CHB infection are present: immune tolerance, immune clearance, low-level replication or nonreplication phase (inactive carrier), and reactivation phase. Up to 12% (average 5%) of immunocompetent patients acutely infected with HBV remain chronically infected (historically defined as having detectable HBsAg in serum for ≥6 months).[55],[57] In these patients, HBsAg generally remains detectable indefinitely and anti-HBs fails to appear. The risk of chronicity after neonatally acquired infection is high (>90%), possibly because neonates have immature immune systems. Of the

infected neonates, 50% have evidence of active viral replication. Furthermore, patients who have a reduced ability to clear viral infections, including those receiving chronic hemodialysis, immunosuppression after transplantation or chemotherapy, or patients with HIV infection, may have a greater risk of developing CHB infection.[35,59]

Ultimate outcomes are linked to the presence or absence of viral replication and by the severity of liver damage. Approximately 50% of all chronic carriers have ongoing viral replication, especially with elevated aminotransferases, and 15% to 20% of these develop cirrhosis within 5 years.[35–38,59] Spontaneous loss of HBeAg (7%–20% per year) has been reported, possibly as a result of the use of antiviral therapy, whereas loss of HBsAg occurs less frequently (1%–2% per year). In general, chronic carriers remain infected throughout their life.[35–38,59] Five-year survival rates decline depending on the severity of disease (55% survival with cirrhosis).[59] Asymptomatic HBV carriers tend to have mild disease manifestations with few complications, even with a long period of follow-up. Finally, the risk of HCC is increased up to 300 times in chronic carriers with active viral replication (HBeAg positive).[59,60] The natural history of HBV is such that patients often clear HBeAg and become HBeAg negative with or without therapy. In patients who are HBeAg negative, there can also be chronic infection, which is defined by low levels of both HBV DNA and surface antigen. HBeAg-negative chronic hepatitis involves higher HBV DNA levels (>2000 IU/mL) with elevated ALT, liver disease, and a high potential for disease progression. Resolved HBV infection means that the individual has cleared the surface antigen and, again, this is the ultimate goal with or without antiviral treatment.

Clinical Manifestations

CASE 80-4

QUESTION 1: W.H. is a 35-year-old male who developed nausea, vomiting, anorexia, scleral icterus, and jaundice within the past month. Within the past week, he became increasingly lethargic, confused, disoriented, and lapsed into a grade IV coma. He is admitted to the ED intubated and transferred to the intensive care unit.

W.H.'s social history is significant for IV drug use for the past 10 years and alcohol misuse (none for the previous 5 years). Physical findings include an older than age appearing, hypertensive (blood pressure is 158/99 mm Hg), bradycardic (heart rate is 58 beats/minute) male in respiratory distress (respiratory rate is 26 breaths/minute) with severe jaundice, scleral icterus, and decreased hepatic dullness to percussion (reduced hepatic mass). He shows sluggish pupillary response and increasing muscle tone; neurologic examination reveals W.H. to be stuporous and nonarousable.

The laboratory evaluation shows the following results:

Hct: 42%
Hgb: 14 g/dL
Platelets: 85,000/μL
PT: 25.8 seconds
International normalized ratio (INR): 3.8
AST: 555 units/L
ALT: 495 units/L
Alkaline phosphatase: 101 units/mL
Total bilirubin: 8.4 mg/dL
HBV DNA: 6,000,000 IU/mL

Hepatitis serologic test results are positive for HBsAg, HBeAg, IgM anti-HBc, and HBV DNA. IgM anti-HAV, IgM anti-HDV, and anti-HCV test results are negative. STAT blood gases reveal a metabolic acidosis with a compensatory respiratory alkalosis profile. W.H.'s serum creatinine is 1.8 mg/dL with a recent reduction in urine output.

What clinical findings that support the diagnosis of acute hepatitis and ALF does W.H. have?

The clinical features of acute HBV infection are similar to those described for HAV infection. W.H.'s initial symptoms include a recent history of nausea, vomiting, anorexia, scleral icterus, and jaundice. These are consistent with diagnosis of acute HBV infection. His serologies, notably a positive IgM anti-HBc and HBV DNA, also support this diagnosis.

ACUTE LIVER FAILURE

The most significant complication of acute HBV infection is ALF, widely defined as a coagulation abnormality (INR >1.5) and any degree of mental alteration (encephalopathy) in a patient of <26 weeks' duration.[58,61] He has hepatic encephalopathy, lethargy, confusion, coma, coagulopathy, hemodynamic instability, declining liver function, and acidosis. Patients with ALF often have cerebral edema (80% mortality rate), a complication of a disrupted blood–brain barrier that allows protein-rich fluid to cross into the extracellular spaces of the brain tissue leading to edema and increased intracranial pressure (ICP) or intracranial hypertension (vasogenic model). Clinical symptoms (sluggish pupillary response and increasing muscle tone) develop when the ICP is >30 mm Hg.[58,62–64] Cerebral edema in the confinement of the cranial vault raises the ICP, which may reduce intracerebral perfusion. The edema can result in cerebral ischemia if the cerebral perfusion pressure (systemic blood pressure minus ICP) is not maintained at >40 mm Hg. Of note, intracranial hypertension in ALF is related to the severity of encephalopathy. Cerebral edema is rarely reported in patients with grade I or II encephalopathy, but occurs in up to 75% of patients with grade IV coma.[65] Diagnostic head imaging tests (computed tomography), elevation of the head of the bed, and intubation (and subsequent hyperventilation) may be necessary medical interventions in this setting.

W.H. has symptoms of cerebral edema and may benefit from 100 to 200 mL of a 20% solution of mannitol (0.5–1.0 g/kg) administered by rapid IV infusion to induce an osmotic diuresis with a subsequent decrease in ICP. The dose may be repeated at least once after several hours provided serum osmolality has not exceeded 320 mOsm/L.[66,67] Because W.H. has a blood pressure of 158/99 mm Hg and a heart rate of 58 beats/minute, and is at risk for intracranial hemorrhage, an ICP monitoring device should be placed.[64,65] Although placement of this device is invasive and bleeding is a potential complication, ICP monitoring devices provide important prognostic information. Patients with a cerebral perfusion pressure of >40 mm Hg that is refractory to mannitol therapy are not candidates for liver transplantation. W.H. also has a coagulopathy typical of ALF.

Decreased levels of clotting factors II, V, VII, IX, and X normally synthesized by the liver account for his prolonged PT and elevated INR.[61–63] Recombinant activated factor VII has been used selectively in patients with ALF, but is usually reserved for administration before any invasive procedures. In addition, consumption of clotting factors by low-grade disseminated intravascular coagulation is common in ALF.

W.H. is also thrombocytopenic and at risk for GI ulceration.[65,66] A platelet transfusion should be considered if his counts drop to <10,000/μL. Because he is not actively bleeding, fresh frozen plasma is not indicated at this time.[65,66] W.H. should also be monitored for cardiovascular and renal abnormalities as a result of his ALF.[61,64] Although W.H. is hypertensive, most patients with ALF are hypotensive and hypovolemic and present with interstitial edema owing to low levels of oncotic proteins. Functional renal failure, also known as hepatorenal syndrome or acute tubular necrosis, occurs in 43% to 55% of patients with ALF.[66,67] In hepatorenal syndrome, renal blood flow is reduced, renin and aldosterone levels are increased, and levels of atrial natriuretic factor are unchanged.[67]

As seen in W.H., patients may develop acid–base disturbances, including respiratory alkalosis as a result of central nervous system–mediated hyperventilation or a lactic acid–induced metabolic acidosis.[63,66] Hyponatremia, hypokalemia, hypocalcemia, hypomagnesemia, hypoglycemia, seizures, infections (bacterial and/or fungal), and pancreatitis are additional findings associated with ALF. Thus, sodium, potassium, calcium, magnesium, blood glucose, and amylase should be monitored closely in W.H.[63,66] Prophylactic antimicrobial therapy reduces the incidence of infections in selected groups of patients with ALF, but no survival benefit has been demonstrated.[63,66] Therefore, if antibiotics are not initiated, surveillance for infection (via chest radiography and blood, urine, and sputum cultures) should be undertaken while having a low threshold for initiating appropriate antibacterial or antifungal therapy. Finally, pulmonary complications (hypoxemia, aspiration, acute respiratory distress syndrome, and pulmonary edema) may also occur in patients with ALF.[66,67]

PROGNOSIS

CASE 80-4, QUESTION 2: What is W.H.'s prognosis?

Although the incidence of ALF is <1%, the prognosis for these patients is poor once encephalopathy has developed.[67,68] Survival depends on the etiology and degree of hepatic destruction, the ability of the remaining liver cells to regenerate, and the management of complications that may develop during the course of illness. Survival rates often depend on the etiology of ALF. Non-A, non-B (NANB) hepatitis and halothane- or drug-induced hepatotoxicity have been associated with worse survival rates compared to those with hepatitis A, hepatitis B, or acetaminophen overdose.[68] Age younger than 14 years, worsening grade of encephalopathy, reduced liver size, and significantly abnormal liver function test (LFT) values (eg, serum bilirubin, aminotransferases, alkaline phosphatase, PT, and serum albumin) are also poor prognostic indicators in patients with ALF.[67,68] W.H. has a poor prognosis because he has evidence of encephalopathy, cerebral edema, and abnormal LFT values.

TREATMENT

CASE 80-4, QUESTION 3: What is an appropriate treatment plan for W.H.'s ALF?

The primary therapy for ALF is supportive care for the patient who is comatose. Systemic therapies with heparin, prostaglandin, or insulin and glucagon have shown limited efficacy.[63] Blood or plasma exchange, hemodialysis, or other methods implemented to detoxify the blood or improve the coma grade do not result in long-term benefits if liver mass is not reconstituted as well. Thiopental may be useful in lowering ICP, but corticosteroids and prolonged hyperventilation are of no value.[63,66] W.H. could benefit from prophylactic histamine H_2-blockers because they have been shown to reduce the incidence of upper GI hemorrhage.[63] The role of

proton-pump inhibitors has not been clearly defined, although limited data have also supported their role in this setting. Blood products (packed red blood cells, fresh frozen plasma, or platelets) should be given as needed if W.H. develops active bleeding, and pulmonary artery monitoring should be implemented to guide management of intravascular volume and gas exchange. W.H. should be closely monitored for additional complications, especially cardiac abnormalities (eg, arrhythmias), hemodynamic changes, renal failure, acidosis, pulmonary complications, and sepsis.

In cases in which prognostic information indicates <20% chance of survival without transplantation, liver transplantation is indicated. Patients with acetaminophen poisoning resulting in ALF, a pH <7.3, a PT >100 seconds, and a serum creatinine >3.4 mg/dL, with grade III or IV encephalopathy, usually require transplantation.[68] Other causes of ALF, a PT >50 seconds, or any three of the following variables irrespective of grade of encephalopathy: age younger than 10 years or older than 40 years; liver failure caused by NANB hepatitis, halothane-induced hepatitis, or idiosyncratic drug reactions; duration of jaundice before encephalopathy >7 days; or serum bilirubin >17.5 mg/dL would indicate a need for transplantation.[67,68] Although these criteria continue to be used worldwide, they are less reliable in patients with moderate illness; sensitivity is acceptable although specificity is poor. Therefore, other models and surrogate markers have emerged to predict survival, such as the model for end-stage liver disease, Acute Physiology and Chronic Health Evaluation II scoring system, and biomarkers such as Gc protein (also known as vitamin D_3–binding protein), α fetoprotein (AFP), or troponin.[68] To date, none of these methods have been flawless in their ability to accurately predict an outcome in ALF.

Coinfection With Human Immunodeficiency Virus

Case 80-4, Question 4: What is the likelihood of HIV and HBV coinfection for W.H.?

Coinfection with other viruses has been reported in patients with HBV infection. For example, markers of prior or active HBV infection are present in >80% of patients with acquired immunodeficiency syndrome, with ~10% of these cases seropositive for HBsAg.[37,38] HIV has also been reported to coexist in up to 13% of patients with CHB infection.[37,38] Compared to patients with CHB infection alone, patients coinfected with CHB and HIV have significantly higher levels of viral replication, lower ALT levels, and more severe histologic disease. CHB infection does not reduce survival in patients who are HIV positive; however, because these patients live longer with effective, potent antiretroviral regimens, hepatic decompensation and manifestations of CHB may still occur.[35,46] In the setting of CHB and HIV coinfection, there are three nucleoside and nucleotide analogs that are active against both viruses—lamivudine, emtricitabine, and tenofovir. Although emtricitabine has activity against HBV based on its pharmacology, it has not been studied in clinical trials and is not FDA approved for CHB treatment. If treating an individual with CHB coinfected with HIV, it is recommended to utilize two antiretroviral drugs—tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF) plus lamivudine or emtricitabine. Of note, lamivudine has been shown to be more resistance prone, demonstrating ~90% resistance at 4 years.[69] Generally, TAF is preferred over TDF because of its improved safety profile (less negative effect on the kidneys and bones), especially in older patients. In addition, entecavir is known to cause resistance to HIV via *M184V* mutation.[70] Therefore, entecavir should not be used unless the patient with coinfection of HIV and CHB is on a fully suppressive antiretroviral regimen.[71] These agents are covered in detail in the section on Treatment. Adefovir and telbivudine are not recommended in the setting of coinfection because they lack activity against HIV and *M204I* mutation in HBV, respectively.[71]

Prevention of Hepatitis B Virus Infection

Screening of high-risk patients (eg, being born in regions of high or intermediate HBV endemicity, PWID, MSM, immunosuppression, people with end-stage renal disease [ESRD] on dialysis, chronic liver disease or evidence of elevated liver enzymes [greater than twice ULN] of unknown etiology, pregnancy, patients with HIV, infants born to HBsAg-positive mothers, having more than one sex partner during the previous 6 months, patients seeking evaluation or treatment for an STI, travelers to countries with intermediate or high prevalence of HBV), high-risk settings (eg, any health care and public safety worker at risk for occupational exposure to blood or blood-contaminated bodily fluids, facilities for developmentally disabled persons, STI and HIV testing and treatment facilities, drug abuse treatment and prevention settings, health care settings targeting services to PWID or MSM, and correctional facilities), blood products, and developing needle exchange programs, cultural outreach, and education may have an impact on reducing HBV transmission. The goals of preventive therapy should be to identify all persons who require immunoprophylaxis for the prevention of infection and provide long-term protection through vaccination to decrease the risk of CHB infection and its subsequent complications. For patients undergoing immunosuppressive therapy, prophylaxis against HBV should be initiated if shown to be positive for HBsAg and anti-HBc and continued until at least 6 months after completion of immunosuppressive therapy. In addition, per updated *Morbidity and Mortality Weekly Report* (*MMWR*) recommendations, medically stable infants weighing ≥4.41 pounds (2 kg) should be administered universal HBV vaccination within 24 hours of birth.

PRE-EXPOSURE PROPHYLAXIS

CASE 80-5

QUESTION 1: P.G., a 55-year-old nursing student, is going to start her clinical rotations. She has no history of hepatitis and has not yet been immunized. She is 62 inches (157.48 cm) tall and weighs 176.37 pounds (80 kg).

What prophylactic regimen should P.G. receive to prevent hepatitis secondary to HBV infection?

Using recombinant DNA technology, Recombivax HB® (10 mg HBsAg/mL) and Engerix-B® (20 mg HBsAg/mL) are yeast-derived HBV vaccines that induce an immunologic response. Most recently, Heplisav-B® (HepB-CpG), a single-antigen recombinant HBV vaccine with a novel adjuvant, was approved in 2018 for use in adults ages 18 years and older. Heplisav-B® is given as a two-dose series with doses separated by 1 month.[72] Because P.G. will come in contact with potentially infectious bodily secretions during her rotations, she should be immunized against hepatitis B with either Recombivax HB®, Engerix-B®, or Heplisav-B®.[72–74]

Vaccine dosing regimen

Relative potency comparisons are not clinically important because comparative trials using Recombivax HB®, Engerix-B®, and Heplisav-B® in the recommended dosages have demonstrated comparable immunogenicity and tolerability. P.G. can be immunized with either product, provided she receives the manufacturer's recommended dosage with each injection. Hepatitis B vaccines are administered as an IM injection in the deltoid muscle of adults and children or in the anterolateral thigh muscle of neonates and infants. The immunogenicity of hepatitis B vaccines is significantly lower when injections are given in the buttocks, probably because the greater amount of fat tissue in the buttocks inhibits interfacing of vaccine and antigen-recognition leukocytes. The results of a small vaccination series suggest that healthy adults who do not respond to hepatitis B vaccine injection to the buttocks have a significantly higher response when vaccinated in the arm. P.G. should receive either the Recombivax HB® (1 mL), Engerix-B® (1 mL), or Heplisav-B® (0.5 mL) vaccine as an IM injection in the deltoid muscle.[75–77] The recommended vaccination schedule is shown in **Table 80-5**.

Table 80-5

Recommended Hepatitis B Vaccine Dosage and Schedules for Adults

Vaccine	Dosage	Dosing Schedule and Route
Hepatitis B Vaccines		
Engerix-B®	20 µg	Three-dose schedule: 1 mL given IM at 0, 1, and 6–12 months
Recombivax HB®	10 µg	Three-dose schedule: 1 mL given IM at 0, 1, and 6–12 months
Heplisav-B®	20 µg	Two-dose schedule: 1 mL given IM at 0 and 1 months
Combined Hepatitis A and B Vaccines		
Twinrix®	HAV: 720 ELISA units plus HBsAg: 20 µg	Standard three-dose schedule: 1 mL given IM at 0, 1, and 6 months *or* Accelerated four-dose schedule: 1 mL given IM on days 0, 7, and 21–30, followed by a booster dose at month 12

ELISA, enzyme-linked immunosorbent assay; HAV, hepatitis A virus; IM, intramuscular.

Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2018;67:1–31.

Vaccine efficacy

Recombinant yeast-derived vaccines (eg, Recombivax HB®, Engerix-B®, and Heplisav-B®) produce similar results.[73,74,78,79] A protective antibody response is defined as having anti-HBs levels of at least 10 IU/mL.[80] This threshold was derived from early HBV vaccine trials in MSM, in which vaccine recipients with serum antibody levels of at least 10 sample ratio units (SRUs) were protected from HBV infection.[75,76] A serum antibody level of 10 SRU is roughly equivalent to 10 mIU/mL of anti-HBs when the international standard is used. For this reason, an anti-HBs level of at least 10 IU/mL is considered a protective antibody titer and is the standard used by the ACIP. Although HBV infections have occurred in vaccine recipients with a

detectable immune response, almost all infections have been asymptomatic, identified only through the presence of anti-HBc. These infections have been limited largely to patients with no response or a poor response to vaccination.[47]

Nonresponders

Case 80-5, Question 2: P.G. has completed her three-dose vaccination series with Engerix-B®. Routine hepatitis serology testing is performed before volunteering for a drug study and reveals that P.G. is anti-HBs negative. Why did P.G. not respond to the hepatitis B vaccine, and how should she be managed?

Two important determinants of vaccine efficacy appear to be the age at vaccination and underlying immune function. In healthy recipients, the immune response to vaccination decreases with advancing age. In one study, 99% of patients ages 0 to 19 years, 93% of those ages 20 to 49 years, and 73% of those older than 50 years of age achieved protective anti-HBs levels (>10 SRU) after three doses of the hepatitis B vaccine.[47] Immunocompromised patients, including those receiving hemodialysis, those infected with HIV, or children receiving cytotoxic chemotherapy, respond poorly to the hepatitis B vaccine. Patients who smoke or are obese also have a reduced response.[75],[76] P.G. has two risk factors for a poor response to the hepatitis B vaccine: She is older than age 50 years and she is moderately obese (ideal body weight for her height is 110.23 pounds [50 kg]).

Vaccine recipients who respond poorly to hepatitis B vaccine are classified either as hyporesponders who can probably be protected by additional doses of vaccine or as true nonresponders. Patients with inadequate initial response to the HBV vaccine series should be revaccinated. Of the hyporesponders (anti-HBs levels <10 IU/mL), 50% to 90% achieve a protective level after a single booster dose or after repeating the entire three-dose series.[77],[80] Of patients not responding to a primary vaccination series with Engerix-B®, 60% produced an immune response after a three-dose series with HBVax

II (Recombivax HB®), suggesting that a repeat course with the alternative HBV vaccine may be a reasonable approach in some patients.[77,80] Revaccination of nonresponders (no detectable anti-HBs) is less successful, and protective levels, if achieved, are not sustained.[47] True nonresponders to HBV vaccination are rare in the immunocompetent population, and these persons may have a genetic predisposition toward nonresponsiveness.[75,77] P.G. should be revaccinated with a booster dose of hepatitis B vaccine. Her anti-HBs levels can be rechecked 1 month after the injection. If she still has not responded, it is reasonable to administer an additional two injections to complete a second vaccination series. She could also be considered for the Heplisav-B® vaccination.

Interchangeability of hepatitis B virus vaccines

CASE 80-6

Question 1: T.M., a 32-year-old hospital laboratory technician, received the first two doses of Recombivax HB®. He has relocated recently and is due for the third dose. The employee health service at his new job uses only Engerix-B® for hepatitis B vaccination.

Can hepatitis B vaccines produced by different manufacturers be used interchangeably?

Although it is recommended that patients receive the complete vaccination series with the same product, it is not absolutely necessary if it is between Recombivax HB® and Engerix-B®. To determine whether a hepatitis B vaccination series initiated with Recombivax HB® could be completed with Engerix-B®, healthy adults received 10 µg of Recombivax HB® at baseline and at 1 month. At 6 months, the subjects were randomly assigned to receive either Engerix-B® 20 µg or Recombivax HB® 10 µg. One month after the third dose, 100% of those who had received Engerix-B® and 92% of those who had received Recombivax HB® had protective anti-HBs levels.[73,74] Chan et al. studied the booster response to either recombinant hepatitis B vaccine or plasma-derived vaccine in

children who had originally been vaccinated with the plasma-derived product (Heptavax-B®). Children were randomly assigned to receive either 5 µg of the plasma-derived vaccine or 20 µg of Engerix-B®. One month after the booster dose, all vaccine recipients had significant elevations in their anti-HBs titers, suggesting recombinant hepatitis B vaccines elicit an adequate booster response in persons who originally received the plasma-derived vaccine.[81] According to ACIP, the immune response from one or two doses of a vaccine produced by one manufacturer, when followed by subsequent doses from a different manufacturer, is comparable with that resulting from a full course of vaccination with a single product type.[47]

T.M. may complete the hepatitis B vaccine series with Engerix-B® provided he receives the recommended dosage of 20 µg administered as a 1-mL IM injection to the deltoid region.

On the contrary, the interchangeable concept may not apply to the newer vaccine Heplisav-B®, which has limited data on immunogenicity and safety if used interchangeably with another vaccine to complete the series. When possible, the two-dose vaccine series of Heplisav-B® should be finished with the same manufacturer. However, if the same manufacturer of the vaccine is unavailable or unknown, it is recommended to complete the vaccination series regardless of the manufacturer to prevent delays.[34]

Duration of response

Case 80-6, Question 2: Does T.M. require a booster dose for sustained protection from HBV infection?

The duration of vaccine-induced immunity has been evaluated in many long-term studies.[82–85] The duration of detectable anti-HBs appears proportional to the peak antibody response achieved after vaccination, and protective anti-HBs levels were sustained in 68% to 85% of patients receiving the plasma-derived HBV vaccine from 6 to 12 years.[82–85] More importantly, the protective efficacy of the HBV vaccine in these trials was high even in patients with anti-HBs levels

>10 IU/mL. HBsAg was only rarely detected, and most HBV infection events consisted of asymptomatic seroconversion to anti-HBc. These studies suggest that successful HBV vaccination confers long-lasting protection without the need for additional booster doses for up to 12 years. The mechanism of sustained protection against HBV, despite low or undetectable anti-HBs levels, is thought to be related to the phenomenon of immunologic memory in previously sensitized B lymphocytes. This amnestic response, in combination with the long incubation period of HBV, may allow the synthesis of protective antibodies to quickly block infection in patients rechallenged with HBV.[80]

In summary, there is no need for routine administration of HBV vaccine booster doses to immunocompetent persons after successful vaccination. Immunocompromised patients may require a persistent minimal level of protective antibody, and ACIP recommends annual antibody testing for patients receiving chronic hemodialysis with administration of a booster dose when antibody levels are <10 IU/mL.[47] Based on the available evidence, T.M. does not require a scheduled booster dose of hepatitis B vaccine.

Indications

Case 80-6, Question 3: Why is it appropriate for T.M. to receive the hepatitis B vaccine, and who else should be vaccinated against HBV?

The ACIP recommends pre-exposure hepatitis B vaccination for the following high-risk groups: PWID, health care workers with exposure to blood, staff of institutions for the developmentally disabled, patients on hemodialysis, patients with chronic liver disease or HIV infection, recipients of blood products, household and sexual contacts of HBV carriers, international travelers to HBV-endemic areas, MSM, sexually active males or females who are in a polygamous relationship, males or females seeking evaluation or treatment for STIs, patients with diabetes ages 19 to 59 years, and inmates of long-term correctional facilities.[47],[86],[87] Because T.M. is a

hospital laboratory technician, he is at high risk for exposure to HBV and should be vaccinated.

Universal hepatitis B vaccination

In addition to the previously listed high-risk groups, all infants should receive hepatitis B vaccination. For all medically stable infants weighing ≥4.41 pounds (2 kg) born to an HBsAg-negative mother, it is recommended to administer the first dose of HBV vaccine within 24 hours of birth. It should be noted that only single-antigen HBV vaccine is to be considered when given to infants at birth. For infants weighing <4.41 pounds (2 kg) born to an HBsAg-negative mother, the time of vaccination should be delayed to the time of hospital discharge or age 1 month, even if the infant's weight is still <4.41 pounds (2 kg). For infants with complications who need to be transferred to a different facility for a higher level of care, it is critical for transferring and receiving facilities to communicate regarding the HBV vaccination and hepatitis B immune globulin (HBIG) status to ensure that proper prophylaxis against HBV occurs in a timely manner. The final dose is to be administered after the age of 24 weeks or 164 days.[51]

The practice of vaccinating only high-risk persons has resulted in little impact on the incidence of HBV disease in the United States. Populations at risk for HBV disease (eg, PWID, persons with multiple sexual partners) generally are not vaccinated before they begin engaging in high-risk behaviors. In addition, many persons who become infected have no identifiable risk factors for infection and, thus, would not be recognized as candidates for vaccination. A program designed to immunize children before they initiate high-risk behaviors is likely to have a greater impact in reducing the incidence of HBV infection. As a means to achieve this goal, the hepatitis B vaccine is now incorporated into the existing pediatric vaccination schedule. The first dose is administered during the newborn period, preferably before the infant is discharged from the hospital, but no later than 2 months of age.[34,47,51] The recommended vaccination schedule for infants is shown in **Table 80-6**. Routine vaccination of

previously unvaccinated children ages 18 months old and younger is also recommended by the ACIP.

Table 80-6

Recommended Schedules of Hepatitis B Vaccination for Infants Born to HBsAg-Negative Mothers

Hepatitis B Vaccine	Age of Infant
Option 1	
Dose 1	Birth (before hospital discharge)
Dose 2	1–2 months[a]
Dose 3	6–18 months[a]
Option 2	
Dose 1	1–2 months[a]
Dose 2	4 months[a]
Dose 3	6–18 months[a]

HbsAg, hepatitis B surface antigen.

[a]Hepatitis B vaccine can be administered simultaneously with diphtheria-tetanus-pertussis, *Haemophilus influenzae* type b conjugate, measles-mumps-rubella, and oral polio vaccines.

Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2018;67:1–31.

CASE 80-7

QUESTION 1: R.M. is a mother of two children ages 11 years and 2 months. Her infant daughter just received a second dose of hepatitis B vaccine as part of her routine well-baby care.

Should R.M.'s son, who did not receive the hepatitis B vaccine during his normal childhood immunizations, receive the vaccine now?

The Centers for Disease Control and Prevention (CDC) addresses the issue of immunizing children and adolescents born before 1991 who are potentially at risk for HBV infection. The current recommendations suggest that adolescents who have not received three doses of hepatitis B vaccine should initiate or complete the series at ages 11 to 15 years. A schedule of 0, 1 to 2, and 4 to 6 months is recommended.[34,51] It is anticipated that universal vaccination of all infants and previously unvaccinated adolescents ages 11 to 12 years, in addition to ongoing immunization of high-risk persons, will reduce the incidence of acute HBV infection, hepatitis B–associated chronic liver disease, and HCC. R.M.'s son should receive either Recombivax HB® 5 µg or Engerix-B® 10 µg IM in the deltoid with repeat doses 1 to 2 months and 4 to 6 months from the initial dose.

Adverse effects

HBV vaccines have generally been well tolerated. The most common side effect is pain at the injection site, observed in 3% to 29% of patients. Transient febrile reactions, defined as temperature >99.9 °F (37.72 °C), occurred in <6% of recipients, and other reactions including nausea, rash, headache, myalgias, and arthralgias were observed in <1% of recipients. Ongoing monitoring of vaccine safety by the FDA and CDC is assessed through the Vaccine Safety Datalink project and Vaccine Adverse Events Reporting System.[46,47] On the basis of these reporting systems, additional "causal" adverse effects associated with vaccination include anaphylaxis (one case per 1.1 million vaccine doses), Guillain–Barré syndrome, and multiple sclerosis. Additional rare adverse events that have been reported but remain to be validated are chronic fatigue syndrome, neurologic disorders (leukoencephalitis, optic neuritis, and transverse myelitis), rheumatoid arthritis, type 1 diabetes, and autoimmune disease.

POSTEXPOSURE PROPHYLAXIS

Percutaneous exposure

CASE 80-8

QUESTION 1: K.N., a 26-year-old phlebotomy student, presents to the ED after accidentally sticking herself with a contaminated needle while drawing blood from an HBsAg-positive patient. K.N. has not been vaccinated previously and has no known prior episodes of hepatitis or liver disease. Her tetanus status is current. She weighs 123.46 pounds (56 kg).

How should K.N. be treated for percutaneous exposure to HBV?

After possible exposure to HBV infection, prophylactic treatment with hepatitis B vaccination and passive immunization with HBIG should be considered.[34,52] The ACIP recommends postexposure immunoprophylaxis after HBV exposure. K.N.'s percutaneous exposure warrants active immunization against HBV and passive immunization with HBIG. The source of K.N.'s exposure is HBsAg positive, and K.N. has not previously received hepatitis B vaccine. She should receive a single dose of HBIG 0.06 mL/kg (3.4 mL) as an IM injection in either the gluteal or deltoid region as soon as possible after the incident, preferably within 24 hours. HBIG is prepared from plasma of persons preselected for high titers of anti-HBs. The ratio of anti-HBs of HBIG in the United States is 1:100,000 as determined by radioimmunoassay. HBIG is superior to regular Ig in the prevention of HBV infection after percutaneous exposure. K.N. should also receive active immunization with HBV vaccine simultaneously with HBIG (at a separate injection site). The second and third doses should be given 1 month and 6 months later. Passively acquired antibodies against HBV from HBIG or Ig will not interfere with active immunization from the vaccine.[87]

If the HBsAg status of the donor source of the percutaneous exposure is unknown, recommendations for prophylaxis against HBV infection will depend on whether the donor source is at high risk or at low risk for being HBsAg positive. High-risk donor sources include MSM, PWID, patients undergoing hemodialysis, residents of mental institutions, immigrants from HBV-endemic areas, and household contacts of HBV carriers.

Sexual exposure

CASE 80-9

QUESTION 1: G.G. is a 20-year-old construction worker who had sexual contact with a partner who recently found out she is HBsAg positive.

What are the current recommendations for a person who has had sexual contact with an HBsAg-positive person?

Sexual transmission of HBV is an important cause of HBV infection, accounting for ~30% to 60% of all new cases annually.[37,38] Passive immunization with a single 5-mL dose of HBIG was found to be highly effective in preventing HBV infection after sexual exposure when compared with a control globulin (with no anti-HBs activity).[34,51,87] The CDC recommends for the susceptible person exposed to HBV through sexual contact with a person who has acute or CHB infection to receive postexposure prophylaxis with 0.06 mL/kg of HBIG as a single IM dose within 14 days of the last exposure.[34,86] Patients should also receive the standard three-dose immunization series with hepatitis B vaccine beginning at the time of HBIG administration.[34]

Perinatal exposure

CASE 80-10

QUESTION 1: S.L., a 7.95-pound (3.2-kg) male, was just born to an HBsAg-positive mother.

Is S.L. at risk for acquiring HBV infection, and how should he be treated?

In many Asian and developing countries, perinatal (vertical) transmission accounts for most HBV infections. Infants born to HBV-infected mothers have a >85% risk of acquiring HBV during the perinatal period. Of those who become infected, 80% to 90% become chronic HBsAg carriers.[85,87] Although fulminant cases have been reported, most hepatitis infections in neonates are asymptomatic. Despite the usually innocuous initial disease, significant adverse consequences are associated with chronic

HBsAg carriage in neonates. CHB infection is associated with chronic liver disease and has been clearly implicated as a major risk factor in the development of primary HCC.[59,60]

Mothers who are HBsAg carriers can transmit HBV to their infants. The risk is related to the presence of HBsAg and HBeAg in the mother, which suggests a high degree of viral replication and infectivity. The likelihood that S.L. will develop HBV infection is high. S.L. requires immediate therapy with HBIG to provide immediate high titers of circulating anti-HBs, and simultaneous vaccination with hepatitis B vaccine to induce long-lasting protective immunity. Screening pregnant patients for the presence of HBeAg and administration of HBIG and hepatitis B vaccine is 85% to 98% effective in preventing HBV infection and the chronic carrier state.[60,80,86] This compares with a 71% efficacy rate with the administration of HBIG alone. Simultaneous administration of HBIG and hepatitis B vaccine does not adversely affect the production of anti-HBs in neonates.[46,47,60,86]

Infants born to mothers who are HBsAg positive should receive simultaneous IM injections of the appropriate doses of hepatitis B vaccine (see Table 80-5) and HBIG (0.5 mL) within 12 hours of birth. The injections should be administered at separate sites. S.L. should receive HBIG (0.5 mL) as soon as possible after birth, administered as an IM injection. He also should receive 0.5 mL of either Recombivax HB® (5 µg) or Engerix-B® (10 µg) as an IM injection at a separate site.

Case 80-10, Question 2: What would the management plan be if the HBsAg status of S.L.'s mother is unknown?

The ACIP has developed recommendations for the prevention of perinatal HBV infection. This includes the routine testing of all pregnant patients for HBsAg during an early prenatal visit. HBsAg testing should be repeated late in the pregnancy for patients who are HBsAg negative, but who are at high risk for HBV infection or who have had clinically apparent hepatitis. Patients admitted for delivery

who have not had prenatal HBsAg testing should have blood drawn for testing. While the mother's test results are pending, the infant should receive hepatitis B vaccine within 12 hours of birth. If the mother is found later to be HBsAg positive, her infant should receive HBIG as soon as possible within 7 days of birth. The second and third doses of the vaccine should be administered at 1 and 6 months, respectively. If the mother is found to be HBsAg negative, her infant should continue to receive hepatitis B vaccine as part of the routine vaccination series.[60]

Evaluation and Management of Patients With Chronic Hepatitis B Virus Infection

CASE 80-11

QUESTION 1: E.A. is a 58-year-old female who presents to the hepatology clinic with a recent history of mild jaundice. Her previous medical history is unremarkable except for a blood transfusion she received during childbirth in 1988.

What initial and follow-up tests should be performed to assess the extent of HBV infection in E.A.?

Initially, a thorough history and physical examination should be performed with greater emphasis placed on risk factors for coinfection, alcohol use, and family history of HBV and liver cancer. Laboratory tests should include assessment of liver disease, markers of HBV replication, and screening tests for HCV, HDV, or HIV. Vaccination against HAV should also be administered as mentioned earlier in the section on Hepatitis A Virus. The decision to treat should be made based on knowledge of the patient's age, ALT level, HBeAg status, HBV DNA levels, and additional clinical features suggestive of chronic liver disease and associated complications. See **Figures 80-5 and 80-6** for the algorithm descriptions. In Figure 80-5, there are three potential scenarios for E.A. if she is HBsAg positive and HBeAg positive without cirrhosis. In scenario one, if her ALT is at or less than the ULN and her HBV DNA >20,000 IU/mL,

then she does not need treatment at this time. Meanwhile, E.A.'s ALT and HBV DNA levels should be monitored every 3 to 6 months and her HBeAg every 6 to 12 months while hoping for seroconversion.[88] On the other hand, in scenario two, if E.A.'s ALT is at least twice the ULN with the HBV DNA >20,000 IU/mL, then she will require antiviral treatment. In scenario three (center part of the algorithm), if E.A.'s ALT level is above the ULN, but less than twice the ULN, and her HBV DNA >20,000 IU/mL, then exclusion of other causes of ALT elevation will need to be made. Treatment is warranted if her ALT continues to be elevated, especially because she is older than 40 years of age. In addition, E.A.'s level of liver staging (fibrosis score ≥F2 or inflammation score ≥A3) will need to be evaluated before initiating treatment. Of note, if HBeAg-positive persons have HBV DNA <20,000 IU/mL, then it represents that seroconversion (HBeAg to anti-HBe) is happening. Their HBV DNA should be checked every 1 to 3 months. They should also be treated if their HBV DNA remains >2000 IU/mL for >6 months.[88]

Figure 80-5 Algorithm for management of HBsAg-positive persons without cirrhosis who are HbeAg-positive. ALT, alanine aminotransferase; CHB, chronic hepatitis B; HBeAg, hepatitis B envelope antigen; HBV DNA, hepatitis B virus DNA; ULN, upper limit of normal. (Source: Adapted from Terrault NA, Lok AS, McMahon BJ, et al. Update on prevention, diagnosis, and treatment of chronic

hepatitis B: AASLD 2018 hepatitis B guidance. *Hepatology*. 2018;67(4):1560–1599. © 2018 by the American Association for the Study of Liver Diseases. Reprinted by permission of John Wiley & Sons, Inc.)

Figure 80-6 Algorithm for management of HBsAg-positive persons without cirrhosis who are HbeAg-negative. ALT, alanine aminotransferase; CHB, chronic hepatitis B; HBeAg, hepatitis B envelope antigen; HBsAg, hepatitis B surface antigen; HBV DNA, hepatitis B virus DNA; ULN, upper limit of normal. (Source: Adapted from Terrault NA, Lok AS, McMahon BJ, et al. Update on prevention, diagnosis, and treatment of chronic hepatitis B: AASLD 2018 hepatitis B guidance. *Hepatology*. 2018;67(4):1560–1599. © 2018 by the American Association for the Study of Liver Diseases. Reprinted by permission of John Wiley & Sons, Inc.)

Similarly, Figure 80-6 describes three potential scenarios for E.A. who is HBsAg positive, but HBeAg negative without cirrhosis. In scenario one, E.A. has an ALT level below the ULN and does not require antiviral treatment regardless of her HBV DNA level. Her ALT and HBV DNA levels will still need to be monitored every 3 to 6 months and HBsAg annually. In scenario two, antiviral treatment is required if E.A.'s ALT level is at least twice above the ULN and her HBV DNA >2000 IU/mL. In this same scenario, if her HBV DNA <2000 IU/mL but she has elevated liver fibrosis and inflammatory

biomarkers (≥F2 and ≥A3, respectively), then E.A. will require antiviral treatment. In scenario three where the HBV DNA is at any detectable level (center part of the algorithm) and E.A.'s ALT level is above the ULN but less than twice the ULN, antiviral treatment is required especially if her ALT elevation persists with HBV DNA ≥2000 IU/mL because she is older than age 40 years. An evaluation of liver fibrosis or inflammation should also be performed.[88]

Periodic screening for HCC with ultrasound examination should also be performed in high-risk populations, such as Asian or African American males older than 40 and Asian females older than age 50 years, persons with cirrhosis, persons with a first-degree family history of HCC, and any HBsAg carrier older than 40 years with persistent or intermittent ALT or HBV DNA elevations.

CASE 80-12

Question 1: C.R., a 48-year-old male, presents to the ED with jaundice, incapacitating fatigue, and vague intermittent abdominal pain for the past month. C.R. was diagnosed with HBV infection 12 years ago. His social history includes injection drug use (none in the past 2 years) and alcohol misuse (none in the past 2 years). Several weeks ago, C.R. noticed darkening of his urine and yellowing of his eyes. In addition, C.R. has a history of severe depression, which is managed with escitalopram.

Physical examination reveals a thin male in no apparent distress. He is afebrile, and his blood pressure, heart rate, and respiratory rate are WNL. Moderate scleral icterus is noted. The abdomen is firm and distended. The liver is enlarged, nontender, and smooth with an edge palpable 5 cm below the costal margin and a span of 15 cm. The spleen is palpable. The cardiac, pulmonary, neurologic, and extremity examinations all are WNL.

C.R.'s laboratory evaluation is significant for the following:

Hct: 39%
Hgb: 11 g/dL
WBC count: 8.8 cells/μL
Platelets: 75,000/μL
PT: 15.4 seconds
INR: 2.1
AST: 326 units/L
ALT: 382 units/L
Alkaline phosphatase: 142 units/mL
Total bilirubin: 4.2 mg/dL

Albumin: 2.8 g/dL
BUN/SCr: 20/1.6 mg/dL (estimated glomerular filtration rate [eGFR] 45 mL/min/1.73)

Hepatitis serology test results are positive for HBsAg, HBeAg, and anti-HBc, and negative for IgM anti-HAV and anti-HCV. HBV DNA is reported as >20,000 IU/mL. A liver biopsy finding reveals periportal inflammation, as well as piecemeal and bridging necrosis.

What clinical findings that support the diagnosis of CHB infection does C.R. have?

The chronic occurrence of jaundice and hepatosplenomegaly with significantly elevated AST and ALT in a young patient such as C.R. is suggestive of chronic hepatitis. Although alcoholic hepatitis secondary to long-term alcohol use is consistent with these clinical features, his serology test results are positive for HBV. Hepatitis serology with positive HBsAg and HBeAg suggests ongoing viral replication and a high degree of infectivity. Serum concentrations of aminotransferases can range from slightly abnormal to greatly elevated, with ALT concentrations generally greater than AST. Serum bilirubin concentrations >3.0 mg/dL are common, serum concentration of alkaline phosphatase usually is increased, and the PT may be prolonged. Patients such as C.R. with a prolonged PT, thrombocytopenia, and low serum albumin concentration generally have a more severe form of chronic hepatitis and can be considered to have decompensated liver disease.

Liver biopsy is important for the diagnosis, treatment, and prognosis of patients with chronic hepatitis. C.R.'s liver biopsy finding reveals the classic triad of periportal inflammation, as well as piecemeal and bridging necrosis. The liver biopsy and hepatitis serology test results are consistent with a diagnosis of CHB infection. Treatment of CHB infection requires knowledge of the natural history of the untreated disease and the potential benefits of intervention. There are seven agents approved by the FDA for treating CHB infection, including six oral nucleoside/nucleotide analogs (entecavir, TDF, TAF, lamivudine, adefovir, telbivudine) and one parenteral formulation of interferon (pegylated interferon α-2a).

Case 80-12, Question 2: Does C.R. require treatment for CHB infection?

The decision to treat C.R. depends on the severity of symptoms, the serum biochemistries, and the liver biopsy results. C.R. has evidence of severe CHB infection and is diagnosed with decompensated cirrhosis. He is symptomatic with jaundice, severe fatigue, and abdominal pain. The results of his LFTs, HBV DNA, and pertinent biomarkers (decreased albumin, elevated PT, low platelets) suggest that his disease is advanced. More importantly, the current American Association for the Study of Liver Diseases (AASLD) guidelines recommend treating all patients with decompensated cirrhosis who are HBsAg positive regardless of their HBV DNA, HBeAg status, or ALT.[88] Therefore, C.R. should be treated to reduce the viral replication, resolve the hepatocellular damage, and prevent long-term adverse hepatic sequelae.[59,87]

GOALS OF THERAPY

Case 80-12, Question 3: What are the goals of therapy for CHB management?

Progression of chronic hepatitis to cirrhosis is likely because of continued replication of the HBV. Loss of active viral replication usually is associated with a decrease in infectivity, a reduction in inflammatory cells within the liver, and a decline in serum aminotransferase activities into the normal range. The disappearance of detectable HBeAg and HBV DNA is considered an indicator of loss of active viral replication.

The goals of therapy for CHB infection are to achieve sustained suppression of viral replication and remission of liver disease.[87,89] Ultimately, achieving these goals should lead to resolving ongoing hepatocellular damage and reducing the development of cirrhosis and HCC, and death. Clinical trials for CHB infection have used the following markers as end points for successful therapy: seroconversion from HBeAg positive to HBeAg negative (with

appearance of anti-HBe), reductions in serum ALT activity, elimination of circulating HBV DNA, and improvement in liver histology (**Fig. 80-7**). The elimination of HBsAg (termination of HBV carrier state) has been difficult to achieve in clinical trials. In addition, the responses to antiviral therapy of CHB can be categorized as biochemical, virologic or histologic, and as on therapy or sustained off therapy.

Figure 80-7 Therapeutic end points for management of chronic hepatitis B. Anti-HBe, hepatitis B envelope antibody; anti-HBs, hepatitis B surface antibody; HBeAg, hepatitis B envelope antigen; HBsAg, hepatitis B surface antigen; HBV DNA, hepatitis B virus DNA.

DRUG THERAPY

Case 80-12, Question 4: Would initiating therapy during the acute phase of HBV infection benefit C.R.?

Pharmacologic interventions in the management of acute HBV infection have been disappointing. Early studies demonstrated a transient decrease in serum aminotransferase activity and bilirubin concentration associated with corticosteroids. More recent studies, however, have resulted in a higher incidence of relapse and mortality in patients receiving corticosteroids.[89–92] Other therapies, including HBIG and interferon (IFN) α, have been ineffective in managing acute viral hepatitis secondary to HBV.[60,93] Nucleoside and nucleotide RT inhibitors reduce HBV DNA levels in patients with chronic disease,[94–96] but their use in acute HBV infection requires further investigation. Thus, administration of antivirals during the acute phase of HBV infection would not have benefited C.R.

Interferon

Case 80-12, Question 5: What drug therapy should C.R. receive to treat his CHB infection?

Previously, IFN α-2a and α-2b were considered effective immunomodulating agents for treating CHB,[93–96] which appeared to activate their target cells by binding to specific cell-surface receptors to induce synthesis of effector proteins. These intracellular proteins induced the antiviral, antiproliferative, and immunomodulatory actions of the host's natural IFNs. Their antiviral activity possibly arose from their ability to abate viral entry into the host cells and modulate several steps of the viral replication cycle (eg, viral uncoating, inhibition of messenger RNA, and protein synthesis).[93–96] It is important to note that IFN should not be used in patients who are pregnant, have decompensated liver disease, or compensated cirrhosis and portal hypertension. The pegylated formulation involves adding polyethylene glycol to IFN α-2a that leads to an increased serum half-life, resulting in a prolonged antiviral effect. As a result, the frequency of administration is adjusted from three times weekly to once a week. The main place of therapy for pegylated interferon α-2a (PegIFN) is to treat younger patients without decompensated

liver disease or portal hypertension with a finite duration of treatment. PegIFN was the only available treatment for CHB infection before the oral nucleoside/nucleotide analogs were developed. Now, PegIFN should only be considered when the nucleoside/nucleotide analogs are unavailable, or their use is contraindicated.

Efficacy

Pegylated Interferon

PegIFN (Pegasys®) was the first and only pegylated interferon α-2a approved for the treatment of CHB infection in the United States, including both variations of the virus (HBeAg positive and HBeAg negative). PegIFN has the advantage of more convenient dosing and additional viral suppression for patients with CHB. Clinical data suggest that this agent has slightly enhanced efficacy than the conventional IFN formulations. An evaluation of monotherapy of PegIFN 180 µg subcutaneously (SQ) weekly was compared with PegIFN SQ weekly plus lamivudine 100 mg PO daily or lamivudine 100 mg PO daily alone.[94] At the end of the 24-week follow-up, significantly more patients who received PegIFN monotherapy or combination therapy had HBeAg conversion than did those who received lamivudine monotherapy. PegIFN (alone or in combination) resulted in HBsAg conversion in 16 patients compared with none in the lamivudine monotherapy group (P = .001). In addition, at the end of treatment, viral suppression was most pronounced in the group that received combination therapy. Similar results were reported in HBeAg-positive patients receiving PegIFN α-2b.[95] In the only published trial performed in HBeAg-negative patients, PegIFN 180 µg weekly (N = 177) was compared with either PegIFN 180 µg weekly plus 100 mg of lamivudine (N = 179) or 100 mg of lamivudine alone (N = 181). Viral suppression was greater in the combination group, but sustained response (HBV DNA and ALT levels at week 72) was comparable in the group that received PegIFN alone or in combination, and superior to the lamivudine monotherapy group. Loss of HBsAg occurred in 12 patients in the PegIFN groups

compared with none in the lamivudine group. Unfortunately, the addition of lamivudine to PegIFN did not improve posttherapy response rates.[96]

Dosing Considerations

The recommended dose of PegIFN is 180 µg SQ weekly for 48 weeks.[94,96] It is possible that more severe flu-like symptoms and headache occur with thrice-weekly dosing when compared to once-weekly administration. In contrast, severe bone marrow suppression tends to occur less often with thrice-weekly administration.[94,96]

Predictors of Response

Case 80-12, Question 6: Would C.R. be likely to respond to PegIFN therapy?

Certain patient variables can predict the response to therapy with PegIFN. The most reliable predictor of a positive response to PegIFN in HBeAg-positive patients is pretreatment ALT and HBV DNA levels.[94,96] Patients with high pretreatment ALT more than two times the ULN and HBV DNA levels <20 IU/mL are more likely to respond to therapy.[94,96] HBeAg seroconversion with PegIFN treatment is associated with improved survival and reduced complications. Other predictors of a positive response include a short duration of disease, negative HIV status, and a high histologic activity index as demonstrated by liver biopsy or other diagnostic tools. No consistent predictor of sustained response in patients who are HBeAg negative exists. Thus, C.R. is not a reasonable candidate for PegIFN therapy. His liver biopsy finding is consistent with chronic disease where he has high pretreatment aminotransferase levels, his HBV DNA is >20,000 IU/mL, and his duration of CHB infection is long.

Adverse Effects

Case 80-12, Question 7: What are some additional reasons for avoiding PegIFN therapy in C.R.?

Adverse effects associated with PegIFN therapy can be categorized as early adverse effects that rarely limit the use of PegIFN and late adverse effects that may necessitate dose reduction or discontinuation of therapy altogether.[94,96] The early adverse effects of PegIFN therapy generally appear hours after administration and resemble an influenza-like syndrome with fever, chills, anorexia, nausea, myalgias, fatigue, and headache. Virtually all patients receiving PegIFN experience these toxicities, and they tend to resolve after repeated exposure to the medication over time. Administration of PegIFN at bedtime may decrease the severity of early onset of the adverse effects. Acetaminophen can be used to treat early adverse effects of PegIFN therapy but should be limited to 2 g/day to minimize the risk of hepatotoxicity. The late onset of more serious adverse effects is usually observed after 2 to 4 weeks of therapy. These toxicities, which limit the use of PegIFN, include worsening of the flu-like syndrome, alopecia, bone marrow suppression, bacterial infections, thyroid dysfunction (both hypothyroidism and hyperthyroidism), and psychiatric disturbances (eg, emotional lability, irritability, depression, anxiety, delirium, and suicidal ideation). The use of PegIFN can also cause a flare (increase) in ALT levels in 30% to 40% of patients. These flares are considered to be a favorable prognostic indicator, but they have been reported to cause hepatic decompensation, especially in patients with cirrhosis. C.R.'s history of severe depression should be considered a precaution to treating him with PegIFN. Furthermore, the use of PegIFN in patients with decompensated liver disease may lead to FHF. Therefore, although approved for CHB treatment, PegIFN is not an optimal medication for C.R.[94,96]

Nucleoside/nucleotide analogs

Case 80-12, Question 8: What other antiviral therapies are available to treat C.R.'s CHB infection?

Although PegIFN has played an important role in the treatment of CHB infection, patients included in most clinical trials represented a highly select group of CHB carriers. Specifically, patients with decompensated liver disease were excluded because they often have leukopenia and thrombocytopenia as a result of hypersplenism, which limits the dose of PegIFN that can be administered. Aside from PegIFN, nucleoside analogs represent an alternative approach to CHB treatment in patients with decompensated liver disease.[89–91] The FDA has approved six oral antiviral agents for the treatment of CHB infection (lamivudine, entecavir, TDF, TAF, adefovir, and telbivudine). Of these agents, the preferred antivirals include entecavir, TDF, and TAF based on their potency and high barrier to viral resistance development. Of note, telbivudine is no longer available in the United States.

Lamivudine

Lamivudine (Epivir-HB®) is the first oral nucleoside analog approved by the FDA for use in patients with compensated liver disease who have evidence of active viral replication and liver inflammation caused by CHB infection. Lamivudine, the (−) enantiomer of 3′-thiacytidine, is an oral 2′-,3′-dideoxynucleoside that inhibits DNA synthesis by terminating the nascent proviral DNA chain and interferes with the RT activity of HBV.[97–99] For CHB treatment, Epivir-HB® is administered as 100 mg PO daily. Lamivudine is well tolerated and reduces serum levels of HBV DNA.[89–91,97,99] Lamivudine is also approved at a higher dosage (300 mg PO daily) in combination with other antiretroviral agents for HIV-1 treatment.

Lamivudine Resistance

Case 80-12, Question 9: What is the risk of developing lamivudine resistance in C.R.?

Considering the high rate of viral turnover and the error-prone nature of the polymerase, particularly the RT enzyme, acquisition of resistance mutations is common. The most common mutation leading to lamivudine resistance is a specific point mutation in the highly conserved methionine motif of the HBV DNA polymerase.[100,101] In this mutation, the methionine residue is changed to a valine or isoleucine. These genotypic mutations in the tyrosine-methionine-aspartate-aspartate (YMDD) locus are associated with a reduced sensitivity to lamivudine and occur after long-term therapy (around 52 weeks). This motif is thought to be representative of the active site of the enzyme, similar to that associated with the HIV RT enzyme, leading to lamivudine resistance.[100,101] Lamivudine-resistant HBV mutants generally are detectable after ≥6 months of chronic therapy. Integrated data from four studies show a 16% to 32% incidence at 1 year, increasing to 47% to 56% at 2 years of therapy, and 69% to 75% at 3 years of therapy.[100,101] The presence of YMDD mutants results in a loss of the clinical response, a rise in ALT levels, and worsening of hepatic histology. Reports of continued improvement despite lamivudine resistance exist, but the long-term consequences of viral resistance, including hepatic decompensation and exacerbation of liver disease, are substantial. Thus, lamivudine has limited clinical utility in patients with CHB and is currently considered a second-line agent.

Adefovir

Adefovir dipivoxil (Hepsera®) is approved for the treatment of CHB in adults with wild-type or lamivudine-resistant virus.[102–104] Adefovir dipivoxil is the oral prodrug of an acyclic nucleotide monophosphate analog, 9-(2-phosphonylmethoxyethyl)-adenine. The active drug is a selective inhibitor of numerous species of viral nucleic acid polymerases and RTs. Previously, two trials reported the efficacy of adefovir 10 mg PO once daily for the treatment of patients who were

HBeAg negative[103] and HBeAg positive.[104] Resistance to adefovir occurred at a much slower rate compared to that with lamivudine. The cumulative probability of resistance in the HBeAg-negative patient trial was estimated to be 0%, 3%, 1%, 18%, and 29% at years 1, 2, 3, 4, and 5 years, respectively.[103] In the trial with HBeAg-positive patients, resistance was estimated to be 20% at 5 years.[104] Other reports have described adefovir resistance rates as high as 20% after 2 years of treatment.[102] Risk factors for adefovir resistance appear to be suboptimal viral suppression and its use as monotherapy. Adverse effects of adefovir include abdominal pain, diarrhea, dyspepsia, headaches, nausea, and nephrotoxicity. Adefovir is rarely used in the United States because of its high risk of causing nephrotoxicity.

Entecavir

Entecavir (Baraclude®) is an oral acyclic guanosine nucleoside derivative with potent activity against HBV.[105–107] The drug inhibits HBV replication at three different steps: (a) the priming of HBV DNA polymerase; (b) the RT of the negative-strand HBV DNA from the pregenomic RNA; and (c) the synthesis of positive-strand HBV DNA. In vitro studies have shown that the drug is more potent than are lamivudine and adefovir and is highly effective against lamivudine-resistant HBV mutants.

In two phase III clinical trials, the efficacy of entecavir was reported in patients with HBeAg-positive and HBeAg-negative CHB infection. Patients with compensated liver disease who had not previously received a nucleoside analog were assigned to receive either entecavir 0.5 mg or lamivudine 100 mg PO once daily for a minimum of 52 weeks. By week 48, HBeAg-positive patients receiving entecavir had higher rates of histologic (72% vs 62%), virologic (HBV DNA undetectable by polymerase chain reaction [PCR]; 67% vs 36%), and biochemical (ALT normalization; 68% vs 60%) responses when compared to that of lamivudine.[106] Of note, the seroconversion rates were similar among the two treatment groups (21% vs 18%; entecavir vs lamivudine, respectively). No viral

resistance to entecavir was detected during the study period, but follow-up data suggest a low rate of resistance (3% by week 96 of therapy).[106] The authors concluded that entecavir was safe and had significantly higher histologic, virologic, and biochemical response rates for HBeAg-positive patients versus HBeAg-positive patients who were treated with lamivudine. In patients who remained HBeAg positive with low levels of HBV DNA replication, a second year of entecavir and lamivudine therapy resulted in seroconversion in 11% and 13% of patients, respectively.[106]

In another trial of HBeAg-negative CHB infection, patients received either entecavir 0.5 mg or 100 mg of lamivudine PO daily for a minimum of 52 weeks. At week 48, patients receiving entecavir had significantly higher rates of histologic (70% vs 61%; $P > .01$), virologic (90% vs 72%), and biochemical (78% vs 71%) response rates.[107] No resistance was observed among patients receiving entecavir. Safety and adverse events were similar in the two groups. Thus, C.R. could receive entecavir 0.5 mg PO daily. As with all of the nucleoside agents, dosage adjustments should be implemented with changes in renal function. Furthermore, entecavir may be used for lamivudine-refractory or lamivudine-resistant patients. In these patients, lamivudine should be discontinued to reduce the risk of entecavir cross-resistance. Furthermore, the dose of entecavir is increased for lamivudine-resistant patients to 1 mg PO daily. In these patients, entecavir resistance has been reported to be 51% after 5 years of therapy. Thus, alternatives may be warranted for these patients.[108–112] With regard to histologic liver improvement, entecavir is ranked superior over TDF.[113]

Tenofovir Disoproxil Fumarate

TDF (Viread®) is approved for the oral treatment of CHB and HIV infections at a dose of 300 mg daily.[114–116] This agent is a potent nucleotide analog that is structurally similar, yet equipotent, but less nephrotoxic than is adefovir. TDF is a prodrug that gets metabolized to its active form, tenofovir. Clinical trials in HBeAg-positive and HBeAg-negative patients with CHB infection have demonstrated the

efficacy of TDF. In the first phase III trial of HBeAg-positive patients with compensated liver disease, a significantly higher proportion of TDF-treated patients had undetectable HBV DNA (76% vs 13%), ALT normalization (68% vs 54%), and HBsAg loss (3% vs 0%) at the end of therapy. Histologic response rates and HBeAg conversion were similar between the two groups. At the end of therapy, patients in the adefovir group were switched to TDF, and any patient who had detectable HBV DNA by week 72 had emtricitabine added to their regimen with subsequent additional serologic benefit.[115]

In the second trial, HBeAg-negative patients with compensated liver disease were given a similar regimen (300 mg of TDF or 10 mg of adefovir daily for 48 weeks).[115] By week 48, a higher percentage of TDF-treated patients had undetectable serum HBV DNA than did those treated with adefovir (93% vs 63%). The proportions of patients having ALT normalization (76% vs 77%) or histologic response (72% vs 69%) were similar. No patients in the study became HBsAg negative. Again, at week 48, patients receiving adefovir were switched to TDF. Patients in both groups who still had detectable HBV DNA by 72 weeks were given emtricitabine. Similar to the HBeAg-positive group, the change to TDF led to additional viral suppression in the patients initially treated with adefovir. In the previous two trials, only seven patients were observed to have virologic breakthrough during 96 weeks of therapy, but no tenofovir-resistant HBV mutations were detected. Current guidelines suggest and clinical data support TDF 300 mg PO daily as a viable first-line agent.[116] Generally, TDF is well tolerated, but it has been reported to cause Fanconi syndrome (rare), renal insufficiency, osteomalacia, and a decrease in bone density.[114] Similar to other agents in this class, the dose of TDF should be adjusted based on renal function (creatinine clearance [CrCl] <50 mL/minute).[114–116] More recent data show TDF to cause weight loss or is weight neutral compared to TAF.

Tenofovir Alafenamide

TAF (Vemlidy®) is the latest oral antiviral approved for the treatment of CHB infection. Similar to TDF, TAF is also approved for HIV-1 treatment as part of combination antiretroviral regimens. TAF is a nucleotide prodrug that is converted to tenofovir diphosphate in a two-step process, which inhibits the RT enzyme and the replication of HBV.[117] TAF has an antiviral profile similar to that of its sibling drug, TDF, but at a dose one-twelfth of TDF. Approved at 25 mg PO daily, TAF exhibits greater plasma stability and more efficiently delivers tenofovir to hepatocytes, resulting in lower tenofovir concentration in the bloodstream. Therefore, TAF leads to improved renal (eGFR and renal tubular function) and bone safety parameters (smaller declines in spine and hip bone mineral density) compared to TDF.[117–119] Interestingly, TAF has been reported to cause weight gain and an increase in triglycerides when used as part of a combination treatment regimen for HIV. The mechanisms behind these adverse effects are currently under investigation.

Two pivotal international phase III clinical studies (Studies 108 and 110) demonstrated TAF's efficacy among 1298 treatment-naive and treatment-experienced adults with CHB infection over 48 weeks. Study 108 was a randomized, double-blind, active-controlled trial that showed TAF was noninferior to TDF in treatment-naive and treatment-experienced patients with HBeAg-negative chronic HBV infection.[118] Study 110 randomized and treated 873 HBeAg-positive patients with either TAF or TDF. The study results were similar showing noninferiority to TDF based on the percentage of participants with a decline in HBV DNA below 29 IU/mL at 48 and 96 weeks.[119] Upon further data analysis through 96 weeks, higher rates of ALT normalization occurred with participants in the TAF study arm compared to those in the TDF arm. No viral resistance developed with either TAF or TDF in the studies.[118,119]

TAF was generally well tolerated by the study participants, and discontinuations from adverse events were 1% compared to 1.2% of participants in the TDF arm. The most common adverse events (incidence ≥5%) reported for TAF included headache, fatigue, abdominal pain, cough, nausea, and back pain. Similar to TDF, TAF has a safety warning of risk of lactic acidosis/severe hepatomegaly

with steatosis and posttreatment severe acute exacerbations of hepatitis B, especially upon discontinuation.[118,119] There have been no reported cases of Fanconi syndrome or proximal renal tubulopathy associated with TAF. Nevertheless, renal monitoring of the serum creatinine, phosphorus, CrCl, urine glucose, and urine protein before initiating and during TAF treatment is clinically recommended. Even though TAF is less nephrotoxic than is TDF, it is not recommended for patients with CrCl <15 mL/minute or patients with ESRD not receiving chronic hemodialysis. TAF is also not recommended for patients with decompensated hepatic impairment (Child–Pugh class B or C).[117–119]

Regarding the drug interaction profile of TAF, it is not recommended to be coadministered with anticonvulsants (eg, oxcarbazepine, carbamazepine, phenobarbital, and phenytoin), antituberculosis medications (eg, rifabutin, rifampin, and rifapentine), or St. John wort. Such coadministration will result in significant decreased serum concentrations of TAF, thus reducing its therapeutic effect. TAF is also a substrate of P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP) transporters. Drugs that strongly affect P-gp and BCRP activity may lead to changes in TAF absorption.[117] Recommendations of the treatments for CHB can be found in **Table 80-7**.

Table 80-7

Treatments for Chronic Hepatitis B Virus Infection

Agent	Dosage Regimen[a]	Pregnancy Category	Approved for Use in Children	Potential ADRs	Potency Against HBV	Resistance Barrier to HBV
Prcfcrrcd Agents						
Entecavir (Barǣlude®)	*Trcatment naive*: 0.5 mg PO daily *Lamivudme resistant*: 1 mg PO daily	C	Vfes; for 22 years old	Lactlc acidosis (decompensated cirrhosls only)	High	High
Tenofovlr disoproxll fumarate (TDF, Vlread*)	300 mg PO daily	B	Vés, for 22 years old	Nephropathy, Fanconl syndrome, osteomalacla, lactlc acidosis	High	High
Tenofovir alafenamide (TAF, Vemlidy*)	25 mg PO daily with food	Limited human safety and efficacy data	No	Lactic acidosis	High	High
Pegylated interferon a 2a (PeglFN, Pegasys*)	i 80 pg SQ every week	C	Yes, for 23 years old	Flu-llke symptoms, fatigue, mood dls-rurbances, cytopenia, autoimmune disorders in adults	Moderate	NA
Not Preferred Agents						
Lamivudine (Epivir-HB®)	100 mg PO daily	C	Yes, for a2 years old	Pancreatitis, lactic acidosis	Moderate	Low
Adefovir (Hepsera*)	10 mg PO daily	C	Yes, for ≥12 years old	Acute fenal failure, Fanconi syndrome, lactic acidosis	Low	Moderate

ADRs, adverse drug reactions; HBV, hepatitis B virus; NA, not applicable; PegIFN, pegylated interferon α-2a; PO, oral; SQ, subcutaneous; TDF, tenofovir disoproxil fumarate; TAF, tenofovir alafenamide.

Case 80-12, Question 10: What other nucleoside or nucleotide therapies are available for managing C.R.'s CHB infection?

C.R. could benefit from one of the preferred oral antiviral agents recommended by the AASLD treatment guidelines for CHB infection, such as TAF or entecavir.[88] TAF would be the optimal treatment for C.R. because it is potent, safe, and effective to suppress the virus at its standard dose of 25 mg PO daily with food. If entecavir is selected, then its dose needs to be adjusted based on C.R.'s impaired renal function. TDF could be considered as a treatment option for C.R., but its dose would also need to be adjusted based on his impaired renal function. It is important to know that TDF would not be preferred for patients with renal impairment, especially when there are better choices because TDF could worsen the renal function. Adefovir should be avoided in patients with renal impairment because it could also exacerbate the condition. Of note, several combination therapies have been evaluated (PegIFN and lamivudine, lamivudine and adefovir, lamivudine and telbivudine), but none are superior to antiviral monotherapy.[120] Combination therapy is superior to lamivudine monotherapy in reducing the rate of resistance in patients. However, there is no such role for combination therapy for entecavir, TDF, and TAF against CHB. Therefore, combination therapy is not appropriate for C.R. at this time.

Laboratory Monitoring

Case 80-12, Question 11: How should C.R. be monitored while on treatment for CHB infection?

According to the guidance from the European Association for the Study of the Liver (EASL), patients should receive liver tests every 3 to 4 months in the first year and then every 6 months thereafter. Check HBV DNA levels every 3 to 4 months in the first year, then every 6 to 12 months thereafter. If the patient is HBeAg positive, then he/she should be assessed for seroconversion after the first year to see if they have cleared HBeAg and produced anti-HBe.[121] The HBsAg should be checked every 12 months in those with undetectable HBV DNA. If they do clear HBsAg, then they should be tested for anti-HBs. Periodic renal monitoring should be performed in those receiving TDF and in those who are at increased risk for renal disease, as well as anyone receiving a nucleoside/nucleotide analog. Renal monitoring should include assessing serum creatinine and serum phosphate levels every 3 months in the first year, and then every 6 months thereafter.[121]

LIVER TRANSPLANTATION

Case 80-12, Question 12: If C.R. fails therapy, continues to decompensate, and develops cirrhosis from his CHB infection, what nonpharmacologic interventions are available?

Liver transplantation should be considered for patients with decompensated cirrhosis. One-year survival rates for patients with cholestatic or alcoholic liver disease who undergo liver transplantation are >90% in most liver transplant centers.[122] Historical data for liver transplants in patients with CHB infection indicated that the spontaneous risk for allograft reinfection was ~80%.[122–125] This reinfection rate was associated with initial liver disease and the hepatitis B viral load at the time of transplantation,

and with allograft failure, retransplantation, or death. However, with appropriate posttransplant HBV prophylactic management, overall survival rates of patients who received a liver transplant for HBV-related cirrhosis have exceeded 85% at 1 year and 75% at 5 years, making liver transplantation a viable alternative for C.R.

CASE 80-12, QUESTION 13: What are the current recommendations for prevention of recurrent HBV infection after liver transplantation?

Historically, the most efficacious approach to prevent HBV recurrence after transplantation was with high-dose IV HBIG given in the anhepatic (recipient liver excised) and postoperative periods. Daily IV HBIG in the early postoperative period with maintenance of serum anti-HBs levels of ≥100 IU/L had an overall survival (84%) that approached what was observed in other transplant recipients without HBV infection.[124,125] Furthermore, patients receiving long-term HBIG administration (>6 months) compared with patients receiving short-term HBIG (<6 months) had a lower risk factor for recurrent HBV infection (35% vs 75%) and longer 3-year actuarial survival (78% vs 48%).[124,125]

HEPATITIS B IMMUNE GLOBULIN DOSAGE, ADMINISTRATION, AND ADVERSE EFFECTS

Over the years, many liver transplant centers routinely administered immunoprophylaxis with IV HBIG 10,000 IU (10 vials, 50 mL in 250 mL of saline) given in the anhepatic phase, then gave 10,000 IU (50 mL infused for 4–6 hours) for the next 6 days postoperatively. HBIG 10,000 IU is generally administered on a monthly basis for life, or discontinued if HBsAg becomes positive, indicating treatment failure.[124,125] This regimen is able to achieve trough anti-HBs titers of ~500 IU/L and up to 2000 IU/L, which provided protection from HBV recurrence in the majority of transplanted patients. Patients who received HBIG oftentimes experience a serum sickness-like syndrome (fever, myalgias) and were managed by receiving premedication (eg, acetaminophen, diphenhydramine), thus

prolonging the HBIG infusion (up to 6 hours), or discontinuing HBIG therapy altogether.[124],[125]

Long-term concerns associated with HBIG administration may include the potential for treatment failure (HBV reinfection from extrahepatic sites despite adequate anti-HBs titers), emergence of mutant viruses, and the prohibitive high cost of therapy (>$60,000/year).[124],[125] Some data suggested that pharmacokinetic modeling and use of maintenance therapy with IM administration of HBIG (eg, 2.5–10 mL every 2–3 weeks) after a reduced induction dose (eg, 10,000 IU anhepatically, then 2000 IU via IV for six doses) could achieve similar outcomes and reduce the cost associated with IV administration of the drug.[124],[125]

Case 80-12, Question 14: What is the role of oral antiviral agents in liver transplant recipients with CHB infection?

The preferred nucleoside/nucleotide analogs include entecavir, TDF, and TAF based on their potent efficacy and high barrier to viral resistance. As discussed previously, TAF is not FDA approved for use in patients with decompensated cirrhosis. However, if a patient requiring tenofovir therapy is at risk for toxicities related to TDF, such as existing renal injury and/or bone toxicity, then it would be reasonable to initiate TAF to prevent recurrence of HBV in patients who undergo transplants for CHB infection.[125],[126] Several transplant centers, however, have implemented clinical protocols that administer entecavir, TDF, or TAF before transplantation to achieve undetectable HBV DNA viral loads at the time of transplant and then combine one of these agents with HBIG in the postoperative setting.[125],[126] Ultimately, these management strategies have emerged as a clinical standard in the preoperative and early postoperative periods because they are effective and have low rates of resistance. Future considerations for preventing recurrent HBV infection after transplantation include combining oral nucleoside (lamivudine, entecavir) with nucleotide (TDF, TAF) analogs, thus avoiding the use of HBIG altogether.[126]

MANAGEMENT OF HEPATITIS B VIRUS IN PREGNANCY

For HBsAg-positive pregnant patients with an HBV DNA level >200,000 IU/mL, the AASLD guidelines recommend initiating antiviral therapy to reduce risks associated with perinatal transmission. This is a conservative recommendation because the evidence for this specific DNA cutoff is limited. If the pregnant patient is HBsAg positive, but her HBV-DNA level is <200,000 IU/mL, then AASLD recommends against initiating HBV treatment. If treatment is warranted based on the criteria mentioned, the preferred agent is TDF owing to its high efficacy in preventing mother-to-child transmission and low viral resistance rate. Other anti-HBV agents studied in the pregnant patient population include lamivudine and telbivudine; however, they are not preferred antiviral agents. Telbivudine is also no longer available in the United States. Currently, there is limited data that show TAF is comparable to TDF with regard to safety and efficacy in the prevention of perinatal transmission.[127] Initiation of antiviral therapy is recommended for the pregnant female anywhere between 28 and 32 weeks of gestation, with continued antiviral therapy until delivery or 3 months after birth.

HEPATITIS C VIRUS

Virology

HCV is recognized as the most common cause of chronic transfusion-associated hepatitis.[128],[129] HCV is a positive-sense, single-stranded RNA virus in the *Flaviviridae* family that is 50 to 65 nm in diameter (see Table 80-1). It causes acute and chronic hepatitis C (CHC) infection in humans. If untreated, CHC can progress to cirrhosis and HCC in a subset of patients.[130] The infectious viral structure is composed of envelope glycoproteins in a lipid bilayer that contain the viral core protein and RNA.[131] After entry into the hepatocyte, the viral RNA is translated through the host

machinery into a polyprotein, which is cleaved during and after translation by both host- and viral-encoded proteases into mature viral proteins and nonstructural (NS) proteins (**Fig. 80-8**).

New and experimental therapies for HCV. *Nat Rev Gastroenterol Hepatol*. 2009;6(7):403–411. © 2009 Springer Nature.)

Epidemiology

The worldwide prevalence estimated that up to 180 million people are infected with CHC. This estimate includes high-risk populations, such as PWID, patients undergoing hemodialysis, patients with cancer, and blood donors. Excluding the high-risk populations, the global prevalence of HCV infection, based on anti-HCV, was 1.6% (1.3%–2.1%) corresponding to 115 (92–149) million past viremic infections.[132–134] The estimated prevalence is conservative because it did not include the abovementioned high-risk populations. The majority of these infections, 104 million, were among adults with an anti-HCV infection rate of 2.0%. Currently, there are six genotypes reported for HCV worldwide. Globally, genotype 1 distribution is most common, accounting for 46% of all infections, followed by genotype 3 (22%), and genotypes 2 and 4 (13% each). The genotype subtype 1b accounts for ~22% of all infections.[135] A further analysis of the genotype distribution across the global regions shows that genotype 1 is prevalent in Australia, Europe, Latin America, and North America (53%–71% of all cases), and genotype 3 accounting for 40% of all infections in Asia.[136–139] Genotype 4 is most prevalent (71%) in Egypt, northern and equatorial Africa, and the Middle East.[138] The prevalence of HCV genotype 5 is found in South Africa and scattered in regions of Europe and North and Eastern sub-Saharan Africa.[140,141] HCV genotype 6 is primarily found in Asia and Southeast Asia.[142]

In the United States, HCV infection is the most common bloodborne infection. Between 2013 and 2016, ~2.4 million people were living with active HCV infection, which corresponds to 1% HCV prevalence among the adult population in this country. Nearly 50% of them were unaware of their infection.[143] HCV infection occurs among persons of all ages, but the highest incidence (defined as the number of new infections in a specific time period) is among persons ages 20 to 39 years, with a male predominance. Blacks and Whites have similar incidence rates of acute disease, whereas persons of Hispanic ethnicity have higher rates. In the general population, the highest prevalence (defined as the number or percentage of persons

in the total population observed infected with HCV) rates of CHC infection are found among persons ages 30 to 49 years and among males.[130],[144],[145] Unlike the racial or ethnic pattern of acute disease, Blacks have a substantially higher prevalence of CHC infection than do Whites. In the United States, the predominant HCV genotype is type 1 (subtypes 1a and 1b) accounting for ~75% of the chronic cases.[144],[146] Historically, having knowledge of the HCV genotype or serotype (genotype-specific antibodies) was helpful in determining treatment, particularly when considering PegIFN and the first-generation protease inhibitors of the direct-acting antiviral (DAA) class. Once the genotype is identified, it need not be tested again; genotypes do not change during the course of infection. Because HCV has a high mutation rate during replication, several quasi-species, a heterogeneous population of HCV isolates that are closely related, may exist in an infected individual.[144],[146] The number of quasi-species increases during the course of infection, which allows HCV to escape the host's immune system, leading to persistent infection.

In 2020, the U.S. Preventive Services Task Force (USPSTF) and CDC expanded their one-time HCV screening recommendations from the "baby boomer" birth cohort (those born from 1945 through 1965) to include all adults regardless of age or setting prevalence (18–79 years) and all pregnant patients during each pregnancy.[143],[146] The USPSTF and CDC also suggest screening individuals younger than 18 and older than 79 years with behaviors, exposures, or conditions/circumstances associated with an increased risk of HCV infection. Similarly, the AASLD/Infectious Diseases Society of America (IDSA) recommends annual HCV testing for all PWID and MSM with HIV who have unprotected sex.[147] These recommendations are derived from several epidemiologic and surveillance health research data about new HCV infection rates. One was reported from two national laboratory companies representing the majority of patients screened for HCV antibody and/or tested for HCV RNA between 2013 and 2017. The data showed there was an increasing number of young patients and patients with milder HCV disease.[148] The CDC estimated a total

number of 44,700 new acute cases of HCV infection in 2017. This was a threefold increase in new cases since 2009 and reflected new infections associated with increasing rates of injection drug use from the opioid epidemic.[143] Furthermore, the National Notifiable Diseases Surveillance System data reported 3621 new acute HCV infection cases in 2018 among individuals younger than 40 years old.[143]

Similar to other hepatitis virus infections, acute HCV infection is defined as having an infection <6 months following acquisition of HCV. Six months is usually the period to define an acute infection based on evidence that most individuals who clear HCV will do so within 6 months. Acute HCV infection could occur whether the person develops clinical signs or symptoms of acute hepatitis. Oftentimes, patients with acute HCV infection are asymptomatic and most are unaware of their recent exposure to hepatitis C. If symptoms from acute infection develop, they usually develop within the first 4 to 12 weeks of infection and may persist between 2 and 12 weeks.[149],[150] The clinical manifestations of acute HCV infection are similar to that of other types of viral hepatitis (eg, jaundice, flu-like symptoms, dark urine and white stool, nausea, anorexia, abdominal pain, and malaise).[151] Approximately 15% to 20% of symptomatic acute liver disease in the United States is reported as resulting from acute HCV.[152] There are many potential sources of exposure to HCV, such as percutaneous transmission (eg, blood transfusion, injection drug use, procedures involving potentially reused needles, tattooing, body piercing, and acupuncture), and nonpercutaneous transmission (eg, perinatal transmission, MSM, high-risk sexual practices, noninjection drug use, and nosocomial exposure to contaminated equipment).

PERCUTANEOUS TRANSMISSION

Injection drug use is the most common route of HCV transmission. The incidence of HCV infection is 48% to 90% among PWID, and the risk of acquiring the infection in these individuals is as high as 90%.[130],[131],[144] Of the PWID with acute hepatitis, 75% are anti-HCV positive and, unlike transfusion-related hepatitis, the incidence of

HCV infection associated with injection drug use has not declined because of the opioid epidemic.[130,131,144] Additional risk factors for HCV infection include the presence of HBV or HIV coinfection. Other populations at risk for acquiring HCV include patients receiving chronic hemodialysis (up to 45%) and health care workers (0%–4% seroconversion after needlestick).[130,131,144]

NONPERCUTANEOUS TRANSMISSION

Nonpercutaneous transmission includes transmission between sexual partners engaged in physically traumatic or rough sex, and from mother to child during the perinatal period. The risk of sexual transmission appears to be highest with MSM exposures, particularly those infected with HIV.[149,150] However, these routes of transmission are less efficient compared to the percutaneous or injection drug use route.

CASE 80-13

QUESTION 1: O.S. is a 30-year-old female who presents to the clinic 3 months after having a diagnosis of CHC infection. Her past medical history shows that she was injecting crystal methamphetamine intermittently for 6 years but denies using any drugs for 3 months. She is accompanied on the visit by her HCV-negative boyfriend. They would like to know what her risk is of transmitting HCV to others. The couple has been in a monogamous relationship for 2 years.

What is the boyfriend's risk of acquiring hepatitis C from O.S.?

The couple does not need to alter their sexual practices. According to the CDC, patients should be counseled not to share needles or any of the injection materials/paraphernalia, such as cookers, cottons, water, or the actual drug. The risk of HCV transmission among long-term, monogamous, serodiscordant couples is very low. Therefore, couples in a monogamous relationship do not need to change their sexual practices. The risk of HCV transmission among MSM is likely higher, especially with rough sexual activity. Household transmission of HCV can potentially occur via sharing razors or toothbrushes, but it is not considered a risk to share food, water, or eating utensils.[143]

Compared with the high incidence of perinatal transmission of HBV from mothers to infants, perinatal transmission of HCV infection is relatively low. In general, it is considered safe for patients infected with HCV to breast-feed their infants, with the exception that most experts recommend stopping breast-feeding if the mother's nipples (or the surrounding area) are cracked and bleeding. The mother can temporarily pump her breast milk (and discard it) and then resume breast-feeding after the nipple region has healed.[143] Additional concerns and areas for investigation related to mother-to-infant transmission of HCV include the timing of transmission (in utero, time of birth) and the natural history of perinatally acquired infection.

Natural History, Pathogenesis, and Risk Factors

Between 75% and 85% of persons who acquire HCV will develop chronic infection.[153] The rate of viral replication is high, between 10^{10} and 10^{12} virions daily, and the lack of proofreading by the viral polymerase leads to a broad genetic diversity. Among those who develop CHC infection, between 20% and 25% will develop cirrhosis 20 to 30 years after HCV acquisition.[154–156] As a result, the host immune system has a major challenge in its mechanisms to eradicate the virus.[157] Nevertheless, a small percentage of persons infected with HCV infection have spontaneously cleared the infection. The host factors or characteristics that are associated with a lower rate of chronicity or spontaneous clearance of acute HCV infection include jaundice, younger age (younger than 20 years), female gender, non-Black race, competent immune status, elevated ALT level, and genotype 1 infection with polymorphisms of the gene encoding the interferon-λ β subunit (IL28B).[158],[159] Of note, individuals with the CC allele of IL28B genotype are more likely to spontaneously clear HCV than do those with the CT or TT alleles.

The pathogenesis of liver damage from HCV infection most likely results from both direct and indirect immune-mediated responses instigated by the virus. In some studies, having genotype 3a has been associated with a higher prevalence of steatosis, which is

associated with fibrosis progression.[154,160,161] Hepatic fibrosis is a dynamic scarring process in which chronic inflammation stimulates production and accumulation of collagen and extracellular matrix proteins. Over time, with CHC infection, the total collagen content increases and fibrosis can develop, with potential progression to cirrhosis. Fibrosis is a precursor to cirrhosis.[160,161] CHC is the leading cause of HCC in Western countries.[162] For persons infected with HCV infection, risk factors that can accelerate fibrosis progression include acquisition of HCV at an older age (older than 40 years), male sex, heavy alcohol intake (>50 g/day, which is ~3.5 drinks), marijuana use, coinfection with HIV or HBV, obesity, and metabolic factors (eg, steatosis and insulin resistance).[163–168] For persons who develop cirrhosis, there is an estimated 1% to 4% risk per year of developing HCC.[156,169] On the other hand, risk factors that are less associated with the progression of liver fibrosis include HCV viral load, HCV genotype and subtype, geography, and smoking.[155]

Diagnosis and Screening

Before engaging persons with CHC infection in clinical care and treatment, an evaluation and staging of liver fibrosis should be performed. Two classes of assays are used in the diagnosis and management of HCV. These include serologic assays that detect specific anti-HCV and molecular assays that detect viral nucleic acid. These assays are not used to assess the severity of disease or predict prognosis in patients infected with HCV. Screening for additional causes, contributors of liver disease, and abnormal liver function tests should be part of the diagnostic process of liver disease. There are nonviral causes of hepatic inflammation, such as hereditary and acquired conditions. These may include alcoholic liver disease, nonalcoholic fatty liver disease (NAFLD), nonalcoholic steatohepatitis (NASH), α-1 antitrypsin deficiency, hemochromatosis (excessive accumulation of iron in the liver), and autoimmune hepatitis.

NONINVASIVE SEROLOGIC ASSAYS AND IMAGING

Laboratory studies that are commonly used to evaluate HCV infection include HCV RNA, anti-HCV, and ALT. Persons who become infected with HCV may develop abnormal laboratory findings in the following order: detectable HCV RNA, elevation in ALT, and anti-HCV.[170],[171]

CASE 80-14

QUESTION 1: N.P. is a 27-year-old law student who presents to clinic for his routine medical evaluation. He reports having recent flu-like symptoms and nausea. He also reports noticing dark urine color and was told by his friends that he is looking "yellow and pale." N.P. has a remote history of injection drug and heavy alcohol use.

Recent laboratory tests reveal the following results:

ALT: 350 units/L
Anti-HCV: positive
HCV RNA level: 1,100,000 IU/mL

What are the clinical and serologic features of acute HCV infection in N.P.?

N.P. clearly presents with a clinical picture consistent with acute HCV infection, including symptoms of fatigue, headache, and dark urine color. His laboratory test results show elevated ALT, positive anti-HCV, and detectable HCV RNA levels.

HCV RNA is usually detected in blood within 1 to 2 weeks of infection by a nucleic acid test. Qualitative, quantitative, and genotype test results are also performed for the HCV RNA. The period from infection until HCV RNA is detectable in plasma (by a commercially available assay) is referred to as the *eclipse phase* or *previremic phase*. During this phase, the probability of establishment of HCV infection in susceptible hepatocytes is most likely. The eclipse phase is followed by an 8- to 10-day "ramp-up" phase in which HCV replication increases exponentially and readily becomes detectable in plasma. The "plateau phase" follows afterward with the HCV RNA viral load levels peaking 6 to 10 weeks after injection and remaining near these peak levels for ~40 to 60 days.[170],[171] During an

acute infection, detection of HCV RNA is not very reliable because RNA levels could fluctuate significantly. However, detectable HCV RNA levels are more uniform and present at the onset of symptoms.[149],[172]

Between 4 and 12 weeks after infection, patients may have liver cell injury resulting in an elevation in serum ALT levels. Increases in ALT can occur 1 to 2 weeks after detectable HCV RNA levels are present, and precede the development of anti-HCV. Usually, after an acute infection, the mean ALT could increase to the 800 units/L range. The CDC uses an ALT >200 units/L during the period of acute illness as part of the diagnostic criteria.[143] The last of the three abnormal laboratory findings associated with HCV infection is the presence of anti-HCV in the blood. Anti-HCV is usually detectable between 8 and 12 weeks after infection. Approximately after 12 weeks, >90% of patients will be positive for anti-HCV. This is referred to as the *serologic window period*, which describes the time period from initial infection until seroconversion.[150] Having detectable anti-HCV does not clearly differentiate acute from CHC infection. Moreover, anti-HCV is not a reliable marker to diagnose acute HCV because only 50% to 70% of patients have detectable anti-HCV at the onset of symptoms.[171],[172]

Case 80-14, Question 2: After N.P. or any other person becomes infected with HCV, what is the typical sequence of laboratory findings?

Laboratory findings will include detectable HCV RNA, then increased aminotransferase levels, and then anti-HCV positive. The gold standard for the laboratory diagnosis of acute HCV infection is anti-HCV seroconversion (negative anti-HCV [before suspected exposure] to positive anti-HCV [following exposure]) combined with a positive HCV RNA viral load test.[152],[171] However, because many patients are unaware of their exposure or risk of infection, they may not present to their health care providers early enough to be evaluated and diagnosed. Oftentimes, acute HCV is diagnosed based on the first-time detection of HCV RNA and newly elevated

ALT compared to negative laboratory results at baseline. Close follow-up of patients who have encountered high-risk exposures is recommended to establish the diagnosis and their treatment care. The laboratory testing for a known exposure to HCV includes measuring for the anti-HCV, HCV RNA, and ALT at initial presentation, 4 weeks from the time of suspected exposure, and 12 weeks from the time of suspected exposure.[143],[173]

Case 80-14, Question 3: According to the CDC 2020 case definition of acute hepatitis C, what level of increased ALT is required as part of the clinical description?

An ALT >200 units/L. N.P.'s ALT result is 350 units/L.

Acute HCV infection rarely causes a life-threatening illness. The CDC 2020 case definition of acute HCV infection includes clinical and laboratory criteria, case classification as probable or confirmed, and criteria to distinguish a new case from an existing case.[143] Clinical criteria of acute infection is described as an illness with an onset of any sign or symptom consistent with acute viral hepatitis (eg, fever, headache, abdominal pain, malaise, anorexia, nausea, vomiting, and diarrhea) combined with jaundice, a peak elevated serum ALT level >200 units/L, or a peak elevated total bilirubin level ≥3.0 mg/dL during the acute illness phase.[143],[172],[173] When the HCV RNA level persists beyond 6 months, the person is diagnosed with CHC infection. As part of the comprehensive patient workup, a complete laboratory and imaging evaluation of a patient with CHC infection includes the following[159],[172],[174]:

- *General*: CBC (platelet count), complete metabolic panel (serum creatinine), and thyroid function tests (thyroid-stimulating hormone [TSH]). Because some studies have shown that persons with vitamin D deficiency have reduced response to hepatitis C treatment, some experts recommend obtaining baseline vitamin D levels (1,25-OH vitamin D).
- *Hepatic inflammation and function*: ALT, aspartate aminotransferase (AST), total and direct bilirubin, alkaline

phosphatase, serum albumin, INR, and α-fetoprotein.

- *Assays to detect coinfections*: hepatitis A antibody, HBsAg, anti-HBc, hepatitis B surface antibody, and HIV antigen and antibody.
- *HCV RNA level (viral load)*: a quantitative HCV RNA level to confirm that the patient has CHC infection, and to establish a pretreatment baseline level. In the absence of treatment, it is not necessary to repeatedly assess the HCV RNA levels because monitoring values over time does not provide useful prognostic information.
- *HCV genotype*: HCV exists as one of six distinct genotypes with significantly different clinical characteristics, mostly with respect to treatment response rates. In the United States, HCV genotype 1 is the most common, accounting for ~75% of cases. During the IFN treatment era, knowing the HCV genotype was important because the response to antiviral therapy was very different among the different genotypes, and treatment protocols differ substantially. Since the FDA approval of DAA drugs and associated successful cure rates or sustained virologic response (SVR), especially with pangenotypic (has antiviral activity against all six genotypes) DAAs, obtaining the genotype is optional in the CHC treatment plan.
- *FibroSure®*: to stage the fibrosis of liver disease
- *Pregnancy*: if the female is of child-bearing age
- *Liver ultrasound or transient elastography*: if there is evidence of concern for advanced liver disease
- *IL28B allele*: This is a single-nucleotide polymorphism at the IL28B gene locus and strongly correlates with HCV treatment response, especially with IFN-based therapies. Because the DAAs have become the gold standard therapy for CHC treatment, testing for IL28B is now obsolete.

Noninvasive serologic assays include serum biomarkers that have clinical utility for predicting the presence or absence of significant fibrosis or cirrhosis. However, they may not be useful in differentiating between the intermediate stages of fibrosis. The

common indirect serum biomarkers used in the clinical setting include the AST to Platelet Ratio Index (APRI), FIB-4, and FibroSure® or FibroTest®. Other screening tools that have been used include the FibroIndex, Forns Index, HepaScore® (FibroScore®), and FIBROSpect® II.

APRI is easily calculated and could predict significant, severe fibrosis or cirrhosis. It is calculated using the patient's AST level and platelet count, and the ULN of the AST level. A meta-analysis of 40 studies found that an APRI cutoff of <0.5 represents the low likelihood of fibrosis (less than or equal to F2 by METAVIR). A cutoff score of >1.5 represents a high likelihood of severe fibrosis/cirrhosis (F3–F4 by METAVIR).[175–178] APRI has good diagnostic utility for predicting severe fibrosis or cirrhosis, but does not accurately differentiate intermediate fibrosis from mild or severe fibrosis. The liver guidelines recommend using APRI with other noninvasive markers of fibrosis.

The FIB-4 Index is a simple, quick, and an inexpensive test that provides results immediately. The result is generated from a formula using the person's age, AST, ALT, and platelet count. A cutoff value of <1.45 has a 90% negative predictive value for advanced liver disease, or low likelihood of fibrosis. A cutoff value >3.25 has a specificity (98%) in confirming cirrhosis and 65% positive predictive value for advanced liver disease. FIB-4 has valid utility in excluding or confirming cirrhosis; however, values between 1.45 and 3.25 do not clearly discriminate fibrosis.[179] Thus, additional methods to predict liver fibrosis are recommended.

FibroSure® and FibroTest® are identical noninvasive blood tests marketed in the United States and Europe, respectively. FibroSure® is the test available in the United States. These tests are utilized to assess liver inflammation and fibrosis. The FibroSure® provides estimates of the grade and stage of fibrosis. It includes the patient's age and gender along with a composite of six biochemical markers associated with hepatic fibrosis: α-2-macroglobulin, haptoglobin, γ-globulin, γ-glutamyltransferase (GGT), apolipoprotein A1, and total bilirubin. The score of >0.31 has a negative predictive value of 91% for the absence of clinically significant fibrosis. The positive

predictive value for the presence of significant fibrosis at a score of >0.48 was 61% and a score of 0.72 was 76%.[180] A score of >0.75 is consistent with cirrhosis (F4 score). The FibroSure® test is considered a fairly reliable "confirmatory test" when the clinical examination is consistent with cirrhosis. Ideally, the test should be performed under fasting conditions. However, there are contraindications to using the FibroSure® test (eg, patient having Gilbert disease, acute hemolysis, extrahepatic cholestasis, posttransplantation, or renal insufficiency), which may result in inaccurate quantitative calculations and predictions.

FibroIndex® is a simple scoring method comprising three biochemical markers: AST, platelet count, and γ-globulin. A cutoff value ≤1.25 has a sensitivity (40%) and specificity (94%) for mild fibrosis (F0 or F1 by METAVIR). In contrast, a cutoff value ≥2.25 has a sensitivity (36%) and specificity (97%) for significant fibrosis (F2 or F3 by METAVIR). Patients with F4 fibrosis were not included in the study.[181]

Forns Index uses a complicated calculation method. It incorporates parameters such as age, GGT, cholesterol, and platelet count. A cutoff value of >4.25 has a negative predictive value of 96% for excluding significant fibrosis (F2, F3, or F4). On the other hand, a cutoff of >6.9 has a positive predictive value of 66% for significant fibrosis (F2, F3, or F4). The Forns Index is useful and has good predictive value in selecting those with a low risk of significant fibrosis, but does not reliably predict more advanced fibrosis or cirrhosis.[182] Patients with genotype 3 HCV infection may have varying cholesterol levels. Hence, the Forns Index should not be used in these patients.

The HepaScore® or FibroScore® algorithm is more complex than are other indirect markers. Additional fibrosis markers (eg, age, sex, total bilirubin, GGT, α-2-macroglobulin, and hyaluronic acid levels) are included in the equation. A cutoff value ≤0.2 has a negative predictive value of 98% to exclude fibrosis. In contrast, a cutoff value ≥0.8 has a positive predictive value of 62% for predicting cirrhosis.[183] The HepaScore® has good utility at excluding significant fibrosis but is not as good at predicting cirrhosis.

Aside from the invasive, indirect markers for predicting liver fibrosis or cirrhosis, there are direct markers of fibrosis. Direct markers of fibrosis include procollagen types (II, III, IV), matrix metalloproteinases, cytokines, and chemokines. These markers exhibit variable effectiveness in predicting liver fibrosis. FIBROSpect® II is the only commercially available test that combines hyaluronic acid, tissue inhibitor of a metalloproteinase-1 (TIMP-1), and α-1-macroglobulin to predict fibrosis stages (F2–F4). An index score of >0.42 indicates the presence of stage F2 to F4 fibrosis. The cutoff values for sensitivity and specificity are 80.6% and 71.4%, respectively.[180],[184] The FIBROSpect® II test is a good tool to use to determine the presence or absence of cirrhosis in patients who have contraindications to liver biopsy, or those who refuse it. These markers may serve as reliable clinical alternatives in patients who are not candidates for liver biopsy. If noninvasive methods provide a clear assessment of hepatic fibrosis, then a liver biopsy may not be needed or warranted.

Noninvasive radiologic imaging of the liver has been an effective diagnostic tool for identifying cirrhosis and stratifying the stages of liver fibrosis. Several tools that are being used include hepatic ultrasound, transient elastography, and magnetic resonance imaging (MRI). Both the ultrasound and MRI should not be used for fibrosis staging unless the patient has cirrhosis. The transient elastography is a noninvasive imaging tool used to measure liver stiffness. Elastography is more accurate than is APRI or FIB-4 in predicting significant or advanced fibrosis. Furthermore, it is as accurate in measuring the degree of liver inflammation and fibrosis as a liver biopsy. Elastography is preferred over liver biopsy. However, there are potential patient factors that could confound the elastography results such as obesity, ascites, inflammation, alcohol intake, and food ingestion.

BIOPSY

Historically, liver biopsy with histologic analysis was the gold standard for establishing severity of fibrosis or fibrosis staging. It

provides information on both the grade (degree of inflammation associated with ongoing liver disease injury) and the stage (amount of currently established fibrosis). Some factors (eg, alcohol consumption, increased hepatic iron concentration, and steatosis) are associated with accelerated fibrosis progression and may elicit concern for advanced fibrosis.[185–187] Some limitations of a liver biopsy include its high cost, invasive technique, associated risks of bleeding and complications, and the probability of incorrectly staging fibrosis in about 20% of patients.[185–187] Because of these limitations and the development of noninvasive serologic tests that provide good estimates of hepatic fibrosis, liver biopsy is now optional.

IMMUNOCOMPROMISED PATIENTS

Approximately 5% of adults with CHC infection have coinfection with HIV.[188] Coinfection with HIV accelerates the progression of hepatic fibrosis and results in a more aggressive course of liver disease, resulting in cirrhosis.[189] Persons with HIV/CHC coinfection are more likely to develop cirrhosis 12 to 16 years earlier than do those who have CHC monoinfection.[190] Furthermore, liver-related morbidity and mortality is a prominent non–AIDS-related complication occurring in persons with HIV/CHC coinfection. In fact, up to 80% to 90% of liver-related deaths in those living with HIV are attributable to HCV infection.[191,192] Therefore, it is critical to treat the CHC infection in coinfected patients once their HIV infection is suppressed.

Kidney transplant recipients also have a high incidence of HCV infection (6%–28%), which may be acquired through dialysis before transplant, or from the allograft or blood products after transplantation.[193,194] After kidney transplantation, elevation in aminotransferases is more common in anti-HCV–positive compared with anti-HCV–negative patients (48% and 14%, respectively), and cirrhosis has been reported with the former.[193,194]

Clinical and Extrahepatic Manifestations

Most patients with acute HCV infection are asymptomatic.[132,144,145] In contrast, ~40% of patients with CHC infection will develop at least one extrahepatic manifestation. Specific extrahepatic conditions may vary, and their prevalence is derived from observational studies. Extrahepatic manifestations and conditions include cryoglobulinemic vasculitis, renal disorders with or without cryoglobulinemia, jaundice, arthralgias, neuropathy, pruritus, dermatologic manifestations (eg, cutaneous leukocytoclastic vasculitis and porphyria cutanea tarda), insulin resistance, and B-cell lymphomas.[195–202] Successful eradication of HCV could reduce the risk of some extrahepatic manifestations and complications (eg, B-cell lymphoma, diabetes, cryoglobulinemic vasculitis, and renal disease), decompensated cirrhosis (eg, ascites, encephalopathy, coagulopathy, or hyperbilirubinemia), and HCC.

Prevention of Hepatitis C

PRE-EXPOSURE PROPHYLAXIS

There are currently no vaccines against HCV, and current measures to prevent HCV infection have largely focused on identifying high-risk persons and counseling them on risk reducing strategies to prevent acquisition. The CDC and the National Institutes of Health have published recommendations that address these issues.[143] Suggested primary preventive measures include those implemented in health care settings, such as reinforcing adherence to universal precautions for the protection of medical personnel and patients, and educating HCV-positive individuals to refrain from donating blood, organs, tissues, or semen. In some situations, the use of organs and tissues from HCV-positive individuals may be considered. For example, in emergency situations, the use of a donor organ in which the HCV status is either positive or unknown may be considered in an HCV-negative recipient after full disclosure and informed consent. Strategies should be developed to identify prospective blood donors with any history of injection drug use. Such individuals must be deterred from donating blood.

Furthermore, safer sexual practices, including the use of latex condoms should be strongly encouraged in persons with multiple sexual partners. In monogamous long-term relationships, transmission is less common.[132–134] Although HCV-positive individuals and their partners should be informed of the potential for transmission, insufficient data exist to recommend changes in current sexual practice in persons with a steady partner. It is recommended that sexual partners of infected persons should be tested for anti-HCV.

In households with an HCV-positive member, sharing razors and toothbrushes should be avoided.[132–134] Covering open wounds is recommended. Injection needles should be carefully disposed of using universal precaution techniques. It is not necessary to avoid close contact with family members or to avoid sharing meals or utensils. No evidence justifies exclusion of HCV-positive children or adults from participation in social, educational, and employment activities. In addition, pregnancy is not contraindicated in HCV-infected individuals. Perinatal transmission from mother to baby occurs in <6% of instances.[132–134] No evidence indicates that breast-feeding transmits HCV from mother to baby; therefore, it is considered safe. Babies born to HCV-positive mothers should be tested for anti-HCV at 1 year.

Finally, needle exchange and other safer injection drug use programs may be beneficial in reducing parenterally transmitted infections.[132–134] Expansion of such programs should be considered in an effort to reduce the rate of transmission of HCV. It is important that clear and evidence-based information be provided to both patients and health care providers regarding the natural history, means of prevention, management, and therapy of HCV infection.

GOALS OF THERAPY

CASE 80-15

Question 1: K.C., a 22-year-old female, presents to the hepatology clinic for evaluation of liver enzyme elevation. She recently saw her gynecologist and

laboratory results revealed marked ALT/AST increase. She denies any recent symptoms or change in health other than flu-like illness a few months ago. She currently works as a waitress at a restaurant. She denies prior medical problems and does not take any prescribed medications, herbal, and over-the-counter (OTC) medications. K.C. reports that she has been using IV heroin since she was 15 at a shopping center and that her best friend has died of an overdose. She went on a binge after he died and was not careful about needle sharing. She previously tested negative for HCV and HIV 1 year ago. Upon physical examination, she has multiple tattoos and body piercings, as well as a few track marks on her arms. Her physical examination is otherwise unremarkable. Liver is not enlarged, and there are no asterixis (no stigmata of liver disease), ascites, or jaundice. Abdominal ultrasound finding is normal. The hepatologist ruled out cirrhosis for K.C. Her laboratory results include the following:

ALT: 45 units/L	Anti-HCV: positive
AST: 64 units/L	HCV RNA level: 10,480,000 IU/mL
Platelets: 240 × 10^9/L	HCV genotype: 1a
Anti-HBs: positive	FibroSure®: 0.40 (F1)
HBsAg: negative	APRI: 0.67
Anti-HBc: negative	FIB-4: 0.87
Fibroscan/transient elastography: pending	HIV-1/2 Ag/Ab: negative

BUN/SCr: 18/0.6 mg/dL (eGFR 105 mL/minute/1.73 m^2)

K.C. wants to be treated for her HCV infection. She agrees to go to Narcotics Anonymous and to receive psychological and risk reduction counseling.

What is the goal of CHC therapy for K.C. and the definition of an SVR12?

K.C. clearly has a clinical presentation consistent with CHC infection including flu-like symptoms, an elevated ALT, positive anti-HCV, and detectable HCV RNA. She does not have HIV and HBV coinfection because her HIV-1/2 Ag/Ab is negative and HBsAg is negative. Coinfection with HIV or HBV could also accelerate the rate of liver fibrosis and progression of the disease for K.C. She has immunity against HBV via vaccination based on being positive for anti-HBs and negative for HBsAg and anti-HBc.

The primary goal of HCV therapy is to achieve virologic cure or SVR12, which is defined as having a negative HCV RNA level 12 weeks after completion of DAA therapy. A negative or undetectable HCV RNA level is <15 IU/mL, which is below the level of detection by sensitive laboratory assays.[132] Among persons who achieve SVR12, >99% proceed to achieve total eradication of HCV.[203–206] K.C. should be counseled that achieving SVR with DAA therapy does not mean that she will be immune from reinfection with HCV. After successfully completing DAA therapy, she should receive an annual test for HCV RNA to ensure that she does not get reinfected.

The impact of SVR is remarkably positive because patients will have an improvement in liver inflammation and fibrosis compared to those who do not achieve SVR. Other studies have also confirmed the long-term histologic benefit.[204–207] In a study involving the general population, patients with advanced fibrosis who underwent antiviral therapy and achieved SVR had reduction in overall mortality, liver-related death, liver failure, and HCC when compared to those who did not achieve SVR.[208],[209] Most of this survival benefit from successful treatment response was associated with improved clinical outcomes, primarily because of lower rates of liver failure. In a meta-analysis of 35 studies, investigators showed a clear benefit in the 5-year overall survival with HCV treatment, including patients with cirrhosis and HIV coinfection.[209] With regard to the extrahepatic manifestations, successful treatment of HCV is associated with improvement or remission of insulin resistance and diabetes mellitus.[210],[211] Overall, SVR is associated with reversal of hepatic inflammation and fibrosis, and can reduce the chance of dying from liver-related complications by at least 60%.[212]

FACTORS THAT PREDICT RESPONSE TO THERAPY

Case 80-15, Question 2: K.C. has heard about HCV infection and how treatment response may be affected by the person's genotype. She asks if her genotype could affect her successful response to HCV therapy?

In the DAA era, K.C.'s genotype should not really affect her response to treatment. Treatment responses are very high (≥98% SVR) across all genotypes when DAA therapies are used. Historically, there were viral and host factors that predicted a person's response to HCV therapy, such as the HCV genotype, HCV RNA level, IL28B genotype, race, age, gender, comorbid conditions, and the degree of hepatic fibrosis. During the IFN treatment era and before the emergence of the potent DAA drugs, the HCV genotype was the predictor of achieving an SVR, where genotype 1 has poor success rates and outcomes.[213–215] In contrast, the role of HCV genotype in predicting treatment response is modestly relevant because several DAAs are highly effective against all genotypes. In addition to the genotype, the HCV RNA level also influenced the successful treatment outcome during the IFN treatment era. Persons with genotype 1 HCV infection and very high HCV RNA levels had ~27% lower chance of achieving SVR.[216] However, the HCV RNA level has very little impact on the SVR in the era of DAA therapy.

Similarly, polymorphisms in the *IL28B* gene were associated with a difference in treatment response rates for persons receiving IFN-based therapies. In the DAA era, IL28B genotype, race, age, and gender do not significantly influence treatment response. The degree of hepatic fibrosis may still influence the SVR rates for persons receiving DAA therapies. Advanced fibrosis, defined as F3 (precirrhosis or bridging fibrosis), and F4 (cirrhosis) were associated with a much lower virologic cure rate across all genotypes (between 10% and 20% lower) during the IFN era.[213–215] This is similarly observed in patients receiving DAA therapies. Patients with decompensated cirrhosis (Child–Pugh class B or C) had lower SVR rates (86%–87%) with 12-week treatment of ledipasvir/sofosbuvir plus ribavirin compared with SVR rates of ≥98% in similarly treated patients with no cirrhosis.[217] Current strategies to improve the SVR rates for patients with cirrhosis include adding ribavirin to the DAA combination therapies and lengthening the duration of therapy.

Current Treatment Strategies

From 1998 to 2013, antiviral therapy evolved from IFN monotherapy to PegIFN monotherapy, to PegIFN plus ribavirin, and to triple therapy with PegIFN plus ribavirin plus a first-generation DAA (eg, boceprevir or telaprevir), which was part of the NS3/4A serine protease inhibitor class. At the time, research methodologies for enhancing the effectiveness of HCV treatments and improving SVR mainly focused on genotype 1, which is the most prevalent genotype in the United States. The DAAs are oral antiviral agents that directly target the specific steps within the replication genome of the HCV. Between 2013 and 2014, antiviral treatment against genotype 1 HCV infection included PegIFN and ribavirin plus either sofosbuvir or simeprevir, which modestly improved the SVR outcomes. Then in 2015, the HCV treatment paradigm significantly shifted to an IFN-free approach where the oral DAAs became the standard of care for CHC infection. The DAAs were superior to PegIFN and ribavirin therapy because of their outstanding SVR rates, better tolerability profiles, and much shorter treatment duration. The treatment duration was significantly reduced from 48 weeks with PegIFN plus ribavirin to between 8 and 24 weeks with DAA combination regimens. The three classes of DAAs are defined by their mechanism of action and therapeutic target. They include the nonstructural proteins 3/4A (NS3/4A) serine protease inhibitors, nonstructural protein 5B (NS5B) RNA-dependent RNA polymerase inhibitors, and nonstructural protein 5A (NS5A) inhibitors.[218]

According to the AASLD/IDSA HCV treatment guidelines, treatment should be offered to all persons with CHC infection because the DAAs are safer, better tolerated, and more effective in achieving virologic cure.[147] However, there are absolute contraindications for DAA treatment: persons with short life expectancies (<6 months); the use of DAA regimens plus ribavirin in pregnant patients, females who may become pregnant, or males whose female partners are pregnant.[219],[220] The main concern is with ribavirin, which is teratogenic. Persons with CHC infection who are of reproductive age and are to receive treatment that includes ribavirin should be strongly advised to use two forms of contraception during treatment and for at least 6 months following the end of treatment.

Similarly, there are relative contraindications when considering CHC treatment initiation. They include active severe substance abuse (eg, excess alcohol use, injecting drugs), psychiatric issues not controlled or stabilized, and social issues that may negatively affect a person's adherence to treatment, laboratory, and scheduled office visits.

DIRECT-ACTING ANTIVIRALS

CASE 80-15, QUESTION 3: Genotyping of K.C.'s HCV infection shows that she has genotype 1a. Which DAA therapy would be effective for patients with genotype 1a HCV infection?

K.C. has many treatment options with the DAA therapies. She has no signs of cirrhosis, or decompensated disease with splenomegaly, ascites, coagulopathy, or esophageal varices. The DAA combination therapies are highly potent and effective in achieving ≥98% SVR rates for persons with genotype 1 (1a and 1b subtypes) HCV infection (**Table 80-9**).[221,222]

Table 80-9

Comparison of Direct-Acting Antiviral Agents for Hepatitis C Virus Treatment

	NS3/4A Serine Protease Inhibitors	NS5B Polymerase Inhibitor	NS5B (Nonnucleoside) Polymerase Inhibitor	NS5A Inhibitors
DAA agents	Glecaprevir Grazoprevir Paritaprevir Voxilaprevir	Sofosbuvir	Dasabuvir	Daclatasvir (not available in the United States) Elbasvir Ledipasvir Ombitasvir Pibrentasvir Velpatasvir
MOA	Block RNA translation and polyprotein processing prevent viral maturation	Blocks viral replication and propagation	Blocks viral replication and propagation	Block the replication complex and virion assembly
Potency	High	Moderate-to-high	Moderate-to-high	High
Barrier to resistance	Moderate-to-high	High	High	Low
Potential for drug interactions	High	Low	Low	Variable
Adverse effects	Headache, fatigue, nausea	Headache, insomnia, pruritus, diarrhea	Minimal	Headache, nausea, fatigue

DAA, direct-acting antiviral; MOA, mechanism of action; NS3/4A, nonstructural proteins 3/4A serine protease inhibitors; NS5A, nonstructural protein 5A inhibitor; NS5B, nonstructural protein 5B RNA-dependent RNA polymerase inhibitor.

NS3/4A serine protease inhibitors

The NS3/4A protease is a trypsin-like serine enzyme, which is essential for the generation of components of the viral RNA replication complex. The NS3/4A serine protease is responsible for cleaving the polyprotein downstream of the NS3 site, allowing the release of functional proteins and the generation of mature proteins. The NS3/4 serine protease inhibitors are macrocyclic noncovalent peptidomimetic inhibitors that reversibly bind to the HCV NS3/4A protease and function through two mechanisms. They disrupt the virus replication process by blocking the NS3 catalytic site or the NS3/NS4A interaction.[222] The NS3/NS4A protease inhibitors also block the cleaving of two cellular proteins in the IFN cascade, thereby affecting IFN-α and IFN-β synthesis.[222] In short, the NS3/4A serine protease inhibitors exert two distinct effects: blocking viral replication by inhibiting viral polyprotein processing and restoring IFN signaling pathways that are believed to be disrupted by NS3/4A. As a result, the NS3/4A serine protease inhibitors prevent viral maturation.

First Generation

The first-generation protease inhibitors for CHC treatment included boceprevir and telaprevir. They were used in combination with PegIFN plus ribavirin for the treatment of genotype 1 infection. Their clinical importance substantially diminished because of the cumbersome administration, substantial adverse effects, drug–drug interactions, and a low barrier to viral resistance. As more potent and better-tolerated protease inhibitors were approved for CHC treatment without PegIFN and ribavirin, telaprevir and boceprevir became clinically obsolete and were removed from the U.S. market in 2014 and 2015, respectively.

Second Generation

The second-generation protease inhibitors were more favored because they have fewer drug–drug interactions, fewer severe adverse effects, and have improved dosing schedules. In spite of their improved efficacy against genotype 1 infection, the newer protease inhibitors have limited efficacy against other genotypes and a low barrier to resistance.[223] The second-generation protease inhibitors currently available in the United States include simeprevir, grazoprevir, paritaprevir, glecaprevir, and voxilaprevir.

Simeprevir Simeprevir (Olysio®) was the first DAA in the second-generation NS3/4A serine protease inhibitor class. It was approved for combination use with PegIFN plus ribavirin, or in combination with sofosbuvir, with or without ribavirin for chronic HCV genotype 1 infection.[224] No dose adjustment is required in patients with renal impairment. Simeprevir cannot be used in patients with moderate (Child–Pugh class B) or severe (Child–Pugh class C) hepatic impairment because of two- to fivefold increases in drug exposure. Higher simeprevir exposure was reported in patients of East Asian ancestry; thus, simeprevir should be used with caution for this patient population.[225] In clinical trials, simeprevir treatment discontinuations from adverse effects were uncommon. However, photosensitivity and rash that led to serious reactions requiring hospitalization for some patients have occurred in the trials.[226,227] Patients taking simeprevir should be cautioned about the risk of photosensitivity and rash, and to use sun-protective measures and/or limit sun exposure while on treatment. If a severe rash or photosensitivity reaction occurs, simeprevir should be discontinued.

Simeprevir is oxidatively metabolized by the hepatic and intestinal cytochrome P450 (CYP) 3A4 isoenzyme. Coadministration with potent inducers and inhibitors of CYP3A4 will affect the plasma concentration of simeprevir. The efficacy of simeprevir is affected by the presence of resistance mutations or polymorphisms of the NS3/4A protease. In particular, the presence of Q80K polymorphism was associated with a lower SVR rate (58% vs 84% if the Q80K was absent).[225] However, data suggest that the Q80K mutation does not

significantly affect SVR rates when simeprevir is coadministered with sofosbuvir, an NS5B polymerase inhibitor.[228] Owing to simeprevir's narrow spectrum of activity (against genotype 1 only) and its adverse effect profile, it is no longer a preferred option in the AASLD/IDSA treatment guidelines for CHC infection.

Grazoprevir Grazoprevir is coformulated in a fixed-dose combination with elbasvir, an NS5A inhibitor. Grazoprevir has activity against HCV genotypes 1, 4, and 6. However, it is only FDA approved for genotypes 1 and 4 because of the elbasvir component. It is a substrate of CYP3A4 isoenzyme and the OATP1B1/3 transporter. The drug–drug interactions with grazoprevir are different compared to other protease inhibitors, where its concentrations are increased by cyclosporine and HIV protease inhibitors via OAT1B1/3 inhibition[229] (see section on Elbasvir/Grazoprevir).

Paritaprevir Paritaprevir is hepatically metabolized by the CYP3A4 isoenzyme. It is coformulated with low-dose ritonavir, an HIV protease inhibitor, for pharmacokinetic-enhancing effects via inhibition of CYP3A-mediated metabolism. Ritonavir does not have any activity against HCV. Paritaprevir and ritonavir are coformulated as a fixed-dose combination with ombitasvir, an NS5A inhibitor (see section on Paritaprevir/Ritonavir/Ombitasvir Plus Dasabuvir).

Glecaprevir Glecaprevir is coformulated in a fixed-dose combination product with pibrentasvir, an NS5A inhibitor. Glecaprevir has pangenotypic antiviral activity against HCV genotypes 1 to 6. It is minimally metabolized and excreted via the bile.[230] The combination is approved for the treatment of persons with CHC infection without cirrhosis and with compensated cirrhosis (Child–Pugh class A) (see section on Glecaprevir/Pibrentasvir).

Voxilaprevir Voxilaprevir is coformulated in a fixed-dose combination with sofosbuvir (NS5B inhibitor) and velpatasvir (NS5A inhibitor). It also has pangenotypic antiviral activity against HCV genotypes 1 to 6. Voxilaprevir is a CYP3A4 and 2C8 substrate. It is also a substrate and inhibitor of OATP1B1, OATP1B3, P-gp, and BCRP.[231] Unlike the other combination DAA regimens, this triple combination regimen is intended to be used as salvage therapy for

DAA treatment failures (see section on Sofosbuvir/Velpatasvir/Voxilaprevir).

It is important to note that the FDA issued a safety announcement in 2019 regarding case reports of worsening liver function or liver failure associated with the use of second-generation NS3/4A protease inhibitors: grazoprevir, glecaprevir, and voxilaprevir.[232] These protease inhibitors are found in DAA combination regimens, such as elbasvir/grazoprevir (Zepatier®), pibrentasvir/glecaprevir (Mavyret®), and sofosbuir/velpatasvir/voxilaprevir (Vosevi®). Many of the case reports described liver failure that occurred in patients who were symptomatic with moderate-to-severe liver impairment (Child–Pugh class B or C), or have other serious liver problems. The FDA recommends the use of these DAA regimens for patients without liver impairment or with mild liver impairment (Child–Pugh class A) only. Zepatier® and Mavyret® should be avoided in persons with any history of prior hepatic decompensation. Vosevi® is indicated for persons who have previously failed DAA treatments and is not recommended in persons with a history of hepatic decompensation unless the benefits outweigh the risk of liver injury or fatality.[232]

NS5A inhibitors

The NS5A inhibitors block the protein complex that is involved in viral replication and the assembly of the virion.[233–235] The NS5A class is relatively potent and effective across all genotypes. However, it has a low barrier to viral resistance and a variable toxicity profile. When coadministered with PegIFN and ribavirin, NS5A inhibitors can substantially reduce HCV RNA levels and improve SVR.[235] The NS5A inhibitors are substrates of P-gp and BCRP drug transporters. They are also substrates of CYP3A4, except for ledipasvir.[236] The available NS5A inhibitors in fixed-dose combinations with other DAAs include ledipasvir, ombitasvir, elbasvir, and velpatasvir. Daclatasvir, the only stand-alone NS5A inhibitor, is no longer available in the United States.

Elbasvir is available in a fixed-dose combination with grazoprevir, an NS3/4A serine protease inhibitor. Before initiating this DAA

combination regimen for treatment of genotype 1a, baseline resistance testing is required to determine the presence of the virus with NS5A resistance-associated substitution (RAS) polymorphisms at the amino acid positions 28, 30, 31, or 93 and to determine dosage regimen and duration[237] (see section on Elbasvir/Grazoprevir).

Ledipasvir is available in a fixed-dose combination with sofosbuvir, an NS5B polymerase inhibitor. Its absorption is optimal in an acidic milieu. Therefore, drugs that increase gastric pH could decrease the plasma concentration of ledipasvir. Coadministration of ledipasvir is not recommended with antacids (eg, aluminum and magnesium hydroxide) and should be separated by 4 hours. On the other hand, ledipasvir could be administered simultaneously with H_2-receptor antagonists or given 12 hours apart. The dose of the H_2-receptor antagonists should not exceed doses comparable to famotidine 40 mg twice daily, which was used in the studies.[236] Ledipasvir can be given with omeprazole, but not >20 mg and under fasting conditions.[236] It is active against genotypes 1, 4, 5, and 6 (see the section on Ledipasvir/Sofosbuvir).

Ombitasvir is available in a fixed-dose combination with the protease inhibitors paritaprevir and ritonavir, and is administered in combination with dasabuvir, an NS5B nonnucleoside inhibitor (see section on Paritaprevir/Ritonavir/Ombitasvir Plus Dasabuvir).

Elbasvir is available in a fixed-dose combination with glecaprevir, an NS3/4A serine protease inhibitor. It is considered one of the newer generations of NS5A inhibitors with pangenotypic activity. Pibrentasvir has potent antiviral activity against common HCV NS5A single-position variants that confer resistance to first-generation NS5A inhibitors (eg, daclatasvir, ledipasvir, and ombitasvir) (see section on Glecaprevir/Pibrentasvir).

Velpatasvir has pangenotypic antiviral activity against genotypes 1 to 6. It is only available in a fixed-dose combination with sofosbuvir, an NS5B polymerase inhibitor. Similar to ledipasvir, velpatasvir requires an acidic milieu for optimal absorption. Its drug–drug interaction profile mirrors that of ledipasvir when velpatasvir is

administered with antacids (eg, aluminum and magnesium hydroxide) and H_2-receptor antagonists. Similar administration recommendations should be taken when using velpatasvir-based regimens. However, the coadministration of velpatasvir and proton-pump inhibitors is not recommended. If considered medically necessary, then velpatasvir-based regimens should be administered with food and taken 4 hours before omeprazole 20 mg[238] (see sections on Sofosbuvir/Velpatasvir and Sofosbuvir/Velpatasvir/Voxilaprevir).

NS5B RNA-dependent RNA polymerase inhibitors

The NS5B RNA-dependent RNA polymerase is involved in posttranslational processing that is necessary for HCV replication. The polymerase has a catalytic site for nucleoside binding and four other sites for nonnucleoside binding to cause an allosteric alteration. The enzyme structure is highly conserved across all six genotypes. The NS5B RNA-dependent RNA polymerase inhibitors essentially block viral replication and propagation. There are two subclasses of NS5B polymerase inhibitors: the nucleoside/nucleotide polymerase inhibitors (NPIs) and nonnucleoside polymerase inhibitors (NNPIs). The NPIs bind to the catalytic site of NS5B, whereas NNPIs function as allosteric inhibitors.[222,223]

Sofosbuvir

Sofosbuvir (Sovaldi®) is the first NS5B NPI available for HCV treatment and has pangenotypic activity. It should not be used as monotherapy against HCV and is most effective when used in DAA combination regimens. Sofosbuvir is available as a 400-mg tablet and is given daily with or without food. It is primarily renally eliminated; however, pharmacokinetic studies suggest that no dose adjustments are required for patients with mild or moderate renal impairment (eGFR >30 mL/minute/1.73 m^2).[239] Nevertheless, serum levels of sofosbuvir are increased in patients with severe renal impairment and receiving hemodialysis. There are insufficient data to recommend dose adjustments in these patients. Sofosbuvir can be

given to patients with moderate (Child–Pugh class B) or severe (Child–Pugh class C) hepatic impairment and cirrhosis without dose adjustments. Sofosbuvir is generally well tolerated. When given with PegIFN and ribavirin, the commonly reported adverse effects of sofosbuvir and ribavirin (with or without PegIFN) were fatigue, headache, nausea, insomnia, and anemia.[240],[241]

As a substrate of the P-gp drug transporter, sofosbuvir has significant drug interactions with potent intestinal P-gp inducers that could decrease its plasma concentration. The coadministration of sofosbuvir with anticonvulsants (eg, carbamazepine, phenytoin, phenobarbital, oxcarbazepine), antituberculosis drugs (eg, rifampin, rifabutin, rifapentine), and St. John wort is contraindicated. Of note, the coadministration of sofosbuvir and amiodarone is also contraindicated. Concomitant use of sofosbuvir and sofosbuvir-based regimens with amiodarone are contraindicated because of episodes of severe bradycardia and fatal cardiac arrest.[242],[243] The proposed mechanism for the major drug–drug interaction between amiodarone and sofosbuvir remains unclear.

Dasabuvir

Dasabuvir is an NS5B NNPI. The NNPI class is less potent than the NPI class, is more specific for genotype 1, and has a low-to-moderate barrier to viral resistance and a variable toxicity profile.[244] Dasabuvir is coadministered and packaged with paritaprevir/ritonavir/ombitasvir (see section on Paritaprevir/Ritonavir/Ombitasvir Plus Dasabuvir).

Case 80-15, Question 4: The current AASLD/IDSA guidelines endorse fixed-dose DAA combination regimens for effective HCV treatment. Which DAA regimen could K.C. benefit from and for what treatment duration?

There are currently four FDA-approved fixed-dose combinations that are effective against HCV genotype 1, as well as other genotypes. K.C. has genotype 1a HCV infection. She could benefit from any of the following regimens:

a. Glecaprevir 300 mg/pibrentasvir 120 mg (Mavyret®) three tablets PO with food once daily for 8 weeks
b. Elbasvir 50 mg/grazoprevir 100 mg (Zepatier®) one tablet PO once daily for 12 weeks
c. Ledipasvir 90 mg/sofosbuvir 400 mg (Harvoni®) one tablet PO once daily for 12 weeks
d. Sofosbuvir 400 mg/velpatasvir 100 mg (Epclusa®) one tablet PO once daily for 12 weeks

Both glecaprevir/pibrentasvir (Mavyret®) and sofosbuvir/velpatasvir (Epclusa®) are DAA combination regimens that have pangenotypic activity against genotypes 1 to 6. Before starting elbasvir/grazoprevir (Zepatier®), K.C. will need to receive baseline resistance testing for the presence of the virus with NS5A RAS polymorphisms at the amino acid positions 28, 30, 31, or 93 to determine the duration and possible addition of ribavirin to the treatment regimen because of her genotype.[237] Ledipasvir/sofosbuvir (Harvoni®) could be considered for K.C.; however, the treatment duration would be for 12 weeks because her baseline HCV RNA level is >6,000,000 IU/mL. Of note, paritaprevir/ritonavir/ombitasvir plus dasabuvir (Viekira Pak®, Viekira Pak® XR) could be another possible treatment option for K.C. because it has activity only against genotype 1 HCV variants. However, this DAA regimen would not be preferred for K.C. because of the pill burden (three to four tablets daily) and a longer duration of treatment (24 months).

ORAL FIXED-DOSE DIRECT-ACTING ANTIVIRAL COMBINATIONS

Elbasvir/grazoprevir

As a fixed-dose combination single tablet, elbasvir 50 mg/grazoprevir 100 mg (Zepatier®) has activity against genotypes 1 and 4 HCV infection. It is a combination of an NS5A inhibitor and NS3/4A serine protease inhibitor. The DAA regimen is administered once daily for either 12 or 16 weeks.[245] This regimen is administered with or without weight-based ribavirin, depending on certain patient

characteristics. Elbasvir/grazoprevir has been studied and approved for the treatment of CHC and HIV coinfection. Patients should have documentation of baseline aminotransferases and be tested for current or previous CHB infection (HBsAg and anti-HBc) to ensure that there is no risk of HBV flares during HCV treatment. The regimen is the first of the newer DAA therapies that could be used in patients with renal impairment, including hemodialysis, without the need for dose adjustments. However, the regimen is contraindicated for use in patients with moderate-to-severe hepatic impairment (Child–Pugh class B or C).

Before administering elbasvir/grazoprevir, patients with genotype 1a infection should undergo baseline testing for the presence of NS5A RAS polymorphisms. Preexisting NS5A polymorphisms that are associated with elbasvir resistance and lower SVR rates with the regimen in patients with genotype 1a are found at amino acid positions M28, Q30, L31, and Y93.[237] Approximately 11% of genotype 1a viruses are estimated to harbor one of these polymorphisms before taking elbasvir/grazoprevir regimen. In the presence of one of the NS5A polymorphisms, ribavirin (weight based) could be added to the regimen and the treatment duration extended to improve SVR rates. Interestingly, the polymorphisms do not affect the SVR rates in persons with genotype 1b virus infection. The polymorphisms in the NS3 protein, especially the Q80L polymorphism in genotype 1a virus, do not appear to affect treatment response and SVR rates. The other difference between the NS5A and NS3 polymorphisms appears to be the long persistence of the NS5A resistance mutations in individuals after completing the DAA treatment.

Elbasvir/grazoprevir is overall well tolerated. From the large clinical trials, the most common adverse effects were headache, fatigue, and nausea.[237],[246] Approximately 1% of patients developed late aminotransferase elevations more than five times ULN without associated bilirubin increases that resolved once the regimen was stopped. Aminotransferase monitoring at baseline and at week 8 of therapy (and at week 12 if the total duration is 16 weeks) is recommended.[245] The regimen should be discontinued if

aminotransferase elevations are accompanied by other signs or symptoms of hepatic injury, such as jaundice, increased bilirubin, or INR. The regimen is primarily metabolized by CYP3A isoenzyme, and grazoprevir is a substrate of OATP1B1/3 transporters. Coadministration of elbasvir/grazoprevir is contraindicated with potent inducers (eg, rifampin, phenytoin, carbamazepine, St. John wort, cyclosporine), efavirenz, and HIV protease inhibitors (eg, atazanavir, darunavir, ritonavir). Furthermore, coadministration of the regimen is not recommended with ketoconazole, nafcillin, modafinil, and other antiretrovirals (etravirine or cobicistat).

Ledipasvir/sofosbuvir

Ledipasvir 90 mg/sofosbuvir 400 mg (Harvoni®) is coformulated as a fixed-dose tablet that is administered with or without food.[222] It is a combination of an NS5A inhibitor and NS5B polymerase inhibitor. The regimen is given with or without weight-based ribavirin, depending on the patient population, and is active against HCV genotypes 1, 4, 5, and 6. The limited spectrum of antiviral activity is based on the ledipasvir component. The duration of therapy ranges between 8 and 24 weeks depending on the genotype, treatment exposure (naive or experienced), and the liver condition (fibrosis stage level). Based on the ION-3 trial, ledipasvir/sofosbuvir could be considered in treatment-naive patients with genotype 1 without cirrhosis who have pretreatment HCV RNA level <6 million IU/mL.[247] The levels of sofosbuvir and its inactive metabolite (GS-331007) might accumulate in the setting of severe renal impairment (eGFR <30 mL/minute/ 1.73 m^2). Therefore, the combination should not be used until further data are available. Otherwise, no dose adjustment is needed for mild or moderate renal impairment, or in the setting of moderate (Child–Pugh class B) or severe (Child–Pugh class C) hepatic impairment.[247]

The ledipasvir/sofosbuvir combination is well tolerated, and the common adverse effects include fatigue, headache, nausea, and insomnia. With regard to drug interactions, ledipasvir is a substrate of the P-gp drug transporter. Similar to sofosbuvir, ledipasvir should

not be coadministered with potent intestinal P-gp inducers because its plasma concentration will significantly decrease. The coadministration of ledipasvir with acid-suppressing agents could increase the gastric pH levels and decrease its solubility and absorption. Coadministration of ledipasvir is not recommended with antacids (eg, aluminum and magnesium hydroxide) and should be separated by 4 hours. On the other hand, ledipasvir could be administered simultaneously with H_2-receptor antagonists or given 12 hours apart. The dose of the H_2-receptor antagonists should not exceed doses comparable to famotidine 40 mg twice daily, which was used in the studies. Ledipasvir can be given with omeprazole, but not >20 mg and under fasting conditions.[236,239] The coadministration of amiodarone and sofosbuvir/velpatasvir is contraindicated because of severe bradycardia and cardiac arrest.[242,243]

The resistance profile of ledipasvir/sofosbuvir has been associated with several NS5A RAS polymorphisms that reduce the susceptibility to ledipasvir, such as Q30R, Y93H/N, and L31M for genotype 1a virus and Y93H for genotype 1b virus.[248] The presence of NS5A RASs does not require adjustment of the regimen's dosage or duration of treatment. Further data are warranted to make any clinical adjustments. The coadministration of amiodarone and ledipasvir/sofosbuvir is contraindicated because of severe bradycardia and cardiac arrest based on a major drug–drug interaction between amiodarone and sofosbuvir[242,243] (see section on Sofosbuvir).

Sofosbuvir/velpatasvir

Sofosbuvir 400 mg/velpatasvir 100 mg (Epclusa®) is a fixed-dose, pangenotypic regimen that comprises an NS5B polymerase inhibitor plus an NS5A inhibitor. It is coformulated as a once-daily single tablet administered for 12 weeks with or without ribavirin. The commonly reported adverse effects include headache, fatigue, nausea, nasopharyngitis, and insomnia.[249] Baseline viral resistance testing is required only for persons with genotype 3 HCV infection.

No dose adjustments are needed for this regimen in patients with mild-to-moderate renal impairment. There are insufficient data regarding the safety and efficacy of this regimen in patients with severe renal impairment (eGFR <30 mL/minute/1.73m^2) or ESRD requiring hemodialysis. For patients with moderate (Child–Pugh class B) or severe (Child–Pugh class C) hepatic impairment, no dosage adjustments are recommended. Thus, close monitoring is recommended for patients with decompensated cirrhosis who are receiving sofosbuvir/velpatasvir and ribavirin.[250]

Sofosbuvir and velpatasvir are substrates of the P-gp and BCRP drug transporters. Therefore, coadministration of the regimen with potent intestinal P-gp inducers can decrease both sofosbuvir and velpatasvir serum levels. The coadministration of this regimen is contraindicated with anticonvulsants, antituberculosis drugs, and St. John wort. Efavirenz can also significantly reduce the serum levels of velpatasvir and should not be coadministered. Velpatasvir is also an inhibitor of the P-gp transporter and thus may increase the absorption of P-gp substrates. Similar to ledipasvir, velpatasvir requires an acid gastric environment for enhanced solubility and absorption. Antacids, H_2-receptor antagonists, and proton-pump inhibitors will increase the gastric pH levels, resulting in decreased absorption of velpatasvir. The manufacturer recommends separating the administration time of 4 hours between sofosbuvir/velpatasvir and antacids (eg, aluminum and magnesium hydroxide). However, H_2-receptor antagonists could be administered simultaneously with or separated 12 hours apart from the DAA regimen at a dose that is comparable with famotidine 40 mg twice daily. Coadministration of velpatasvir and proton-pump inhibitors is not recommended. If considered medically necessary, then velpatasvir-based regimens should be administered with food and taken 4 hours before omeprazole 20 mg.[231],[238] The coadministration of amiodarone and sofosbuvir/velpatasvir is contraindicated because of severe bradycardia and cardiac arrest based on a major drug–drug interaction between amiodarone and sofosbuvir[242],[243] (see section on Sofosbuvir).

Paritaprevir/ritonavir/ombitasvir plus dasabuvir

The coformulated tablet of paritaprevir 75 mg/ritonavir 50 mg/ombitasvir 12.5 mg is given with dasabuvir 250 mg. It is the only combination regimen that contains ritonavir, an HIV protease inhibitor, as a pharmacokinetic enhancer. The regimen is often referred to as *PrOD* (Viekira Pak®, Viekira® XR). PrOD can be taken with or without weight-based ribavirin, depending on the patient population, for the treatment of genotype 1 (1a and 1b subtypes) without cirrhosis or with compensated cirrhosis. PrOD is also indicated in combination with ribavirin in liver transplant patients with HCV genotype 1 as long as hepatic function is normal and fibrosis is mild (METAVIR score ≤2).[251] Paritaprevir/ritonavir/ombitasvir, with or without dasabuvir, can be administered in CHC-infected patients with renal impairment. Dose adjustment for the regimens is not warranted for patients with mild hepatic impairment (Child–Pugh class A). However, the regimens are contraindicated in patients with moderate-to-severe hepatic impairment (Child–Pugh classes B and C). Hepatic decompensation was reported when the regimen is used, with or without dasabuvir, in patients with underlying cirrhosis.[252] Most of the reported cases occurred within 1 to 4 weeks of drug initiation, and some cases resulted in the need for liver transplantation or death.

PrOD is available in immediate-release and extended-release tablet formulations. For the immediate-release formulation (Viekira Pak®), two tablets (each containing ombitasvir 12.5 mg/paritaprevir 75 mg/ritonavir 50 mg) are administered once daily. Dasabuvir is coadministered with the regimen as a single 250-mg tablet twice daily. In short, the number of pills for Viekira Pak® is four tablets a day. For the extended-release formulation (Viekira® XR), it is a four-drug combination tablet containing ombitasvir 8.33 mg/paritaprevir 50 mg/ritonavir 33.33 mg/dasabuvir 200 mg. The dosage regimen is three tablets administered once daily with ribavirin (weight-based dosing) in two divided doses. These regimens should be taken with food and are generally well tolerated. The commonly reported adverse effects in the trials that used the regimen with ribavirin

included nausea, pruritus, insomnia, diarrhea, and asthenia.[253],[254] Fatigue and headache were the most common side effects and may be attributable to the ribavirin component. Decreases in the hemoglobin level, by 2 to 2.5 g/dL, were observed in patients taking regimens with ribavirin. The incidence of severe anemia (hemoglobin <8 g/dL) is uncommon.[253],[254]

The components of PrOD are both substrates and inhibitors of CYP450 enzymes. The coadministration of paritaprevir/ritonavir/ombitasvir and dasabuvir is contraindicated with anticonvulsants, rifampin, St. John wort, and oral contraceptives containing ethinyl estradiol and salmeterol.[251] Close monitoring and dose adjustments of certain drugs (eg, 3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA], cyclosporine, tacrolimus, and antiarrhythmics) are recommended when given with the PrOD regimen. The use of paritaprevir, ombitasvir, and dasabuvir can select for viral resistance mutations in NS3, NS5A, and NS5B, respectively, which will reduce the activity of a particular antiviral agent.

Glecaprevir/pibrentasvir

Glecaprevir 300 mg/pibrentasvir 120 mg (Mavyret®) is the first pangenotypic fixed-dose tablet comprising an NS3/4A serine protease inhibitor and NS5A inhibitor. It offers a potent 8-week treatment option for persons with no cirrhosis with renal disease or HIV coinfection.

Glecaprevir/pibrentasvir is administered as three tablets once daily with food to increase absorption. The manufacturer packages a daily packet containing three tablets to ensure medication adherence. For treatment-naive persons without cirrhosis, the treatment duration is 8 weeks for all genotypes. However, the treatment duration is extended to 12 weeks for treatment-naive persons with compensated cirrhosis (Child–Pugh class A). For treatment-experienced persons, the treatment duration will range between 8 and 16 weeks depending on their previous HCV regimen and genotype.[230],[255] Data from the clinical trials do not support the use of

glecaprevir/pibrentasvir for the treatment of patients with genotype 1 HCV infection who are both NS3/4A protease inhibitor and NS5A inhibitor experienced because of higher rates of virologic failure and treatment-emergent drug resistance.[255]

Table 80-10

Combination Direct-Acting Antiviral Regimens for Treatment-Naive Patients Without or With Compensated Cirrhosis

DAA Combination Therapy	Trade Name	Dosage Regimen	Genotype Coverage	Duration of Therapy	Safe in Decompensated Cirrhosis?	Use in CKD, ESRD
Preferred Therapies						
Glecaprevir 300 mg/pibrentasvir 120 mg	Mavyret®	Three tablets PO daily with food	1–6	8 weeks	No	Safe in HD
Sofosbuvir 400 mg/velpatasvir 100 mg	Epclusa®	One tablet PO daily	1–6	12 weeks	Yes	≥30 mL/minute
Sofosbuvir 400 mg/velpatasvir 100 mg/voxilaprevir 100 mg	Vosevi®[a]	One tablet PO daily with food	1–6	12 weeks	No	≥30 mL/minute
Dependent on Patient's HCV Genotype						
Ledipasvir 90 mg/sofosbuvir 400 mg	Harvoni®	One tablet PO daily	1, 4, 5, 6	8 weeks[b] 12 weeks	Yes	≥30 mL/minute
Elbasvir 50 mg/grazoprevir 100 mg	Zepatier®[c]	One tablet PO daily	1 (1a[c], 1b), 4	12–16 weeks	No	Safe in HD
Paritaprevir 75 mg/ritonavir 50 mg/ombitasvir 12.5 mg + dasabuvir 250 mg	Viekira Pak®, Viekira Pak® XR	Dosing regimen variable depending on genotype and cirrhosis condition	1a, 1b	12–24 weeks	No	Safe in HD

CKD, chronic kidney disease; ESRD, end-stage renal disease; HD, hemodialysis.

[a]Vosevi®: not for first-line use, but only for salvage DAA therapy.

[b]Harvoni®: for patients with genotype 1, HIV-negative, and have HCV RNA level <6 million IU/mL.

[c]Zepatier® is eligible only if there are no baseline NS5A resistance-associated substitution (RAS) polymorphisms for genotype 1a; patients with genotypes 1b and 4 can use Zepatier® without screening for RAS.

Source: AASLD/IDSA HCV Guidance Panel. Recommendations for testing, managing, and treating hepatitis C. Updated August 27, 2020 [Internet]. 2020 [cited August 27, 2020]. Accessed October 1, 2020. http://hcvguidelines.org/

Before initiating glecaprevir/pibrentasvir, all persons should be tested for current or prior hepatitis B infection by measuring HBsAg and anti-HBc. Glecaprevir/pibrentasvir is not recommended in patients with moderate hepatic impairment (Child–Pugh class B) and

is contraindicated for use in patients with severe hepatic impairment (decompensated cirrhosis or Child–Pugh class C) because of higher exposures of the drugs, especially of glecaprevir.[255]

Nausea, fatigue, and headache were the more common adverse effects reported from the clinical trials. Regarding drug–drug interactions, glecaprevir and pibrentasvir are substrates and inhibitors of P-gp and BCRP transporters. They are weak inhibitors of CYP3A, CYP1A2, and UGT1A1 substrates. The coadministration of glecaprevir/pibrentasvir with potent CYP3A4 inducers (eg, rifampin, St. John wort, and carbamazepine) is not recommended because of reduced plasma concentrations of glecaprevir/pibrentasvir that could lead to decreased efficacy and potential treatment failure. The coadministration of atazanavir with glecaprevir/pibrentasvir is contraindicated because of an increased risk of ALT elevations and plasma concentrations of the drugs.[255] Similarly, the coadministration of glecaprevir/pibrentasvir is not recommended with HMG-CoAs that are metabolized by CYP3A4 enzyme (eg, atorvastatin, simvastatin, and lovastatin) because of their increased plasma concentrations that could lead to increased risk of myopathy. Alternative statins such as rosuvastatin, pitavastatin, and pravastatin could be considered with close monitoring for adverse effects.

Sofosbuvir/velpatasvir/voxilaprevir

Sofosbuvir 400 mg/velpatasvir 100 mg/voxilaprevir 100 mg (Vosevi®) is the first pangenotypic fixed-dose combination tablet that includes one agent from each of the DAA class (NS3/4A serine protease inhibitor, NS5B RNA-dependent RNA polymerase inhibitor, and NS5A inhibitor), thereby targeting the essential steps of the virus life cycle. It is administered as one tablet once daily with food. Safety and efficacy have not been established in patients whose eGFR <30 mL/minute/1.73 m^2. This regimen plays an important role in patients who have experienced treatment failure with other DAA therapies. The presence of NS5A, NS3/4A, or NS5B RASs do not influence the likelihood of patients achieving SVR with Vosevi®.[256] Therefore,

sofosbuvir/velpatasvir/voxilaprevir is reserved as a viable option for patients. Unfortunately, the presence of voxilaprevir does not make this regimen an option for treatment-experienced patients who have moderate-to-severe hepatic disease (Child–Pugh class B or C cirrhosis).[257]

The common adverse effects reported from clinical trials include fatigue, headache, diarrhea, and nausea. The solubility of velpatasvir in the fixed-dose regimen depends on the gastric pH. Its solubility decreases as pH increases. Drugs that increase the gastric pH, such as antacids, H_2-receptor antagonists, and proton-pump inhibitors will decrease the plasma concentration of velpatasvir. They will increase the gastric pH levels, resulting in decreased solubility and absorption of velpatasvir. The manufacturer recommends separating the administration time of 4 hours between sofosbuvir/velpatasvir/voxilaprevir and antacids (eg, aluminum and magnesium hydroxide). However, H_2-receptor antagonists could be administered simultaneously with or separated 12 hours apart from the DAA regimen at a dose that is comparable with famotidine 40 mg twice daily. Coadministration of velpatasvir and proton-pump inhibitors is not recommended. If considered medically necessary, then velpatasvir-based regimens should be administered with food and taken 4 hours before omeprazole 20 mg.[231,238]

Sofosbuvir, velpatasvir, and voxilaprevir are metabolized by P-gp and BCRP drug transporters. Voxilaprevir is also a substrate of OATP1B1 and OATP1B3. In vitro observations have reported the metabolism of velpatasvir by CYP2B6, CYP2C8, and CYP3A4 and of voxilaprevir by CYP1A2, CYP2C8, and CYP3A4 (mainly).[231] Therefore, potent inducers of P-gp, CYP2B6, CYP2C8, or CYP3A4 (eg, carbamazepine, rifampin, St. John wort) could significantly decrease the plasma concentrations of sofosbuvir, velpatasvir, and voxilaprevir resulting in a subtherapeutic effect of the regimen. Similarly, sofosbuvir/velpatasvir/voxilaprevir should not be coadministered with cyclosporine because of the risk of substantially increased exposure of voxilaprevir.[231] Similar to other sofosbuvir-based regimens, the coadministration of

sofosbuvir/velpatasvir/voxilaprevir with amiodarone is contraindicated because of severe bradycardia and cardiac arrest based on a major drug–drug interaction between amiodarone and sofosbuvir.[242],[243]

COINFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS

CASE 80-16

QUESTION 1: F.X., a 32-year-old transgender female, presents to the Infectious Diseases clinic for medical care and medication management. She is newly diagnosed with HIV and CHC coinfection by her primary care physician. F.X. is treatment naive for both infections. She reports having condomless sex with multiple partners in the past few months and admits to nonadherence to TDF/emtricitabine (Truvada®) for pre-exposure prophylaxis. Her laboratory results are the following:

Hct/Hgb: 38/15.1	HIV-1/2 Ag/Ab: positive
Platelets: 200 × 10^9/L	HIV viral load: 68,000 copies/mL (5.2 logs)
Albumin: 4.0 g/dL	Absolute $CD4^+$: 358 cells/mm^3
ALT: 66 units/L	CD4%: 18%
AST: 54 units/L	FibroSure®: 0.50 (F2)
Anti-HCV: positive	APRI: 0.68
HCV RNA level: 22,510,000 IU/mL	FIB-4: 1.16
HCV genotype: 4	Elastography: results pending
Anti-HBs: positive	Anti-HAV: positive

HBsAg: negative
Anti-HBc: negative
BUN/SCr: 22/1.0 mg/dL (eGFR 115 mL/minute/1.73 m^2)

What is the treatment approach for managing F.X.'s HIV/CHC coinfection?

F.X. is immunized against HBV based on her serum anti-HBs, negative HBsAg, and negative anti-HBc levels. She is also immunized against HAV because she is positive for the antibodies.

As previously mentioned, coinfection of HIV with CHC accelerates the progression of hepatic fibrosis and could result in a more aggressive course of liver disease. Therefore, we should manage F.X.'s HIV infection first before initiating DAA therapy for her CHC infection. The Infectious Diseases team will initiate F.X. on bitegravir/TAF/emtricitabine (Biktarvy®) today as part of the rapid-start HIV treatment approach because they do not have her baseline HIV resistance result (genotype and phenotype) and HLA-B*5701 allele result (specific for abacavir). Medication education and adherence counseling are provided to F.X. She is scheduled for follow-up laboratory blood tests in 1 month.

Case 80-16, Question 2: F.X. returns to the Infectious Diseases clinic 6 weeks after starting her antiretroviral therapy for a follow-up routine visit. She reports tolerating the antiretroviral therapy well and admits to complete medication adherence. Her 1-month follow-up laboratory blood test results shows:

HIV viral load <20 copies/mL (undetectable)
Absolute $CD4^+$: 468 cells/mm^3
CD4%: 20%
ALT: 54 units/L
AST: 40 units/L
Elastography results: normal
Child–Pugh score: class A
CBC: WNL
Comprehensive metabolic panel: WNL
BUN/SCr: 20/0.9 mg/dL (eGFR 110 mL/minute/1.73 m^2)

Could F.X. be started on a DAA therapy for her CHC infection?

Because F.X.'s HIV is suppressed with the current antiretroviral therapy, she could begin therapy for her CHC infection. Moreover, her good medication adherence will help ensure her successful response to DAA therapy. There are multiple clinical trials that demonstrate high SVR rates in patients with HIV/CHC coinfection and taking DAA therapies. In these trials, the participants did not have cirrhosis, and most had CD4 counts above 200 cells/mm^3.[258–260] Similarly, there are observational cohort studies that report HIV/CHC

coinfected persons with advanced liver disease and lower CD4 cell counts also have SVR rates comparable to those with CHC monoinfection.[261–263] There are five key clinical trials that involve DAA therapy for patients with HIV/CHC coinfection: ION-4 (ledipasvir/sofosbuvir × 12 weeks for genotypes 1 or 4; SVR12 = 96%), C-EDGE CO-INFECTION (elbasvir/grazoprevir × 12 weeks for genotypes 1, 4, and 6; SVR12 = 96%), ASTRAL-5 (sofosbuvir/velpatasvir × 12 weeks for genotypes 1–4; SVR12 = 95%), EXPEDITION-2 (glecaprevir/pibrentasvir × 12 weeks for genotypes 1–4; SVR12 = 98%), NIAID ERADICATE (ledipasvir/sofosbuvir × 12 weeks for genotype 1; SVR12 = 98%).[258,259,264–266]

Case 80-16, Question 3: The Infectious Diseases team decides to initiate F.X. on DAA therapy. Which DAA therapy would be effective and appropriate for her?

F.X. has genotype 4 HCV infection, which is not a prevalent genotype in the United States but is more common in other countries such as Egypt, the Middle East, and parts of Africa. Approximately 75% of persons infected with HCV in the United States have genotype 1 (subtypes 1a or 1b). Based on the excellent potency of the DAAs, F.X. would most benefit from receiving the pangenotypic combination therapies, such as glecaprevir/pibrentasvir (Mavyret®) and sofosbuvir/velpatasvir (Epclusa®). Both are approved to treat HIV/CHC coinfection. F.X.'s Child–Pugh score and elastography result show that she does not have moderate-to-severe fibrosis. Therefore, she is eligible for glecaprevir/pibrentasvir (Mavyret®) three tablets PO daily with food for 8 weeks' duration. If sofosbuvir/velpatasvir (Epclusa®) is selected, then the regimen is dosed as one tablet PO daily with or without food for 12 weeks. In addition, F.X. could also benefit from taking elbasvir/grazoprevir (Zepatier®) one tablet PO daily for 12 weeks. Baseline RAS testing is not necessary before starting Zepatier® because F.X. has genotype 4 HCV infection. It is recommended only for patients with genotype 1a

HCV infection. The final treatment decision will depend on the type of insurance coverage that F.X. has.

Case 80-16, Question 4: Which DAA regimens are not preferred for F.X.?

The third pangenotypic DAA combination therapy, sofosbuvir/velptasvir/voxilaprevir (Vosevi®), would not be considered for F.X. because she is treatment naive. It is reserved for treatment-experienced persons with HCV infection who have failed previous DAA therapies. Ledipasvir/sofosbuvir (Harvoni®) is not approved for HIV/CHC coinfected persons with an HCV RNA level >6 million IU/mL. F.X. has an HCV RNA level of 22,510,000 IU/mL.

Case 80-16, Question 5: What counseling points should be provided to F.X. when she takes either Mavyret® or Epclusa®?

F.X. should take the DAA therapy as prescribed, either Mavyret® three tablets PO daily with food for 8 weeks, or Epclusa® one tablet PO daily with or without food for 12 weeks. She may experience fatigue, nausea, and headache during the treatment period, especially in the first month. F.X. should drink plenty of water and reduce her normal physical activities to manage the fatigue. She can take OTC ibuprofen or naproxen to alleviate the headache symptoms. For nausea, she could take Epclusa® with food, or take it with a light snack or nongreasy food. F.X. should avoid taking acetaminophen (>2 g/day) and iron supplements because they may damage her liver. She should be scheduled for follow-up quantitative HCV RNA levels at the end of her DAA therapy to determine treatment response. Subsequently, F.X. should be scheduled for the critical HCV RNA level 3 months after she completes the DAA therapy. If her HCV RNA level is negative or undetectable (<15 IU/mL) 3 months after treatment completion, then F.X. has achieved SVR12 or virologic cure.

HEPATITIS D VIRUS

Virology and Epidemiology

Hepatitis D (or "Delta") virus is a small, single-stranded circular RNA virus (36 nm) (see Table 80-1).[267–269] HDV is considered an incomplete virus that requires the presence of HBV to be pathogenic in humans.[270,271] Between 62 and 72 million persons are infected with HDV globally, particularly in the Mediterranean Basin, the Middle East, Asia, West and Central Africa, Colombia, Venezuela, and the South Pacific.[267–269,272] Vaccination for HBV significantly reduces the incidence of HDV. However, immigration from endemic areas, increased injection drug use, sexual practices, and body modification procedures have resulted in an increase in HDV prevalence in some regions. In the United States, an estimated 7500 HDV cases occur annually.[273,274] The prevalence of HDV is greatest among persons with percutaneous exposure (eg, PWID) and those with hemophilia (20%–53% and 48%–80%, respectively) and may be affected by additional factors such as the duration of infection.[273,274] The modes of transmission of HDV are similar to those reported for HBV infection. Therefore, HDV clearly represents a potential infectious hazard to patients susceptible to HBV and those who are CHB carriers. Generally, two major patterns of infection occur with HBV: coinfection and superinfection. Because infection by HDV requires the presence of active HBV, preventing HBV infection will prevent HDV infection in a susceptible patient.[274,275]

Pathogenesis

Although its prevalence is considered less common compared to other types of viral hepatitis, HDV is described as the most severe and rapidly progressive form of chronic viral hepatitis. Progression to cirrhosis occurs in 10% to 15% of patients within 2 years and in 70% to 80% within 5 to 10 years.[275,276] Limited data suggest that HDV

antigen and HDV RNA are cytotoxic to hepatocytes; however, the immune response may also be important.[274,275] Several autoantibodies associated with chronic HDV infection may play a role in propagating liver disease and could partially explain the differences in disease severity observed in persons with CHB/HDV coinfection compared to those with only CHB monoinfection. Furthermore, coinfection with CHB and HDV results in an increased risk of HCC and mortality compared to CHB monoinfection.[277–281]

Diagnosis and Serology

Quantitative measurement of the HDV RNA level by reverse transcription polymerase chain reaction (RT-PCR) confirms the presence of HDV and is currently the most accurate diagnostic tool available.[273,274] ELISA and radioimmunoassay tests for IgM anti-HDV are also commercially available. Measurement of anti-HDV is generally not useful for early diagnosis because detectable antibody levels are usually achieved late in the clinical course of the infection. Anti-HDV IgM is detectable before anti-HDV IgG in acute HDV coinfection and is diagnostic for acute HDV infection. Anti-HDV IgM levels are not sustained in self-limiting HDV infection but may persist in patients with chronic HDV infection. Also, anti-HDV IgM does not distinguish coinfection (HBV and HDV acquired simultaneously) from superinfection (HDV acquired in CHB carriers).

Differentiation between coinfection and superinfection is made by the presence or absence of anti-HBc IgM. In acute coinfection, serum anti-HDV IgM and HDV RNA appear together with anti-HBc IgM. On the other hand, in patients with superinfection, HDV biomarkers are present in the absence of anti-HBc IgM. The presence and titer level of anti-HDV, in the case of persistent infection, also correlate with the severity of the disease. Titers of anti-HDV IgG >1:1000 indicate ongoing viral replication.[275]

HDV antigen is present in the serum in the late incubation period of acute infection and lasts into the symptomatic phase in up to 20% of patients. Because this antigen is transient, repeat testing may be

required to detect its presence. HDV RNA is an early marker of infection in patients with both acute and chronic HDV infection.[273],[274] HDV RNA is detectable in 90% of patients during the symptomatic phase of HDV infection. HDV RNA levels are not detectable after symptomatic resolution but remain elevated in chronic infection.

Natural History

Coinfection with HDV and CHB is correlated with a higher risk of severe or fulminant liver disease than with any other human viral hepatitis.[275],[282] The rate of chronic disease after coinfection with HDV is similar to that of CHB infection alone, whereas superinfection with HDV is linked to a high rate of chronicity; however, the clinical course may be variable. Approximately 15% of patients superinfected with HDV develop rapidly progressive disease with hepatic decompensation or cirrhosis within 12 months of the infection. Another 15% of patients have a benign course of illness. Most patients (70%) have a slow progression to cirrhosis depending on age, injection drug use, and level of viral replication.[275] Finally, HBsAg-positive, HBeAg-positive patients who are superinfected with HDV are more likely to develop fulminant disease compared to those who are HBsAg-positive, anti-HBe, and are superinfected and develop chronic disease.[275],[282]

Prevention

HDV replication is dependent on HBV replication; therefore, successful immunization with HBV vaccine also prevents HDV infection.[267–269] No immunoprophylactic therapies are available for patients with CHB infection who are also at risk for superinfection with HDV. Prevention of HDV superinfection is based on behavioral modification, such as the use of condoms to prevent sexual transmission and use of needle exchange programs to minimize transmission by injection drug use.

Treatment

Currently, there is no FDA-approved treatment for HDV infection in the United States. The only treatment option available for chronic HDV infection is PegIFN, which has limited efficacy and a significant adverse effect profile (eg, flu-like symptoms, myalgias, and arthralgias).[88,121,283] On the other hand, bulevirtide is the first antiviral agent studied against CHB/HDV coinfected persons in Europe. It is an entry inhibitor that binds to and inactivates the human sodium taurocholate cotransporting polypeptide (NTCP) surface receptors. The NTCP surface receptors are found on the hepatocytes and serve as essential HBV and HDV entry receptors. As a result, bulevirtide prevents HBV and HDV from entering the hepatocytes. It was approved in July 2020 by the European Medicines Agency, the European equivalent of the FDA, as the first antiviral treatment for persons with HDV infection.

Bulevirtide was approved as 2 mg to be self-administered as a once-daily SQ injection with or without nucleoside/nucleotide analogs, such as TDF.[283,284] A more recent study was performed evaluating the efficacy and safety of high-dose bulevirtide (5 mg bid or 10 mg daily) as monotherapy or in combination with TDF or PegIFN. The study findings showed that monotherapy of bulevirtide 10 mg achieved a continuous HDV RNA decline and is generally safe and well tolerated. There was also strong synergistic antiviral activity observed when bulevirtide was given with PegIFN against HDV.[284] The potential promise of bulevirtide as an effective antiviral has paved the way for the development of other future investigational drugs against chronic HDV infection, such as peginterferon λ-1a, nucleic acid polymers, and viral assembly inhibitors. The goal of treatment is to eradicate HDV along with HBV. HDV is eradicated when both serum HDV RNA and HDV antigen in the liver become persistently undetectable. Notably, it is only when HBsAg clearance has taken place that complete clinical resolution occurs. Supportive care is the general strategy used to treat HDV infection. Because the development of FHF is more frequent with

HDV infection, close monitoring for evidence of severe liver failure is warranted.

In patients with decompensated cirrhosis caused by HDV, liver transplantation is the most appropriate intervention because PegIFN may precipitate hepatic decompensation.[285–288] The presence and amount of HBV DNA before transplantation is the most significant outcome marker, often predicting the posttransplant reinfection rate. Patients who receive a liver transplant for chronic HDV infection have a lower incidence of posttransplant HBV infection than do those with HBV infection alone (67% vs 32%, respectively).[287,288] This is thought to be related to an inhibitory effect of HDV on HBV replication. Furthermore, 3-year survival is higher for patients with HDV cirrhosis than that for patients undergoing transplantation for HBV cirrhosis alone (88% vs 44%, respectively) and is similar to that of patients having liver transplantation for other indications.[122–124]

HEPATITIS E VIRUS

Virology, Epidemiology, Transmission, and Pathogenesis

HEV is an icosahedral, nonenveloped virus of the Hepeviridae family (see Table 80-1). The HEV genome is a single-stranded polyadenylated RNA and, unlike HAV, has an RNA genome that encodes for NS proteins through overlapping open reading frames.[289,290] HEV sequences have been classified into four genotypes (1, 2, 3, and 4). Genotype 1 consists of epidemic strains in developing countries; genotype 2 has been found in Mexico; genotype 3 has been associated with acute cases of hepatitis and with domestic pigs in the United States, European countries, and Japan; and genotype 4 has been found in Asian countries.[291–294]

HEV occurs in endemic areas such as Africa, Southeast and Central Asia, Mexico, and Central and South America as both

epidemic and sporadic infections.[292,293,295,296] Sporadic infections also occur in nonendemic areas and are usually associated with travel into areas of endemicity. The attack rate (the percentage of exposed patients who become infected) of HEV is low compared with HAV (1% vs 10%, respectively). In endemic areas, outbreaks usually occur between 5 and 10 years apart and are often associated with times of heavy rainfall, after floods or monsoons, or after the recession of flood waters.[294–296] The overall case fatality rate for the general endemic population is 0.5% to 4%, whereas for reasons unknown, pregnant patients have a much greater case fatality rate of 20%.[188] In particular, the fetal complication rate is increased, especially if the infection occurs in the third trimester of pregnancy. The frequency of death in utero and immediately after birth is also greater than that seen with acute hepatitis of other causes.[188]

Transmission of HEV is via the fecal–oral route, and the most common source of transmission is ingestion of fecally contaminated water.[295,296] Poor climatic conditions in conjunction with inadequate personal hygiene and sanitation have led to epidemics of HEV infection. Additional routes of transmission include vertical and bloodborne transmission, as well as consuming raw or undercooked meat of infected animals such as boar or deer and domestic animals such as pigs.[292,293]

Interference with the production of cellular macromolecules, alteration of cellular membranes, and alteration of lysosomal permeability are some of the proposed mechanisms of hepatic injury.[291,293] In addition, immune-mediated mechanisms are believed to be responsible for lysis of virally infected hepatocytes by direct lymphocyte cytotoxicity or antibody-mediated cytotoxicity.

Diagnosis

Initial assays for detection of anti-HEV included electron microscopy to detect HEV antigen on the surface of HEV particles in the stool and serum and immunohistochemistry to detect the antigen in liver

tissue.[291,293,294] Fluorescent antibody-blocking assay is currently used to detect anti-HEV reacting to the HEV antigen in serum, but although highly specific, this assay lacks sensitivity (50%) in acute HEV infection.[291,293,294] Additional cloning and sequencing of HEV have led to the development of Western blot assays and ELISA that detect anti-HEV using recombinant expressed proteins from the structural region of the virus. RT-PCR has also been used to confirm the diagnosis of HEV by detecting HEV RNA from serum, liver, or stool.[291,293,294] Clinically, HEV is a diagnosis of exclusion.

Clinical Manifestations and Natural History

Typical HEV clinical symptoms include jaundice, dark urine, tender and enlarged liver, elevated liver enzymes, abdominal pain, nausea, vomiting, and fever. Protracted coagulopathy and cholestasis have also been reported in more severe cases, possibly related to genotype 4.[291–293] Two phases of illness exist, including a prodromal and preicteric phase. Peak serum aminotransferase levels reflect the onset of the icteric phase and generally return to baseline by 6 weeks.[291–293] Stool is often positive for HEV RNA at the onset of the icteric phase and persists for an additional 10 days beyond this period. Viral shedding may occur for up to 52 days after the onset of icterus. Detection in the serum occurs during the preicteric phase before detection of virus in the stool and becomes undetectable after the peak in aminotransferase activity. Because HEV RNA is not detectable in the serum during symptoms, diagnostic tests using HEV RNA have limited utility, and a correlation between PCR detection and infectivity has not been observed. Serologically, HEV IgM becomes detectable before the peak rise in ALT, whereas antibody titers peak with high ALT levels and subsequently decline. In most patients, HEV IgM is present for 5 to 6 months after the onset of illness. HEV IgG appears after HEV IgM and remains detectable for up to 14 years after acute infection. However, the duration of protective immunity has not been fully elucidated.[291–294] In nonfatal cases, acute HEV hepatitis is followed by complete recovery

without any chronic complications. There is protection from reinfection; however, the duration of protection is variable.

Prevention and Treatment

Currently, there are no immunoprophylactic measures for HEV disease, and effective prevention strategies are dependent on improved sanitation in endemic areas. Travelers going to endemic areas should be educated regarding the risks of drinking water, eating ice, or eating uncooked shellfish or uncooked and peeled fruits and vegetables. Drinking water should be boiled to inactivate HEV. No vaccines or postexposure prophylaxis treatments are available to prevent HEV infection.

IMMUNIZATIONS FOR PERSONS WITH VIRAL HEPATITIS

Hepatitis A Vaccines

HAV infection is generally self-limiting in healthy individuals. However, persons with CHC infection are more likely to develop severe manifestations of acute HAV infection. Therefore, they should receive the hepatitis A vaccine if they do not have immunity to HAV.[297] Hepatitis A immunization could be completed in a two-dose, single hepatitis A antigen vaccine (Havrix®, Vaqta®) or as a three-dose hepatitis A/B combination vaccine (Twinrix®).[34,36] It is not recommended to check postvaccination hepatitis A titers because of the very high response to hepatitis A vaccine.

Hepatitis B Vaccines

All persons with CHC infection should receive hepatitis B vaccine, unless they have immunity to hepatitis B or are chronically infected

with hepatitis B. There are a few vaccine options available including the three-dose series using recombinant HBV vaccines (Engerix-B®, Recombivax HB®), the two-dose hepatitis B vaccine series using the CpG 1018 adjuvant that can be completed in 1 month (Heplisav-B®), and a three-dose series hepatitis A/B combination vaccine (Twinrix®).[34,51]

Pneumococcal Vaccines

Persons ages 19 through 64 years with chronic liver disease should receive one dose of the 23-valent polysaccharide pneumococcal vaccine (PPSV23).[34] Adults ages 65 years and older, including those with liver disease, should receive one dose of pneumococcal conjugate vaccine (PCV13) and a dose of PPSV23, with the dose of PPSV23 given at least 1 year after the PCV13 and at least 5 years after any previous dose of PPSV23 they may have received.[34] Vaccine options for PCV13 and PPSV23 include Pneumovax 23® and Prevnar 13®, respectively. PCV13 and PPSV23 vaccines are typically spaced 1 year apart. ACIP does not have current recommendations for giving PCV13 specifically for chronic liver disease.

Other Adult Routine Vaccines

Adults with CHB and CHC infections should continue receiving the standard routine vaccinations, such as the annual influenza and a one-time tetanus diphtheria acellular pertussis (Tdap) or tetanus diphtheria (Td) booster every 10 years. If age 50 or older, Zoster vaccination is recommended. Depending on the comorbidities of the persons with viral hepatitis infection, there may be additional immunizations that should be considered. For example, *Haemophilus influenzae* type b (Hib), meningococcal ACWY (MenACWY), and meningococcal B (MenB) vaccines should be administered in persons with a high-risk condition such as asplenia.

SUMMARY

Viral hepatitis continues to be a significant infectious disease burden globally. To date, prevention strategies through universal vaccination are the most effective methods for minimizing the incidence of HAV, HBV, and HDV coinfected with HBV infections. Patient education about the common ways of spreading these infections may also result in behavioral modifications that could reduce the overall incidence of infection. Once HBV and HCV progress to chronic infection stage, more efficacious and better-tolerated antiviral therapies are required to treat these infections. Similarly, therapeutic modalities that reduce the progression of these infections are necessary to prevent end-stage liver disease and the development of additional complications (eg, encephalopathy, intractable ascites, coagulation disorders, and HCC). Newer therapeutic agents are becoming available as better understanding of viral replication is established, as well as appropriate models for viral hepatitis study. Furthermore, viral kinetics and genomic-based approaches could optimize responses to drug therapies, especially in CHB- and CHC-infected persons. The economic impact and quality of life of these newer antiviral therapeutics on this population and the health care system remain to be fully elucidated.

Parasitic Infections

Sheila M. Seed, Janelle I. Herren, Samar E. Nicolas, Larry Goodyer, and Caroline S. Zeind

CORE PRINCIPLES		CHAPTER CASES
MALARIA		
1	Malaria in humans is caused by protozoan parasites of the genus *Plasmodium: Plasmodium falciparum*, *P. vivax*, *P. ovale*, or *P. malariae*. Early symptoms of malaria are nonspecific, with fever present in the majority of patients; and approximately two-thirds of persons who are infected may experience symptoms such as headache, muscle aches and pains, and malaise.	**Case 81-1 (Question 1)**
2	Travelers with symptoms of malaria should seek medical evaluation as soon as possible. *P. falciparum* is the species	**Case 81-1 (Questions 1–3, 5)**

	that is most likely to cause severe malaria and has the highest mortality. Mortality is higher in those with no immunity such as travelers from nonendemic areas, whereas adults living permanently in the country and exposed to malaria do develop semi-immunity. Suspected or confirmed malaria, especially *P. falciparum*, is a medical emergency necessitating early intervention. In instances when the traveler develops a febrile illness consistent with malaria and access to medical care is not readily available, a reliable supply of malaria treatment can be self-administered presumptively as a temporary measure.	
3	Travelers to malaria-endemic areas need to understand the risk of malaria and know how to best prevent it with mosquito-avoidance measures and chemoprophylaxis (where appropriate). Pregnant females are at greater risk for malaria and its associated complications. Females who are pregnant or likely to become pregnant should be advised to avoid travel to endemic areas if possible. If travel cannot be deferred, use of an effective chemoprophylaxis regimen is essential.	**Case 81-1 (Question 4), Case 81-2 (Questions 1–3), Case 81-3 (Question 1), Tables 81-1 and 81-2**
4	Several factors must be considered when selecting a chemoprophylactic drug regimen, including drug resistance,	**Case 81-1 (Question 4), Case 81-2 (Questions 1–3), Case**

	patient-specific factors, adverse effects, precautions, and contraindications and what to do in case of a missed dose.	**81-3 (Question 1), Tables 81-1 and 81-2**
AMEBIASIS		
1	Amebiasis is caused by *Entamoeba histolytica*, and is implicated in amebic dysentery and hepatic abscesses. Diagnosis of amebic dysentery may include the following information: history of travel, stool and biopsy specimens, and ultrasound to exclude liver abscesses. Treatment for amebiasis calls for a combination of agents with both luminal-acting and extraintestinal effects. Amebic cyst passers and pregnant females must be treated to avoid invasive disease and transmission of the infection.	**Case 81-4 (Questions 1, 2), Case 81-5 (Questions 1, 2), Case 81-6 (Question 1), Case 81-7 (Question 1), Table 81-3**
GIARDIASIS		
1	The signs and symptoms of giardiasis could be insidious and vague, but patients usually present with diarrhea and bulky, foul-smelling stools along with laboratory confirmation of *Giardia lamblia*.	**Case 81-8 (Question 1)**
2	The major treatments for giardiasis are metronidazole and tinidazole or nitazoxanide.	**Case 81-8 (Question 2), Table 81-3**
ENTEROBIASIS		
1	The signs and symptoms of the infection may be subtle, but the specific	**Case 81-9 (Questions 1, 2),**

	diagnostic test for *Enterobius vermicularis* is the cellophane tape swab. Therapy for enterobiasis includes the antihelminthic agents: albendazole, pyrantel pamoate, or mebendazole. Household measures to eradicate the infection need to be addressed.	**Table 81-3**
CESTODIASIS		
1	Primarily, this includes *Taenia saginata* and *T. solium*, and symptoms of infections are nonspecific. It is critical to differentiate these two infections from other cestode infections. Praziquantel remains an effective agent for all species of cestodes. Cysticercosis, a complication caused by the larval cysts of *T. solium* that may be associated with central nervous system infection (neurocysticercosis), is serious and requires separate diagnostic testing and controversial therapy. Praziquantel, which is indicated for most cestodiasis, is well tolerated.	**Case 81-10 (Questions 1, 2), Table 81-3**
PEDICULOSIS		
1	Head and body lice are associated with dermatologic reactions, which can be treated with a number of agents: permethrin, pyrethrin, malathion, and ivermectin. Special attention needs to be focused on correct application procedures, drug resistance, and lice decontamination measures.	**Case 81-11 (Questions 1, 2), Tables 81-3 and 81-4**

SCABIES

1	Scabies produces pruritic rash and excoriations of the interdigital area of the upper and lower limbs. Treatment includes lindane, permethrin, and crotamiton. Clothes and personal items of person who is infected and their family members need to laundered >122 °F (>50 °C) to avoid reinfection.	**Case 81-12 (Question 1), Table 81-3**

INTRODUCTION

Parasitic infections affect individuals not only in developing countries but also in developed countries, contributing to an immense burden of disease globally. There are three main classes of parasites that cause disease in humans that will be reviewed in this chapter: protozoa, helminths, and ectoparasites. Of all the parasitic infections, malaria has the highest number of deaths.[1]

MALARIA

Epidemiology

According to World Health Organization (WHO) estimates, malaria was responsible for an estimated 228 million cases in 2018 with an estimated 405,000 deaths, predominately children in sub-Saharan African nations.[1] The global malaria burden continues to be disproportionately high, with ~93% of malaria cases and 94% of deaths in sub-Saharan Africa.[2] Within regions of high malaria transmission, children younger than 5 years of age are particularly susceptible, with 67% of all malaria deaths occurring in this age

group.[2] Although malaria is no longer an endemic infectious disease in the industrialized countries of North America, Europe, Australia, New Zealand, and Japan, travel to malaria-endemic regions, as well as immigration and refugee migrations into nonendemic areas, have resulted in increases in the numbers of imported cases of malaria in industrialized countries.[3],[4] Millions of U.S. travelers visit malaria-endemic areas each year, and ~2000 cases of malaria are diagnosed in the United States annually, mostly in returned travelers.[5]

Distribution of Malaria Species

Malaria in humans is caused by protozoan parasites of the genus *Plasmodium: Plasmodium falciparum*, *P. vivax*, *P. ovale*, or *P. malariae*.[6] The distribution of the four *Plasmodium* species of malaria varies worldwide. However, the vast majority of imported cases are caused by *P. falciparum* or *P. vivax*[3]; the proportion of imported cases caused by *P. falciparum* or *P. vivax* within a country reflects both the destinations that travelers select and, to a larger degree, the nature of immigrant communities.[3] In addition, *P. knowlesi*, a species normally found in monkeys, has been documented as a cause of human infections and some deaths in forest fringe areas of Southeast Asia.[6]

Life Cycle of the Malaria Parasite and Transmission

The life cycle of the malaria parasites in the human host is complex.[7] All species are transmitted by the bite of an infective female *Anopheles* mosquito that carries malaria-causing parasites and injects the asexual forms or sporozoites into the human bloodstream. Over a period of 5 to 16 days (depending on the species), the sporozoites grow, divide, and produce daughter cells, or merozoites, per liver cell. Infections caused by *P. vivax* and *P. ovale* may remain in a dormant stage for extended periods of time within the liver

(hypnozoites) and cause relapses by invading the bloodstream for months or years later. The merozoites exit the liver cells and reenter the bloodstream and begin a cycle of invading red blood cells and asexual replication, thus producing and releasing newly formed merozoites from the red blood cells. Through this process, symptoms can develop 1 week after being bitten by an infected mosquito, although in *P. falciparum* malaria, this can occur up to 3 months or occasionally longer. The characteristic malarial paroxysms of chills and fever usually coincide with the periodic release of merozoites and other pyrogens in the blood. In *P. falciparum* infections, this periodicity may not always be apparent. A subpopulation of merozoites differentiate into sexual forms of the parasite, resulting in male and female gametocytes that circulate in the bloodstream (**Fig. 81-1**). If the gametocytes in the host blood are ingested by a female *Anopheles* mosquito during a blood meal, fertilization and an asexual division occurs in the mosquito midgut, where they develop into oocysts. Each oocyst grows and divides, producing thousands of active haploid forms, called *sporozoites*; once mature, the oocyte bursts, releasing sporozoites, making their way to the mosquitos' salivary glands. Inoculation of the sporozoites into a new human host perpetuates the malaria life cycle.

Figure 81-1 *Plasmodium falciparum* gametocytes.

Although the majority of cases of malaria are transmitted by the bite of an infective female *Anopheles* mosquito, occasional transmission has occurred by blood transfusion, needle sharing, organ transplantation, or congenitally from mother to fetus.[3]

Drug Resistance

The development of drug resistance has emerged as one of greatest threats to malaria control.[1–3] Resistance to antimalarial drugs has been confirmed for two malaria species, *P. falciparum* and *P. vivax*, whereas the development of drug resistance is currently unknown for *P. malariae* or *P. ovale*. Of note, there have been two cases of chloroquine-resistant *P. malariae* reported from Indonesia, although the clinical significance remains undefined.[8]

Chloroquine-resistant *Plasmodium falciparum* (CRPf) has become widespread, and is now found throughout most malaria-endemic areas, including all of sub-Saharan Africa, South America, the Indian subcontinent, Southeast Asia, and Oceania. Presently, CRPf, is not found in Mexico, the Caribbean, Central America, Argentina, and parts of the Middle East.[8] *P. falciparum* resistance has also developed to nearly all of the other currently available antimalarial agents, such as sulfadoxine/pyrimethamine, mefloquine, halofantrine, and quinine, along with the emergence of resistance to artemisinin derivatives in parts of Southeast Asia. In some parts of the world, the impact of multidrug-resistant malaria can be extensive.

Chloroquine-resistant *P. vivax* has also emerged as a global public health concern. First identified in 1989 among Australians living in or traveling to Papua New Guinea, chloroquine-resistant *P. vivax* has now been identified also in Southeast Asia, on the Indian subcontinent, and in South America. Because these areas are also coendemic for CRPf, this has had minimal impact on chemoprophylactic recommendations because the antimalarial choice for these areas is not chloroquine.[3]

Several online resources are available to retrieve updated malaria information and country-specific risks from several sources, including

the Centers for Disease Control and Prevention (CDC) and WHO.[1,3,7]

Acute Malaria

SIGNS AND SYMPTOMS

CASE 81-1

QUESTION 1: P.T., a 26-year-old male college student, presents to the emergency department (ED) with malaise, myalgia, headache, and fever of 5 days' duration. A native of Uganda, he recently visited his parents who live in a remote area of Uganda, and he returned home to the United States 4 weeks ago. Two days before admission to the ED, he had an abrupt onset of coldness and chills, followed 1 hour later by a high fever, sweating, headache, nausea, and vomiting. The episode of chills and fever lasted about 24 hours, after which he became asymptomatic. On the afternoon of admission, he had another bout of chills that preceded a fever of 104 °F (40 °C).

When interviewed for his medical and travel history, he mentioned that he did not take malaria prophylaxis thinking that he was protected because he was born and raised in Uganda, and then as a teenager moved to the United States to live with relatives and to attend school. He also did not use mosquito-avoidance measures during his recent trip to Uganda.

Physical examination reveals a slender Black male who is acutely ill and has severe abdominal pain. Abdominal examination reveals a soft, tender spleen that is slightly enlarged. Blood pressure (BP) is 110/70 mm Hg; pulse, 120 beats/minute; respiration rate, 32 breaths/minute with crackles on pulmonary auscultation; and temperature, 104 °F (40 °C). Laboratory findings include the following:

Hemoglobin (Hgb), 11 g/dL
Hematocrit (Hct), 34%
White blood cell (WBC) count, 5300 cells/μL with 76% neutrophils (normal, 45%–65%), 23% lymphocytes (normal, 15%–35%), and 1% monocytes
Platelets, 26,000/μL
Creatinine, 1.5 mg/dL
C-reactive protein (CRP), 228.9 mg/dL
Bilirubin, 1.0 mg/dL

Urinalysis reveals trace amounts of albumin and the presence of urobilinogen. Thick and thin films of P.T.'s blood are prepared and a parasitemia of 20% is reported. A Giemsa stain of the thin film demonstrates *P. falciparum* gametocytes.

How is P.T.'s presentation consistent with *P. falciparum* malaria and what are his risk factors?

P.T. recently visited Uganda, where *P. falciparum* is endemic. The incubation period ranges between 1 week and 3 months, although it may occur later in rare cases.[9,10] Early symptoms of malaria are nonspecific, with fever presenting in most patients and is often accompanied by rigors, as in P.T.'s presentation. Approximately two-thirds of persons who are infected usually experience symptoms such as headache, muscle aches and pains, and malaise, whereas about one-third of patients experience dry cough in the absence of other respiratory symptoms, diarrhea, and other gastrointestinal (GI) symptoms.[6] P.T.'s presentation is consistent with the majority of malaria-infected travelers because ~90% of them do not become symptomatic until they return home.[11–14] Given the nonspecific symptomatology with malaria, it is important that a good travel history is obtained as part of the evaluation. P.T.'s history of travel to an endemic area, the cyclical paroxysmal episodes of chills and fever, the presence of thrombocytopenia, abdominal pain, splenomegaly, and the identification of *P. falciparum* gametocytes in P.T.'s blood confirm the diagnosis of malaria.

Because P.T. grew up in Uganda in his early years but has been living for over a decade in the United States (a nonendemic country), he is considered to be in a high-risk group known as "travelers visiting friends and relatives" or VFR travelers.[15] When he returned to Uganda, an endemic country, to visit his parents, his loss of immunity over a period of time placed him in a high-risk group for malaria. Unfortunately, P.T. neglected to take malaria chemoprophylaxis because he thought his risk was low. Health care providers should raise awareness of the importance of malaria prophylaxis as well as other prevention strategies for VFR travelers.

TREATMENT

Case 81-1, Question 2: How should *P. falciparum* malaria in P.T. be treated?

Unfortunately, P.T. has acquired *P. falciparum* malaria, the species most likely to cause severe malaria with the highest mortality rate. Thus, P.T.'s treatment is a medical emergency, requiring immediate attention because mortality correlates with diagnostic and therapeutic delay.[9] P.T. would be classified as having severe malaria with complications, which could result in organ damage, including cerebral malaria. This is a particular feature of *P. falciparum*, which, unlike the other forms causes red blood cell adhesion to blood vessel walls, causing local damage and ischemia to end organs. His clinical symptoms along with the results of 20% parasitemia support the classification of severe *P. falciparum* malaria.

Specific treatment guidelines for treatment of malaria in the United States are provided by the CDC[16] at https://www.cdc.gov/malaria/diagnosis_treatment/treatment.html, and those by the WHO[17] are available at https://apps.who.int/iris/rest/bitstreams/1411121/retrieve.

Because P.T.'s condition is critical, he should be admitted to an acute care unit and started on intravenous (IV) artesunate for at least 24 hours. According to the WHO and CDC guidelines for severe malaria, IV or intramuscular artesunate is the drug of choice for treatment of severe malaria.[18] In the United States, only the IV form of artesunate is used. Previously, quinidine was the only U.S. Food and Drug Administration (FDA)-approved IV antimalarial drug in the United States and required close cardiac monitoring.[16] Quinidine has been discontinued by the manufacturer, and will no longer be available in the United States. Therefore, as of May 2020, the FDA-approved injectable artesunate is the only treatment available. Until commercially available, it is only available through the CDC under the expanded-use investigational new drug (IND) protocol.[19] If parenteral artesunate is not available, the preferred oral therapy until artesunate can be obtained is artemether–lumefantrine (Coartem®) because of its fast onset of action.[16] For questions on the diagnosis and treatment of malaria, providers may call the CDC Malaria Hotline: 770-488-7788 or 855-856-4713(toll free), after hours 770-488-7100, or contact them via email: malaria@cdc.gov.

Once P.T. has received at least 24 hours of parenteral therapy and is able to tolerate oral therapy, he would complete 3 days of therapy with an artemisinin-based combination therapy (ACT), such as artemether–lumefantrine (Coartem®).[16] The artemisinin component is effective in rapidly clearing parasites from the blood. If an ACT is unavailable, other options are atovaquone–proguanil (Malarone®) and quinine plus doxycycline or clindamycin. If no other options are available, mefloquine is a last resort, because of the risk of neuropsychiatric adverse effects. The risk of death is greatest within the first 24 hours, requiring careful monitoring for management of complications as well as supportive care. P.T. should be monitored weekly up to 1 month after initiation of IV artesunate treatment for hemolytic anemia, a rare but delayed adverse reaction.

If P.T. presented with a case of uncomplicated malaria, he would only need to be treated with one of the abovementioned oral options.[16]

Managing other *Plasmodium* species

Case 81-1, Question 3: How would P.T.'s treatment of malaria differ if it had been a different *Plasmodium* species?

If P.T. had been infected with one of the other species of *Plasmodium* (*P. vivax*, *P. ovale*, or *P. malariae)*, treatment is dependent on whether it was acquired in a chloroquine-resistant area. Currently, there is no widespread evidence of chloroquine resistance with *P. malariae* infections; therefore, patients may be treated with chloroquine or hydroxychloroquine. *P*. *ovale* or *P. vivax* infections acquired in an area without chloroquine resistance may be treated with chloroquine or hydroxychloroquine plus primaquine or tafenoquine (Krintafel®).[16] Tafenoquine can only be used in infections treated with chloroquine and in patients age 16 years or older. For those infected with *P. vivax* or *P. ovale* acquired in an area with chloroquine resistance, they may be treated with artemether–lumefantrine or atovaquone–proguanil or quinine plus tetracycline or

doxycycline or clindamycin, or, if no other options, mefloquine plus primaquine.

Chloroquine-resistant *P. vivax* has been documented in Papua New Guinea and Indonesia, Brazil, Columbia, Ethiopia, Guatemala, Guyana, India, Myanmar, Peru, the Republic of Korea, Solomon Islands, Thailand, and Turkey.[9,17]

The use of primaquine or tafenoquine in patients with *P. ovale* and *P. vivax* is to prevent relapses from hypnozoites that remain dormant in the liver.[2] Before primaquine or tafenoquine is used in any patient, glucose-6-phosphate dehydrogenase (G6PD) deficiency must be ruled out by laboratory testing because it can cause hemolysis that can be fatal in G6PD-deficient individuals.

PREVENTION OF MALARIA

Case 81-1, Question 4: What malaria chemoprophylaxis recommendation would have been options for P.T. before his travel to visit his parents in Uganda? What guidance would you provide to P.T. regarding antimalarial options, adverse effects, counseling parameters, and mosquito-avoidance measures?

Travelers to malaria-endemic areas, such as P.T., should receive malaria prophylaxis and should follow mosquito-avoidance measures.[8] The goal of malaria prevention is to prevent malaria caused not only by *P. falciparum* but also by all species. It is important to assess an individual's level of risk, which includes the destination country, the detailed itinerary, including specific activities (eg, backpacking in the wilderness), types of accommodations, and style of travel.

Pregnancy, lactation, and other conditions, human immunodeficiency virus (HIV) disease, other immunocompromised diseases, as well as drug resistance at the destination will impact the risk assessment. Travelers should be made aware of the ABCD principles with regard to malaria protection: be made *A*ware of the risks, avoid *B*ites from mosquitoes (dusk to dawn), *C*hemoprophylaxis is needed to prevent infection, and prompt

*D*iagnosis and treatment if a fever develops after returning from malaria-endemic areas.[20]

Because P.T. is a first-generation immigrant living in a nonendemic country and was returning to Uganda, his country of origin, as a VFR traveler, he was considered at high risk for contracting malaria. Recommendations for drugs used for malaria prophylaxis are provided by the CDC[6] at https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-related-infectious-diseases/malaria. It is important to understand that other countries may have differing guidelines with regard to prophylaxis recommendations for travelers going to the same region.

Given P.T.'s travel destination to Uganda with *P. falciparum* estimates at >85%, appropriate options for malaria prophylaxis are atovaquone–proguanil, doxycycline, mefloquine, or tafenoquine. It is important that P.T. understands the differences in the agents, including proper administration, their adverse effect profile, and potential drug interactions. **Table 81-1** provides a summary of the various agents for malaria prophylaxis and highlights adverse effects, contraindications, precautions, and potential drug interactions.[5,6,8,21] The importance of beginning chemoprophylaxis before travel should be emphasized. Although medications for malaria prophylaxis may be available at the destination location, travelers are strongly discouraged from obtaining chemoprophylaxis medications while abroad because the quality of these products is not known. These products may be counterfeit or may have been manufactured using substandard manufacturing practices or may contain contaminants.[22,23]

Table 81-1

Antimalarial Drugs Used for Malaria Prophylaxis

Drug	Usage	Adverse Effects	Contraindications and Precautions	Drug Interactlons
Atovaquone–proguaml (Rxed drug combination)	Prophylaxis in all areas Begin taking daily 3 days before travel to malanous area Take daily (same time each day) while in malarlous area and for 7 days after leaving such areas. Take with food or a milky drink In the United States and European Union, a pediat nc formulation is available (quarter strength = 62 5 mg atovaquone and 25 mg proguanil) CDC sancbons atovaquone/proguanll for infants >11 pounds (&5 kg). WHO allows use in infants wdgbing >24 2 pounds (>1 I kg). Partial doses may need to be prepared by a pharmacist and dispensed in capsules	Nausea. vomiting. abdominal pain. Increased transam-Inase, seizures, and rash	Corttraindicated in severe renal impairment (creatl nine clearance <30 mL/minute) Not recommended in pregnancy or breastfeeding (use only during pregnancy if potential beneRts of therapy outweigh potemiai risk to Infam) Contraindicated in children <5 kg	Tetracycline. rifampin. and rifabutin signiflcantiy decrease atovaquone level (avoid concurrent use). May interact with antiretroviral protease mhibitors ritonavir. darunavir. atazanavir, indinavlr, and lopinavir, in addition to the non-nucleoside reverse transcriptase inhibitors nevirapine, etravirine. and efavifenz; monitor when used Metocloptamide may reduce bioavailabllity of atovaquone; avoid use of thrs agent as an antiemetic to treat vomiting ihat may occur with atovaquone at treatment doses. Avoid use with clmeiidine and fluvoxamine because of interference with proguanil s metabollsm.
Chloroquine phosphate	Prophylaxis only in areas with chloroquine-sensitive malaria Begin 1–2 weeks before travel to malarlous areas Take weekly (same day of the week) while in malarlous area and for 4 weeks after leaving such areas. Chloroquine sulfate (Nivaqulne*) Is not available in the United States and Canada. but It is available in most malaria-endemic countries in both tablet and syrup forms	May exacerbate psoriasis; pruritus In black-skinned individuals. nausea. headache. skin eruptions, reversible corneal opaciry. nail and mucous membrane discoloration. nerve deafness. photophobia. myopathy. retinopathy with daily use. blood dyscrasias, psychosis. seizures. and alopecia	Contraindications persons hypersensitive to 4-aminoquinoline compounds and In G6PD-deficlent individuals (hemolysis is rare when given at prophylactlc and therapeutic doses) Preexlsting retinopathy. diseases of the central nervous system, myasthenia gravis, disorders of the blood-producing organs, a history of epilepsy or psychosis Dosage reduction may be required. hepatic function Impairments	May increase risk of prolonged QTc interval when given with other QT prolonging agents (eg. sotalol. amlodarone. and lumefantrine); antiretroviral rilpivirine prolongs QTc. avoid combination of chloroquine with any of these agents Chloroquine inhibits CYP2D6, and when used concomitantly with substrates of this enzyme (eg. metoprolol. propranolol. fluoxetine. paroxetine. and flecamide): increase monitoring for side effects Chloroquine absorption may be reduced by antacids or kaolin. space apart by ≥ ¾ hours. Avoid concomltant use of timetidine and chloroquine because cimetidlne can Inhibit chloroqulne's metabolism; avoid concurrent use of CYP3A4 Inhibitors such as ritonavir. ketoconazole. and erythromycin because they may increase chloroquine levels Chloroquine may Increase digoxin levels, requlring careful monitonng Use with caution with calcineurin inhibitors because therr levels may be Increased by chloroquine. Chloroquine inhibits bioavailabllity of ampicillin. space apart doses by 2 hours Chloroquine may decrease the bioavailability of ciprofloxacm and methotrexate

Drug	Usage	Adverse Effects	Contraindications and Precautions	Drug Interactions
Daxycycline	Prophylaxis in all areas Begin 1–2 days before travel to malarious areas Take daily at the same time each day while In the malarious area and for a weeks after leaving such areas.	Gl upset (nausea, vomitlng, abdominal pain, and diarthea (less frequent than with other tetracycllne agents); esophageal ulceration; vaginal candidiasis, photosensltivUy, alierglc reactions, blood dyscraslas, azocemia in renal dlseases, and hepatitis	Contraindicated In children ages younger than 8 years and In pregnant females Breastfeeding. excreted Into bteast rnilk, may cause permanent discoloration of reeth, damage to toolh enamel, impairment of skeletal growth, and photosensitivity in breastfed mfants	Phenytoin, carbamazepine, and barbiturates may decrease doxycycllne's half-life Anticoagulants: may requlre reduction In anticoaguiam dose while taking daxycycline, close monitoring of prothromb In time Absorption may be impaired by concomitant ingestion of bismuth subsallcylate, preparations comainlng Iron, caicium, magnesium, or aluminum; avoid taking these preparations withIn 3 hours of taking doxycyclirte Daxycycline may Interfere with bactericidal activlty of penicillin: avoid use of both drugs together.
Hydroxy chloroquine sulfate	An alternative to chloroquine for prophylaxis only in areas with chloroquine-sensitive malaria Same frequency as chloroquine			
Mefloquine	Prophylaxis in areas with mefloqulne-sensltlve malaria Begin a2 weeks before travel to malarious areas Take weekly on the same day of the week while in the malarious area and for A weeks after leaving such areas Travelers should receive a copy of the FDA Medication Guide when receiving a prescription for mefloquine	Dizzlness, diarrhea, nausea, vivid dreams, mghtmares, irritabilIty, mood alterations, headache, insomnia, anxlety, seizures, and psychosis	Contraindicated in persons allergic to mefloquine or related compounds (qumine, qulnidine) and in persons with active depressron, a recent history of depression, generallzed anxiety disotder, psychosis, schizophrenia, other major psychiatric disorders, or seizvites Caution: in persons with psychiatric disturbances or a previous history of depression Not recommended for persons with cardiac conduction abnormalltles Use with caution or avoid in mdividuals taking antiarrhythmic or p-blockmg agents, calcium channel blockers, antihlstamines, HI-blocking agents, tricyclic amldepressants, or phenothiazines. Use in second and thlrd trimesters of pregnancy for females who cannot defer travel to high-risk areas Is sanctioned by manufacturer, CDC, and WHO. Breastfeeding small amounts secreted in breast milk; effect on breastfed infants is unknown	May interact with antimalarial drugs that alter cardiac conduction; mcreased toxicitles with lumefantrine (available in the United States in fixed combination to treat uncomplicated *Plasmodiurn falaparum* malaria): avoid or use with caution because of potentially causmg fatal prolongatlon of the QTc Intervai May lower plasma concentrations of anticonvulsam agents, such as valproic acid, carbamazepine, phenobarbital, and phenytoin: avoid concurrent use May Increase levels of caiclneurin inhibitors and mTOR inhibitors (tacrolimus, cyclosporine A, and sirolimus) Rotent CYP3AA inhibitors (eg, clarithromycin, erythromycm, ketoconazole, voriconazole, and itraconazole, ritonavir, lopinavir, darunavir, atazanavir, and cobicistat) may increase the levels of mefloquine, Increaslng the risk of QT prolongation CYP3A4 inducers (eg, efavirenz, nevlraplne, etravirine, rifampin, and rifabutm) may reduce plasma concentrations of mefloquine and concurrent use should be avoided. Boceprevir and telaprevir (drugs used to treat hepatitis C) may increase mefloquine levels

Drug	Usage	Adverse Effects	Contraindications and Precautions	Drug Interactions
Primaquine	Prophylaxis for short-duration travel to areas with princlpally *Plasmodium vivax* Used for presumptive antirelapse therapy (terminal prophylaxis) to decrease the risk of relapses of *P vivax* and *P ovale* Start therapy 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas A documented normal G6PD level shouid be obtained before starting primaquine therapy	GI upset; hemolysis in G6PD deficiency, methemoglobinemia	Contraindicated in individuals with G6PD deficiency (G6PD level shouid be obtained before starting primaquine therapy because G6PD deficiency must be ruled out by laboratory testing.) Contraindicated during pregnancy and lactation (unless the infant being breastfed has a documented normal G6PD level)	Use with caution in rnedications that cause QT prolongation.
Tafenoquine	Prophylaxis in all areas Begin 3 days before travel to malarious area. Take weekly (same day of the week) while in malarious area and for 1 week after leaving such areas. Take with food to Increase absorption. swallow whole do not break, crush, or chew tablets A documented normal G6PD level shouid be obtained before starting tafenoquine Used for presumptive anti-relapse therapy to decrease the risk of relapses of *P vivax* and *P ovale* (300 mg single dose)	Dizziness, nausea, vomiting. headache. back pain, diarrhea	Not for use in chlidren < 16 years old Contraindicated In patients with G6PD deficiency (G6PD level shouid be obtained before starting therapy-G6PD deficiency must be ruled out) Contraindicated In pregnancy and lactation (unless the Infant being treated has a documented normal G6PD level) Not recommended on those with psychiatric dlsorders, meth	Co-adminlstration with metformIn may result in increased levels of metformin and Increase risk of lactic acidosis. Monitor for adverse effects or reduce metformin dose. Co-administration of dofetilide is contraindicated may increase dofetilide concentratlons and arrhythmias Penicillamine-increased risk of hematological and renal adverse effects

Malaria prophylaxis. In: Keystone JS, Kozarsky P, Connor B, Nothdurft H, Mendelson M, Leder K, eds. *Travel Medicine*. 4th ed. Elsevier, Inc.; 2019:145–168.

P.T. should be counseled regarding mosquito-avoidance measures, not only for malaria but also for protection against *Aedes*

mosquitos (responsible for transmission of dengue, chikungunya, and the Zika viruses). Because malaria transmission occurs primarily between dusk and dawn, contact with mosquitos can be reduced by remaining in well-screened areas, using mosquito bed-nets (preferably insecticide-treated nets), using insecticide sprays, wearing clothes that cover most of the body, and treating clothing with permethrin. **Table 81-2** summarizes strategies to optimize protection against mosquitos and items that travelers can include in a travel kit for malaria prevention.[24],[25] In addition to mosquito-avoidance measures, it is important to emphasize to travelers, such as P.T., to inspect themselves and their clothing for ticks during outdoor activity and at the end of the day (see Chapter 82, Tick-Borne Diseases for further information).

Table 81-2
Mosquito Protection Measures

Protective Measures		Comments
Clothing	Wear a long-sleeved shirt, long pants, and socks. Treat clothing with permethrin 24–48 hours before travel to allow them to dry or purchase pretreated clothing.	Permethrin-treated clothing will retain repellant activity through multiple washes. Repellants used on skin can also be applied to clothing and must be reapplied after laundering. Clothing treated with other repellent products (eg, DEET) provides protection from biting arthropods, but will not last through washing and will require more frequent reapplications. Repellent still must be applied to exposed skin for maximum protection.
Insecticides	Permethrin: highly effective insecticide–acaricide and repellent	Other synthetic pyrethroids are available. Useful as an area repellent such as plug-in device/aerosol spray or burning coils
Repellents	Apply lotion, liquid, or spray	Repellents may be used with

for use on skin and clothing	repellent to exposed skin. Ensure adequate protection during times of the day when mosquitos are most active (*Anopheles* mosquitos responsible for malaria bite mainly from dusk to dawn; *Aedes* mosquitos responsible for yellow fever, Zika, Chikungunya bite more in daylight hours). Reapply repellants as protection wanes and mosquitos start to bite. The higher the percentage of active ingredient, the longer it will last. Purchase repellents before traveling.	sunscreen. General recommendation: use separate products, applying sunscreen first and then applying the repellent. Combination sunscreen and repellent products are not recommended, because sunscreen may need to be reapplied more frequently and in larger amounts than do repellents. Travelers may need to reapply sunscreen more often because limited data show a one-third decrease in the sun protection factor of sunscreens when DEET-containing insect repellents are used after a sunscreen is applied.
	DEET DEET formulations worldwide: concentrations range from 5% to 100%. For most activities, 10%–35% DEET will usually provide adequate protection. Higher percentage of active ingredient is recommended for mosquito-borne disease endemic areas.	Gold standard of insect repellents for several decades In the United States, registered for use by the general public since 1957 Can be applied to exposed skin, clothing, mesh insect nets or shelters, window screens, tents, or sleeping bags DEET should never be applied under clothing, avoid spraying on synthetic fabrics.
	Picaridin (KBR 3-23 [BayRepel®] and Picaridin outside of the United States; chemical name: 21-(2-hydroxyethylo)-1-piperidinecarboxylic acid 1-methylpropyl ester)	A reasonable alternative to DEET; concentration of ≥20% should be used in mosquito borne–disease endemic areas.
	OLE or PMD, the synthesized version of OLE	Note that EPA-registered repellent products contain the active ingredient OLE (or PMD)

		"Pure" OLE (essential oil is not formulated as a repellent) is not recommended because it has not undergone validated safety and efficacy testing and is not registered with the EPA as an insect repellent. Should use high concentrations of OLE or PMD in mosquito-borne disease endemic areas if using as an alternative to DEET
	IR3535® (chemical name: 3-[*N*-butyl-*N*-acetyl]-aminopropionic acid, ethyl ester)	Some evidence suggests it may not be reliable against *Anopheles* mosquitos.

DEET (chemical name): *N,N*-diethyl-m-toluamide or *N,N*-diethyl-3-methyl-benzamide; EPA, Environmental Protection Agency; OLE, oil of lemon eucalyptus; PMD (chemical name): para-menthane-3,8-diol.

STANDBY EMERGENCY TREATMENT

Given the risk of complications and death because of the delay initiating treatment of malaria, the concept of standby emergency treatment (SBET) was introduced in the late 1980s and then updated to provide travelers with a treatment dose of an appropriate antimalarial drug to be carried and taken in case of a febrile illness, when prompt medical attention is unavailable within 24 hours of the onset of symptoms.[26–28] The major issue with SBET is the difficulty for travelers to make a self-diagnosis of malaria based on clinical symptoms. For those situations in which the traveler does not have access to medical care and develops a febrile illness with symptoms

consistent with malaria, a supply of medications could be administered presumptively until medical evaluation is available.

Case 81-1, Question 5: Would P.T. have been a candidate for SBET because of his trip to Uganda?

In the United States, two malaria treatment regimens that could be prescribed for self-treatment are available: atovaquone–proguanil and artemether–lumefantrine. Because P.T. was traveling to a remote region in Uganda, discussing this option with a travel health provider would have been important in preparation for his trip. P.T. is a good candidate for SBET, and could have taken a reasonable supply of a full course of an approved malaria treatment regimen with him on his trip. It is important to note that the use of the same or related drugs that are taken for prophylaxis are not recommended to treat malaria. Thus, if P.T. was taking a reliable supply of atovaquone–proguanil as SBET, then atovaquone–proguanil would not be selected for malaria prophylaxis. Either mefloquine or doxycycline would be acceptable choices for malaria prophylaxis.

The introduction of rapid diagnostic tests (RDTs), which are based on the immunochromatographic detection of plasmodial proteins, has become an important component of the current global malaria control strategies, alongside ACTs for falciparum malaria across most areas of endemicity.[29] The use of RDTs is being evaluated as a tool for self-use by travelers to determine whether it will help them decide whether or not to use SBET.[26] Future directives will continue to evaluate the feasibility and utility of RDTs in providing guidance to travelers on whether to initiate SBET.

CASE 81-2

Question 1: L.P., a 32-year-old male who owns a small business in the United States, is planning to visit his seriously ill grandmother who lives in the eastern province of Maluku in Indonesia. L.P. immigrated to the United States when he was 21 years old, and he has not previously had a chance to go back to Indonesia. Given his concern for his grandmother's health, his wife, S.T., who is

26 weeks pregnant, wants to join him and also bring their 5-year-old daughter. S.T. is also from Indonesia and moved to the United States 7 years ago.

What are the malaria risks of each member of the family?

Malaria prevention strategies for both short-term and long-term travelers consist of a combination of mosquito-avoidance measures and chemoprophylaxis. It is important to assess the individual risk of each traveler, including a detailed itinerary of the specific cities, types of accommodations, and activities (eg, backpackers, adventure travelers).

Similar to the previous case of P.T. (Case 81-1), VFR travelers, such as L.P. and S.T., are at high risk because they are first-generation immigrants living in nonendemic countries who are returning to their countries of origin. They may consider themselves to be at no risk because they were raised in a malarious country (Indonesia) and consider themselves immune. They should be advised that any acquired immunity is lost quickly, and they are considered to have the same risk as nonimmune travelers. Because S.T. is pregnant, she should be advised that malaria infection in pregnant females can be more severe with increased risk for adverse pregnancy outcomes than that in nonpregnant females. In particular, falciparum malaria acquired during pregnancy has been associated with an increased risk of miscarriage and still birth, intrauterine growth retardation, as well as other complications, and maternal mortality.[7] She should be advised to avoid travel to eastern Indonesia because it is an endemic region. Their 5-year-old daughter should also follow preventive measures because infants, children, and adolescents of any age can contract malaria, and they are traveling to a malarious region.

Case 81-2, Question 2: L.P. and his wife S.T. have not finalized their decision if they will travel together to visit L.P.'s grandmother and bring their daughter. What resources are available to them to review options for malaria prevention, so that they can weigh the risks and benefits of traveling to Indonesia?

In eastern Indonesia, including Papua New Guinea, chemoprophylaxis is recommended for L.P. and his family that will protect them against CRPf infections. The CDC *Health Information for International Travel*[6] (commonly referred to as the *Yellow Book*) or the CDC Travelers Health website https://wwwnc.cdc.gov/travel serve as a useful resources for both travelers and clinicians regarding updated information on parasitic diseases and immunization requirements, based on length of stay, activities planned, and risk of disease in a particular country. In addition, the CDC Malaria Hotline mentioned previously provides malaria support. Other useful resources include the Morbidity and Mortality Weekly Reports and the WHO.

Non-falciparum prophylaxis/treatment

It is important to note that nearly all *P. falciparum* is chloroquine resistant and *P. vivax* and *P. falciparum* are the two most commonly encountered species in travelers to eastern Indonesia (refer to the section Prophylaxis for *Plasmodium falciparum*). There have been reports confirming a high prevalence of chloroquine-resistant *P. vivax* in Papua New Guinea and Indonesia.[15] Therefore, atovaquone–proguanil, doxycycline, mefloquine, or tafenoquine would be recommended as options for prophylaxis. Mefloquine is a first-line option for prophylaxis during pregnancy.[16]

With regard to treatment, there are three options for chloroquine-resistant *P. vivax* infections: atovaquone–proguanil, quinine sulfate plus doxycycline or tetracycline, or, if no other options are available, mefloquine can be considered. Mefloquine would be an appropriate choice during all trimesters of pregnancy. An alternative option for treatment of pregnant females in their second or third trimester is artemether–lumefantrine. Limited data suggest that atovaquone–proguanil can be used in pregnancy to treat malaria when other options are not suitable. In addition, infections with *P. vivax* and *P. ovale* can relapse as a result of hypnozoites that remain dormant in the liver. Therefore, a 14-day course of primaquine or a single dose (300 mg) of tafenoquine therapy is recommended with appropriate

screening for G6PD deficiency before treatment. Primaquine and tafenoquine are contraindicated during pregnancy.[16]

Prophylaxis for Plasmodium falciparum

There are several equally effective prophylactics for most regions where there is *P. falciparum*—atovaquone–proguanil, doxycycline, mefloquine, and tafenoquine. Selection of an antimalarial agent depends on individual factors, patient preference regarding the regimen, the side effect profile, and contraindications (see Table 81-1).[6]

Prophylaxis for *P. falciparum* can be achieved by taking the combination of atovaquone and proguanil administered once daily 1 to 2 days before entering malarious areas, continued for the duration of malaria exposure, and for 1 week after return. Mefloquine should be taken beginning ≥2 weeks before entering malarious areas, and continuing through 4 weeks after leaving the endemic area. A third option is doxycycline beginning 1 day before entering malarious areas, continued for the duration of the stay, and for 4 weeks after leaving the malarious area. Lastly, tafenoquine is not only highly effective for the prevention of *P. vivax* but also prevents *P. falciparum* infections. It should be taken daily 3 days before entering malarious areas, continued weekly for the duration of stay, and for 1 week after leaving the malarious area. Tafenoquine requires G6PD deficiency testing before use.

In pregnant patients, such as S.T., should she insist on traveling to CRPf areas, mefloquine is the only medication recommended for malaria prophylaxis during pregnancy. Atovaquone–proguanil is not recommended for use during pregnancy because data are still lacking to fully evaluate its safety, and tafenoquine and doxycycline are contraindicated in the United States. Given the prevalence of CRPf and chloroquine-resistant *P. vivax* in eastern Indonesia, chloroquine would not be recommended and mefloquine would be an appropriate option for S.T. who is in her second trimester.

Given the risks of acquiring malaria during pregnancy, L.P. and S.T. should reconsider their decision to travel together. With regard

to their 5-year-old daughter, mefloquine and atovaquone–proguanil are options because doxycycline is contraindicated in children age younger than 8 years, and tafenoquine is contraindicated in children age younger than 16 years. Practical advice should be emphasized, including physical barriers (eg, clothes, mosquito nets), insect repellent, and minimizing the stay in the endemic area also decrease the likelihood of transmission. Table 81-2 summarizes strategies to optimize protection against mosquitos and items that travelers can be advised to include in a traveler kit for malaria prevention. Considerations when selecting a drug for malaria prophylaxis are available by the CDC[6] at https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-related-infectious-diseases/malaria#:~:text=For%20destinations%20where%20malaria%20cases,Prophylaxis%20Information%2C%20by%20Country.

MALARIA VACCINE

Case 81-2, Question 3: Could L.P. be vaccinated as an alternative to chemoprophylaxis?

Currently, no malaria vaccine is available in the United States there have been numerous challenges in the development of a vaccine, including the technical complexity of developing a vaccine against a parasite and the lack of a traditional market.[29] As a result of successful in vitro *P. falciparum* cultivation and advances in genetic engineering and monoclonal antibody research, some progress has been made. In October 2021, WHO announced that the RTS,S/AS01 (RTS,S) malaria vaccine was recommended for broader use among children living in areas with moderate to high transmission of *P. falciparum* in sub-Saharan Africa and other regions based upon data from a pilot study conducted in Kenya, Ghana, and Malawi.[29] This vaccine may still be years from widespread use on a global scale and is dependent on whether a country decides to adopt this vaccine or not. The malaria parasite

undergoes many transformations during its development, and each stage expresses a different plasmodial genome that generates a large number of antigens. The development of a malaria vaccine relies on the identification and characterization of these antigens and the subsequent production of monoclonal antibodies. Presently, there are over a dozen vaccine candidates in clinical development that are being evaluated. A Malaria Vaccine Technology Roadmap has been designed by leading global health organizations that is focused on accelerating the development of a highly effective malaria vaccine.[30]

CASE 81-3

Question 1: G.S., a 30-year-old female, comes to the community pharmacy with a prescription for mefloquine that she obtained from a local travel medicine clinic. She explains that she will be traveling to sub-Saharan Africa for 6 weeks with a group of female friends, and she is concerned about experiencing adverse effects to mefloquine and what to do if she misses a dose while she is on her 1-month safari trip. She also wants your advice regarding malaria prevention. She currently takes an oral contraceptive and also a multivitamin daily and has no known drug allergies.

What guidance should be given to G.S. regarding mefloquine and advice on approaches to malaria prevention?

It is important to consider patient-specific factors in G.S. and drug-related factors. Given her concerns, G.S. can be advised to start early with mefloquine prophylaxis (2.5–3 weeks before her trip), which will be taken weekly on the same day.[7] This will allow her to assess her tolerability to mefloquine because the majority of adverse effects occur within the first three doses. If there are any tolerability issues that occur, this will enable her to switch to another agent.

In terms of overall malaria prevention strategies, the importance of adherence to malaria prophylaxis should be emphasized, because G.S. will begin mefloquine before her trip and will continue therapy while she is in the malarious region, and for 4 weeks after leaving the area.

Owing to the long half-life of mefloquine, should G.S. miss a prophylaxis dose by 1 to 2 days, the blood levels of the medication may still be sufficient. If 1 to 2 days late, she may take the dose as soon as possible and resume her regular weekly schedule. If she has missed her dose by more than 2 days, she needs to take a dose as soon as possible, and that day becomes her new scheduled weekly day. Prophylactic medications taken daily have a shorter half-life and are less likely to maintain sufficient blood levels. If a traveler is 1 to 2 days late, they should take the dose as soon as possible and resume the daily schedule at the new time of day.[6]

Personal protection measures should be reviewed with G.S., including habitat avoidance, the use of insect repellants, protective clothing, and bed-nets (see Table 81-2).[24],[25] For example, if G.S. selects a product containing *N,N*-diethyl-m-toluamide or *N,N*-diethyl-3-methylbenzamide (DEET), she should be counseled on using a sunscreen product separately (rather than a combination product). Sunscreen may need to be reapplied more often and in larger amounts than the insect repellent because limited data have shown a one-third decrease in the sun protection factor of sunscreens when DEET-containing insect repellents are used after a sunscreen is applied.[24]

AMEBIASIS

Prevalence and Mortality

Amebiasis is an infection caused by the intestinal protozoan parasite *Entamoeba histolytica* (**Fig. 81-2**), resulting in diarrhea or amebic dysentery. Extraintestinal infections may occur when the parasite spreads to other organs, the most common being the liver, resulting in hepatic abscesses.[31],[32] This parasitic infection is distributed globally, affecting >50 million people with >100,000 deaths annually.[33] Those most affected are people living in or traveling to

endemic areas, or recent immigrants from such areas where there are suboptimal sanitary conditions, particularly in tropical or subtropical developing countries. Symptoms may not appear until years after exposure to *E. histolytica*.[34] Transmission occurs by the fecal–oral route via direct person-to-person contact or by consumption of contaminated food and water.[35] Risk factors include poor sanitary conditions, anal sexual exposure, and household contact with a person who is infected. Other intestinal amebae are *E. dispar, E. moshkovskii*, and *E. bangladeshi*.[36] Most individuals are infected with *E. dispar* (80%) or *E. moshkovskii*, which are antigenically different strains from the pathogenic *E. histolytica* (10%). *E. dispar* does not cause symptomatic invasive disease.[37,38] Further studies are needed to determine whether *E. moshkovskii* and *E. bangladeshi* are pathogenic in humans.[39,40] Amebiasis can be asymptomatic, or it may present as colitis or dysentery. Extraintestinal lesions include abscesses in the liver, lungs, skin, and, rarely, the brain.[31,32,35–38]

Figure 81-2 *Entamoeba histolytica*.

Life Cycle

Infection occurs by ingestion of mature cysts present in fecally contaminated water or food. Excystation occurs in the lumen of the small intestines where eight trophozoites are released from one cyst and migrate to the large intestine (**Fig. 81-3**). Trophozoites multiply by binary fission. In noninvasive infections, trophozoites remain in the intestinal lumen. In invasive infections, trophozoites invade the intestinal mucosa producing ulcerations, resulting in amebic dysentery.[41] Trophozoites may enter the bloodstream traveling to the liver, and, in rare instances, to the brain, lungs, and genitals forming abscesses. Both trophozoites and cysts are passed in the feces of an infected individual. Trophozoites do not survive outside the host body; if ingested, they will be destroyed by gastric juices. The cyst form can survive days to weeks in the external environment, only killed by temperatures in excess of 131 °F (55 °C) or hyperchlorinated water.[37],[38],[42]

Figure 81-3 *Entamoeba histolytica* trophozoites.

Amebic Dysentery

DIAGNOSIS

CASE 81-4

QUESTION 1: J.D., a 45-year-old recent immigrant from Africa, presents to an urgent care clinic with a 12-day history of watery diarrhea with occasional blood, abdominal pain, and fever. On physical examination, he is a thin male with abdominal discomfort and occasional nausea. His vital signs include BP 150/90 mm Hg, heart rate 94 beats/minute, and temperature 99.68 °F (37.60 °C). He has no signs of jaundice or lymphadenopathy. Examination is remarkable for slight abdominal distension and rebound tenderness in the right lower quadrant. Liver function test results are normal. Stool samples collected reveal positive findings for occult blood. Microscopic examination of stool for ova and parasites is ordered; light microscopy result reveals trophozoites and cysts. Colonoscopy revealed flask-shaped intestinal mucosal ulcerations. The result of the tissue biopsy of the ulceration showed trophozoites. Antigenic testing of stool samples confirmed the presence of *E. histolytica*.

What clinical findings does J.D. have that support the diagnosis of amebic colitis?

Patients presenting with acute amebic colitis may present with bloody or watery diarrhea, abdominal pain, constipation, tenesmus, fever, rectal bleeding (especially in children), nausea, and anorexia.[34,43–45] On physical examination, patients may present with elevated temperature, tachycardia, and hypertension in cases of severe colitis. Intestinal amebic dysentery may be suspected in patients from endemic areas with bloody or watery diarrhea, abdominal pain, and fever. Diarrhea lasting >10 days should be evaluated for intestinal parasites.[46] Almost all patients presenting with amebic colitis will have heme-positive stools. Microscopic examination of stool samples can only identify the presence of trophozoites or cysts, but cannot differentiate between pathogenic and nonpathogenic strains of the *Entamoeba* species. Three stool samples from different days over a 10-day period need to be collected, because cysts are sporadically excreted in feces and may be missed if only one sample is tested. Serology tests detect antibodies against *E. histolytica*, but cannot determine between a current or past infection because antibodies are produced 7 to 10

days after infection and may last for years. A negative serology test result rules out *E. histolytica*.[47] There are various antigen assay detection kits commercially available, with varying specificity and sensitivity to differentiate the type of species found in the stool. J.D. is a recent immigrant from an endemic country and is presenting with symptoms consistent with amebic colitis. The stool antigen test finding confirmed J.D. has amebiasis, with the presence of *E. histolytica.*

CASE 81-4, QUESTION 2: What medications are available to treat J.D.'s symptomatic infection? What medication regimen is preferred?

Treatment is necessary if *E. histolytica* has been specifically identified to prevent disease progression and transmission to contacts.[34,45] Treatment is not necessary with *E. dispar* infections.[34,43,44] Treatment involves the elimination of both trophozoites and cysts from the intestinal lumen. There are two classes of drugs to treat J.D.'s amebiasis: tissue amebicides and intraluminal amebicides. Those presenting with mild-to-moderate intestinal symptoms or severe intestinal symptoms or extraintestinal disease should be treated with a tissue amebicide followed by a course of intraluminal amebicide therapy.[45] J.D.'s symptomatic amebic colitis needs to be treated with both a tissue amebicide and an intraluminal agent. Tissue amebicides include nitroimidazoles, nitazoxanide (Alinia®), and chloroquine. The drugs of choice with a 90% cure rate are the 5-nitroimidazoles, metronidazole (Flagyl®), and tinidazole (Tindamax®).[32,45] Nitazoxanide shows promise, but the data are limited; chloroquine is ineffective in intestinal illnesses. Metronidazole will kill the trophozoites in the intestines and the tissues, but it does not eradicate the cysts from the intestine. To eradicate colonization, therapy should be followed up with an intraluminal amebicide, such as paromomycin, diloxanide furoate (Furamide—not approved in the United States or Canada), or iodoquinol (Yodoxin®).

J.D.'s amebic colitis should be treated with metronidazole 750 mg orally or IV three times a day for 5 to 10 days.[41] Alternative treatment with tinidazole 2 g orally once daily for 3 days is often better tolerated because of its shorter duration of therapy. Common adverse effects of metronidazole are nausea, metallic taste, and abdominal discomfort. Patients should be warned of a possible disulfiram reaction with alcohol consumption during and up to 72 hours after the completion of therapy.[48] This should be followed by an intraluminal amebicide; the drug of choice is paromomycin 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days, and second-line agents include diloxanide or iodoquinol[31] (see **Table 81-3**). The most common adverse effects of paromomycin are abdominal pain/cramping, nausea, and diarrhea.

Table 81-3

Drug Therapy of Various Parasitic Infections[a]

Drug of Choice	Dosage	Adverse Effects	Warnings
Amebiasis			
Asymptomatic including cyst passers			
Luminal amebicides			
Raromomycln (drug of choice)	*Adults and children*: 25–35 mg/kg/day PO in three divided doses for 5-10 days	Nausea. vomiting. diarrhea. and cramps	Contraindicated In Gl obstructlons
lodoqutnol	*Adults*: 650 mg PO tid X 20 days *Children*: 30–40 mg/kg/day (max. 2 g/day) PO In three divided doses X 20 days	Nausea. vomiting. and headaehe	Avoid use in elderly because of optic nerve damage
Diloxamde furoate (not available in the United 5tates)	*Adults*: 500 mg PO tid X 10 days *Children*: 20 mg/kg/day In three divided doses X 10 days	Flatulence. nausea. and abdominal pain	
Symptomatic or invasive intestinal infections			
Tissue amebicides			
Metronidazole (drug of choice)	*Adults*: 750 mg PO/IV tid X 7–10 days *Children*: 35–50 mg/kg/day PO/IV in three divided doses X 7–10 days	Nausea. headaehe. metallic taste, disulfiram reaction wlth alcohol, and abdominal dlscomfort	Avoid use in first trimester of prégnancy.
Tinldazole	*Adults*: 2 g PO once daily X 3 days *Children >3 years*: 50 mg/kg (max. 2 g) once daily X 3 days	Metallic or bitter taste, anorexia. nausea. vomiting. epigastric dls-comfort. and fatigue	Contraindicated in first trimester of prégnancy and in those breastfeeding
Followed by luminal amebicide to eliminate intestinal colonization—see abovementioned for dosing.			
Amebic liver abscess			
Metronidazole (drug of choice)	*Adults*: 750 mg PO/IV tid X /–10 days *Children*: 35–50 mg/kg/day In three divided doses X 7–10 days	Nausea. headaehe. metallic taste, disulfiram reaction wlth alcohol. and paresthesia	Avoid use in first trimester of prégnancy.
Tinidazole	*Adults*: 2 g PO once daily X 5 days *Children >3 years*: 50 mg/kg (max. 2 g) once daily X 5 days	Metallic or bitter taste, anorexia. nausea. vomiting. epigastric dls-comfort, and fatigue	Contraindicated in first trimester of prégnancy and In those breastfeeding
Followed by luminal amebicide agent to eliminate intestinal colonization—see abovementioned for dosing.			
Ascariasis (Roundworm)			
Albendazole	*Adults and children*: 400 mg PO once	Nausea. vomiting. headaehe. and abnormal liver funetion tests	Avoid during prégnancy.
Mebendazole (wlthdrawn from market in the United States)	*Adults and children*: 100 mg bid PO X 3 days of 500 mg PO single dose May repeat in 3 weeks if necessary	Headaehe. diarrhea. abdominal pain. and dizziness	Avoid during prégnancy Use with caution in hepatic disease and inftammatory bowel dlseases.
Enterobiasis (Pinworm)			
Mebendazole	*Adults and children*: 100 mg PO once. repeat in 2 weeks	Diarrhea and abdominal pain	Avoid during prégnancy Use with caution in hepatic disease and Inflammatory bowel dlseases.
Pyrantel pamoate	*Adults and children*: 11 mg/kg PO once (max. 1 g). repeat in 2 weeks	Nausea. vomiting. headaehe. diz-ziness, diarrhea. and abdominal cramps	Avoid in prégnancy Use with caution in hepatic disease.
Albendazole	*Adults and children*: 400 mg PO once; repeat in 2 weeks	Nausea. vomiting. headaehe. and abnormal liver funetion tests	Avoid during prégnancy.
Filariasis			
Diethylcarba-rnazine	*Adults*: day 1.50 mg PO; day 2. 50 mg tid; day 3. 100 mg tid: days 4-14.6 mg/kg/day in three doses *Children*: day 1.25–50 mg. day 2. 25–50 mg tid. day 3. 50–100 mg tid. days 4-14.6 mg/kg/day In three doses	Severe allergic or febrile reac-tions. Gl dlsturbance, and. rarety. encephaiopathy	

Drug of Choice	Dosage	Aduerse Effects	Warnings
Albendazole	400 mg PO once daily For 10 days	Nausea. vomiting, headache, and abnormal liver funetion tests	Avoid during pregnancy
Flukes (Trematodes)"			
Praziquantel	*Adults and children*: 40 mg/kg PO In two dlvided doses 4 hours apart (*Schistosomo haematobium*, S *mansom*. and S. *Intercalatum*) 60 mg/kg PO In three divided doses 4 hours apart or two dlvided doses 6 hours apart (S *japonicum* and S *mekongi*)	Malaise. headache. dizziness. sedatlon. fever. and abdominal distress	Contraindlcated with other strong CYP inducers (rlfampin) Contramdicated in ocular cysticercosls
Giardiasis			
Metronidazole	*Adults*: 250 mg PO tid or 500 mg bid with meals X 5–7 days *Children*: 15 mg/kg/day PO tid X 5–7 days	Nausea, headache. metallic taste. and disuiflram reaction with alcohol	Avoid use in first trimester of pregnancy
Tinidazole	*Adults*: 2 g PO single dose *Children*: 50 mg/kg single dose	Metallic or bitter taste, anorexia. nausea. vomiting. epigastric discomfort, and fatigue	Contraindlcated in first trimester of pregnancy and those breastfeeding
Nitazoxanide	*Adults and children*: >12 years: 500 mg PO bid X 3 days *Children*: 7.5 rng/kg bid for 3 days in children >12 years old	Abdominal pain, diarrhea, vomiting. and headache	Has not been studied in those with hepatic or renai impairment
Raromomycin (drug of choice in first trimester Of pregnancy)	*Adults*: 500 mg PO tid for 10 days *Children*: 25 mg/kg/day in three divided doses X 5–10 days	Nausea, vomiting, diarrhea, and cramps	Contramdicated In Gl obstruetions Use with caution in renai impairment.
Albendazole	400 mg PO daily X 5 days	Nausea. vomiting. headache. and abnormal liver funetion tests	Avoid during pregnancy
Mebendazole	200 mg PO tid for 5 days	Headache, diarrhea. abdominal pain. dizziness	Avoid during pregnancy. Use with caution in hepatic disease and inflammatory bowel diseases.
Hookworm			
Mebendazole	*Adults and children*: 100 mg PO bid X 3 days *or* 500 mg PO single dose	Headache. diarrhea. abdominal pain. and dizziness	Avoid during pregnancy Use with caution in hepatic disease and Inflammatory bowel diseases.
Albendazole	400 g PO single dose	Nausea. vomiting, headache, and abnormal liver funetion tests	Avoid during pregnancy
Lice			
1% Permethrin (Nlx*)	See Table 81-4 for instruetions.	Occasional allergtc reaction. mild stinging. and erythema	Use with caution In those sensitive to ehrysanthemums. Not recommended for eyebrow or eyelashes infestations.
Ivermectin	*Adults and children*: 200 (ig/kg X 3, day 1, 2, and 10	Fever. pruntus. sore lymph nodes. headache. joint pains. and, rarely, hypotension	Use with caution in those with severe asthma
Leishmaniasis			
Sodium stiboglueonate	*Adults*: 20 mg /kg IV or IM X 20–28 days *Children*: Same as in adults	Gl. malaise. headache arthralgias. myalgias. anemia. neutropenia. and thrombocytopenia, ECG abnormalities (St- and T-wave changes)	Use with caution in those with cardlac disease Use with caution in those with real or hepatic impairment
Llposoma! amphotericin B	Immunocompetent: 3 mg/kg/day on days 1–5. 14. and 21. Repeat if needed Immunocompromlsed: 4 mg/kg/day on days 1 through 5, 10. 17.24. 31. and 38. Seek advice If lurther therapy is needed	Hypotension, chllis, headache, anemia, thrombocytopenia. fever. and elevated serum creatinine	

Drug of Choice	Dosage	Adverse Effects	Warnings
Scabies			
5% Rermethrin (Elimite® cream)	Apply toplcally to whole body. Remove cream by washing (shower or bath) after 8–14 hours.	Rash, edema, and erythema	Use with caution In those sensitive to chrysanthemums.
Alternatives for scabies			
Ivermectin	*Adults*: 200 pg/kg PO; repeat in 2 weeks	Nausea, diarrhea, dizziness, vertigo, and pruritus	Use with caution In those with severe asthma.
Lindane (Kwell*)	Apply topically once.	Not recommended in pregnant females, infants, and patients with massively excoriated skin. Second-Ilne therapy when other alternatives have failed	Not recommended by American Academy of Pediatrics Second-line only US boxed warnlng because of neurologic toxicity Banned in California, United Kingdom, Australia
Crotamiton 10% (Eurax*)	Apply topically to whole body, especlally to folds and creases. May repeat in 24 hours. Cleansing bath 48 hours after last application	Local skin irrltation	Do not apply to raw, weeping skin Not to be swallowed
Tapeworm[c,d]			
Praziquantel	*Adults and children:* 5–10 mg/kg PO single dose	Malalse, headache, dizziness, sedation, eosinophilia, and fever	Contraindicated with other strong CYP inducers (eg, rifampin) Contraindicated in ocular cysticercosis
Hydatid cysts[e]			
Albendazoie	*Adults*: 400 mg bld x 8–30 days, repeat if necessary *Children*: 15 mg/kg/day x 28 days, repeat if necessary (surgical resection may precede drug therapy)	Diarrhea, abdominal pain, rarely hepatotoxicity, and leukopenia	Avoid use during pregnancy.
Trichomoniasis			
Metronidazole	*Adults*: 2 g PO x 1 day or 250 mg PO tid x 7 days *Children*: 15 mg/kg/day PO tid x 7 days	Nausea, headache, metallic taste, dlsulfiram reaction with alcohol, and paresthesia	Avoid use in first trimester of pregnancy.

bid, twice daily; CYP, cytochrome P450; ECG, electrocardiogram; GI, gastrointestinal; IM, intramuscularly; IV, intravenously; PO, orally; tid, three times daily.

[a]Does not include drugs used in the treatment and prophylaxis of malaria. (See Table 81-1 for the drugs used for malaria prophylaxis, as well as guidelines by the Centers for Disease Control [CDC] and World Health Organization [WHO] for treatment and prophylaxis of malaria.)

[b]*Schistosoma haematobium*, *S. mansoni*, *S japonicum*, *Clonorchis sinensis*, and *Paragonimus westermani*.

[c]Off-label use for tapeworms. Dose for *Hymenolepis nana* is 25 mg/kg single dose.

[d]*Diphyllobothrium latum* alternative treatment: adults, niclosamide 2 g orally once; children, 50 mg/kg (max. 2 g) orally once.

[e]*Echinococcus granulosus* and *E. multilocularis*.

Paromomycin and metronidazole cause diarrhea, which may hinder evaluation of treatment efficacy and should therefore not be taken simultaneously.[49]

In those with a confirmed diagnosis of amebiasis, one study showed the addition of the probiotic *Saccharomyces boulardii* with metronidazole reduced the duration of bloody diarrhea and aided in the clearance of cysts when compared to metronidazole alone.[50]

J.D. must be monitored for the improvement of symptoms of diarrhea and abdominal pain. A follow-up stool sample should be examined to confirm response 1 week after completing therapy. Close contacts with J.D. should be screened for *E. histolytica* infection and receive treatment if their test result is positive. For contacts whose test result is negative, no treatment or follow-up screening is required.[51]

Amebic cyst carrier

CASE 81-5

Question 1: A.T., a 60-year-old female, presents to her primary care physician (PCP) for her annual examination after multiple trips to Southeast Asia. A.T. is currently asymptomatic, but her stool test result was positive for *E. histolytica* cysts.

Should A.T. be treated?

A.T. is an asymptomatic cyst passer. Cyst passers often do not develop invasive infections, and sometimes can clear the infection spontaneously.[32] Detection of the nonpathogenic cyst *E. dispar* does not require treatment, but all asymptomatic patients with positive test results of *E. histolytica* must be treated to reduce the transmission to others.[31,32]

Case 81-5, Question 2: What medications should be used to treat A.T.?

Intraluminal amebicides are the drugs of choice in the treatment of asymptomatic amebiasis. Paromomycin is the drug of choice, 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days with meals. Diloxanide furoate (not commercially available in the United States) or iodoquinol may also be recommended, but paromomycin has a higher efficacy rate when compared to diloxanide.[52] A.T.'s stools must be tested 1 week after completing therapy to ensure eradication of the infection.[51]

Close contacts with A.T. should be screened for *E. histolytica* infection and receive treatment if their test result is positive.[51]

Extraintestinal infections

CASE 81-6

Question 1: M.B. is a 29-year-old male presenting to the ED for worsening upper right quadrant abdominal pain, fever, and chills that started 2 days ago. Upon physical examination the patient shows signs of difficulty breathing during inspiration, with pain radiating to the shoulder and back and abdominal tenderness. Rales at the right base could be heard on examination. Laboratory results are significant for leukocytosis with neutrophilia, mild anemia, elevated alkaline phosphate, and alanine aminotransferase. Blood serology shows high antibody titers for *Entamoeba*. Computed tomography (CT) confirmed the presence of an abscess in the right lobe of the liver.

How should M.B. be managed?

Extraintestinal infections occur in <1% of patients with *E. histolytica*, of which liver abscesses are the most common. The right hepatic lobe is the most frequently affected area because of the portal circulatory system of the colon.[44] M.B.'s clinical presentation and laboratory findings are consistent with a hepatic abscess. Diarrhea is reported in ~50% of those with hepatic invasion.[44] The drug of choice for amebic liver abscess is metronidazole for 5 to 10 days followed with a luminal agent such as paromomycin.[34] Aspiration or drainage of the abscess is not recommended unless there is a failure to respond to therapy after 4 to 5 days, evidence of

a secondary infection, or impending rupture into the pericardium. After the completion of therapy, M.B. should be monitored for regression of the abscess with ultrasounds, and lesions may take up to 12 months to resolve. Complications of hepatic abscesses may include perforation of the abdominal cavity, septic shock, or superinfections. Infections outside of the intestines or liver are extremely rare, and dissemination of the amebae to the brain, lung, or skin is almost always associated with amebic liver abscess.[46,53]

Treatment During Pregnancy

CASE 81-7

Question 1: N.L., a 25-year-old female refugee from Sudan, presents to the clinic with an 8-day history of watery stools with blood streaks, abdominal cramping, and a fever. She is currently 11 weeks pregnant and has received no prenatal care before her arrival in the United States 4 weeks ago. Physical examination reveals a temperature of 100.4 °F (38 °C), HR 82 bpm, and BP 140/85 mm Hg. An examination of fresh stools is positive for occult blood and trophozoites. Stool antigen test confirmed the presence of *E. histolytica.* Bacteria culture results are negative for *Campylobacter*, *salmonellosis*, and *shigellosis*. Ultrasound imaging and CT findings are negative for the presence of liver abscesses. A diagnosis of intestinal amebiasis is made.

How would you manage N.L.'s infection? What are your concerns regarding her current condition?

N.L. needs to be treated for her intestinal amebiasis. The treatment of choice is metronidazole, but she is in her first trimester of pregnancy. Nitroimidazoles such as metronidazole and tinidazole should be avoided during the first trimester of pregnancy. Metronidazole readily crosses the placenta, and its effects on the development of the fetus are unknown.[48,54] N.L. should be treated with paromomycin 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days. Paromomycin is an aminoglycoside that is poorly absorbed in the bowel with an excellent safety profile. The most common adverse effects are nausea, vomiting, and abdominal

cramps.[34],[43] N.L.'s stools must be tested 1 week after completing therapy to ensure eradication of the infection.[51]

If N.L.'s infection does not resolve or progresses to fulminant colitis or amebic liver abscess, she will safely be beyond her first trimester, and should be treated appropriately with a tissue amebicide such as metronidazole followed by a luminal agent such as paromomycin, or second-line agents such as iodoquinol or diloxanide furoate. If iodoquinol is chosen, the most common adverse effects are headache, nausea, and vomiting. Optic nerve damage is a concern with elderly patients, so iodoquinol should be avoided in this population. Reported cases of peripheral neuropathy have occurred in doses in excess of the recommended dose. The most common adverse effect with diloxanide furoate is flatulence. It is not commercially available in the United States.[36],[45]

Close contacts with N.L. should be screened for *E. histolytica* infection and receive treatment if their test result is positive. For contacts whose test result is negative, no treatment or follow-up screening is required.[51]

GIARDIASIS

Prevalence and Transmission

Giardia is a globally endemic illness caused by the protozoa *Giardia lamblia*.[55] The highest number of cases are typically seen in developing countries with inadequate sanitary conditions, untreated water, or contaminated food. Although primarily seen in Asia, Africa, and South America, it is the most frequent parasitic intestinal disease in the United States.[55],[56] Those at greatest risk live in rural areas with poor sanitation, low socioeconomic conditions, and have contact with infected individuals or travel internationally. *Giardia* is most prevalent in children and immunocompromised individuals. Presentation of illness varies between individuals from self-limiting

diarrhea to more severe symptoms of chronic diarrhea, abdominal cramps, loose pale greasy stools that float, fatigue, weight loss, and malabsorption of fat, lactose, vitamins A and B_{12}, but many present with no symptoms.[56] In high-risk areas, children may experience impaired growth because of malabsorption, even in the absence of acute diarrhea.[56,57] Severe *Giardia* infections may lead to mucosal damage in the small intestines.

Life Cycle

Infection occurs with the ingestion of cysts in contaminated water, food, or by the fecal–oral route. In the small intestine, excystation releases trophozoites (each cyst produces two trophozoites).[55] Trophozoites replicate in the lumen of the proximal small bowel, where they can be free or attached to the mucosa by a ventral sucking disk. Encystation occurs as the parasites transit toward the colon and are excreted in the feces. The cysts are hardy, surviving in environmental elements such as cold water and chlorination for weeks (**Fig. 81-4**).[56,58]

Figure 81-4 *Giardia lamblia* cyst.

Diagnosis

SIGNS AND SYMPTOMS

CASE 81-8

Question 1: K.P., a 32-year-old male who returned 2 weeks ago from a mission trip from Uganda, presents to the clinic with diarrhea, pale-colored foul-smelling greasy stools, bloating, and fatigue. He states he has been having diarrhea and flatulence for about 4 weeks. He experienced other bouts of diarrhea while on his year-long mission, but it resolved itself quickly, and his symptoms occurred typically after drinking out of one of the town's water sources. He has lost 15 pounds (6.80 kg) since the diarrhea started. He denies any blood or mucus in his stool and has no fever. Laboratory findings are the following: fecal fat content >9 g (normal 2-7 g over a 24-hour period), and complete blood count (CBC) results are anemia with thrombocytopenia and low levels of vitamin A. Three separate stool sample results were positive for *G. lamblia* cysts with antigenic tests confirming the presence of *G. lamblia*.

What clinical findings does K.P. have that support the diagnosis of giardiasis?

Patients with *Giardia* may be asymptomatic, and present with self-limiting diarrhea or with symptoms of chronic diarrhea with abdominal pain, yellowish greasy foul-smelling stools, abdominal distension, weight loss, or flatulence. Patients presenting with chronic diarrhea may suffer from dehydration and malabsorption of fat, lactose, and vitamins A and B_{12}.[56,59] The typical incubation period is 6 to 15 days after ingestion of the cysts. Infections may occur with as few as 10 cysts.[60] A giardiasis diagnosis is confirmed by signs and symptoms and the presence of cysts or trophozoites in stool samples. One stool sample may miss the presence of cysts, so multiple stool sample tests (at least three) are recommended.[58,61,62] Stool antigen test by either enzyme-linked immunosorbent assay (ELISA) or direct fluorescent antigen (DFA) are more sensitive than is traditional wet mount microscopy, and should be performed if a patient presents with symptoms consistent with giardiasis but have multiple negative results for cysts. A differential diagnosis ruling out bacterial (*Salmonella*, *Shigella*, *Campylobacter*) and viral (rotavirus, norovirus) causes should be made because the presentation may be similar. *Giardia* differs from these infections by its length of illness (7–10 days before first presentation) and evidence of weight loss.[58]

K.P.'s history of missionary work in Uganda is considered high risk. He may have consumed contaminated food or water, particularly if he drank untreated water from the town water source. His symptoms are consistent with chronic giardia: foul-smelling greasy stools, periods of diarrhea and constipation, fatigue, and bloating. Some patients will also present with flatulence, nausea or vomiting, or dehydration.[60] His laboratory results are consistent with malabsorption: fecal fat content is >9 g (normal fecal fat content is >7 g)[59]; a result >7 g is indicative of fat malabsorption resulting in steatorrhea.[61] Chronic infections may also present with anemia and low vitamin A and B_{12} levels. K.P. had *G. lamblia* cysts identified in the stool after three tests and confirmed with antigenic testing. A definitive diagnosis of *Giardia* can be made.

Case 81-8, Question 2: How should K.P. be treated?

Treatment of choice for K.P.'s giardiasis is a nitroimidazole. Tinidazole 2 g as a single oral dose with food may be preferred to metronidazole because of the single-dose treatment with similar rate of efficacy and better tolerance.[58,62] Other first-line medications include metronidazole 250 mg orally three times a day for 5 to 7 days and nitazoxanide (Alinia®) 500 mg orally twice a day with food for 3 days. Paromomycin 500 mg orally three times daily with food for 10 days is an alternative treatment and is the drug of choice during the first trimester of pregnancy.[63] Albendazole (Albenza®) 400 mg orally once daily for 5 days is well tolerated and has activity against other parasites such as hookworm.[64,65] Quinacrine[66] and Furazolidone[67] are effective options, but are not commercially available in the United States.

K.P. should be counseled to practice good hygiene, washing hands with soap and water for at least 20 seconds, to control transmission of disease.[65] Symptoms of diarrhea typically subside in 1 to 2 days and completely resolve in 10 days. Symptoms of malabsorption may take up to 4 to 8 weeks to resolve.[68,69] If treatment failure occurs, another course of therapy is necessary. Refractory strains have been treated with success with either higher doses or a longer course of therapy.[68]

ENTEROBIASIS

Prevalence

Human enterobiasis or pinworm infection is caused by the intestinal nematode *Enterobius vermicularis.* It is the most common helminthic infection worldwide. The highest rate of infection occurs in school-age children (5–10 years), institutionalized persons, and household members or caretakers of an infected individual. Transmission occurs via the fecal–oral route, with finger sucking considered a

source of infection for children. If one family member is infected, all members of the family must be treated.[70–72]

Life Cycle

Humans are the only host of *E. vermicularis*. The entire life cycle occurs in the GI system for ~4 weeks. Infected eggs are ingested from food, water, or contaminated hands that have scratched the perianal area. Person-to-person transmission may occur from contaminated clothing or bed linen. Once eggs are ingested, they hatch in the small intestine.

Copulation occurs in the ileum, where the male typically dies and passes in the stool.[73] The gravid female settles into the large intestine and cecum. The female body fills with ~11,000 eggs and makes nocturnal migrations to the rectum and anus, where oxygen is needed for the maturation of eggs. Eggs are then deposited in the area around the anus, causing severe pruritus.[74]

SIGNS AND SYMPTOMS

CASE 81-9

QUESTION 1: B.D. is a 5-year-old boy presenting to the pediatrician. B.D.'s mother states he has been scratching the perianal area for the past week. The intense itching has been keeping him up most of the night. B.D. is 45 inches (114.30 cm) tall and weighs 41.88 pounds (19 kg). A cellophane tape swab is placed over the skin of the perianal area, and evidence of *E. vermicularis* eggs are found under the microscope.

What signs and symptoms does B.D. exhibit to confirm a diagnosis of pinworm?

Many infected with pinworms are asymptomatic or present with mild symptoms; the most common symptom being nocturnal perianal pruritus and scratching because of the deposit of eggs to the perianal skin. The intense scratching may lead to secondary bacterial infections and sleep disturbances. Patients with major infestations may present with abdominal pain, anorexia, or insomnia.

Enterobiasis infections rarely cause serious disease, but it may result in dysuria or vaginal infections.[75,76]

B.D. is presenting with perianal itching, inability to sleep because of intense itching, and a positive "tape test" finding showing *E. vermicularis* eggs indicative of a pinworm infestation (**Fig. 81-5**).

Figure 81-5 Adult male *Enterobius vermicularis image*. (Source: Centers for Disease Control and Prevention. DpDx—Laboratory identification of parasitic diseases of public concern. Enterobiasis Image Gallery. Accessed October 26, 2020. https://www.cdc.gov/dpdx/enterobiasis/index.html.)

Case 81-9, Question 2: How should B.D.'s infection be managed? Should his parents be treated?

There are three options for the treatment of pinworm: albendazole (Albenza®), mebendazole (Emverm®), and pyrantel pamoate

(Reese's Pinworm Medicine®—available without a prescription). For B.D., any of the following regimens is appropriate: albendazole 400 mg orally in a single dose, mebendazole 100 mg orally in a single dose, or pyrantel pamoate 11 mg/kg (maximum 1 g) orally in a single dose. A second dose of the same agent must be repeated in 2 weeks.[76,77]

Albendazole and mebendazole are antihelminthic agents that selectively interfere with the microtubules of nematodes, leading to their death.[78] Because these medications do not kill existing eggs, a second dose should be repeated in 2 weeks to kill worms that hatch from these eggs.[75] Albendazole is considered the drug of choice in the treatment of enterobiasis with a 90% cure rate.[77,79] Both albendazole and mebendazole are well tolerated, with abdominal pain as the most common adverse effect reported.[80] Pyrantel pamoate is a depolarizing neuromuscular agent that acts by paralyzing adult worms, resulting in their expulsion in the stool. The most common adverse effects are nausea and vomiting. The liquid formulation must be shaken well before use, and may be mixed with fruit juice or milk.[81]

All members of B.D.'s family need to be treated simultaneously. Other preventative methods include proper hand hygiene, particularly after toilet use and before meals, trimming of fingernails, and frequent washing of bed linen and undergarments using hot water.[75]

CESTODIASIS

Description

Intestinal cestodes (tapeworms) are segmented worms; adults primarily live in the GI tract, but larvae can live in any organ.[82] There are several species that affect humans: *Taenia saginata* (beef tapeworm), *T. solium* (pork tapeworm), *Diphyllobothrium latum*

(broad or fish tapeworm), *T. asiatica* (Asian tapeworm), and *Hymenolepis nana* (dwarf tapeworm). Humans become infected by eating raw or undercooked meat (pork or beef) or fish (*D. latum*).[83]

A tapeworm attaches to the mucosa of the intestines by a scolex, the anterior portion of the tapeworm or the "head of the tapeworm."[82–84] The crown of the scolex is referred to as the *rostellum*; it may be armed with hooklets or unarmed (no hooklets). Proglottids or segments form behind a short neck. As each proglottid matures, they form a chain called a *strobili*, giving the tapeworm its ribbonlike appearance. The length of the strobili varies by species (*T. saginata* may have >2000 proglottids). Mature proglottids contain eggs that are indistinguishable between species. A definitive diagnosis is made by examining the scolex, proglottids, and eggs.

Tapeworms obtain nutrients through their skin directly from the host, and they do not invade the tissue mucosa or acquire blood; therefore, symptoms are often absent or mild in nature.[83] Typical symptoms involve the GI tract, and mild eosinophilia and elevated immunoglobulin (Ig)E levels may be detected. *T. solium* infections may lead to cysticercosis; neurocysticercosis, the most serious form, involves the central nervous system. It is important, therefore, to seek treatment with any tapeworm infection.

Life Cycle

Humans are the only definitive host for *T. saginata* and *T. solium*. Cattle or pigs are infected by ingesting vegetation contaminated with eggs or gravid proglottids passed in feces. Eggs hatch and invade the intestinal wall and migrate to the muscles, where they develop into cysticerci, thin-walled cysts that contain a single larval scolex.[85] Humans become infected by eating raw or undercooked meat. In humans, the cysticerci develop in the small intestines to an adult worm over a period of 2 months and can survive for years. Adult worms produce proglottids, which mature and become gravid, detach from the worm, and migrate to the anus or are passed in feces.[85]

Epidemiology

It is estimated that the prevalence of *Taenia* infections is ~170 to 200 million cases worldwide.[86],[87] *T. solium* occurs worldwide where pigs are raised, but it is most prevalent in Latin America, sub-Saharan Africa, China, India, and Southeast Asia.[82],[83] *T. saginata* can occur anywhere raw or undercooked beef is eaten. Most prevalent areas of occurrence are Eastern Europe, Russia, East Africa, Latin America, Indonesia, and China.[86] Rural and poor socioeconomic areas in developing countries with poor hygiene are at greatest risk.[87] Most cases of neurocysticercosis in industrial countries are primarily seen in refugees, immigrant populations, or travelers from endemic countries.

Cysticercosis

Cysticercosis is caused by the larval cysts of the *T. solium* tapeworm. The larvae migrate to muscle tissue, brain, subcutaneous tissue, or the eye. When the infection develops in the central nervous system, it is called *neurocysticercosis*, and is responsible for one-third of acquired epilepsy cases worldwide.[87] Signs and symptoms vary by location of the cyst. Clinical manifestations of cysts in the muscle may be absent other than a lump under the skin. Cysts that deposit in the eye may cause floaters in the eye or blurry vision.[88] Clinical manifestations of neurocysticercosis depends on how many cysts are found and the location; symptoms include seizures, focal neurologic deficits, cognitive decline, and increased intracranial pressure.[88],[89]

Diagnosis of neurocysticercosis is made by clinical presentation and radiologic imaging such as magnetic resonance imaging (MRI) or CT scans.[86] Treatment should be customized for each patient, depending on the size, location, and stage of the cysticerci. Treatment includes use of antihelminthic agents, such as praziquantel and/or albendazole. Coadministration of corticosteroids and antiepileptic drugs are used to manage seizures and the

inflammatory response because of the cysticidal activity of praziquantel therapy. Severe cases may require surgery.[89–92]

Taenia Saginata and *Taenia Solium*

SIGNS AND SYMPTOMS

CASE 81-10

QUESTION 1: P.R. is a 25-year-old missionary who lived 2 years in Ghana. She recently returned to the United States and is experiencing with perianal itching and diffuse abdominal discomfort (primarily cramping). She states she has lost about 15 pounds (6.80 kg) over the past few weeks. She reports no fever but mild constipation and nausea, and states that she sees "moving pieces of rice-looking objects" in her stool. Laboratory test results show slightly elevated eosinophil count and IgE levels and low levels of vitamin B_{12}. Three stool samples, obtained on separate days, and a cellophane tape test of the perianal area revealed the presence of *T. saginata eggs*.

Are P.R.'s symptoms consistent with *Taenia* infection? How can infections be differentiated?

Patients presenting with tapeworm infections may present with a range of symptoms. Many present with no symptoms, but if symptoms are present, then they are often mild. Symptoms include abdominal pain, cramps, flatulence, constipation, nausea, vomiting, headache, vitamin deficiency, or weight loss. More severe symptoms include appendicitis and pancreatitis. Patients may report the voiding of segments from the anus and in the feces. Some patients may present with moderate eosinophilia and elevated IgE because of the weak immunogenic activity of the adult worms.[84]

The eggs of *T. saginata* and *T. solium* are morphologically indistinguishable. A definitive diagnosis of species is made by examining the scolex (in rare cases) or, more likely, the mature gravid proglottids. Eggs and proglottids are only detected in the feces 2 to 3 months after the infection has been established. The CDC recommends three separate stool samples on different days to establish a diagnosis.[88] *T. solium* scolex is characterized by a scolex

with four large suckers and rostellum with two rows of hooks (see **Fig. 81-6**).[84,93,94] *T. saginata* has a scolex with four suckers, but no rostellum or hooks (see **Fig. 81-7**).[93] Biomolecular assays are more accurate than are microscopic stool examinations to distinguish between species, but are only available in a research laboratory setting.[94]

Figure 81-6 Scolex of *Taenia solium* image. (Source: Centers for Disease Control and Prevention. DpDx—Laboratory identification of parasitic diseases of public concern. Taeniasis Image Gallery. Accessed October 26, 2020. https://www.cdc.gov/dpdx/taeniasis/index.html.)

Figure 81-7 Scolex of *Taenia saginata* image. (Source: Centers for Disease Control and Prevention (CDC). DpDx—Laboratory identification of parasitic diseases of public concern. Taeniasis Image Gallery. Accessed October 26, 2020. https://www.cdc.gov/dpdx/taeniasis/index.html.)

Case 81-10, Question 2: How should P.R. be treated and how should treatment be evaluated?

The drug of choice for both *T. saginata* and *T. solium* infections is praziquantel (Biltricide®) 5 to 10 mg/kg as a single oral dose.[95] Other dosing is species dependent.[96] Praziquantel works by killing the adult worm but does not destroy the eggs. Typical adverse effects include malaise, headache, dizziness, abdominal discomfort, and, rarely, urticaria. P.R. should be advised to swallow the tablet whole

with water and a meal. The bitter taste of the tablet may cause P.R. to gag or vomit, so it is advisable to swallow the tablet promptly. Praziquantel cannot be chewed, but it may be halved or quartered. It is contraindicated to administer praziquantel with strong cytochrome P450 (CYP450) inducers, such as rifampin, because adequate blood levels of praziquantel may not be achieved.[95] P.R. should also be advised not to drive or operate heavy machinery on the day of treatment and the following day because of possible central nervous system effects. Praziquantel has a high cure rate (up to 98%) in *T. saginata* and *T. solium* infections.[96]

An alternative regimen is niclosamide 2 g as a single oral dose (chewed) for adults and 50 mg/kg in children. It is not available for human use in the United States. For those infections resistant to praziquantel and niclosamide, nitazoxanide has been used with success in *T. saginata* infections.[83] With any treatment, it is recommended to examine stool samples for eggs 1 and 3 months after treatment to confirm eradication of the infection.[94]

Recovery of the scolex for species identification may be necessary; purging of the bowel is recommended.[83] There are two options: Administer electrolyte–polyethylene glycol before therapy or administer castor oil or magnesium sulfate solution within 2 hours of taking the antihelminthic drug. The tapeworm and its fragments should pass within 6 to 12 hours. Patients should be instructed to collect all feces for up to 72 hours to collect all fragments.

PEDICULOSIS

Prevalence

Pediculosis (lice infections) can be caused by *Pediculus humanus capitis* (head lice) (**Fig. 81-8**), *P. humanus* (body lice), or *Pthirus pubis* (crab lice). Lice infections remain a major problem throughout the world, and infestations can be present in all socioeconomic

groups.[97] It is estimated that treatment costs for head lice may exceed $1 billion in the United States.[98]

Figure 81-8 *Pediculus humanus capitis* (head lice).

Life Cycle

Head and body lice have similar life cycles, but their habitat preferences distinguish the two varieties. The life cycle of lice has three stages: egg, nymph, and adult. After fertilization, the female lays eggs (up to 10 a day), which attaches tightly to hair or seams of clothing. The eggs (nits) (see **Fig. 81-9**) hatch in 7 to 10 days and produce nymphs, which go through three molts to become adults. Lice feed by injecting a small amount of their saliva into the host and withdraw small amounts of blood; without these meals, they will die. The lice penetrate the host skin via stylets within their head and attach themselves by a circlet of teeth on their proboscis. Crab lice are usually found in pubic hair, less frequently on facial hair, eyebrows, eyelashes, and axillary hairs.[97,99,100]

Figure 81-9 Nit or egg of lice on hair shaft.

Epidemiology

The highest incidence of head lice is seen among schoolchildren ages 3 to 12 years and in household members. It is less common in Black Americans because of different hair texture. The incidence of head lice infestation in the United States has been estimated to be between 6 and 12 million cases.[98] Body lice infest clothing by laying their eggs on the fabric. Head and crab lice infest hair by laying their eggs at the base of hair fibers. Hair and body lice are transferred between hosts by personal and clothing contact, whereas crab lice are transmitted by sexual contact.

SIGNS AND SYMPTOMS

CASE 81-11

Question 1: B.G., a 30-year-old homeless female who primarily lives in a tent city by the river, presents to a free clinic for intense itching all over her body. Upon examination, it is noted that she has a number of pustular lesions all over her body, and she complains of unbearable itchiness on her legs and abdomen.

The skin is particularly thick and discolored around her midsection. The triage nurse says she has “lice all over her body and in her hair.”

Are the symptoms in B.G. consistent with lice infection?

The most common complaint of patients with head and body lice is pruritus of the scalp, ears, neck, and other body parts. Chronic infestations may result in hyperpigmentation and thickening of the skin. These changes are often seen in the waist, groin, and upper thigh areas (“vagabond’s disease”). In severe infestations, intractable itching and scratching can result in folliculitis, hemorrhagic macules or papules, or secondary bacterial infections.[101–103] In contrast, schoolchildren who are exposed frequently to head lice may have only minor pruritus affecting the scalp, ears, and neck.[104] Lice infestation is diagnosed by identification of live nymph or adult lice on the scalp or body. The presence of live lice should be confirmed before initiating pharmacologic treatment.[102],[103]

Treatment

Case 81-11, Question 2: How should B.G. be treated for lice infection of the head, body, and genital areas?

Concurrent treatment for the pustular bacterial lesions and lice infestation should be initiated in B.G. First-line treatment of head lice in adults, children, and pregnant and lactating females is permethrin 1% (Nix®) rinse. Alternative topical pediculicides are 0.5% malathion (Ovide®) lotion and pyrethrin 0.33% plus 4% piperonyl butoxide (Rid®). Permethrin and pyrethrins are well tolerated and the least expensive of the available agents.[103] Recent studies indicate that there may be differences in efficacy among the topical agents. Resistance of head lice to 0.5% malathion lotion has been documented in the United Kingdom. The formula used in the United States contains terpineol, dipentene, and pine needle oil, possibly responsible for delaying resistance in the United States.[98],[105] Lindane

is FDA approved as a second-line therapy and should be used only when other alternatives have failed (and not for children under 110.23 pounds [50 kg]) because of neurologic toxicities (see **Table 81-4**).[98]

Table 81-4

Application of Nonprescription and Prescription Options for Head Lice[a,b]

Nonprescription Products	Application Directions
Permethrin 1% (Nix®)	Apply to damp hair that has been first shampooed with nonconditioning shampoo and towel dried. Leave on for 10 minutes and rinse off.
	Repeat in 7–10 days if live lice are seen (retreatment at 9 days is optimal). Alternative treatment schedule: 0, 7, and 13–15 days Conditioners and silicon-based products reduce residual effects of permethrin.
Pyrethrins plus piperonyl butoxide (Rid®) (available as mousse and shampoo)	Apply to dry hair and leave on for 10 minutes before rinsing off. Retreatment schedules same as permethrin. Significant resistance has been developed reducing its effectiveness.
Prescription Products	
Malathion 0.5% (Ovide®) lotion	Apply to dry hair, let air-dry, then wash off after 8–12 hours. Repeat in 7–9 days if live lice are seen. Highly flammable because of alcohol content. Instruct patients to let hair air-dry uncovered—do not use hair driers, curling irons, or flat irons while hair is wet. Resistance seen in the United Kingdom. Current U.S. formulation differs from European formulation—less resistance seen in the United States.
Benzyl alcohol 5% (Ulesfia™)	Apply a sufficient quantity to dry hair to saturate the scalp and the entire length of hair. Leave on for 10 minutes, then rinse off. Reapplication process is same as that for permethrin.
Spinosad 0.9% suspension	Apply to dry hair to saturate the scalp and work out to end of hair (may require the entire contents of bottle). Leave on for

(Natroba™)	10 minutes and rinse off. Retreat in 7 days if live lice are seen.
Ivermectin 0.5% lotion (Sklice™)	Apply to dry hair and scalp, leave on for 10 minutes, and rinse off. Only one application is needed.

There are various treatment options for head lice. Lack of adherence or failure to follow instructions may lead to resistance or failure to eradicate the louse.

[a]All topical products should be rinsed off over a sink with warm water—not in a shower or bath to limit exposure to the skin.

[b]Nits can be removed from the hair using a sturdy fine-tooth comb, especially for infants and young children.

Sources: Adapted from: Devore CD, Schutze GE, The Council on School Health and Committee on Infectious Diseases, American Academy of Pediatrics. Head lice [published correction appears in *Pediatrics*. 2015 Oct;136(4):781–782]. *Pediatrics*. 2015;135(5):e1355–e1365. doi:10.1542/peds.2015-0746; Centers for Disease Control and Prevention. Lice—Head lice—Treatment. Updated October 2019. Accessed August 12, 2020. http://www.cdc.gov/parasites/lice/head/treatment.html.

Body lice can be eliminated by bathing and laundering clothing in hot water. Because of B.G.'s severe infestation, she should also apply a topical pediculicide. Products for head lice may be used for body lice, with treatment repeated in 7 to 10 days.[97],[106] Oral medication such as ivermectin is not FDA approved, but has shown to be effective in some difficult-to-treat cases.[107] First-line treatment of pubic lice is permethrin 1% or pyrethrins plus piperonyl butoxide.[101] Alternative regimes include malathion 0.5% lotion to be rinsed off after 8 to 12 hours or ivermectin 250 µg/kg to be repeated in 14 days.[108] The pruritus in B.G. can be symptomatically treated with an antihistamine and a low-potency topical steroid.

Several "natural products" such as melaleuca plus lavender oil, coconut oil plus anise oil, tea tree oil, petrolatum shampoo, eucalyptus, mayonnaise, and Cetaphil® have been used in the management of lice.[109–111] None are FDA approved, and have not been proved to be more efficacious. Manual removal of nits by a fine-tooth comb can be a tedious task, but necessary because none of the pediculicides are 100% ovicidal. Application of vinegar-based

products 3 minutes before combing has been reported to make the process of “nit picking” easier.[98]

PETROLATUM

To remove lice from B.G.’s eyelids or eyelashes, ophthalmic-grade petrolatum ointment can be used.[101] Petrolatum is applied to the eyelashes and lid margins with cotton swabs two to four times daily for 10 days. This regimen will either suffocate the lice or physically remove them. Use of regular petrolatum may cause irritation to B.G.’s eyes.

DECONTAMINATION MEASURES

Treatment for pediculosis should include thorough decontamination to avoid reinfection. All personal articles of clothing, including bedding, should be washed and dried in temperatures >130 °F (54.44 °C).[98] Items that cannot be washed can be dry-cleaned or placed in a plastic bag for 2 weeks. Furniture and carpeting should be vacuumed; pediculicide spray is not recommended. Hairbrushes, combs, and other plastic articles can be decontaminated by soaking in hot water.[111] In institutions and schools where lice infestations are a problem, outer clothing (coats, hats, scarves) of individuals should be isolated in separate plastic bags at the beginning of the day. In addition, personal items (hats, combs) should not be shared. These measures will reduce reinfection significantly.

SCABIES

Prevalence

Scabies is a contagious skin infestation caused by the female mite, *Sarcoptes scabiei var. hominis*. Infestations occur throughout the world and across all ages and socioeconomic groups. The mite is transmitted by an infested individual through close skin contact; transmission through fomites (towels, clothing) is less likely, although

it may occur in crusted scabies.[112] Crusted scabies (Norwegian scabies), typically seen in immunocompromised individuals, is a more severe form that is highly infectious. Scabies outbreaks are often seen in institutional settings such as nursing homes and prisons.[112] Typical presentation is the presence of a pimple-like rash with intense itching that is often more severe at night. Most common sites of lesions are in the interdigital finger webs, wrists, elbows, buttock, and genitalia.[113–115] Those presenting with crusted scabies have thick crusts of skin containing a large number of mites and eggs.

Life Cycle

Adult females deposit eggs and feces (scybala) as they burrow under the skin. Once the eggs hatch, larvae are released, which eventually mature to nymphs and adult mites. The female mite can live up to 6 weeks producing two to four eggs daily. The classic presentation of skin lesions is a result of the burrowing action of the mites and hypersensitivity reactions to their excrement.

TREATMENT

CASE 81-12

Question 1: A.H., a 30-year-old licensed practical nurse (LPN) working at a long-term care facility presents to her PCP with a pruritic rash with excoriations in the interdigital webs of her hands and wrists. Several patients and nurses in the same facility have similar symptoms as well as her husband and 10-year-old daughter. Burrows were present in her finger webs with a definitive diagnosis made from a skin scraping test. Microscopic examination revealed eggs of *S. scabiei* and scybala.

How should A.H. and her family be treated? What special instructions and precautions should accompany therapy?

There are several treatment options available for scabies. The treatment of choice in patients 2 months or older is permethrin 5% cream.[114] A thin layer must be applied to the skin from the neck to

the soles of feet for 8 to 14 hours and then washed off. A second application 1 to 2 weeks later may be necessary if living mites are still observed. Permethrin is considered safe for pregnant and lactating females.[114],[115] Although not FDA approved, oral ivermectin 200 mg/kg as a single dose and repeated in 2 weeks is also considered first-line treatment and has the advantage of ease of administration and low cost. A repeat dose is needed because of its limited ovicidal activity.[114] Ivermectin is not recommended for children age younger than 5 years, <33.06 pounds (<15 kg), or for pregnant or lactating females.[114] Lindane should be considered only as a second-line therapy because of reported toxicities and should not be used for children weighing 110.23 pounds (50 kg).[115],[116] Lindane is useful if first-line therapies are not tolerated or if treatment fails. Only Lindane shampoo is currently available in the United States; the lotion is no longer available. Other alternative agents include topical ivermectin, malathion, benzyl benzoate, and topical sulfur.[115],[117]

Symptoms after exposure to scabies may take several weeks to appear for first-time infections. Sexual partners and any other persons who have prolonged contact with an infested individual should be treated.[108] All members of the family should be treated at the same time to avoid reinfestation. Pruritus may persist, even with successful treatment, for up to 2 weeks; if symptoms persist after 2 weeks, evaluate for treatment failure. Combination treatment with topical permethrin and oral ivermectin is recommended for crusted scabies.[117]

A.H. must be educated on the nonpharmacologic measures to manage scabies. All bedding and clothing must be washed in hot water (140 °F [60 °C]) and hot dried or dry-cleaned. Items that cannot be washed, such as stuffed toys, may be placed in a sealed plastic bag for 48 to 72 hours because mites cannot survive for more than 72 hours away from human skin.[108],[117] Fumigation of living areas is not recommended.

ACKNOWLEDGMENT

The authors gratefully acknowledge Lin H. Chen, MD, Division of Infectious Diseases, Mount Auburn Hospital, for her expert review of this chapter.

Tick-Borne Diseases

Caroline S. Zeind, Michelle Ceresia, and Lin H. Chen

CORE PRINCIPLES		CHAPTER CASES
LYME DISEASE		
1	Lyme disease is a multisystem spirochetal disease caused primarily by the bacterium *Borrelia burgdorferi* (and occasionally by *Borrelia mayonii*) and is transmitted to humans through the bite of infected black-legged ticks. Geography, tick species, and duration of attachment are used to guide clinical decision-making.	**Case 82-1 (Question 1)**
2	Although clinical features of Lyme disease are diverse and vary with the stage and duration of infection, the presence of an erythema migrans skin rash is universally the most common feature.	**Case 82-2 (Questions 1, 2)**

3	Most cases of localized (early) Lyme disease can be treated effectively with a few weeks of antibiotics (range of 10–21 days); however, if left untreated, infection can spread to the joints, the heart, and the nervous system.	**Case 82-2 (Questions 3, 4) Case 82-3 (Question 1) Case 82-4 (Question 1)**
RELAPSING FEVER		
1	Relapsing fever is a bacterial infection caused by certain species of *Borrelia* spirochetes. Of the two types of relapsing fever, tick-borne relapsing fever occurs in the western United States and louse-borne relapsing fever is generally restricted to refugee settings in developing parts of the world.	**Case 82-6 (Question 1)**
BORRELIA MIYAMOTOI		
1	The first human cases of *Borrelia miyamotoi* were described in the United States in 2013. *Borrelia miyamotoi* has been identified as a tick-borne organism transmitted by Ixodes ticks and is endemic in the same areas as Lyme disease, anaplasmosis, and babesiosis.	**Case 82-6 (Question 2)**
SOUTHERN TICK-ASSOCIATED RASH ILLNESS		
1	Southern tick-associated rash illness is a tick-borne disease transmitted by the lone star tick and whose etiology is unknown. Patients bitten may occasionally develop a rash similar to the rash of Lyme disease.	**Case 82-7 (Question 1)**

ANAPLASMOSIS

1	Anaplasmosis, a tick-borne disease caused by the bacterium, *Anaplasma phagocytophilum*, was first recognized as a disease of humans in the United States in the mid-1990s. If not treated appropriately, illness can be severe and potentially fatal.	**Case 82-8 (Questions 1, 2)**

BABESIOSIS

1	Babesiosis is an illness caused by parasites that infect red blood cells and are spread by certain ticks, with symptoms ranging from asymptomatic disease to potential fatality, especially in immunocompromised patients.	**Case 82-9 (Questions 1, 2)**

COLORADO TICK FEVER, TICK-BORNE ENCEPHALITIS, AND OTHER VIRALLY MEDIATED TICK-BORNE DISEASES

1	Colorado tick fever is a virally mediated tick-borne disease that can be more severe in children than in adults. Other virally medicated tick-borne diseases include those caused by Powassan, Bourbon, and Heartland viruses.	**Case 82-10 (Question 1)**

TICK PARALYSIS

1	Tick paralysis occurs worldwide, affecting humans and livestock. It can be reversed by tick removal.	**Case 82-11 (Question 1)**

PREVENTION OF TICK-BORNE ILLNESSES

1	Prevention of tick-borne diseases is always preferable to acquisition. Personal protective measures and other methodologies aid in prevention.	**Case 82-5 (Question 1)**

INTRODUCTION

Currently, the majority of emerging infectious diseases are arthropod-borne and are caused by ticks and mosquitoes.[1] Unfortunately, with few exceptions, these emerging diseases cannot be prevented by vaccinations. Ticks belong to the class Arachnida, which includes scorpions, spiders, and mites.[2] Tick-borne diseases have become increasingly problematic worldwide, transmitting pathogens that cause diseases in humans and animals.[3] As a vector of human illness worldwide, disease can be spread by ticks, either by transmission of microorganisms or by injection of tick toxin into a host. Ticks can transmit bacterial, rickettsial, protozoal, and viral disease pathogens to humans and can often harbor more than one agent simultaneously (**Table 82-1**).[3–5] In the United States, major vector ticks are expanding their geographic range to new human populations, thus increasing the public health threat posed by ticks.[3]

Tick Genus

Only two of the three families of ticks are of medical significance to humans: the soft-bodied ticks, Argasidae, and the hard-bodied ticks, Ixodidae.[2] Four of the 13 genera of Ixodidae transmit disease in the United States: *Dermacentor, Ixodes, Amblyomma,* and *Rhipicephalus.* Among the five genera of Argasidae, only *Ornithodoros* are known to transmit pathogens to humans in the United States. Most hard ticks have a 2- to 3-year life cycle, comprising the larval, nymphal, and adult stages.[2] They require one blood meal during each stage before they can mature into the next stage, and they usually remain attached to a host for hours or days. In contrast, soft ticks may have multiple nymphal stages, and both nymphal and adult forms can feast on blood multiple times, usually for only 30 minutes. However, Argasidae can survive many years without blood sustenance and are long-lived.[2] Humans are the inadvertent hosts for the life cycle of almost all ticks and tick-borne diseases.

LYME DISEASE

Lyme disease, or more accurately Lyme borreliosis, is a multisystem spirochetal disease caused by several genospecies of the spirochete

Borrelia burgdorferi sensu lato.[6],[7] Lyme disease, which is transmitted by a tick bite, was first recognized in the United States in the mid-1970s, after a mysterious outbreak of arthritis near Lyme, Connecticut.[6] However, illness consistent with late manifestations of Lyme disease was described in Europe more than a century ago. In Europe and North America, Lyme disease is now recognized as the most commonly reported vector-borne disease.[4],[7]

Etiologic Agent

Three genomic subgroups of *B. burgdorferi* worldwide account for most human infections: *Borrelia afzelii, Borrelia garinii*, and *B. burgdorferi* sensu stricto (hereafter referred to as *B. burgdorferi*).[7],[8] Although all three groups have been found in Europe, most isolates are *B. garinii* or *B. afzelii,* the North American strains identified to date belong to the *B. burgdorferi* as the cause of Lyme disease.

Tick Vectors

There are four species of Ixodes ticks that commonly bite humans. In Europe and Asia, *Ixodes ricinus* and *Ixodes persulcatus* are principal vectors, respectively. In the United States, the black-legged or deer tick, *Ixodes scapularis,* is the principal vector in areas of the Northeastern, Mid-Atlantic, and North Central states, whereas *Ixodes pacificus,* the western black-legged tick, is the principal human-biting vector in the western United States.[7],[8]

The tick acquires the *B. burgdorferi* spirochete from feeding on an infected reservoir host, such as mice, shrews, and other small mammals and various species of birds. The spirochete remains dormant in the tick's midgut until the tick feeds again. The spirochete then passes through the salivary ducts of the tick and is injected through the skin of the new host with the tick bite.[7],[9],[10] Few spirochetes are transmitted from the tick to its host during the first 24 to 36 hours of attachment. An infected nymphal tick, however,

invariably transfers spirochetes when attached to its host for more than 72 hours.

Most humans are infected through the bites of nymph ticks, which feed during the spring and summer months. Larval and nymph ticks are small, <3 mm, the size of a freckle or poppy seed. Therefore, the tick often goes unnoticed, and fewer than half of patients with Lyme disease recall having been bitten by a tick. The tick feeds on small, medium, or large mammals, lizards, or birds during its larval and nymphal (immature) stages.[2] Larval ticks are not relevant vectors for Lyme disease, however, because they are rarely infected and become so only after feeding on an infected host.[3] Adult ticks parasitize only medium or large mammals.[2] Although adult ticks can also transmit Lyme disease bacteria, because they are much larger, individuals are more likely to discover and remove them before transmission of bacteria.

Humans are inadvertent hosts of any stage of the tick. Although the tick can feed on many different animals, each tick species has preferred hosts. The complex interplay of spirochete, host, and vector in a particular area influences the risk of Lyme disease after a tick bite. Lyme disease is not transmitted directly between people, and there has not been substantive evidence of human transmission through sexual contact, semen, urine, or breast milk.[7]

Clinical Features and Diagnosis

LOCALIZED (EARLY) STAGE

Although clinical features of Lyme disease are diverse and vary with the stage and duration of infection, the presence of an erythema migrans (EM) skin rash is universally the most common feature, occurring in 60% to 90% of cases in North America.[7] The development of an EM rash at the site of the tick bite is typically the first indication of transmission and early infection in most North American patients.[9] The EM rash, which reflects the innate immune response, occurs at the site of the tick bite between 3 and 30 days (an average of 7 days) after the tick bite, typically before the onset of

fever.[4] Malaise, headache, fever, muscle and joint aches, swollen lymph nodes, and the characteristic EM skin rash are the typical early signs and symptoms.[6]

Lyme disease is diagnosed based on patient symptoms, physical findings (eg, EM rash), and the possibility of tick exposure.[5,9–11] Because it is a multisystem condition, if left untreated, infection can spread to the joints, the heart, and the nervous system. Although laboratory methods can be helpful if used correctly, serologic tests are insensitive during the first few weeks of infection. Although not necessary, in some cases, acute and convalescent titers may be helpful in some cases. During this stage, patient with an EM rash, systemic symptoms, and the possibility of tick exposure may be diagnosed clinically. Appropriate antibiotics should be initiated in early stages of Lyme disease.

DISSEMINATED STAGE

During the disseminated stage, serologic tests are usually positive and a conventional or modified two-tier testing protocol is recommended.[5,9,12] The Lyme disease presentation and testing can be complex, and the reader is referred to the Centers for Disease Control and Prevention (CDC) and other resources for further information.[5] During this stage, a variety of manifestations may occur (**Table 82-2**).

Table 82-2

Lyme Disease Clinical Manifestations

Early Localized Stage
▪ EM skin rash: red ring-like or homogenous expanding rash; classic rash not present in all cases ▪ Flu-like symptoms: malaise, headache, fever, myalgia, arthralgia ▪ Lymphadenopathy
Disseminated Stage
▪ Flu-like symptoms ▪ Lymphadenopathy ▪ Multiple secondary annular rashes

Cardiac Manifestations

- Myocarditis or pericarditis
- Conduction abnormalities, for example, atrioventricular node block

Neurologic Manifestations

- Bell palsy or other cranial neuropathy
- Meningitis
- Radiculoneuritis, myelitis
- Motor and sensory radiculoneuropathy, mononeuritis multiplex
- Subtle cognitive difficulties
- Encephalitis, encephalomyelitis, subtle encephalopathy, pseudotumor cerebri (all rare)

Rheumatologic Manifestations

- Transient, migratory arthritis, and effusion in one or multiple joints
- Migratory pain in tendons, bursae, muscle, and bones
- Baker cyst
- Arthritis may recur in same or different joints (if untreated)

Additional Manifestations

- Conjunctivitis, keratitis, uveitis
- Mild hepatitis
- Splenomegaly

EM, erythema migrans.

Source: Centers for Disease Control and Prevention. *Tickborne Diseases of the United States. A Reference Manual for Healthcare Providers*. 5th ed. 2018. Accessed January 1, 2021. https://www.cdc.gov/ticks/tickbornediseases/TickborneDiseases-P.pdf.

Treatment

The clinical manifestations of Lyme disease should govern the treatment strategy.[4,11] Patients who receive appropriate treatment in the early stages of Lyme disease usually recover rapidly and completely. Oral treatment regimens commonly used in early-stage disease include doxycycline, amoxicillin, or cefuroxime axetil (**Table 82-3**).[6] Patients with disseminated (late) Lyme disease should be evaluated for severity and may require intravenous (IV) treatment.[5,12]

Table 82-3

Treatment Recommendations for Localized (Early) Lyme Disease

Adults
Doxycycline 100 mg, twice per day orally (10–21 days)[a]
Or
Amoxicillin 500 mg three times per day orally (14–21 days)
Or
Cefuroxime axetil 500 mg twice per day orally (14–21 days)
Children
Amoxicillin 50 mg/kg per day orally, divided into three doses (maximum, 500 mg per dose) (14–21 days)
Cefuroxime axetil 30 mg/kg per day orally, divided into two doses (maximum, 500 mg per dose) (14–21 days)
(>8 years): may use Doxycycline 4 mg/kg per day orally, divided into two doses (maximum, 100 mg per dose) (10–21 days)[a]

Note: For patients intolerant of amoxicillin, doxycycline, and cefuroxime axetil, the macrolides azithromycin, clarithromycin, or erythromycin may be used, although they have a lower efficacy. Patients treated with macrolides should be closely observed to ensure resolution of clinical manifestations.

[a]Recent publications suggest the efficacy of shorter courses of treatment for early Lyme disease.

Source: Centers for Disease Control and Prevention. *Tickborne Diseases of the United States. A Reference Manual for Healthcare Providers*. 5th ed. 2018. Accessed January 1, 2021. https://www.cdc.gov/ticks/tickbornediseases/TickborneDiseases-P.pdf.

CASE 82-1

Question 1: C.T., a 57-year-old female, contacts her primary care physician (PCP) with symptoms of low-grade fever and muscle aches 2 days after camping in the western part of Massachusetts during the month of August. She explained that she was canoeing and hiking with her family in the woods, and on the last day of their trip, she noticed a small tick on her back and immediately destroyed it. A small, itchy spot that she felt at the site of the tick bite is no longer symptomatic. C.T. asks her PCP whether she needs any laboratory tests and/or preventive treatment.

Given her presentation and tick bite history, what would be appropriate steps to management?

The routine use of antibiotic prophylaxis or serologic testing is not recommended for Lyme disease prevention following a recognized tick bite.[5,12] With regard to C.T.'s situation, the use of serologic testing is not recommended because the antibody response to *B. burgdorferi* is not detectable for the first few weeks after a tick bite. Therefore, the blood tests for antibodies to *B. burgdorferi* are unlikely to be positive, because C.T.'s tick bite occurred only 2 days ago.[9,11,12]

The risk of developing Lyme disease can be affected by the rate of transmission of the spirochete from infected ticks to humans, the length of time before the tick is removed during its bite, the degree of blood engorgement of the tick (scutal index), the prevalence of spirochete infestation of ticks in an area (which varies with the tick species), and the reservoir competency of host animals in the region.[3]

Although transmission rates of Lyme disease from an infected tick bite are estimated at ~10%, the risk is reduced dramatically if the tick is removed within 24 hours of attachment. The small, itchy spot experienced by C.T. may represent a hypersensitivity reaction to the bite. These erythematous, noninfectious skin lesions develop within 48 hours of tick detachment or may occur while the tick is still attached. They are usually <5 cm in diameter; they may have an urticarial appearance and usually disappear in 1 or 2 days.[5,7]

Prophylactic antibiotic preventive therapy with a single dose of 200 mg of oral doxycycline (children age 8 years or older at 4 mg/kg to a maximum 200-mg dose) can be offered if all of the following criteria are met: (a) there are no contraindications to doxycycline use; (b) administration can start within 72 hours of tick removal; (c) the tick can be reliably identified as a nymphal or adult *I. scapularis* tick with certainty of the duration of attachment of 36 hours or more based on the degree of engorgement or time of exposure; and (d) the local rate of infection of ticks by *B. burgdorferi* in the area of exposure is

≥20% based on current ecologic evidence.[3] Routine testing of ticks themselves for tick-borne infections is not recommended.[12]

Antibiotic prophylaxis after *I. pacificus* tick bites is generally not necessary because of relatively low prevalence of *B. burgdorferi* infestation of *I. pacificus* ticks.[12] However, C.T. had exposure in a region where *B. burgdorferi* is highly prevalent among *I. scapularis* ticks. If there is uncertainty regarding the duration of tick attachment, she may be offered a dose of doxycycline prophylaxis.

ERYTHEMA MIGRANS

Signs, Symptoms, and Disease Course

CASE 82-2

Question 1: M.W., a 30-year-old female, presents with right knee pain and multiple, large, discrete skin rashes that she has had for the past 10 days. Three months ago, in July, she visited friends in Cape Cod, Massachusetts, and spent much of her time engaged in outdoor activities. Two months ago, her husband noticed a circular area of intense redness, ~9 cm (~3.54 in) wide, in her left armpit. The rash grew considerably larger during the next 2 weeks and had a red outer border. M.W. attributed the expansion of the rash to having scratched the mildly itchy area. The rash gradually disappeared. In late August, M.W. experienced fatigue, nausea, and headache for a week and thought it was "summer flu." In early September, she experienced right knee pain; ibuprofen produced some relief.

On examination, she was afebrile and had mild soft tissue swelling of the right knee. Her white blood cell (WBC) count was normal. Serum samples contained antibody titers to *B. burgdorferi* demonstrated by a sensitive ELISA (enzyme-linked immunoassay) followed by immunoglobulin M (IgM) and IgG immunoblots. A Venereal Disease Research Laboratory (VDRL) test for syphilis and a pregnancy test were negative. M.W. has no contraindications to doxycycline and is started on a 4-week course of oral doxycycline 100 mg twice daily.

What characteristics of M.W.'s skin rash are consistent with the EM of Lyme disease?

The EM of Lyme disease usually develops within 3 to 30 days (average 7 days) of a usually asymptomatic tick bite at the site of inoculation of the spirochete. The rash begins as an erythematous (red) macule or papule typically on the thigh, back, shoulder, calf, groin, popliteal fossa, flank, axilla, buttock, or upper arm.[5,7,12] In children, EM is often found on the head at the hairline, neck, arms, or legs. It expands outwardly at 2 to 3 cm/day to a diameter of 5 to 70 cm (mean, 16 cm), occasionally with some central clearing. Some cases of EM in the United States lack central clearing. The rash may be warm to the touch and is usually painless, but some patients have mild burning or itching. Up to 50% of patients with EM have multiple secondary lesions that most likely represent blood-borne spread of the spirochete to other skin sites rather than multiple tick bites.[6] If untreated, EM generally fades within several weeks; if treated, it usually resolves in several days.[5,7,12]

Low-grade fever and other nonspecific symptoms, such as malaise, headache, myalgias, or arthralgias, may accompany EM.[5,7,12] Some individuals may have no symptoms. Cough, rhinitis, sinusitis, and other respiratory symptoms do not usually occur in Lyme disease.[4] Pitfalls in the diagnosis of EM exist. Lesions are sometimes misdiagnosed. M.W.'s skin rash was large (>9 cm), red, and had a red outer border. It gradually faded over the course of a few weeks. These characteristics are consistent with a diagnosis of EM.

Serologic Testing

Case 82-2, Question 2: What might have been the rationale for the laboratory tests that were undertaken in M.W.?

Guidelines currently recommend a modified two-tier approach of enzyme immunoassays (EIAs).[9,11,12] The sensitivity of such testing in Lyme arthritis cases is 97% to 100%.[9,11] However, routine use of serology testing for patients with early EM cannot be recommended presently. Syphilis and other known biologic causes (periodontal

spirochetes) of false-positive serologic testing should be excluded. Rheumatoid factor or antinuclear antibody tests usually are negative in Lyme disease. These tests help differentiate rheumatoid arthritis or systemic lupus erythematosus from Lyme disease. The WBC count is normal or mildly elevated in Lyme disease. M.W. had a normal WBC. Pregnancy was ruled out before initiating a tetracycline. Most interesting in M.W. is the presence of secondary EM lesions representing disseminated infection.

The presence of EM as an early indicator of Lyme disease gives clinicians the best opportunity for early diagnosis and treatment.[5,12] In the United States, the expression of EM is the *only* manifestation of Lyme disease that is sufficiently distinctive to allow clinical diagnosis in the absence of confirmatory laboratory information.[5,12] Early treatment can prevent sequelae of disseminated disease.

LYME DISEASE TREATMENT

Antibiotics

Case 82-2, Question 3: Why was doxycycline selected to treat M.W.?

Borrelia burgdorferi is susceptible to amoxicillin, tetracyclines, and some second- and third-generation cephalosporins. It is only moderately sensitive to penicillin G and is resistant to first-generation cephalosporins, rifampin, co-trimoxazole, aminoglycosides, chloramphenicol, and the fluoroquinolones.[5,12]

Penicillin, tetracycline, and erythromycin historically were the drugs of choice for the treatment of Lyme disease because they can be administered orally; they are relatively inexpensive and appear to have good in vitro activity. However, this in vitro activity does not translate to in vivo efficacy. Doxycycline is an agent of choice for treatment of Lyme disease. Amoxicillin and cefuroxime axetil are also first-line options. In Europe, in contrast, penicillin still is used

with continued success. A non–doxycycline regimen is preferred in pregnant or breast-feeding females and in children younger than 8 years of age.[5,12]

Compared with the third-generation cephalosporins, the oral second-generation drug cefuroxime axetil has good in vitro activity and efficacy. But it is more expensive than oral amoxicillin or doxycycline. Of the third-generation cephalosporins, ceftriaxone has the most potent in vitro activity and a long half-life for once-daily dosing in an outpatient program. Ceftriaxone is expensive, however, and has a higher incidence of diarrhea than other β-lactams, probably owing to extensive biliary excretion.

The macrolide azithromycin is considered second-line in the treatment of Lyme disease.[9] The combination of a macrolide with lysosomotropic agents, especially hydroxychloroquine, anecdotally has been suggested to be associated with increased symptom relief probably related to combined anti-inflammatory activity rather than direct antimicrobial activity.[3] Doxycycline is well absorbed orally and is less expensive than parenteral ceftriaxone or cefotaxime. Doxycycline has a long serum half-life of 18 to 22 hours. In addition, doxycycline penetrates the cerebrospinal fluid (CSF) at concentrations of ≥10% of serum levels, even in the absence of meningeal inflammation. Although not as significant as with tetracycline, doxycycline can complex with divalent or trivalent cations in the gut, with an associated decrease in oral absorption. On the other hand, administering doxycycline with food, to minimize nausea, is recommended.[3] Compared with other tetracyclines, doxycycline has the least affinity for divalent calcium cations, and oral absorption is reduced by only 20% if given with milk. The major side effect of doxycycline is phototoxicity, which is of concern because Lyme disease usually occurs during sunny times of the year. A less recognized side effect is the risk of doxycycline-induced esophageal ulceration. Patients should be instructed to never take doxycycline or other tetracyclines near bedtime and to take the medication while standing up with at least 240 mL of clear fluid, especially with the capsule formulation. Despite less in vitro activity compared with some β-lactam antibiotics, *B. burgdorferi* is

sufficiently susceptible to doxycycline, and clinical experience with doxycycline has been very favorable. In conclusion, doxycycline was a suitable choice for M.W.

Chronic Lyme Arthritis

Case 82-2, Question 4: M.W. continues to have knee inflammation for 3 months after receiving a second course of antibiotic treatment and is now considered to have Lyme arthritis. Should antibiotic therapy be repeated for M.W.'s arthritis?

Acute Lyme arthritis occurs from the accumulation of neutrophils, cytokines, immune complexes, complement, and mononuclear cells induced by the spirochete.[13] Appropriate antimicrobial treatment of acute Lyme arthritis is usually successful, and doxycycline, amoxicillin, or cefuroxime axetil is recommended for adult patients, such as M.W., if there is no clinical evidence of neurologic disease.[12] Treatment for Lyme arthritis typically requires 28 days of therapy.[12] A minority subset of patients may have persistent Lyme arthritis.[13] It is very unlikely that this is attributable to the continued presence of *B. burgdorferi* in the joint, but rather to the patient's continued inflammatory response or autoimmunity.[13] Polymerase chain reaction (PCR) testing of synovial fluid can be considered, and if negative, symptomatic therapies may be offered rather than repeated antibiotic courses. Such patients often respond well to synovectomy, suggesting that the presence of synovitis may not be the result of persistence of the infection. Nonsteroidal anti-inflammatory agents, disease-modifying antirheumatic agents, intra-articular corticosteroid injections, or synovectomy may be offered.[3],[12] However, it should be noted that before the antibiotic treatment era for Lyme disease, even the most prolonged cases of persistent Lyme arthritis eventually improved without treatment, although sometimes lasting for months to years.[13]

Neurologic Lyme Disease

CASE 82-3

Question 1: E.S., a 60-year-old female, presents to her PCP with symptoms of early neurologic Lyme disease, including mild memory and cognitive deficits. Serum two-tier IgG seropositivity was confirmed.

Should E.S. be treated with antibiotics? If so, how long should she be treated? She has no known allergies.

Although rare, late neurologic complications of Lyme disease may present as encephalopathy, peripheral neuropathy, or encephalomyelitis.[5,12] Although the Lyme *Borrelia* species found in Europe do not strictly overlap with those species found in the United States, there are no data to support a differential response to antibiotic.[11] Based on these studies, oral doxycycline can be considered as first-line therapy for neurologic Lyme disease in Europe and for ambulatory patients with early neurologic Lyme disease in the United States. An oral antibiotic treatment regimen may suffice in cases of early neurologic disease, but parenteral regimens are appropriate for severe cases.[14] The regimens may need to be adjusted depending on the person's age, medical history, underlying health conditions, and allergies.[5] In conclusion, E.S. can be treated with doxycycline administered orally with a duration range of 14 to 21 days and should be reassessed following treatment.

Post-Lyme Disease Syndromes

CASE 82-4

Question 1: A friend who has been treated with a 4-week course of antibiotics for Lyme disease calls you to say that she has lingering symptoms and she thinks it is "chronic Lyme disease." She would like more information about it.

How should you respond?

Chronic Lyme disease is a confusing term, and most authorities agree that there may be "post-treatment Lyme disease syndrome" (PTLDS).[5] Although the exact cause is unknown, most medical experts believe that the lingering symptoms that can occur are the result of residual damage to tissues and the immune system. Clinical findings in patients may include fatigue, widespread musculoskeletal pain, cognitive difficulties, or subjective symptoms of such severity that a substantial reduction in quality of life has occurred. The subjective symptoms must include an onset within 6 months of the initial Lyme disease diagnosis and persistence for at least 6 months after completion of antimicrobial therapy. If adherence to a recommended Lyme treatment regimen is confirmed, the existence of symptomatic, chronic infection by *B. burgdorferi* is difficult to confirm. After appropriately targeted antibiotic therapy for early Lyme disease, treatment failure is exceedingly rare. The organism has not been shown to develop antibiotic resistance.[3] For these patients with chronic subjective symptoms for more than 6 months, repeated or prolonged antibiotic therapy is not useful or recommended.[5,12]

The friend should be encouraged to seek additional diagnostic workup for other diseases. Even in patients who have had verified Lyme disease, the aches and pains of daily living they experience appear to be more related to their post-treatment symptoms than to Lyme disease itself.[5]

Lyme Disease Prevention

CASE 82-5

QUESTION 1: A family living in a Lyme disease endemic area is concerned regarding their risk for contracting the disease.

How would you advise them on Lyme disease prevention and overall protection from tick-borne disease?

Although some vector-borne diseases are prevented through vector control, this has proven difficult for tick-borne diseases

because of a lack of efficacy or environmental concerns with the use of pesticides. Evaluated methods include habitat destruction by fire, chemical spraying agents such as acaricides to achieve tick eradication, culling or removal of host deer, or protection of mice from tick infestation.[14]

Currently, there are limited vaccines available for tick-borne and mosquito-borne illnesses.[15] A Lyme disease vaccine for humans is no longer available in the United States. Citing low demand, the U.S. manufacturer discontinued production in 2002. Clinical trials are currently underway for candidate *Lyme borreliosis* vaccines.[16]

The first step in prevention of Lyme disease is personal protection and tick avoidance.[17],[18] Tick repellents may be applied to the skin or clothing. One basic chemical category of insect repellant is the synthetic agents, such as *N,N*-diethyl-*m*-toluamide (DEET), picaridin (also known as icaridin in Europe), and insect repellent (IR) 3535 (ethyl butylacetylaminopropionate). The second chemical category of repellant is the plant-derived oils and synthetics, such as oil of lemon eucalyptus or PMD (para-menthane-3,8-diol), which is an extract of the leaves of lemon eucalyptus, *Corymbia citriodora*, a synthesized version of oil of lemon eucalyptus.

The use of DEET skin repellent has evolved as the standard repellant for mosquito and tick-borne diseases. In combination with a permethrin clothing, DEET appears to offer adequate protection. DEET has been tested against *Ixodid* ticks for repellence and is more effective than dibutyl phthalate, dimethyl phthalate, pyrethrum, and two combination products.[17],[18] DEET is generally safe; however, excessive DEET application has been associated with seizures in children.[18],[19] These are rare events, however, and if the products are used according to their labeling, the adverse reaction risk is low, even for children age older than 2 months.[3] Prolonged or excessive application is not recommended. It may be prudent to use the lowest effective concentration of DEET-containing repellents, such as those containing 20% to 30%. To minimize DEET toxicity, the product should be applied sparingly, inhalation or introduction into the eyes should be avoided, repellent-treated skin should be washed when coming inside, use on children's hands (that are likely to have

contact with the eyes or mouth) should be avoided, and it should be applied only to intact skin or clothing.

Picaridin was developed in Europe in the 1990s and released in the United States about 10 years ago. A couple of advantages over DEET include the lack of a chemical odor and its nonsticky or greasy feel. It is also safe to use on plastics, whereas DEET may damage certain synthetics including eyeglass frames. IR 3535, originally marketed in the United States as a skin emollient and moisturizer, was then adopted for use as an insect repellant. Plant-derived IRs, such as oil of lemon eucalyptus or PMD, have demonstrated efficacy against the tick vectors of Lyme disease (*I. scapularis*, *I. pacificus*) and Rocky Mountain spotted fever (RMSF, *Dermacentor andersoni*).[1]

A literature review between 2000 and 2012 on the efficacy of repellants against various mosquito and tick species noted that there are only limited studies conducted on tick behavior and repellant efficacy against the tick species *Ixodes.*[19],[20] The use of picaridin, IR 3535, and PMD were also reviewed as part of this study. Results of this study found that the use of IR 3535 provided the longest protection against *I. scapularis*, whereas DEET and commercial products containing picaridin or PMD demonstrated a better response than IR 3535 against *I. ricinus*.[18] In situations in which environmental exposure to disease-transmitting ticks, biting midges, sandflies, or blackflies is anticipated, topical repellants containing IR 3535, picaridin, or oil of eucalyptus (or PMD) would offer better protection than topical DEET alone.[1] (Refer to Chapter 81, Parasitic Infections, Table 81-2, Mosquito Protection Measures for additional information on insect repellants.)

Physical barriers to ticks, such as wearing protective garments—long pants and long-sleeved shirts—tucking shirts into pants and pants into boots, and wearing closed-toed shoes, prevent infection.[1] Ticks are easier to spot on light-colored clothing. Checking the body for ticks regularly is recommended; any ticks that are found should be promptly removed. Avoiding tick habitats is the best protection against tick-borne diseases. Effective postexposure antibiotic prophylaxis can be administered in Lyme disease endemic areas after a tick bite.

The geographic range of Lyme disease in North America and elsewhere continues to expand rapidly with increases in the frequency of tick-borne diseases.[3,21] Although research to improve the diagnosis and treatment of Lyme disease and other tick-borne diseases has led to advancements, there have been fewer studies and resources allocated on avoidance and prevention of exposure.[3,21] To better understand the locations where people most frequently encounter infected ticks, a systematic review and meta-analysis was conducted on spatial risk factors for tick-borne disease and tick bites in eastern North America.[21] This study examined three scales: the residential yard, the neighborhood surrounding (but not including the yard), and outside the neighborhood. There were 19 studies that met inclusion criteria from 1237 citations with one additional study that was included by a reviewer. The total study population represented 2741 cases of tick-borne illness and 1447 individuals who experienced tick bites or ticks crawling on them. Using random effects models, study investigators derived pooled odds ratio estimates. The findings of this analysis revealed significant disease risk factors at all three scales. However, analysis of variance revealed that the risk at the neighborhood scale was 57% greater than risk at the yard sale and 101% greater than the risk outside the neighborhood. The results of this study highlight the need to better characterize sources of variation in risk at the neighborhood scale. Moreover, the meta-analyses suggest that implementation of risk-reducing interventions at each scale could be effective; however, those applied at the neighborhood scale are most likely to protect human health.

RELAPSING FEVER

Relapsing fever, a bacterial infection caused by a variety of *Borrelia* species, causes episodes of fever, nausea, headache, and muscle and joint aches. Of the two types of relapsing fever, tick-borne relapsing fever (TBRF) occurs in the western United States and

louse-borne relapsing fever (LBRF) is generally restricted to refugee settings in developing parts of the world.[7]

Tick Vector

The predominant tick vector for relapsing fever is of the genus *Ornithodoros,* a soft-bodied tick. These ticks feed on wild rodents or domestic animals and, incidentally, on humans. In North America, three tick species carry the agents of endemic relapsing fever with apparent strict specificity. In fact, the names of the responsible *Borrelia* species have been adopted from the three tick species that transmit them: *Ornithodoros hermsii, Ornithodoros parkeri,* and *Ornithodoros turicata.*[22] Although the ticks themselves may serve as reservoir hosts, the *Borrelia* usually circulate among wild rodents, ticks, and possibly birds.[6] Similar to Lyme disease, greater worldwide variations of endemic cycles and vectors for TBRF may exist than in North America.

TICK GEOGRAPHY

In North America, relapsing fever is an uncommon disease largely confined to the geographic distribution of the tick species that harbor the *Borrelia.* In the United States, most cases of TBRF have occurred in 14 western states and are caused by *Borrelia hermsii*.[6] These ticks are usually found in the remote natural settings of the mountains and semiarid plains of the far west and Mexico. TBRF can develop when people visit tick- or rodent-infested cabins or summer homes. Although TBRF is spread by multiple tick species, *O. hermsii* is the tick responsible for most cases in the United States usually at altitudes of 1500 to 8000 feet. The health significance of *O. parkeri* and *O. turicata* transmits its *Borrelia* at lower altitudes in the Southwest, where they inhabit caves and the burrows of ground squirrels, prairie dogs, and burrowing owls.

SPIROCHETAL BEHAVIOR

Ticks acquire spirochetes from blood feeding on small wild rodents. If high levels of *Borrelia* are present in the animal's blood, large numbers of spirochetes will be ingested by the tick and reside in the tick's midgut. During the next few days, the spirochetes invade the midgut wall, traverse the hemolymph system, and within a few weeks infect the salivary glands as well as other tick tissues and organs. Females may develop infected ovaries and transmit *Borrelia* to offspring in some *Ornithodoros* species, but this is rare in *O. hermsii.*[21] Having reached the tick's salivary glands, the spirochetes are poised to invade the tick's next host.

TICK BEHAVIOR

In contrast to the hard-bodied ticks, these soft ticks feed rapidly, often detaching after 30 to 90 minutes.[21],[22] They feed at night while people are sleeping, and their bite is usually painless. Therefore, most people are unaware that they have been bitten.[18]

Disease Characterization

The hallmark of endemic relapsing fever is an abrupt onset of high fever (often >102.2 °F [39 °C]) after an incubation period of 4 to 18 days.[21] The patient may experience shaking chills, severe headache, abdominal pain, myalgias, arthralgias, nausea, vomiting, and malaise. A few cases of acute respiratory distress syndrome have recently been recognized.[21] The fever usually breaks in 3 days (range, 12 hours to 17 days) in untreated patients.[21] After a variable afebrile period of 3 to 36 days (usually 7 days), cyclic periods of fever and constitutional symptoms reappear. Each febrile attack progressively diminishes in severity. Three to five relapses typically occur in untreated patients.

Routine laboratory testing is of little value. Moderate anemia and an increased erythrocyte sedimentation rate (ESR) are common. Leukocyte counts may be normal, yet moderate-to-severe thrombocytopenia is commonly observed but is considered nonspecific. The diagnosis of relapsing fever is made by direct

observation of the spirochete on a peripheral blood smear while the patient is febrile.[21] Observation of the smear is enhanced with Wright or Giemsa staining. Few diagnostic laboratories perform antibody serology tests; however, these tests lack specificity.[21] Skin biopsy of a rash to identify the spirochete is unreliable. Direct culture of the spirochete from the blood into a special culture medium is the most specific diagnostic tool, but this is a slow technique confined to research laboratories.

TREATMENT

These *Borrelia* have not demonstrated antibiotic resistance. Successful treatment regimens usually include a 7- to 10-day course of antibiotics.[6],[21] Tetracycline (500 mg every 6 hours for 10 days) is the preferred regimen. Erythromycin is an effective alternative at a dose of 500 mg (or 12.5 mg/kg) every 6 hours for 10 days. For individuals experiencing central nervous system (CNS) involvement, ceftriaxone (2 g/day for 10–14 days) is preferred. Hospitalization and administration of IV antibiotics may be required in patients who are severely ill.

CASE 82-6

QUESTION 1: T.J. is a 49-year-old male who visits his PCP with a sudden onset of high fever, severe headache, malaise, nausea, vomiting, and myalgias. He returned a week ago, at the end of August, from a stay in a rustic cabin on the north rim of the Grand Canyon. His PCP orders a manual complete blood count (CBC) and chemistry panel and asks the laboratory to observe a blood smear with Giemsa staining. T.J.'s recent visit and outdoor activities are consistent with areas with prior outbreaks where relapsing fever has been documented. After confirming the presence of *Borrelia* in the blood smear, the PCP prescribes a 10-day course of tetracycline. Two hours after the first dose, T.J.'s wife calls the physician's office with concerns that the disease is worsening. T.J. experiences an increased temperature, faintness, and chills and has a rapid pulse and respiration rate.

What do these symptoms represent? Is this an adverse drug reaction?

Up to 54% of patients with relapsing fever experience a reaction, a Jarisch–Herxheimer reaction, to the first dose of antibiotic (see

Chapter 72, Sexually Transmitted Diseases).[22] It may occur in LBRF, TBRF, and in other spirochetal diseases such as syphilis or Lyme disease.[4] The dramatic reaction consists of a rise in temperature, chills, myalgias, tachycardia, hypotension, increased respiratory rate, and vasodilation.[21] Treatment of the reaction consists of supportive care. Severe reactions may require hospitalization for vital sign monitoring and management of hypovolemia. Although this is a reaction to the administration of an antibiotic drug, it is not an allergic response, and the antibiotic should be continued.

BORRELIA MIYAMOTOI

Case 82-6, Question 2: T.J. continues with antibiotic therapy and his symptom resolves. Given his clinical presentation and findings, his diagnosis and treatment were appropriate. How does *B. miyamotoi* typically present and what treatment options are available?

Borrelia miyamotoi is a bacterial species that is closely related to the bacteria that cause TBRF and distantly related to *B. burgdorferi* that causes Lyme disease. Although first identified in 1995 in ticks from Japan, *B. miyamotoi* has been detected in two species of North American ticks, the black-legged or deer tick (*I. scapularis*) and the western black-legged tick *I. pacificus*). The first human cases of infection were identified in Russia and described in 2011, followed by the first recognized cases in northeastern United States in 2013.[23] To date, there are <60 well-documented cases of *B. miyamotoi* in the United States. Because ticks are also known to transmit several diseases, including Lyme disease, anaplasmosis, and babesiosis, researchers and healthcare providers need to learn more about the transmission and signs and symptoms of this infection. Although Lyme disease most commonly occurs in June and July, *B. miyamotoi* infection occurs most commonly in July and August and may be spread by larval black-legged ticks.[5]

Patients with *B. miyamotoi* infection generally experience nonspecific symptoms such as fever, chills, headache, myalgia, and arthralgia.[23],[24] Unlike Lyme diseases, rash was an uncommon

finding, with only 4 out of 51 patients experiencing a rash. The blood tests that are used for Lyme disease are not helpful in the diagnosis of *B. miyamotoi* infections. Currently, the PCR tests that detect DNA from the organism or antibody-based tests are used for confirmatory diagnosis. Although studies have not yet been conducted to evaluate treatment regimens, in published case series, patients were successfully treated with antibiotics and dosages used for treatment of Lyme disease.[6] Patients with *B. miyamotoi* have been successfully treated with a 2- to 4-week course of doxycycline, and amoxicillin and ceftriaxone have also been used. *B. miyamotoi* disease will continue to be evaluated, and it may be an emerging tick-borne infection in the northeastern region of the United States.

SOUTHERN TICK-ASSOCIATED RASH ILLNESS

CASE 82-7

QUESTION 1: G.T., a 47-year-old male living in southern Missouri, recently experienced a rash resembling EM after a lone star tick bite.

Because this tick is not a vector for Lyme disease, what could be the cause and how should he be managed?

Amblyomma americanum (the lone star tick) is found throughout the southeast and south-central United States and along the Atlantic coast as far north as Maine, and its territory is expanding.[5] The lone star tick aggressively bites humans in the southern states, as opposed to *I. scapularis* ticks.[6,25] Spirochetes detected by microscopy and culture have been found in 1% to 5% of lone star ticks and are named *Borrelia lonestari.*[2,6,25] *Borrelia lonestari* and *B. burgdorferi,* however, were ruled out as the cause of EM like skin lesions known as Southern tick-associated rash illness (STARI) in one Missouri investigation.[6,25] Attempts to culture the agent of this Lyme-like illness, although exhaustive, have been unsuccessful.[25] The causative agent of STARI has not yet been confirmed. There are differences in the appearance and content of the rashes of STARI and the EM of Lyme disease. For example, Lyme EM rashes show

an abundance of plasma cells contrasted with a predominantly lymphocytic infiltrate seen in STARI.[25]

G.T.'s diagnosis was based on symptoms, geographic location, and tick bite information. Because the cause of STARI is unknown, no diagnostic tests are available, nor is it known if antibiotic treatment is necessary or beneficial for patients. However, because STARI resembles Lyme disease, limited data support treating STARI with regimens similar to those used for Lyme disease.[25] For example, doxycycline may be given for 10 to 30 days, with longer durations reserved for evidence of dissemination beyond the rash, such as fever, severe headache, lymphadenopathy, or multiple rashes.[26]

OTHER BACTERIAL DISEASES: TULAREMIA

Tularemia

ETIOLOGY AND EPIDEMIOLOGY

In 1911, George W. McCoy and Charles W. Chapin from the U.S. Public Health Service investigated a plague-like disease in wild ground squirrels harvested in Tulare County, California, and discovered the infectious etiology of tularemia.[26] The bacterium is a small, pleomorphic, catalase-positive, nonmotile, aerobic, nonencapsulated, gram-negative coccobacillus now named *Francisella tularensis* in honor of Edward Francis for his fieldwork and contributions to tularemia research. He proposed the terminology *tularemia* because the disease is associated with bacteremia.[26]

Although tularemia is found worldwide, it occurs primarily in the Northern Hemisphere.[23] The important reservoir hosts for *F. tularensis* are wild rabbits, ticks, and deer flies.[26] The North American tick vectors are *Dermacentor variabilis* (dog tick), *Amblyomma americanum* (lone star tick), and *Dermacentor*

andersoni (wood tick). Tick-borne tularemia occurs most often in the spring and summer, matching the likelihood of exposure.[5] Before 1950, most human cases of the disease developed from direct contact with infected animals, usually hares or rabbits, and tularemia cases that occurred in the fall or winter were usually associated with hunting season exposure. Tick bite transmission, however, now accounts for more than half of tularemia cases west of the Mississippi River in the United States. In summer months, tick or fly bites appear to be the main mode of transmission of tularemia to humans. Other animals, such as domestic cats, are susceptible to tularemia and are known to have transmitted tularemia to humans.[5] Tularemia outbreaks have also occurred among hamsters purchased from pet shops. Individuals should be careful when handling any sick or dead animal. Other modes of transmission include ingestion of, or contact with, infected meat, water, or soil; inhalation of aerosolized bacteria; or bites from infected animals, mosquitoes, or deerflies.[26] Direct person-to-person transmission has not been reported.

CLINICAL PRESENTATION

The clinical manifestations of tularemia are related to the mode of transmission, patient characteristics, and bacterial subspecies causing infection.[26] Classically, six types of tularemia presentation have been identified: ulceroglandular, glandular, typhoidal, oculoglandular, oropharyngeal, and pneumonic. The last three forms were presumably not tick-borne, reflecting alternative avenues of transmission. Today, the clinical manifestations fall into two main groups: ulceroglandular and typhoidal.[26]

Ulceroglandular is the most common form of tularemia, accounting for ~75% of cases.[26] Sixty percent of ulceroglandular cases are characterized by an ulcer that forms at the site of entry, usually on the lower extremities, perineum, buttocks, or trunk from arthropods that tend to bite the lower extremities or on the upper extremities from mammalian bites.[23] The lesion starts as a firm, erythematous papule that ulcerates and heals over the course of several weeks. It is accompanied by regional, painful lymphadenopathy, usually

inguinal or femoral. Typhoidal tularemia, occurring in ~25% of cases, is characterized by fever, chills, headache, debilitation, abdominal pain, and prostration. Fever and chills are common with all forms of tularemia.[26]

After exposure to the bacteria and an incubation period of 4 to 5 days, patients become ill with a sudden onset of fever, chills, headache, cough, arthralgias, myalgias, fatigue, and malaise. The severity of symptoms is quite variable, ranging from a mild, limited disease (probably type B tularemia) to rare cases of septic shock (probably type A tularemia). A hallmark manifestation is a high fever without an accompanying increase in pulse, or pulse–temperature disparity.[23] Common complications are mild hepatitis, secondary pneumonia, and pharyngitis. With antibiotic treatment of uncomplicated tularemia, mortality rates are only 1% to 3%. Increased morbidity and mortality are seen in the more rare typhoidal forms.[26] The most lethal form of tularemia is from pulmonary infection.[26] In the healthcare setting, standard precautions are all that is required when caring for patients who are infected with tularemia because they are not a source for secondary infection. However, any suspected outbreaks should be reported and investigated.[26]

DIAGNOSIS

Tularemia can be difficult to diagnose as routine laboratory testing is of little help in establishing a diagnosis and is limited to the demonstration of an antibody response to the bacteria. Because an antibody response to the illness requires 10 to 14 days for detection, treatment is usually empiric. The diagnosis is based on clinical suspicion from the epidemiologic history and the presence of compatible findings. The customary serologic test demonstrates *F. tularensis* antibody agglutination. Although a single-tube agglutination test with a titer of 1:160 or more (or 1:128 or more using a microagglutination study) in a suspected case is highly suggestive of a tularemia diagnosis, a fourfold or greater rise in titers between the acute and convalescent stages 2 weeks apart is

diagnostic.[27] After a bout of tularemia, detectable antibodies may persist for many years.[26]

TREATMENT

Antibiotic treatment options for tularemia have included streptomycin, gentamicin, doxycycline, and ciprofloxacin. Streptomycin was historically the drug of choice for tularemia, but it is often unavailable commercially. Some clinicians believe that gentamicin is the best alternative aminoglycoside for the treatment of nonmeningitic tularemia. Its advantages compared with streptomycin include lower minimal inhibitory concentrations (MICs), less vestibular toxicity, and wider commercial availability. Although considered comparable in efficacy to streptomycin, gentamicin has been associated with increased treatment failure and relapse. Tobramycin is inferior to gentamicin or streptomycin and should not be used.

In many of the reported studies of antimicrobial therapy for tularemia, short courses of treatment were used. To prevent tularemia from worsening or relapsing, longer regimens (10–14 days) should be used, especially in more severe cases. Jarisch–Herxheimer reactions can occur with antibiotic treatment of tularemia. Antibiotic prophylaxis for people exposed to those with tularemia is not recommended, but prophylactic antibiotics might be used for suspected bioterrorism attacks of tularemia. Acute febrile illness with pneumonia and other signs of infection occur 3 to 5 days after exposure to airborne tularemia organisms from an intentionally set weapon. No tularemia vaccines are available in the United States. A partially protective one was developed in the former Soviet Union but was only used for at-risk personnel such as for certain laboratory workers.[24] Personal protective measures, as discussed for Lyme disease, should be used when spending time outdoors in endemic areas.[26]

RICKETTSIA: ROCKY MOUNTAIN SPOTTED FEVER, *RICKETTSIA PARKERI* INFECTION, EHRLICHIOSIS, AND ANAPLASMOSIS

Rocky Mountain Spotted Fever

RMSF is the most prevalent and virulent rickettsial disease in the United States. As early as 1872, RMSF infected White settlers of the Northwest and it may have been prevalent in Native Americans of the region before that time. It was first described in residents of the Bitterroot, Snake, and Boise River valleys of Montana and Idaho in the late 1800s. Howard Ricketts discovered the causative agent, *Rickettsia rickettsii,* in 1908.[27] The rickettsia is a small (0.3 × 1 μm), pleomorphic, weakly gram-negative, obligate intracellular coccobacillus that can survive only briefly outside of a host.[27]

EPIDEMIOLOGY

RMSF is found throughout North America, including the United States, Canada, and Mexico, and in parts of Central and South America.[27] It has not been documented outside of the Western Hemisphere. The term "Rocky Mountain spotted fever" is actually a misnomer because the disease has shifted eastward from the Rocky Mountain states, and over 60% of the RMSF cases now occur in North Carolina, Missouri, Oklahoma, Arkansas, and Tennessee.[5,27,28] More recently (between 2013 and 2016), over 360 cases and 21 fatalities have occurred in Arizona.[5] Most RMSF infections arise from tick exposure in rural or suburban locations, although rare outbreaks in urban environments have occurred.

The prevalence of RMSF is highest in children ages 5 to 9 years.[29] Another peak prevalence is seen in males older than 60 years. Risk factors include male sex, residence in wooded areas, and exposure to tick-infected dogs. RMSF, like other tick-borne diseases, is highly seasonal, with greatest incidence in late spring and early summer.[27]

TICK VECTORS AND HOSTS

In the east, south, and west coasts of the United States, the tick vector for RMSF has been identified as the dog tick, *D. variabilis.*[2] In the Rocky Mountain states, the wood tick, *D. andersoni,* is the vector.[25] In Mexico, the tick vectors are *Rhipicephalus sanguineus* and *Amblyomma cajennense,* with the latter also being responsible in Central and South America.[25] The brown dog tick, *R. sanguineus*, has been identified as a new tick vector for RMSF in a defined area of Arizona.[27–29]

Dermacentor ticks feed on humans only during their adult stage.[27] Larval *Dermacentor* ticks may be infected while feeding on small mammals that have sufficient rickettsemia for transmission, such as chipmunks, ground squirrels, cotton rats, snowshoe hares, and meadow voles. Dogs are not considered reservoirs for *R. rickettsii* but are susceptible to RMSF and may introduce infected ticks into households.[27],[28] Adult ticks transmit the rickettsia transovarially to their progeny with high efficiency and establish newly infected tick lines. If the rickettsia burden is large in the adult tick, however, it may cause tick death, thereby reducing infected tick lines. Therefore, there must be nontick reservoirs, as mentioned previously, to develop newly infected tick generational lines; otherwise, RMSF would slowly disappear. In summary, ticks are both vectors and hosts for *R. rickettsii.*[27] Humans are dead-end accidental hosts of *R. rickettsii*.[27]

DISEASE COURSE, SYMPTOMS, AND FATALITIES

Rickettsia rickettsii is usually transmitted to humans from an infected tick bite.[27] The organism can also gain access to humans through broken skin if an infected tick is being crushed with bare fingers, and such crushing may generate infectious aerosols that might be inhaled. Conjunctival contact with infected tick tissues or feces provides another route for rickettsial entry. Contaminated blood transfusions and needle stick injuries have also transmitted *R. rickettsii*.[27]

After introduction of the organisms into the body, the rickettsia spread hematogenously with a predilection for the vascular endothelium, especially in capillaries and medium-sized blood vessels.[28] During an incubation period of 2 to 14 days, induced phagocytosis allows rickettsial entry into endothelial cells, where they replicate by binary fission in the cytoplasm and nuclei of infected cells. This induces a generalized vasculitis leading to activation of clotting factors, capillary leakage, and microinfarctions in various organs.[27] Exotoxins are not secreted by rickettsia; however, they do induce oxidative and peroxidative damage to host cell membranes, resulting in necrosis.[27] In severe infections, hypotension and intravascular coagulation may coexist and culminate in cell, tissue, or organ destruction.

Dehydration is an early sign of RMSF, followed by increased vascular permeability, edema, decreased plasma volume, hypoproteinemia, reduced serum oncotic pressure, and prerenal azotemia. RMSF is a multisystem disease, but a particular organ may be the major focus of the disease. If the brain or lungs are severely infected, death can ensue. An increased severity of illness is associated with edema, particularly in children, and hypoalbuminemia. Hypotension is present in 17% of patients and hyponatremia in 56%. Extensive infection of the pulmonary microvascular endothelium can cause noncardiogenic pulmonary edema.

A common finding in RMSF is myalgia (72%–83%) or muscular tenderness, which are manifestations of skeletal muscle necrosis. Striking creatinine kinase elevations have been described. Thrombocytopenia resulting from consumption of platelets during intravascular coagulation processes occurs in 35% to 52% of patients. True disseminated intravascular coagulation with attendant hypofibrinogenemia is exceptional, however, even in severe or fatal cases.[28] Blood loss or hemolysis in some may cause anemia, which is seen in 30% of patients and reflects blood vessel damage. Fatalities usually occur 8 to 15 days after illness onset if no treatment is given or is delayed. Long-term sequelae from severe forms of RMSF can include partial paralysis of the lower extremities,

gangrene of extremities requiring amputation, deafness or hearing loss, incontinence, and movement or speech disorders, but these occur in a minority of patients who receive prompt antibiotic therapy.[27]

"Fulminant" RMSF is best defined as a disease with a rapidly fatal course with death occurring in ~5 days. This form of disease is characterized by an early onset of neurologic signs and late or absent skin rash; it is highly associated with glucose-6-phosphate dehydrogenase deficiency, advanced age, male sex, and possibly heavy alcohol use.[27],[28] In the pre-antibiotic era, RMSF mortality rates were as high as 30%, but they have fallen to 5% in antibiotic-treated cases today.[2],[28]

The classically defined triad of RMSF symptoms at initial presentation is fever, rash, and headache, but this is found in only up to 5% of cases during the first 3 days of illness and up to ~60% of cases 2 weeks after exposure.[27],[29] The RMSF skin rash typically begins 2 to 4 days after fever onset as pink, 1- to 5-mm blanchable macules that later become papules.[28] It begins on the ankles, wrists, and forearms, and soon thereafter involves the palms or soles. It then spreads to the arms, thighs, and trunk, and typically evolves into a petechial exanthem. The utility of these findings in the differential diagnosis is limited because rash may be absent, transient, or late; it may never become petechial, or it may have an unusual distribution.

DIAGNOSIS

As for most tick-borne diseases, confirmatory serologic analysis is not particularly useful in early diagnosis of disease. The initial diagnosis is made based on clinical signs and symptoms and medical history. Because RMSF can be a severe or even fatal illness, antirickettsial treatment should begin immediately to prevent morbidity and mortality.[27],[28] *Rickettsia rickettsii* is difficult to culture. Immunohistologic demonstration of *R. rickettsii* in biopsy specimens of rash lesions is the only approach that can yield diagnostic results in a timely manner, but this approach is applicable only to those

presenting with a skin rash, and these tests are not readily available.[27]

The best serologic test for RMSF is the indirect immunofluorescence assay (IFA) test, but antibodies typically appear only after 10 to 14 days.[27] More striking laboratory abnormalities of RMSF disease include a normal leukocyte count with a shift to the left, hyponatremia, thrombocytopenia, elevated serum transaminases or creatinine kinase, and CSF pleocytosis. These findings are observed late in the disease course, however, and are not helpful in early disease recognition.

Clinical findings and history are essential to early diagnosis and successful treatment. Therapy must precede laboratory confirmation of RMSF.[27] In a febrile, tick-exposed person with a rash, RMSF should be considered. RMSF should be strongly considered in febrile children, adolescents, or males age older than 60 years, especially if they reside in or have traveled to the southern Atlantic or south-central United States from May through September. A delay in treatment for RMSF beyond 5 days of symptom onset can be rapidly fatal as the mortality rate increases from 5% to 22%.

TREATMENT

Doxycycline should be initiated immediately as first-line treatment for RMSF in both adults and children whenever RMSF is suspected. The recommended treatment is doxycycline 100 mg every 12 hours for children weighing <100 pounds (<45 kg): 2.2 mg/kg body weight given twice a day. The standard duration of treatment is 7 to 14 days, including at least 3 days after the temperature has normalized.[5,6] The use of doxycycline to treat suspected RMSF in children is standard practice by the CDC and the American Academy of Pediatrics (AAP) Committee on Infectious Diseases as the use of alternative antibiotics increases the risk of death. Contraindications to doxycycline use include history of severe hypersensitivity reactions to tetracyclines, and in some pregnant patients in which the case of RMSF seems mild, chloramphenicol may be considered as an alternative antibiotic.[27] However, oral formulations of

chloramphenicol are not available in the United States, and there are severe risks of adverse of effects with this agent, including gray baby syndrome and aplastic anemia.[27] The erythromycins, penicillins, sulfonamides, aminoglycosides, and cephalosporins are not effective for RMSF, and sulfa drugs may worsen infection.

A crucial component in the management of RMSF is appropriate supportive care.[5] Those with severe disease should be hospitalized and managed with hemodynamic, renal, pulmonary, and fluid support as needed.[5]

PREVENTION

In addition to the same guidelines for prevention of Lyme disease, keeping pets free of ticks can reduce exposure. Ticks must not be crushed in a way that might introduce rickettsia into cutaneous lesions, mucous membranes, or the conjunctiva. No RMSF vaccine is available.[27] Antirickettsial antibiotic prophylaxis after a tick bite is not warranted as there is no evidence that this approach is effective and it may delay the onset of the disease.

Spotted Fever Group *Rickettsia*

In addition to *R. rickettsii*, the agent of RMSF, many other rickettsial pathogens have been recognized and grouped broadly as "Spotted Fever group Rickettsia (SFGR)."[30] In the United States, these pathogens include *Rickettsia parkeri* and *Rickettsia* 364D, and internationally, there is a growing number of tick-borne SFGR that are pathogenic to humans.[5,31] Doxycycline treatment is effective and is the antibiotic of choice for tick-borne SFGR infections.[5]

Ehrlichiosis and Anaplasmosis

SPECIES IDENTIFICATION, TICK VECTORS, AND DISEASE HOSTS

Although ehrlichiosis and anaplasmosis are transmitted by two different species of ticks and generally occur in different regions of

the United States, patients may have a similar clinical presentation.[5],[6] The term “ehrlichiosis” may be more broadly applied to different infections, including *Ehrlichia chaffeensis* and *Ehrlichia ewingii*, which are transmitted by the lone star tick generally in the southeastern and south-central United States, from the eastern seaboard extending westward to Texas. A third species, provisionally called *Ehrlichia muris*-like (EML), was identified among patients in the upper Midwest; however, the tick responsible for transmitting EML is unknown, and the clinical presentation is undifferentiated from other *Ehrlichia* species.

Anaplasmosis is a bacterial disease, caused by *Anaplasma phagocytophilum,* which was first recognized as a disease in humans in 1994.[5] Although previously known as human granulocytic ehrlichiosis (HGE), a taxonomic change in 2001 identified that this organism belongs to the genus *Anaplasma* and resulted in the name change to human granulocytic anaplasmosis (HGA). To date, the highest incidence of HGA in the United States is reported in the upper Midwest and northeastern states with transmission by the black-legged tick (*I. scapularis*). Along the West Coast, it is transmitted by the western black-legged tick *(I. pacificus*).

CLINICAL AND LABORATORY FINDINGS

Human ehrlichiosis and anaplasmosis usually present as nonspecific, febrile, flu-like illnesses resembling RMSF. The symptoms caused by infection generally develop 1 to 2 weeks following the bite of an infected tick and are variable. Patients who are immunocompromised (eg, receiving corticosteroids, cancer chemotherapy, long-term immunosuppressive therapy following organ transplant), or who have HIV infection or splenectomy may experience more severe disease and greater risk of mortality.

The following signs often are noted: hypertransaminemia, leukopenia (often with a shift to the left), and thrombocytopenia. A skin rash is an uncommon feature of ehrlichiosis and is rarely seen with anaplasmosis. However, up to 60% of children can experience a rash caused by *E. chaffeensis.* The diagnosis of ehrlichiosis and

anaplasmosis must be made based on clinical findings, as treatment should never be delayed pending the results of confirmatory laboratory testing or be withheld based on an initial negative laboratory result. In patients presenting with known tick exposure, fever, thrombocytopenia, and increased liver function test, a peripheral smear should be performed. A peripheral blood smear showing neutrophilic morulae supports a provisional diagnosis, although this characteristic finding is not present in most cases. Confirmatory testing by serology or PCR or direct culture is still required to establish a diagnosis.[32] As with many other tick-borne diseases, serologic findings of antibody response to ehrlichiosis or anaplasmosis assist only by retrospectively confirming the diagnosis.

TREATMENT AND PREVENTION

CASE 82-8

Question 1: G.T., a 65-year-old male living in northwest Wisconsin, presents with an influenza-like illness in late May. He has a 2-day history of fever, shaking chills, headache, myalgias, nausea, and anorexia. On examination, his temperature is 102.92 °F (39.40 °C), but other physical findings are unremarkable. No skin rashes are found. G.C. states that he had multiple tick bites 1 week ago while he was fur trapping. The physician suspects anaplasmosis. Blood is drawn for serology, CBC with differential, chemistry profile, and a Wright stain microscopic examination. Immediately available abnormal results include neutrophilic morulae on microscopy, a WBC count of 2500/μL, a platelet count of 80 × 10^3/μL, C-reactive protein of 136 mg/L (normal, 4–8 mg/L), aspartate aminotransferase (AST) of 150 IU/L, and lactate dehydrogenase of 700 IU/L. Serology is still pending.

What of G.T.'s history and symptoms are consistent with a diagnosis of HGA?

G.T.'s history is significant for HGA. He was in the right place, the upper Midwestern United States, and was outdoors during the right season; most patients are diagnosed with HGA in May through August, and his history fall within the usual 1- to 2-week incubation period from tick bite to onset of illness.

His symptoms are also important. Nearly 100% of patients with HGA have a fever of >99.68 °F (>37.60 °C). Other symptoms in G.C.

consistent with HGA are rigors (shaking chills), headache, myalgias, nausea, and anorexia. Matching laboratory findings include neutrophilic morulae. The laboratory findings of leukopenia and thrombocytopenia strongly support the diagnosis of anaplasmosis. Evidence of mild-to-moderate hepatic injury, as seen by the elevated liver enzyme results, is helpful in HGA diagnosis.

CASE 82-8, QUESTION 2: What antibiotic treatment should be initiated?

Doxycycline is the first-line treatment for G.T. and should be used for both adults and children of all ages whenever anaplasmosis or ehrlichiosis is suspected.[4,5] In patients such as G.C. who are treated within the first 5 days of the disease, a good response to doxycycline occurs with fever resolution generally in 2 days.[32] Fever persisting for more than 2 days after doxycycline treatment suggests that the diagnosis is incorrect.

PROTOZOA: BABESIOSIS

Babesia, Ticks, and Hosts

There are more than 100 species of *Babesia* having a worldwide geographic range.[5] However, only relatively few species have caused documented cases of human infection, including *Babesia microti, Babesia divergens*, and *Babesia duncani* and currently an unnamed agent designated MO1.[5,33] The most common cause of human babesiosis is *B. microti*, which is transmitted by *I. scapularis* ticks, primarily in the endemic regions in the Northeast and upper Midwest of the United States; however, sporadic cases of babesiosis have occurred in other regions, including the West Coast. In addition to the Ixodes ticks, *Babesia* species are also transmitted by *Dermacentor, Haemaphysalis,* and *Rhipicephalus* ticks. Because *B. microti* is typically transmitted by the nymphal stage of *I. scapularis*

tick (about the size of a poppy seed), infected patients may not recall a tick bite.

SYMPTOMS AND DIAGNOSIS

CASE 82-9

Question 1: H.S., age 70 years, lives in Martha's Vineyard in Massachusetts. During the month of July, he enjoyed a day of boating, fishing, and hiking at a nearby lake. About a week later, he felt fatigued and lost his appetite. He presents to his local PCP in the middle of August with fever, headache, drenching sweats, aches, and pains and occasional dark-colored urine. He does not recall a tick bite. On physical examination, he has splenomegaly and hepatomegaly. Laboratory tests show a severe normochromic, normocytic anemia, decreased hemoglobin, hemoglobinuria, thrombocytopenia, and increased liver enzymes. His temperature is 104 °F (40 °C). Examination of a Giemsa-stained thin blood smear reveals the presence of unpigmented ring-shaped intraerythrocytic parasites in >5% of his erythrocytes.

What was the clue to the diagnosis of babesiosis?

The diagnosis of babesiosis was confirmed by the direct observation of the protozoan inside the red blood cells. Although the Giemsa-stain test is a commonly used tool, it is subject to false-negative results because the rate of parasitemia is typically low. Usually, multiple blood smears need to be examined because <1% of erythrocytes may be infected early in the course of the disease when most people seek medical help.[4,33] Because blood smear inspection is often not successful in diagnosing babesiosis or may only detect a few parasites, additional supportive laboratory results are advocated, such as serology using IFA for IgM and IgG antibabesial antibodies or PCR detection of babesial DNA in the blood.[3]

The clinical findings in patients with babesiosis are similar to those of malaria, ranging in severity from asymptomatic to severe complications and death.[12] Most patients with *B. microti* babesiosis are asymptomatic, although some people may develop nonspecific flu-like symptoms, such as fever, chills, sweats, headache, myalgias, and nausea. This form of babesiosis can be viewed as a distinct,

occult, asymptomatic disease with few known sequelae.[33] A number of transfusion-acquired infections have been documented, reflecting the existence of an asymptomatic form of babesiosis in blood donors. In 2018, the Food and Drug Administration (FDA) approved the first *B. microti* blood donor screening tests.[5]

A second form of babesiosis has been termed a “mild-to-moderate viral-like illness.”[33] It has a gradual onset of fatigue and malaise and later fever accompanied by one or more of these symptoms: chills, sweats, headache, arthralgias or myalgias, anorexia, or cough.[33] Rash is rare. It can last weeks to months, sometimes with a prolonged recovery time of up to a year or more.[33]

A third form of babesiosis is a potentially life-threatening hemolytic one that occurs in people predisposed to severe infection because of advanced age, immune suppression as a result of HIV disease or immunosuppressants, malignancy, or prior splenectomy.[33] Although babesial infection is as prevalent in children as it is in adults, it is more severe in adults older than 50 years of age. Complications seen in severe babesiosis include acute respiratory failure, disseminated intravascular coagulation, congestive heart failure, coma, and renal failure, with a 5% to 9% mortality rate.[3],[33]

In the northeastern United States, infections commonly occur in patients with spleens, as in H.S. Clinically apparent cases are most common in 50- to 60-year-old patients, many of whom do not recall a tick bite. Most symptoms of babesiosis are caused by hemolysis or the systemic inflammatory responses to parasitemia.[33] The usual incubation period is 1 to 6 weeks after a tick bite based on limited data.[33] Nonspecific, viral-like symptoms that are gradual in onset appear first, as in H.S.’s case, followed several days later by the other symptoms H.S. displayed. A hallmark of the disease is hemolytic anemia of varying severity. A high index of suspicion for babesiosis should be maintained in any patient with an unexplained febrile illness who lives in or has traveled to a region where the infection is endemic during June through August, as in H.S.’s case, particularly if there is a history of tick bite.

TREATMENT

Case 82-9, Question 2: The PCP institutes a regimen of atovaquone plus azithromycin for H.S. Is this an appropriate treatment regimen? What other drugs have been used?

The discovery of an original human babesiosis treatment regimen combining clindamycin and quinine was a fortuitous one. In 1982, an 8-week-old infant with presumed transfusion-acquired malaria was initially treated with chloroquine. Because of a lack of response, treatment was switched to quinine plus clindamycin, and the patient's fever decreased. A correct diagnosis of babesiosis was subsequently confirmed. Although this treatment combination is still used, frequent side effects (eg, tinnitus, vertigo, and diarrhea) occur, often resulting in dose reduction or discontinuation.[11,33] Treatment failures with this regimen have occurred in patients who underwent splenectomy, patients with HIV infection, or those receiving concurrent corticosteroids.[3]

For mild-to-moderate babesiosis, atovaquone plus azithromycin is the regimen of choice, as H.S. received. This regimen has also achieved cures in pediatric cases, although a controlled trial study has not been performed.[33] On the other hand, persistent relapsing babesiosis and emergence of resistance have occurred in immunocompromised patients receiving this regimen.[33,34] It has been suggested that the usual 7- to 10-day course treatment regimen may not be adequate in these patients.[34] Combination therapy of azithromycin with atovaquone is better tolerated than clindamycin–quinine combinations. The dosing is atovaquone 750 mg orally every 12 hours and azithromycin 500 to 1000 mg orally on day 1 and 250 to 1000 mg on subsequent days for 7 to 10 days.[12,33] Increased azithromycin doses of 600 to 1000 mg/day may be used in immunocompromised patients.[11,12] Children should receive atovaquone 20 mg/kg (maximum, 750 mg dose) every 12 hours and azithromycin 10 mg/kg (maximum, 500-mg dose) on day 1 and 5

mg/kg (maximum, 250-mg dose) orally thereafter for 7 to 10 days.[12,33]

For severe babesial illness, the IV clindamycin plus oral quinine should be given.[33] Dosing recommendations for adults are clindamycin 300 to 600 mg IV every 6 hours *plus* quinine 650 mg orally every 6 to 8 hours for 7 to 10 days; children should receive clindamycin 7 to 10 mg/kg (maximum, 600-mg dose) IV every 6 to 8 hours plus quinine 8 mg/kg (maximum, 650 mg dose) orally every 8 hours for 7 to 10 days.[11,12,33]

Antimicrobials should be used in all patients with symptomatic, active babesiosis once the diagnosis is confirmed by PCR or blood smear, owing to the risk of disease complications.[12] Antibody-seropositive, symptomatic patients without identifiable parasites on blood smear or PCR positivity should not be treated. Similarly, asymptomatic patients should not be treated regardless of serologic results, blood smear examinations, or PCR findings. A course of treatment should be considered in asymptomatic patients, however, if these tests are positive and repeat testing demonstrates persistent parasitemia for >3 months.[12]

Partial or complete red blood cell transfusions may be lifesaving in severe babesiosis for patients having high-grade parasitemia (10% or more infected erythrocytes), significant hemolysis, or pulmonary, renal, or hepatic compromise.[11] Rapidly increasing parasitemia leading to massive intravascular hemolysis and renal failure mandates immediate treatment for this form of the disease. Patients receiving antibiotic treatment, in particular those with severe or persistent symptoms, should be evaluated for co-infection with *B. burgdorferi* or *A. phagocytophilum* or both.

Babesiosis prevention is the same as for other tick-borne diseases. Asplenic patients should avoid areas where babesiosis is endemic. To date, no supportive data for the use of prophylactic antibiotics to prevent babesial infection after a tick bite are available.[33] Although developed for use in cattle, babesial vaccines are not available for humans.

VIRUSES: COLORADO TICK FEVER, TICK-BORNE ENCEPHALITIS, AND OTHER VIRALLY MEDIATED TICK-BORNE DISEASES

Colorado Tick Fever

VIRUS IDENTIFICATION, TICKS, AND HOST RESERVOIRS

"Mountain fever" has been described since the first immigrants arrived in the Rocky Mountains. It was later renamed Colorado tick fever (CTF), and the Colorado tick fever virus (CTFV) was identified as the cause.

CTF is caused by a double-stranded RNA *Coltivirus*. It is an intraerythrocytic virus. At least 22 strains of CTFV are known, but antigenic variation among human strains is low.[35] The virus is an arbovirus because it replicates inside ticks. The primary nidus of infection is thought to be CTFV invasion of hematopoietic progenitor erythroblasts, and it remains sheltered in mature erythrocytes.[35,36]

CTF is a viral illness transmitted by the bite of an infected tick.[35] Although at least eight tick species have been found to be infected with the virus, adult *D. andersoni* ticks are the primary tick vector that transmits CTF to humans.[35,36] *Dermacentor andersoni* feeds on numerous mammals, but ground squirrels, porcupines, and chipmunks are the primary reservoirs for CTFV as well as the ticks themselves.[35,36] Transstadial transmission of CTF virus within the tick ensures it is infected for life.[35]

PREVALENCE

CTF is contracted in forested mountain areas at higher elevations of the western Black Hills and Rocky Mountain regions of the United States and Canada, especially on the south-facing brush slopes and dry rocky surfaces of mountains east of the Continental Divide.[35,36] Although CTF can develop from March to October, May through July are peak incidence months.[5,6]

SYMPTOMS

CASE 82-10

QUESTION 1: P.J., a previously healthy 27-year-old graduate student living in Atlanta, Georgia, returns from a 1-week late-spring break camping trip with her friends in the eastern Colorado Rocky Mountains. Four days later, she experiences fever, chills, headache, myalgias, conjunctivitis, and lethargy. She recalls no tick bites and has no skin rashes. Suspecting RMSF, her physician prescribes doxycycline. P.J.'s symptoms and fever initially resolve, but 2 days later her symptoms return. Physical examination at this time reveals a temperature of 102.20 °F (39 °C). Routine laboratory tests are normal, although leukopenia is observed with a WBC count of 2400/μL.

How do P.J.'s symptoms suggest a diagnosis of CTF?

Symptoms of CTF usually start 3 to 5 days after a tick bite, although more than half of patients do not remember being bitten.[35,36] The most common initial symptoms are fever of rapid onset, headache, chills without true rigors, and myalgias.[35] A rash, which may be petechial, maculopapular, or macular, can occur in 5% to 15% of patients.[39] About half of patients with fever experience a "biphasic" pattern of fever and other symptoms, which means they have several days of fever, then improve for several days, and then have a second period of fever and illness.[35,36] Sequelae are rare, although fatigue and malaise may last for months.[36] One- to three-week periods of convalescence are usual. Children, however, experience complications more frequently than adults. Patients with suspected CTF should defer from donating blood or bone marrow for at least 6 months after their illness because the virus may stay in red blood cells for several months and can be passed to others via blood transfusions.

LABORATORY FINDINGS

Moderate-to-significant leukopenia is the most important finding in CTF. Leukocyte counts are usually normal on the first day, but decrease to 2000 to 4000/μL by the fifth or sixth day of illness with a lymphocytic predominance.[36] In one-third of confirmed CTF cases,

however, the leukocyte counts remained around 4500/μL. Counts return to normal within a week of fever abatement in most cases. Thrombocytopenia may occur.[35,36] Although the CSF may show a lymphocytic pleocytosis, this does not distinguish CTF from other causes of meningoencephalitis.[36]

DIAGNOSIS AND TREATMENT

CTF diagnosis can be made serologically, either with IFA staining of erythrocytes, complement fixation, or ELISA.[35,36] The most sensitive isolation system is intracerebral injection of infected blood into suckling mice.[35,36] A reverse transcriptase PCR of specimens can be diagnostic within the first 5 days of illness, whereas serologic tests are more relevant for diagnosis 2 weeks after symptom onset.[36] There is no specific treatment available for patients with CTF infection, which is usually self-limiting. Supportive care should be provided. The best protection for CTF is tick prevention strategies.[36]

TICK-BORNE ENCEPHALITIS

Tick-borne encephalitis (TBE), a life-threatening neurologic disease, is a growing public health concern in Europe and Asia as the incidence of TBE virus has significantly increased in the past decade.[5,37] TBE virus is divided into three subtypes: Central European (western subtype), Siberian, and Far Eastern (Russian spring–summer or eastern subtype) and is endemic to central and eastern Europe, Russia, and the Far East, with some overlap in geography.[5,37]

The etiologic agents are spherical, lipid-enveloped RNA viruses in the genus *Flavivirus.*[5,38] The western subtype is transmitted to humans by *I. ricinus,* and the Siberian and Far Eastern subtypes are transmitted by *I. persulcatus,* although *Ixodes ovatus* is the vector in Japan.[41] A minority of TBE cases have followed the consumption of infected unpasteurized milk or cheese directly without a tick vector.[38] The main virus reservoirs are small rodents.[38] Ticks are vectors, and humans are accidental hosts of the virus. Ticks can become infected for life by the virus at larval, nymphal, or adult stages; can acquire it

during mating; and can maintain the virus transovarially and transstadially.[38] TBE viruses are transmitted from the saliva of an infected tick very rapidly, within minutes of the bite, so early removal of the tick may not prevent subsequent encephalitis.

As the disease name implies, the ultimate outcome of the infectious process is manifested as CNS involvement, with symptoms of aseptic meningitis, meningoencephalitis, and meningoencephalomyelitis. TBE begins as a febrile headache with progression to CNS manifestations. There is no antiviral treatment available, and treatment is supportive, including management of any complications. Two inactivated cell culture–derived preventive human TBE vaccines are available in Europe, in adult and pediatric formulations (FSME-IMMUN and Encepur®).[5] The adult formulation of FSME-IMMUN is also licensed in Canada. Two other inactivated TBE vaccines are available in Russia (TBE-Moscow and EncVir®). The reader is referred to the CDC for information regarding vaccination to TBE-endemic countries.[5]

POWASSAN DISEASE

Powassan virus infection is an RNA virus belonging to the genus *Flavivirus* that is related to West Nile, St. Louis encephalitis, and TBE viruses.[5] Powassan disease is now recognized in the United States, Canada, and Russia. In the United States, ~60 cases have been reported in the past decade primarily from northeastern states and the Great Lakes region. The incubation period ranges from 1 week to 1 month. Many people who become infected are asymptomatic. Signs and symptoms of illness can include fever, headache, vomiting, and malaise. Because the Powassan virus can infect the CNS, progression of disease to meningoencephalitis with confusion, seizures, and memory loss may occur. There are currently no vaccines or treatment for Powassan disease. Supportive care should be provided to patients with suspected disease.

TOXINS: TICK PARALYSIS

Tick Paralysis

CASE 82-11

Question 1: C.M., a 7-year-old girl residing in Spokane, Washington, tells her parents that both of her legs feel weak. The next day, her mother notices that C.M. has worsened and immediately takes her to the pediatrician. The physician finds that C.M. has begun experiencing flaccid paralysis in both legs and the lower trunk, although she is alert and oriented. The pediatrician finds that there is a tick attached to C.M.'s scalp under her hair and removes it. C.M. is back to full health in 2 days.

What happened?

Tick paralysis (tick toxicosis) occurs worldwide in humans and many animals, and was first described by the explorer Hovell in Australia in 1824.[39] Although 60 tick species worldwide can produce tick paralysis in animals and humans, it is predominantly caused in humans by *D. andersoni* and *D. variabilis* in North America.[39] In Australia, *Ixodes holocyclus* is the culprit.[39]

Most human cases occur during the spring and summer in Australia and North America. In the United States, it is most common in the Pacific Northwest and adjacent areas of southwestern Canada and in the Rocky Mountain states.[39] In children, girls are more commonly affected; however, in adults, more males are affected.[41] Of epidemiologic significance, a young girl's long hair provides camouflage for feeding ticks.[39]

The cause of tick paralysis is the secretion of a neurotoxin present in the large salivary glands of female ticks. They must usually be attached to a host for 4 to 5 days before symptoms develop.[39] The toxin affects motor neurons, decreases acetylcholine release, and may have a mechanistic similarity to botulinum toxin.[39] Paresthesias and symmetric weakness in the lower extremities with motor difficulties progress to an ascending flaccid paralysis in several hours or days. Cerebral sensorium is usually spared, pain is absent, and the blood and CSF are normal.[39] If the tick is not removed, the

toxicosis can progress to respiratory paralysis and death.[39] Initially reported mortality rates of 10% have fallen dramatically with our modern intensive care units and available respiratory care.[39] A Washington State case series of 33 patients conducted over the course of 50 years revealed a mortality rate of 6%, with the last two patients' deaths occurring in the 1940s.[39] Children are likely more vulnerable to tick paralysis than adults because the dose of neurotoxin present per kilogram of body weight is higher.[38] Diagnosis should include a complete body examination of the skin for the presence of an engorged tick.[38]

In North America, tick removal commonly results in complete recovery within hours to days. In Australia, the disease is more acute, and paralysis may continue to progress for 2 days after tick removal. Recovery from the disease in Australia may take several weeks. Treatment is supportive. Antitoxin derived from dogs is the treatment of choice for animals, but it also has been used occasionally in humans in Australia with severe tick paralysis.[39] Local experts must determine its use on a case-by-case basis because of the risk of serum sickness or acute allergic reactions.[38]

MIXED INFECTIONS

Because the tick vectors and mammalian hosts are the same for babesiosis, anaplasmosis, and Lyme disease in the northeastern United States, all three diseases, theoretically, could be transmitted to a human from one tick bite. Human co-infection by the agents of Lyme disease, babesiosis, or anaplasmosis can occur, especially in endemic areas.[6] Co-infection may alter the natural course for each disease or increase clinical manifestations, especially flu-like symptoms, in concurrent Lyme disease with babesiosis or HGA. Because the same tick vector in Europe and Russia can carry Lyme disease and TBE, dual infection may result in more severe disease.[38]

Dual infection may affect the choice of initial antibiotic therapy. For example, although amoxicillin is sometimes used to treat early Lyme disease, it is not effective for HGA. Doxycycline, however, is useful in both of these diseases. Thus, some cases of Lyme disease that were believed to be treatment failures may actually have been confounded by co-infection. Patients with concurrent Lyme disease and babesiosis have more symptoms and a longer duration of illness compared with patients with single infections. When moderate-to-severe Lyme disease is diagnosed, the possibility of concomitant babesial or anaplasma infection should be considered in regions where both diseases are endemic. Neutropenia and thrombocytopenia are associated with anaplasmosis, anemia and thrombocytopenia are associated with babesiosis, and neither is routinely found in Lyme disease.[6] For patients with Lyme disease who experience a prolonged flu-like illness that fails to respond to appropriate antiborrelial therapy in an endemic area, clinicians should consider testing for babesiosis and anaplasmosis.[6]

SUMMARY

Tick-borne diseases have become an increasingly complex and serious global problem. We continue to encounter growing numbers of cases of tick-borne human disease of known or unknown causes. Most of the research into tick-borne human disease demonstrates a close historical relationship of endemic tick–deer–rodent cycles for various microorganisms. Scientists continue to search for improvements in diagnosing, treating, and preventing tick-borne diseases, as well as controlling the tick populations that transmit microbes. The threat posed by human-biting ticks has become more widespread across various regions and, across tick species, more spatially diffuse (including backyards, neighborhood green spaces, and public recreation areas).[3,21] More research and coordinated strategies are needed to better understand and reduce tick-borne disease risk. Because patients present frequently with nonspecific

signs and symptoms, a high index of suspicion is crucial to include a tick-borne illness in the differential diagnosis of those presenting with symptoms compatible with a tick-borne illness. It is essential to obtain a careful history of possible tick exposure and consider the epidemiology of infected ticks when considering the possibility of tick-borne illnesses. It is also important to increase awareness of personal protection strategies and tick avoidance.

Anxiety Disorders

Tamara Bystrak and Amanda Eloma

CORE PRINCIPLES		CHAPTER CASES
CLINICAL ASSESSMENT AND DIFFERENTIAL DIAGNOSIS		
1	Anxiety disorders are characterized by anxiety that is out of proportion to any actual threat and is excessive for the situation or distressing to the point that it interferes with daily functioning. Both medical and medication-related factors can cause or exacerbate anxiety.	**Case 83-1 (Question 1), Figure 83-1, Tables 83-1, 83-2**
GENERALIZED ANXIETY DISORDER		

CORE PRINCIPLES		CHAPTER CASES
1	Generalized anxiety disorder (GAD) is defined in the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition, (*DSM-5*) as a chronic state of waxing and waning anxiety that is associated with an inability to control symptoms of anxiety and worry. The severity of anxiety and the degree of impairment in daily activities are the main determinants of whether medication should be used to treat GAD.	**Case 83-2 (Question 1), Table 83-3**
2	First-line therapies for the treatment of GAD include psychotherapy or pharmacotherapy. Pharmacologic treatment options include selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), or buspirone. Benzodiazepines can be used for bridging purposes while awaiting the efficacy onset of the previously mentioned treatments, or as a rescue medication for patients currently in a high state of anxiety. Specific treatment for GAD should be chosen based on prior therapy, comorbid psychiatric and medical conditions, pharmacokinetic drug properties, and patient preference.	**Case 83-2 (Questions 2, 3), Tables 83-4–83-6**

CORE PRINCIPLES		CHAPTER CASES
3	When beginning treatment with benzodiazepines for GAD, patients should be educated about possible adverse effects, risk of abuse or dependence, and drug–drug interactions. Possible effects on pregnancy, teratogenicity, and breast-feeding should also be discussed with females of child-bearing potential.	**Case 83-2 (Questions 4) Case 83-3 (Question 1) Case 83-4 (Questions 1, 2) Case 83-5 (Questions 1–3), Table 83-7**
4	Patients beginning treatment with SSRIs or SNRIs should be counseled regarding possible adverse effects that may occur early in treatment, as well as those that may occur later and display a more chronic time course. In addition, all patients being treated with medications for GAD should be counseled regarding the duration of drug therapy.	**Case 83-2 (Questions 5, 6)**
PANIC DISORDER		
1	Panic disorder is characterized by short episodes of intense fear, associated with perceived physical symptoms such as increased heart rate, increased respiration, gastrointestinal disturbance, tremor, or feelings of bodily disassociation that may be misdiagnosed or remain undiagnosed because symptoms are attributed by the patient to a medical illness.	**Case 83-6 (Question 1), Table 83-8**

CORE PRINCIPLES		CHAPTER CASES
2	Therapy for panic disorder includes cognitive behavioral therapy (CBT), medications, or combination therapy. Medications used include SSRIs, venlafaxine extended release (XR), tricyclic antidepressants (TCAs), or benzodiazepines. The expected short-term adverse effects of antidepressants (eg, jitteriness) should prompt using a lower initial medication dose and be discussed with the patient.	**Case 83-6 (Questions 2–4), Table 83-6**
SOCIAL ANXIETY AND SPECIFIC PHOBIAS		
1	Both social anxiety and specific phobias involve fears that are excessive and lead to avoidance behaviors to minimize fear. Social anxiety involves a generalized and intense anxiety involving social interactions, whereas specific phobias involve intense fear associated with specific objects or situations (eg, spiders or elevators). CBT and medications (SSRIs or venlafaxine XR) are both first-line treatment options.	**Case 83-7 (Questions 1–3), Tables 83-6, 83-9**
POSTTRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER		

CORE PRINCIPLES		CHAPTER CASES
1	Posttraumatic stress disorder (PTSD) and acute stress disorder occur in persons who have experienced a severely distressing traumatic event. Reexperiencing symptoms, avoidance, hyperarousal, and negative alterations in cognition and mood cause considerable psychological distress, as well as impairment in occupational functioning and personal relationships.	**Case 83-8 (Question 1), Table 83-10**
2	Trauma-focused psychotherapy is considered the preferred first-line treatment for PTSD, although there are also several first-line medication options (SSRIs or venlafaxine XR). Adjunctive treatment for psychiatric comorbidities such as depression or sleep is often indicated. Treatment goals include reducing the core symptoms of PTSD and improving patient functioning.	**Case 83-8 (Questions 2–4), Table 83-6**
OBSESSIVE–COMPULSIVE DISORDER		

CORE PRINCIPLES		CHAPTER CASES
1	Obsessive–compulsive disorder (OCD) is characterized by chronic obsessions and/or compulsions that can be extremely disabling and usually consume at least an hour a day. OCD can be treated with medications (SSRIs preferred, venlafaxine XR, or clomipramine), psychotherapy (CBT with or without exposure therapy), or combined modalities for optimal therapy. Despite combination therapy, up to 40% of patients may continue to experience disabling symptoms.	**Case 83-9 (Questions 1–5), Table 83-6**
2	Owing to incomplete remission of symptoms with monotherapy in many patients suffering from OCD, augmentation strategies involving the combination of antidepressants or adjunctive antipsychotics may be considered with vigilant monitoring for increased adverse effects and drug–drug interactions.	**Case 83-10 (Questions 1–3)**

INTRODUCTION

Anxiety can be described as an uncomfortable feeling of vague fear or apprehension accompanied by characteristic physical sensations. It is a normal reaction to a perceived threat to one's physical or psychological well-being. Anxiety is normally provoked by stress and

involves activation of neurobiologic systems that, when activated, contribute to self-preservation. There are two basic components to anxiety: mental features (eg, worry, fear, difficulty concentrating) and physical symptoms (eg, racing heart, shortness of breath, trembling, pacing). Certain medical illnesses (eg, pheochromocytoma, hyperthyroidism) and/or substances (eg, sympathomimetics, caffeine) can result in both the physical and psychological manifestations of anxiety. However, when the anxiety is attributable to an external cause such as a medical illness or a medication, the anxiety abates when the physiologic cause is removed.[1]

If the anxiety is not the result of an external cause, is out of proportion to the actual threat, or persists beyond the presence of the threat, it may be classified as an anxiety disorder. To guide treatment, pathologic anxiety should be differentiated according to whether it occurs (a) as a primary anxiety disorder, (b) as a secondary anxiety disorder owing to medical causes or substances, (c) in response to acute stress (eg, loss of a loved one, marital or financial problems), or (d) as a symptom associated with other psychiatric disorders.[1]

Classification and Diagnosis of Anxiety Disorders

The *Diagnostic and Statistical Manual of Mental Disorders.* Fifth Edition (*DSM-5*) classifies primary anxiety disorders into seven types: generalized anxiety disorder (GAD), panic disorder, agoraphobia, specific phobia, social anxiety disorder, separation anxiety disorder, and selective mutism.[1] Obsessive–compulsive disorder (OCD) and posttraumatic stress disorder (PTSD) are each classified under unique headings in the *DSM-5*. Each disorder involves an unhealthy level of anxiety, but the characteristic type and severity of symptoms, course of illness, and efficacy of drug and nondrug treatments vary, indicating underlying biologic differences. The *DSM-5* secondary anxiety disorders include “anxiety disorder due to a general medical condition” and “substance/medication-

induced anxiety disorder."[1] Anxiety disorders often present in addition to other psychiatric disorders, such as mood disorders. Both are associated with dysregulations in the limbic system and, therefore, share similar symptoms, including fatigue, impaired concentration, restlessness, difficulties with sleep, and somatic symptoms. However, mood disorders have a prominent mood component.[2]

Neurobiology of Anxiety

The limbic system, which is involved in emotion, learning, and memory, is composed of a set of structures integral to behavior, including the hippocampus and the amygdala. Hippocampal brain circuits are essential for conversion of short-term to long-term memory and for spatial memory, whereas the amygdala circuits are involved with emotion and its expression. A neurocircuit arising from the output pathways of the amygdala is believed to mediate fear and anxiety responses in humans.[3] Dysregulated or exaggerated output through various amygdala-related circuits may be a common element underlying the different anxiety disorders, but the specific type of dysfunction probably differs among the various disorders. If it is assumed that a dysregulation of the stress response is the basis of anxiety disorders, then the genesis of anxiety is probably related primarily to interactions between neural pathways in and between the limbic system structures, the sympathetic nervous system, and the hypothalamic–pituitary–adrenocortical (HPA) axis.[2,4] Many neurotransmitter and neuroendocrine systems interact to modulate the actions of the limbic pathways, including corticotrophin-releasing hormone (CRH); the monoamine neurotransmitters, epinephrine and norepinephrine (NE); the indolamine neurotransmitter, serotonin (5-hydroxytryptamine [5-HT]); the inhibitory amino acid, γ-aminobutyric acid (GABA); the excitatory amino acid, glutamate; and the neuropeptides, cholecystokinin (CCK), neuropeptide Y, and substance P.[3,5] As such, the genes from which these products are derived and regulated are an active area of research. Furthermore,

epigenetic mechanisms are being investigated to explore the complex relationship between gene–environment interactions.[6]

Interaction of the Hypothalamic–Pituitary–Adrenocortical, Noradrenergic, and Serotonergic Systems

In the event of an acute threat, a fear stimulus is transmitted via the thalamus to the amygdala, which then projects to both the hypothalamus and the brainstem. This results in various peripheral reactions such as increased heart rate, increased heart stroke volume, and vasodilation of blood vessels carrying blood to the muscles. This is accompanied by a release of NE by the locus coeruleus (LC), the main area of NE cell bodies in the brain. Central release of NE results in vigilance, arousal, the ability to focus attention on the threat, and symptoms of anxiety (eg, tachycardia, tremor, sweating). NE innervation of the hippocampus results in an increased state of memory formation, whereas innervation of the amygdala potentiates the formation of aversive memories.[4] Normally, this is important in allowing us to encode emotionally laden memories, but when overactive, it may result in a constant state of arousal and hypervigilance.

During a perceived threat, CRH is released in the hypothalamus, and it activates the anterior pituitary to release adrenocorticotropic hormone (ACTH). This stimulates the release of glucocorticoid steroids from the adrenal cortex. Although short-term elevation of glucocorticoids allows the body to adapt to a stressful situation by supporting HPA activation and mobilizing energy stores, prolonged elevation of the same glucocorticoids impairs neural plasticity and may even result in neuronal death. When CRH is infused into the LC in rodents, it causes anxiety-like behaviors.[2,4,7]

Although the inhibitory neurotransmitter 5-HT is involved in stress reactions, its role is not entirely clear. Serotonin has roles in sleep, appetite, memory, impulsivity, sexual behavior, mood, motor function, and seems to decrease aggressive behavior. The site of most 5-HT

cell bodies in the brain is the raphe nuclei. There is considerable interconnectivity between the raphe nuclei and the LC, and they tend to mutually inhibit one another. Under normal circumstances, 5-HT connections from the hippocampus decrease activity in the amygdala, which would dampen fear and anxiety responses. However, under conditions of stress, the LC accelerates firing, inhibits the raphe nuclei firing, and increases CRH release—all of which sensitize the limbic system and cause arousal and sensitivity to memory of any stressful or aversive stimuli. This primes the system to a state of arousal to deal with the threat.[2] Although the specific etiology of anxiety is only hypothesized, the current use of treatments activating the 5-HT system, or other inhibitory systems such as the GABA system, supports the hypothesis.

Epidemiology and Clinical Significance of Anxiety Disorders

As a group, anxiety disorders are the most common psychiatric illnesses. Epidemiologic surveys indicate that 13% to 28% of Americans suffer from an anxiety disorder at some time in their lives, with similar prevalence in other parts of the world.[8,9] Anxiety disorders are more common in females than in males.[9] Medical illness is associated with higher rates of anxiety compared with the general population.[10] In addition, 50% to 60% of people with major depressive disorder (MDD) have a lifetime history of one or more comorbid anxiety disorders.[7,11,12] Concurrent anxiety and depression are associated with greater disability, poorer treatment outcomes, and higher suicide rates than with either depression or anxiety alone.

Today, most anxiety disorders can be successfully treated with medications, cognitive or behavioral therapies, or combinations thereof. However, less than one-third of those affected seek help. Many who do seek help by reporting physical symptoms of anxiety to primary care providers are not properly diagnosed, and therefore remain untreated.[9] A significant portion of patients with anxiety also do not believe in taking medication for emotional problems.[13]

Because anxiety is a feeling with which everyone is familiar, there is a tendency to trivialize the impact it can have on the functioning and quality of life of those with anxiety disorders. Increased understanding about pathologic anxiety is needed in society and with health care professionals, so that people seek and receive appropriate treatment. A list of consumer and professional resources for information about anxiety disorders and treatment can be found in **Table 83-1**.

Clinical Assessment and Differential Diagnosis of Anxiety

CASE 83-1

Question 1: R.R., a 49-year-old female, reports to her provider about having trouble sleeping, feeling tired and nervous, and worrying constantly. R.R. was divorced 2 years ago, and she retained custody of their 15-year-old daughter. Since her divorce, R.R. has returned to work as a nurse, but she worries constantly that she will not be able to earn enough money to support herself and her daughter. She has hypertension, asthma, seasonal allergies, and gastroesophageal reflux disease, for which she is prescribed hydrochlorothiazide 12.5 mg/day, losartan 50 mg/day, montelukast 10 mg/day, albuterol one to two puffs every 4 to 6 hours as needed (PRN) wheezing and shortness of breath, and pantoprazole 40 mg/day. She also takes over-the-counter (OTC) loratadine 10 mg/day and pseudoephedrine 60 mg every 4 to 6 hours PRN for allergies, naproxen 200 mg every 8 to 12 hours PRN for

occasional back pain, and polyethylene glycol 17 g daily PRN for constipation. R.R. drinks three or four cups of coffee each morning and one or two glasses of wine 4 nights each week to help her calm down when she has had a stressful day. She denies any history of psychiatric illness, but states she has always been a “worrier.”

What factors should be considered in the clinical assessment and differential diagnosis of R.R.’s symptoms of anxiety?

A diagnostic decision tree such as that in **Figure 83-1** can be used to assist the clinician in differentiating among various causes of anxiety and different anxiety disorders. According to *DSM-5* criteria for primary anxiety disorders, the symptoms should not be secondary to any medical (drug or disease) causes (**Table 83-2**).

Figure 83-1 Diagnostic decision tree for anxiety disorders. GAD, generalized anxiety disorder; OCD, obsessive–compulsive disorder;

PTSD, posttraumatic stress disorder.

Table 83-2
Secondary Causes of Anxiety

Medical Illnesses
Endocrine and metabolic disorders: hyperthyroidism, hypoglycemia, Addison disease, Cushing disease, pheochromocytoma, PMS, electrolyte abnormalities, acute intermittent porphyria, anemia
Neurologic: seizure disorders, multiple sclerosis, chronic pain syndromes, traumatic brain injury, CNS neoplasm, migraines, myasthenia gravis, Parkinson disease, vertigo, essential tremor
Cardiovascular: mitral valve prolapse, CHF, arrhythmias, post-MI, hyperdynamic β-adrenergic state, hypertension, angina pectoris, postcerebral infarction
GI: PUD, Crohn disease, ulcerative colitis, irritable bowel syndrome
Respiratory: COPD, asthma, pneumonia, pulmonary edema, respirator dependence, pulmonary embolus
Others: HIV infection, systemic lupus erythematosus
Psychiatric
Depression, mania, schizophrenia, adjustment disorder, personality disorders, delirium, dementia, eating disorders
Drugs
CNS stimulants: amphetamines, methylphenidate, caffeine, cocaine, diethylpropion, ephedrine, MDMA (ecstasy), nicotine (and withdrawal), PCP, phenylephrine, pseudoephedrine
CNS depressant withdrawal: barbiturates, benzodiazepines, ethanol, opioids
Psychotropics: antipsychotics (akathisia), bupropion, buspirone, SNRIs, SSRIs, TCAs
Cardiovascular: captopril, enalapril, digoxin, disopyramide, hydralazine, procainamide, propafenone, reserpine
Others: albuterol, aminophylline, baclofen, bromocriptine, cycloserine, dapsone, dronabinol, efavirenz, fluoroquinolones, interferon-α, isoniazid, isoproterenol, levodopa, lidocaine, mefloquine, metoclopramide, monosodium glutamate, nicotinic acid, NSAIDs, pergolide, quinacrine, sibutramine, statins, steroids, theophylline, thyroid hormone, triptans, vinblastine, yohimbine

CHF, congestive heart failure; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; HIV, human immunodeficiency

virus; MDMA, 3,4-methylenedioxymethamphetamine; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; PCP, phencyclidine; PMS, premenstrual syndrome; PUD, peptic ulcer disease; SNRIs, serotonin norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

SECONDARY CAUSES OF ANXIETY

A diagnosis of anxiety disorder attributable to a general medical condition is warranted when symptoms are believed to be the direct physiologic consequence of a medical condition, such as hyperthyroidism or hypoglycemia.[1] A complete physical and laboratory workup, with a thorough medical and psychiatric history, is needed to exclude reversible causes before a primary anxiety disorder diagnosis is considered. Because new onset of anxiety disorders in elderly persons is uncommon, this can often be attributed to a medical or substance-related cause. The presence of anxiety may complicate the medical picture and have a negative impact on the course of illness. Also, it should be noted R.R. is 49 years old, and the median age for onset of menopause is 52 years. Although not a medical illness, menopausal symptoms also may include sleep disturbances and mood swings.

When evaluating for possible causes of anxiety, it is also important to consider all medications a person is taking, including OTC drugs such as cough and cold preparations.[14] A diagnosis of substance-induced anxiety disorder is warranted when anxiety symptoms occur in relation to substance intoxication or withdrawal or when medication use causes the symptoms. Among the medications R.R. is taking, pseudoephedrine might be contributing to her anxiety. Other medications that can cause anxiety are listed in Table 83-2. Psychoactive substance abuse, withdrawal from central nervous system (CNS) depressants (eg, alcohol, barbiturates, benzodiazepines), excessive caffeine intake, and nicotine withdrawal may go unrecognized as underlying precipitants of anxiety. R.R.'s current pattern of alcohol use may become problematic if she uses alcohol to self-medicate her anxiety symptoms.

Anxiety in response to life stressors may be severe and functionally detrimental, but could be considered appropriate for the circumstances. Usually, this type of anxiety is self-limiting and brief, subsiding over days to weeks as the person adapts to the new situation. If the person has no history of an anxiety disorder and the symptoms last only a few months, a diagnosis of adjustment disorder with anxious mood may be appropriate. If the symptoms are severe and continue for a prolonged period, a primary anxiety disorder may be present.[1] The initial onset of a chronic anxiety disorder often occurs during a stressful period. Short-term or intermittent therapy with anxiolytic medication or counseling can be extremely beneficial in helping persons cope during times of acute stress. In contrast, management of primary anxiety disorders usually requires more extended treatment.[13]

In summary, the factors in R.R.'s case warranting further investigation include her medical illness (asthma), possible onset of menopause, use of pseudoephedrine and caffeine, and adjustment to recent life changes (divorce, returning to work, becoming a single mother). These factors need to be addressed and treated, if possible, before a diagnosis of an anxiety disorder can be applied and appropriately managed.

GENERALIZED ANXIETY DISORDER

Epidemiology and Clinical Course

GAD is one of the most common anxiety disorders, with a lifetime prevalence of about 9%. GAD is twice as common in females than in males.[1,15] Onset is usually gradual and may be associated with increased life stressors. GAD usually begins between the mid-teens and mid-50s, and the median age of onset is 30 years.[9,15] As such, GAD presents the latest of all anxiety disorders.[1] Whites are more likely to report anxiety symptoms than do Asians, Hispanics, and African Americans.[16] The typical course of GAD is described as

being chronic and recurrent, but much is unknown about the long-term course of illness. Without treatment, it appears that less than half of GAD cases undergo remission.

Most people with GAD have at least one other psychiatric disorder. Common comorbid disorders include panic or social anxiety disorder, simple phobia, OCD, and MDD.[8] Evidence suggests that GAD itself may be a risk factor for suicidal ideation, particularly among females.[17]

Diagnostic Criteria

GAD is characterized by excessive anxiety and worry about life issues for 6 months or longer.[1] The patient usually has great difficulty controlling the worry, which is accompanied by at least three of the associated symptoms listed in **Table 83-3**. Although some physical symptoms are similar between GAD and other anxiety disorders, if the anxiety is related solely to another anxiety disorder (eg, obsession with germs, fear of social situations), a diagnosis of GAD is not warranted.

Table 83-3

Symptoms of Generalized Anxiety Disorder

Anxiety and worry are associated with at least three of the following symptoms (or one in children):
Restlessness, feeling keyed up, or on edge
Easy fatigue
Difficulty concentrating or mind going blank
Irritability
Muscle tension
Sleep disturbances

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders.* 5th ed. American Psychiatric Association; 2013.

Etiology and Pathophysiology

Genetic factors play a significant role in the etiology of GAD. Genes involved in the hereditary development of GAD are believed to be the same as those for neuroticism and major depression, with environmental factors determining which disorder is expressed in an individual.[5,18,19] Biologic studies in GAD have found abnormalities in noradrenergic, serotonergic, and CCK and GABA-A receptor function.[5] Several studies report decreased α_2-adrenergic receptors in patients with GAD, and this is believed to represent downregulation of receptors in response to high catecholamine levels.

Treatment of Generalized Anxiety Disorder

NONPHARMACOLOGIC TREATMENTS

Management of GAD can involve both psychological and pharmacologic therapies. It is undetermined whether a combination of psychotherapy and pharmacotherapy is more or less efficacious than is each alone.[26] Nondrug treatments such as supportive psychotherapy, dynamic psychotherapy, cognitive behavioral therapy (CBT; including Internet- or computer-based programs), relaxation training, and meditation are often helpful in relieving anxiety and improving coping skills.[20–22] Cognitive therapy is aimed at identifying negative thought patterns provoking or worsening anxiety and making them more positive. CBT has been associated with significant reductions in anxiety that are maintained for 6 to 12 months, as well as decreased psychiatric comorbidity in GAD.[20]

BENZODIAZEPINES

Benzodiazepines are widely prescribed anxiolytic agents, and their efficacy in treating GAD and other anxiety disorders, particularly in the short term, is well established.[23] Benzodiazepines offer rapid symptom relief, but are associated with risks such as dependence, withdrawal, and cognitive impairment, and therefore are not recommended for the long-term management of GAD.

Mechanism of action

Benzodiazepines potentiate GABA by binding to sites on the central GABA-A receptor that serve as the main inhibitory neurotransmitter in the CNS.[24] Benzodiazepines have four distinct effects: anxiolytic, anticonvulsant, muscle relaxant, and sedative-hypnotic. Benzodiazepines with a rapid onset and short duration of action are commonly used to decrease anxiety as well as induce sedation before surgery and other medical procedures.

Clinical comparison of benzodiazepines

The 14 benzodiazepines commercially available in the United States are marketed for different indications, which reflect manufacturers' labeling decisions, because anxiolytics can be effective sedatives and vice versa. **Table 83-4** compares the indications, dosing, and clinical profiles of marketed oral benzodiazepines. Midazolam and clobazam are not included in Table 83-4 because these agents are not used in the treatment of anxiety. Approximate conversions between different benzodiazepines can also be found (**Table 83-5**); however, different resources report varying equivalency factors. Check multiple resources and consider using the most conservative conversion estimation. Also, in many circumstances, it may be appropriate to initiate the new drug at a slightly lower than equivalent dose, which can be titrated further if needed and tolerated.

Table 83-4

Clinical Comparison of Benzodiazepine Agents[a]

Generic (Brand Name)	FDA-Approved Indications	Usual Dosage Range	Rate of Onset Following Oral Administration	Half-Life (hours)[a]
Alprazolam (Xanax®)	Anxiety, anxiety associated wlth depression, panic disorder	0.5–6 mg/day (up to 10 mg/day for pamc disorder)	Fast	12–15
Chlordiazepoxide (Librium®)	Anxiety, preoperative anxiety, acute alcohol withdrawai	15–100 mg/day	Intermedlate	>100
Clonazepam (Klonopin®)	Anticonvulsant, panic disorder	0.5–12 mg/day	Intermedlate	20–50
Glorazepate (Tranxene®)	Anxiety, alcohol withdrawai, anticonvulsant	15–60 mg/day	Fast	>100
Diazepam (Valium®)	Anxiety, muscle relaxant, acute alcohol withdrawai, preoperative anxiety, anticonvulsant	4–40 mg/day	Very fast	>100[b]
Estazolam (Prosom®)	Sedative-hypnotic	1–2 mg HS	Intermedlate	24
Flurazepam (Dalmane®)	Sedatlve-hypnotic	15–30 mg HS	Fast	>100
Lorazepam (Ativan®)	Anxiety, anxiety associated with depresslon, anticonvulsant, premedication for anesthetic procedure	2–6 mg/day	Intermediate	10–20
Oxazepam (Serax®)	Anxiety, alcohol withdrawai	30–120 mg/day	Slow	5–14
Quazepam (Doral®)	Sedative-hypnotic	7.5–15 mg HS	Fast	47–100
Temazepam (Restoril®)	Sedative-hypnotic	15–30 mg HS	Intermediate	10–20
Triazolam (Halcion®)	Sedative-hypnotic	0.125–0.25 mg HS	Intermediate	1.5–5

Midazolam and clobazam are omitted because these agents not used in the treatment of anxiety.

FDA, U.S. Food and Drug Administration; HS, at bedtime

[a]Parent drug + active metabolite.

[b]Diazepam metabolizes to desmethyldiazepam, which metabolizes to temazepam, which metabolizes to oxazepam.[249–251]

Table 83-5
Benzodiazepine Approximate Dosage Equivalence[a]

Generic (Brand Name)	Approximate Dose Equivalence (mg)
Alprazolam (Xanax®)	0.5
Chlordiazepoxide (Librium®)	25
Clonazepam (Klonopin®)	0.5
Diazepam (Valium®)	10
Lorazepam (Ativan®)	1
Oxazepam (Serax®)	20
Temazepam (Restoril®)	20

[a]Reported dose equivalences are approximate because different resources quote varying equivalents.[249–251]

ANTIDEPRESSANT AGENTS

Antidepressants are the recommended first-line treatment for most patients with GAD. Although the anxiolytic effects of benzodiazepines occur almost immediately, the anxiolytic effects of antidepressants occur gradually over several weeks. Therefore, it is possible for short-term benzodiazepine therapy (<12 weeks) to be prescribed in combination with an antidepressant during initial treatment of many anxiety disorders, including GAD.[25]

As shown in **Table 83-6**, selective serotonin reuptake inhibitors (SSRIs) have since gained first-line status for treating all five primary anxiety disorders.[26] Use of these agents, in addition to serotonin norepinephrine reuptake inhibitors (SNRIs), first line is increasingly common when compared to alternatives owing to their tolerability profile. SSRIs and SNRIs also have utility in treating comorbid depression.

Table 83-6

Summary of Comparative Medication Treatment Options for Anxiety Disorders

Disorder	FDA-Approved First-Line Treatments (Unless Otherwise Noted)	Second-Line Treatments	Possible Alternatives
Generallzed anxiety disorder	Benzodiazeplnes (short-term use only) Buspirone Duloxetine Escltalopram Paroxetine Venlafaxine XR	Otalopram Pregabalin Sertraline	Atypical antipsychotics* Fluoxetine Mirtazapine Tricydic antidepressants"
Panic disorder	Citalopram' Escitalopram' Fluoxetine Fluvoxamine' Paroxetine Sertraline Venlafaxine XR	Benzodiazepines (eg. alprazolam. clonazepam. dlazepam. lorazepam) Clomipramine Imlpramine Mirtazapine	Anticonvulsants Atypical antipsychotics Pbenelzine
Social anxiety disorder	Esdtalopramc Fluvoxamine CR Paroxetine Sertraline Venlafaxine XR	Benzodiazepines (eg. alprazolam. clonazepam) Citalopram Pregabalin	Atypical antipsychotfcs Duloxetine Fluoxetine Gabapentln Mirtazapine Phenelzlne[0] Tranylcypromine[0]
Posttraumatic stress disorder	Fluoxetine[1] Paroxetine Sertraline Venlafaxine XR'	Citalopram Escitalopram Fluvoxamine Mirtazapine	Amitriptyline[0] Anticonvulsants Atypical antipsychotics* Buproplon Duloxetine Imlpramine[0] Nefazodone[1,] Phenelzlne" Prazosin
Obsessive–compulsive disorder	Escitalopram" Fluoxetine Fluvoxamine Fluvoxamine CR Paroxetine Sertraline	Otalopram Clomipramine[0] Venlafaxine	Anticonvulsants* Antipsycbotic agents* Pheneizine

[a]Adjunctive therapy only.

[b]Documented efficacy, but not recommended for first-line treatment because of undesirable clinical properties (side effects, potential toxicity, drug interactions).

[c]Not U.S. Food and Drug Administration (FDA) approved for the indication, but evidence supports use.

Early GAD controlled studies found tricyclic antidepressants (TCAs) such as doxepin, imipramine, and amitriptyline comparably effective or superior to benzodiazepines in treating GAD.[23] However, TCAs are not widely used for treating anxiety disorders because attention has turned to other much safer and better tolerated antidepressants, including SSRIs and SNRIs.

Paroxetine and escitalopram are SSRIs approved for GAD by the U.S. Food and Drug Administration (FDA). Sertraline and citalopram

have also been studied for this indication, and sertraline is the preferred first-line agent according to one treatment guideline.[25] Overall, SSRIs and SNRIs are recommended for first-line use, and specific agents should be selected based on patient-specific factors (eg, risk for discontinuation syndrome, drug interactions, tolerability, and patient preference).[21,26] Patients with GAD may experience an initial increase in anxiety during SSRI treatment, especially fluoxetine. Therefore, lower than normal SSRI starting doses should be used in this population.[27]

Venlafaxine and duloxetine are FDA-approved SNRIs for the treatment of GAD. Newer SNRIs including levomilnacipran, and venlafaxine's active metabolite, desvenlafaxine, have not been well studied in the management of anxiety. Preliminary data suggest that these agents may be useful for the treatment of anxiety symptoms associated with depression, although further randomized controlled trials (RCTs) are needed to confirm this finding.[28–30] The side effect profile of SNRIs is similar to that of the SSRIs. Dose-related nausea is the most common side effect, which usually subsides after 1 to 2 weeks of continued therapy. Similar to SSRIs, vigilance for worsening anxiety is required on initiation of treatment with SNRIs. Low doses should be utilized to mitigate this potential effect. Unlike SSRIs, SNRIs can cause increased blood pressure. Significant increases in blood pressure with venlafaxine are not usually seen within the dosage range used for GAD (75–225 mg/day), but can occur with higher doses.

Long-term studies report remission of GAD during 6 months of continued treatment with venlafaxine XR.[31] Duloxetine's effectiveness has been demonstrated in short- and long-term trials, with the latter citing a decrease in relapse of GAD in patients treated with 60 to 120 mg/day.[32–36] In a comparison of duloxetine 60 to 120 mg/day and venlafaxine XR 75 to 225 mg/day, these agents achieved criteria for noninferiority and demonstrated comparable tolerability.[37]

Mirtazapine is a noradrenergic and specific serotonergic antidepressant with limited controlled data in the treatment of GAD, although there is some data supporting its use in patients with

comorbid MDD.[38,39] Mirtazapine is unlikely to cause anxiety as a side effect, owing to its 5-HT receptor type-2 blocking activity (see Chapter 86, Depressive Disorders, for more information regarding the clinical use of various antidepressant agents). Vilazodone is a serotonin reuptake inhibitor and partial 5-HT1A agonist. Although only FDA approved for MDD, vilazodone has displayed efficacy for the treatment of GAD in an 8-week placebo-controlled trial.[40] Vortioxetine, a serotonin reuptake inhibitor with additional effects at numerous serotonergic receptors, has been studied in short- and long-term treatment of GAD with mixed results.[41–45]

As mentioned previously, lower initial doses of antidepressants are recommended to avoid acute worsening of anxiety symptoms. Slow titration and patient education regarding adverse reactions associated with antidepressants, including the black box warning for suicidality, is also recommended.[46] Although decreases in anxiety symptoms during antidepressant treatment may appear within the first 2 weeks, response is gradual and generally continues for 8 to 12 weeks or longer. Therefore, optimal trials of antidepressants in GAD should allow at least 8 weeks of adequate doses before a lack of response is determined. Continued improvements may occur for 4 to 6 months in some patients with GAD treated with antidepressants.[47,48]

Overall, advantages of antidepressants compared with benzodiazepines in treating GAD include their superior efficacy for cognitive symptoms, such as excessive worry, as well as for common comorbid disorders such as depression and other anxiety disorders. Antidepressants also have a safer withdrawal syndrome and lack potential for abuse and dependence versus benzodiazepines.

OTHER AGENTS USED TO TREAT GENERALIZED ANXIETY DISORDER

Buspirone was marketed in the United States as the first of a nonbenzodiazepine class of anxiolytics, the azapirones, and is FDA approved for the treatment of GAD. Buspirone works as a partial

agonist of the 5-HT type 1A receptor, reducing 5-HT neurotransmission.[49] In addition, buspirone enhances dopaminergic neurotransmission by blocking presynaptic dopamine receptor-2 autoreceptors and also facilitates noradrenergic activity.[50] Buspirone is effective in treating cognitive anxiety symptoms, and is not associated with abuse or dependence; however, it has a delayed onset of anxiolytic effects, and is not appropriate for as-needed use. Buspirone can be used alone or in combination with an SSRI or SNRI. Because buspirone must be taken two or three times daily, it may not be the best choice for patients with a history of poor medication adherence.

Pregabalin, a schedule V controlled substance, may be recommended as a second-line agent following use of SSRIs or SNRIs.[21,25] Pregabalin binds to the α2-δ-subunit of voltage-gated calcium channels in the CNS to inhibit excitatory neurotransmitters (eg, glutamate, NE). Pregabalin appears to be efficacious in managing symptoms of GAD compared with active comparators, including benzodiazepines and venlafaxine.[46,51] Pregabalin is commonly used as an adjunctive agent in combination with SSRIs or SNRIs.[52] It may also be used as a second-line treatment option for patients who have failed or experienced intolerable side effects to antidepressants. Some guidelines support use of pregabalin as a first-line agent for GAD.[21,53] Considerations need to be made for individuals with renal disease or those with a history of substance abuse.[26] Pregabalin exhibits a dose–response effect that appears to plateau at 300 mg/day, although one long-term continuation study of up to 24 weeks suggests pregabalin 450 mg/day may be effective in preventing relapse compared with placebo.[54] Further, an open-label study of doses up to 600 mg/day maintained response for up to 1 year.[55]

Hydroxyzine is a first-generation histamine-1 receptor antagonist. Its anxiolytic effect is believed to be influenced by serotonergic antagonism. Hydroxyzine has displayed efficacy in several studies, although analysis of data suggests possible bias. It may be a reasonable second- or third-line option, but should not be used as monotherapy in patients with comorbid MDD.[21] Owing to its

anticholinergic side effects, exercise caution in the elderly and/or with other anticholinergic or CNS depressant medications. In addition, hydroxyzine is contraindicated in early pregnancy.[56]

Finally, atypical antipsychotics are utilized off label in patients with GAD, although current guidelines highlight that use of these agents should not be initiated in primary care and should be reserved after multiple antidepressant class failures.[25] Aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have been studied for treatment-resistant GAD, with the bulk of evidence and current guidelines supporting use of quetiapine.[21,26,57] These agents may be useful in patients who fail to respond to first-line treatment options; however, their side effects (eg, metabolic syndrome, extrapyramidal side effects) should be discussed before use.[21,25,26]

Clinical Presentation and Assessment of Generalized Anxiety Disorder

CASE 83-2

Question 1: L.V., a 32-year-old male, has been employed as a teacher for the past 10 years. He has had an excellent work record until 8 months ago, when excessive absences and a tendency to become easily upset at students and coworkers became noticeable. On clinical assessment, L.V. reports feeling "on edge," irritable, and tense, with frequent stomach upset and diarrhea. He has no history of mental illness; however, he admits to being stressed and worrying too much about "insignificant things." He cannot seem to control these symptoms regardless of how hard he tries. L.V. denies any symptoms indicative of panic disorder or OCD.

L.V.'s physical examination is unremarkable, and his family history is only notable for his sister who is described as a "nervous person." L.V. denies past or present use of any illicit substances and drinks three to four beers at social events, which he has not enjoyed recently. His mental status examination reveals the following:

- *Appearance and behavior:* L.V. is neatly groomed and dressed and speaks coherently, but he constantly fidgets and taps his right foot.
- *Mood:* L.V. is anxious and worried about the clinician's evaluation, and admits to occasionally feeling depressed and hopeless because of his

anxiety. He often has difficulty falling asleep, but generally remains asleep throughout the night.

- *Sensorium:* L.V. is oriented to person, place, and time.
- *Thoughts:* L.V. denies any auditory or visual hallucinations, or suicidal or homicidal ideation.

L.V. states, at times, that he is unable to relax, particularly in the classroom around his students. His work has been difficult for him lately, and the principal has told him that his job is in immediate jeopardy unless he improves his performance. L.V. states that he just wants to be able to perform his job as he used to and be able to "chill out" and get back to his old life. His insight and judgment are good, and he is motivated to obtain treatment. The provider's provisional diagnosis is GAD.

What clinical features of GAD are present in L.V., and how can his symptoms be assessed objectively?

L.V. exhibits the following target symptoms associated with GAD: excessive worry that is difficult to control, irritability, tension, and inability to relax. Other typical symptoms of anxiety present in L.V. include gastrointestinal (GI) problems (upset stomach and diarrhea), being startled easily, and fidgeting. These target symptoms are not necessarily diagnostic of any particular disorder, but other factors in association with these symptoms are consistent with GAD. The absence of physical or other psychiatric illnesses, as well as use of any illicit substances and lack of recent use of alcohol, excludes possible secondary causes of anxiety. The 8-month duration of symptoms is consistent with a diagnosis of GAD, and L.V.'s age is consistent with the usual onset of GAD. More importantly, the symptoms are causing significant occupational impairment for L.V. and interfering with his quality of life. Therefore, a diagnosis of GAD is appropriate in L.V.

The Hamilton Anxiety Rating Scale for Anxiety (HAM-A) is a useful assessment tool to evaluate clinical anxiety, and it is the standard instrument used in GAD clinical trials. A HAM-A score of >18 is generally correlated with significant anxiety. A reduction of the score to 7 to 10 is associated with no symptoms, defined as remission.[58] The HAM-A can be used to assess baseline anxiety symptoms in patients such as L.V. and to monitor response throughout treatment. The Sheehan Disability Scale is a patient-rated instrument

commonly used to assess functional impairment caused by GAD and other anxiety disorders. It measures three domains (eg, work/school, social life, and family life) from 1 to 10. A score of 1 reflects mild disability, whereas a score of 10 suggests severe impairment.[58]

Indications for and Selection of Treatment

Case 83-2, Question 2: Based on the information presented in L.V.'s case, how can it be determined whether treatment is indicated? What factors should be considered in choosing the most appropriate treatment for L.V.?

L.V. meets the diagnostic criteria for GAD, and is suffering significant disability in his work life from his anxiety disorder. He also has insight into his illness, and desires treatment that will enable him to improve his job performance and quality of life. Appropriate treatment of GAD can help achieve these goals, and is therefore indicated for L.V.

Treatment options for GAD include both pharmacologic and nondrug therapies. Psychosocial treatments such as CBT can be effective in treating GAD, but use of these therapies alone is generally reserved for patients with mild-to-moderate symptoms. In L.V.'s case, prompt treatment is needed because his job is in immediate jeopardy, owing to impairments associated with his anxiety. Therefore, pharmacotherapy in combination with psychological therapy, if available, is indicated for L.V.

Among potential drug therapies, short-term use of benzodiazepines and maintenance with SSRIs, SNRIs, or buspirone are all considered first-line treatments for GAD.[21,25,26] A primary consideration when choosing among these options is whether any comorbid psychiatric conditions are present. Antidepressants are the recommended initial choice, especially for patients with concurrent depression. Other medical or psychiatric disorders may also be present, which can guide selection toward a treatment that may be dually effective. Another consideration when selecting treatment for GAD is how quickly therapeutic effects are needed.

Benzodiazepines reduce anxiety within a few hours, whereas antidepressants and buspirone have delayed onsets of anxiolytic effects. Medication cost is another potential factor, and generic benzodiazepines or SSRIs are inexpensive options.

In L.V.'s case, a benzodiazepine may be a good initial choice because of the need for quick symptom relief relating to his problems at work. L.V. is young and healthy, with no past or present history of substance abuse or alcohol use that might make benzodiazepines unsuitable for him. Although L.V. drinks beer on occasion at social gatherings, he has not participated in these events recently, and he should continue to avoid alcohol if a benzodiazepine is initiated. GAD is often chronic, and antidepressants or buspirone are recommended over benzodiazepines for long-term treatment. Therefore, one of these agents would also be appropriate to use in this case.

Benzodiazepine Treatment

FACTORS INFLUENCING BENZODIAZEPINE SELECTION

Case 83-2, Question 3: The provider decides to treat L.V.'s GAD with paroxetine for maintenance and a benzodiazepine for quick control of his anxiety during the first several weeks until the onset of paroxetine's anxiolytic effects. What factors are important in the selection of a particular benzodiazepine agent for L.V.?

Of the available benzodiazepines, none have demonstrated clear superior efficacy in the treatment of GAD. However, certain agents have been used more extensively than others. Alprazolam, lorazepam, clonazepam, and diazepam have been successfully used in the treatment of GAD. Benzodiazepines differ in their pharmacokinetic properties, and these are generally the main factors considered in drug selection (see Table 83-4).

Benzodiazepines can be differentiated according to their elimination half-lives and metabolism to active or inactive compounds. Diazepam (Valium®) and chlordiazepoxide (Librium®)

have half-lives between 10 and 40 hours, and are metabolized by hepatic oxidative pathways to the active metabolite desmethyldiazepam (DMDZ).[24] The metabolite DMDZ has a long half-life of ~100 hours, and chronic dosing of benzodiazepines that get converted to DMDZ can result in drug accumulation and prolonged clinical effects.[59] This can be especially detrimental in the elderly, those with liver disease, those taking drugs that interfere with benzodiazepine metabolism, or poor metabolizers. Although long durations of action make once-daily dosing possible, small, divided daily doses are often used clinically to minimize side effects.

As highlighted in Table 83-4, the elimination half-life of clonazepam ranges from 20 to 50 hours, making once-daily dosing feasible. Alprazolam (Xanax®, Niravam®) and lorazepam (Ativan®) have intermediate half-lives of 10 to 20 hours, and oxazepam (Serax®) has a short to intermediate half-life of 5 to 14 hours. Alprazolam, lorazepam, and oxazepam usually need to be taken three or four times a day for sustained clinical effects, although an extended-release (XR) preparation of alprazolam allows daily or twice-daily dosing. Alprazolam XR may be associated with fewer CNS side effects than is the immediate-release (IR) form because peak alprazolam blood levels are lower.[60]

Notably, lorazepam, oxazepam, and temazepam (also referred to as the LOT benzodiazepines) are free of active metabolites and are unlikely to accumulate with chronic administration. These three benzodiazepines are preferred over longer acting agents in patients with liver disease and in the elderly. Unlike phase 1 oxidative metabolism, the phase 2 glucuronidation of the LOT benzodiazepines does not appear to decline with age.[61]

Benzodiazepines are readily absorbed after oral administration.[24] Lipid solubility varies among the agents, resulting in differences in rates of absorption and speed of onset, as well as in duration of clinical effects (see Table 83-4). Diazepam and clorazepate have the highest lipid solubilities and the quickest onset of action, which can be desirable when rapid anxiolysis is needed; however, both can produce a “drugged” or “high” feeling in some patients. Highly

lipophilic benzodiazepines are also more quickly redistributed out of the brain, which decreases their duration of action acutely.

Diazepam, lorazepam, and midazolam are also available for parenteral (intravenous [IV] and intramuscular [IM]) administration[24] for treatment of severe agitation or seizures, or for induction of preoperative sedation and anxiolysis. IM injection of diazepam can be very painful. Lorazepam is the preferred agent when IM dosing is needed for quick control of anxiety or agitation. Cost is another important factor in benzodiazepine selection. Brand-name benzodiazepines can be relatively expensive, but all are available in less costly generic versions. Potential drug interactions should also be considered in the selection of an agent because they can alter pharmacokinetics and clinical effects (see Case 83-4, Question 1).

Because L.V. is young and healthy and is not taking any other medications, the clinician could choose any benzodiazepine. A shorter acting high-potency agent, such as lorazepam or alprazolam, would be a reasonable as-needed option for L.V. Appropriate starting doses would be lorazepam 0.5 to 1 mg tid or alprazolam 0.25 to 0.5 mg tid. Dosages can be increased every 3 to 4 days, if needed, within the dosage ranges indicated in Table 83-4. L.V. should notice a decrease in his anxiety symptoms within the first few days of treatment. Prescription of a generic formulation is recommended to reduce treatment costs.

ADVERSE EFFECTS AND PATIENT COUNSELING

Case 83-2, Question 4: Alprazolam 0.25 mg tid is prescribed for L.V. in addition to paroxetine. What side effects may occur with benzodiazepine treatment, and how should L.V. be counseled regarding benzodiazepine therapy?

Sedation and feelings of tiredness are the most common side effects of benzodiazepines, although sedation may be beneficial in alleviating insomnia that often accompanies anxiety. Tolerance usually develops to the sedative effects of benzodiazepines within 1 to 2 weeks of continued treatment. Consequently, benzodiazepine

sedative-hypnotics are recommended for only short-term use.[21,24,26] Tolerance does not appear to develop to the anxiolytic or muscle relaxant effects of benzodiazepines.

Benzodiazepines can cause cognitive impairment and anterograde amnesia (decreased memory for new information after taking the drug), which is dose related and reversible on medication discontinuation. Tolerance often develops to the cognitive adverse effects, although these may also persist throughout therapy in some patients.[62] Newer studies have demonstrated a possible association with long-term benzodiazepine use and dementia.[63,64] Use of alcohol during benzodiazepine therapy greatly increases the risks of memory problems and sedation, as well as for other more dangerous effects, including respiratory depression. Elderly individuals are more sensitive to sedative, cognitive, and psychomotor effects of benzodiazepines, and tolerance to these effects may occur more slowly than in the younger population.[65,66]

Other psychomotor effects, such as poor coordination and delayed reaction time, can also occur during benzodiazepine treatment.[24] These effects are also dose related, but usually subside within a few weeks of continued treatment. Long-acting benzodiazepines taken at night may cause residual daytime effects, which could result in car accidents and hospitalization, especially in older individuals.[67] The link between benzodiazepine use and falls, especially in the elderly, is also well documented.[68] Rapid dosage escalation and use of high doses of benzodiazepines have been identified as major risk factors for falls. However, even use of low doses of short-acting agents greatly increases the risk of falling in the elderly.[68–70]

Respiratory depression is another potential adverse effect of benzodiazepines, but it is usually only clinically relevant in patients with severe respiratory disease, in overdose situations (see Case 83-5, Question 1), or when combined with alcohol or substances that depress breathing, such as opioids, gabapentin or pregabalin, muscle relaxants, or antihistamines.[71] It is recommended that benzodiazepines be avoided in patients with sleep apnea, especially those who are nonadherent with their positive airway pressure device. Respiratory complications are encountered most often with

IV administration. Severe and life-threatening cardiorespiratory depression has also occurred with the concurrent use of benzodiazepines and olanzapine IM (Zyprexa®), loxapine (Loxitane®), or clozapine (Clozaril®). Further, it should be noted that benzodiazepines increase the risk of death in prescription drug overdoses, typically in combination with other medications or drugs of abuse.[72]

Paradoxical disinhibition, with increased anxiety, irritability, and agitation, can occur infrequently with benzodiazepines,[24] primarily in elderly or developmentally disabled individuals.[73] Other unusual behaviors, such as increased anger, hostility, depression, suicidal ideation, and rage, have been attributed to benzodiazepine use in a small number of cases.[24,74] Most of these reports were anecdotal, and involved patients with preexisting psychiatric disorders such as bipolar disorder or schizophrenia.

Concerns related to abuse and dependence are one major drawback to the clinical use of benzodiazepines. These agents are classified as schedule IV controlled substances. Diazepam, alprazolam, and lorazepam are more likely to be abused than are oxazepam and chlordiazepoxide.[75] This difference is commonly attributed to the quicker onset of effect and high potency, which may be associated with a subjective euphoric sensation. The XR alprazolam formulation is reported to have a lower abuse potential than does IR alprazolam because of its slower onset of effect smaller peak-to-trough ratio and lower maximal plasma concentrations.[60] The potential problems with benzodiazepine abuse and dependence can be avoided or minimized in several ways. First, patients with GAD who have a history of alcohol or substance abuse should not be treated with benzodiazepines.[75] Second, patients should be counseled about directions for use, the anticipated duration of benzodiazepine use, the possibility of withdrawal symptoms, and the importance of gradual drug tapering when therapy is discontinued.

In summary, L.V. should be told that he may experience sedation and difficulties in thinking, concentration, or memory during the first week or so of therapy, but these side effects will likely resolve over time as he develops tolerance. He should be extremely careful while

driving or performing other tasks requiring psychomotor skills, especially during the first week. He should avoid the use of alcohol while he is taking benzodiazepines. The distinction between "addiction" and appropriate therapeutic use, which may be accompanied by some degree of physical dependence, should be explained.

DURATION OF TREATMENT

CASE 83-2, QUESTION 5: Two weeks later at his clinic appointment, L.V. is still doing well, and has shown further improvements in his GAD symptoms. He has been taking the prescribed alprazolam and paroxetine for 1 month, and his paroxetine has been increased to 40 mg/day during this time. How long should medication therapy continue?

GAD is a chronic disorder fluctuating in severity, and often requires long-term treatment. When benzodiazepines are used for acute anxiolytic effects during initiation of antidepressant treatment for GAD, they are commonly limited to short-term (2–6 weeks) therapy. L.V. has demonstrated good response after 1 month of combined alprazolam and paroxetine therapy. Because the anxiolytic effects of paroxetine usually occur between 2 and 4 weeks of therapy and he is taking a therapeutic paroxetine dose, it is appropriate to start discontinuing alprazolam at this time. Although it is unlikely, L.V. may experience significant withdrawal symptoms even after only 1 month of benzodiazepine treatment. Thus, the alprazolam dose should be gradually decreased for several weeks, according to tolerability of the taper.[76] In patients who are treated with short-acting benzodiazepines for longer durations, switching to an equivalent dose of a longer acting benzodiazepine, such as diazepam, may simplify the withdrawal schedule.[77]

There is no consensus about the optimal duration of drug therapy for GAD. However, recent recommendations suggest that effective medication treatment be continued for at least 6 to 12 months after initial response.[23,78] Continuation treatment with antidepressants significantly reduces the risk of GAD relapse in 6 months.[79]

Therefore, paroxetine therapy should be continued for another 5 to 11 months in L.V.'s case. After that time, gradual paroxetine discontinuation may be considered, and reinstitution of treatment is warranted if relapse occurs.

Case 83-2, Question 6: Two months later L.V. returns to the clinic after several "no shows." L.V. reports that he missed his appointments because he has started a new relationship and has been very busy. He self-discontinued paroxetine about 4 weeks ago after reading information online about the risk of sexual dysfunction with paroxetine. He denies experiencing sexual dysfunction, but did not want to take the chance. He refuses to be on an SSRI/SNRI, but would like another pharmacologic option because he has noticed return of some symptoms since stopping paroxetine. What should you discuss with L.V. and how should treatment proceed?

It is important to encourage L.V. to discuss any medication questions or concerns with his provider before making any self-directed changes. Among the SSRIs/SNRIs, paroxetine has been reported to have the highest potential for sexual dysfunction.[80,81] Given that L.V. is refusing an SSRI/SNRI, a reasonable next option would be pregabalin. Although GAD is an off-label indication for pregabalin, there is substantial evidence supporting its use, and it is recognized as second-line therapy in clinical practice guidelines.[25,54,55,82] Educate L.V. that pregabalin's incidence of treatment-emergent sexual dysfunction is uncertain and other possible side effects may occur (eg, drowsiness, dizziness).[83] Discuss the potential risk of dependence and abuse and to avoid alcohol use. Initiate pregabalin at 150 mg/day in two to three divided doses followed by weekly increases of up to 150 mg/day, based on patient response and tolerability.

SYMPTOMS AND MANAGEMENT OF BENZODIAZEPINE WITHDRAWAL

CASE 83-3

QUESTION 1: T.B., a 48-year-old female, is prescribed diazepam 10 mg bid for its muscle relaxant effects after sustaining back and other injuries from a collision between her road bike and an automobile 7 months ago. However, she has been taking diazepam 20 mg bid for the past 2 weeks, because she likes how it makes her feel. Five days ago, T.B. ran out of diazepam, and was unable to refill her prescription, because it is 10 days early. A brief mental status examination reveals mild confusion and irritability. Physically, T.B. is trembling and reports nausea and insomnia. Her medical history indicates no current medical problems or psychiatric illnesses, and T.B. denies the use of tobacco, alcohol, or other drugs of abuse.

How should T.B. be treated?

Because T.B. has not taken her prescribed diazepam for 5 days, it is likely she is experiencing a withdrawal syndrome from long-term benzodiazepine use. Her mental and physical symptoms are consistent with benzodiazepine withdrawal. The benzodiazepine withdrawal syndrome implies some degree of physical dependence, and its onset, duration, and severity can vary according to dose, duration of treatment, speed of withdrawal, and elimination half-life of the agent used.[75,76] Withdrawal symptoms that follow discontinuation of agents with short half-lives usually appear within 1 to 2 days, and may be more intense and shorter in duration than after discontinuation of long-acting benzodiazepines. Withdrawal symptoms usually appear 4 to 7 days after discontinuation of long-acting agents and may last several weeks. Symptoms of benzodiazepine withdrawal, which are listed in **Table 83-7**, are generally mild when the drug is tapered gradually during discontinuation.[76] Rarely, serious symptoms such as life-threatening seizures or psychosis may occur during benzodiazepine withdrawal. General risk factors for seizures include head injury, alcohol dependence, electroencephalogram abnormalities, and use of other drugs that lower the seizure threshold.

Table 83-7

Symptoms of Benzodiazepine Withdrawal

Common	Less Common	Rare

Common	Less Common	Rare
Anxiety	Nausea	Confusion
Insomnia	Depression	Delirium
Irritability	Ataxia	Psychosis
Muscle aches or weakness	Hyperreflexia	Seizures
Tremor	Blurred vision	Catatonia
Loss of appetite	Fatigue	

Resumption of her previous diazepam dosage (40 mg/day) should effectively treat her withdrawal symptoms. However, because she is showing signs of sedative, hypnotic, or anxiolytic use disorder (cravings, using more than prescribed), it would be desirable to begin tapering diazepam.

Various dosage reduction regimens have been proposed for benzodiazepine discontinuation. Even when managing withdrawal from low-dose benzodiazepine use, doses should be reduced slowly for 4 to 16 weeks.[76] The rate of the drug taper should be individualized to the patient, but a general recommendation is a 10% to 25% decrease in the dosage every 1 to 2 weeks. The first half of the benzodiazepine taper (down to 50% of the original dose) is generally easier, and can proceed more quickly than does the last half of the taper.[76] In T.B.'s case, the discontinuation period may take several months.

In general, the same benzodiazepine the patient has been taking should be used to manage withdrawal. However, because withdrawal symptoms are more severe during discontinuation of short-acting compared with long-acting benzodiazepines, a long-acting agent can be substituted at an equivalent dosage (see Table 83-5) and then tapered.[76,77] In difficult cases, adjunctive medications, such as anticonvulsants, similar to carbamazepine, phenobarbital, and pregabalin, or propranolol, have been used to ease tolerability of the gradual withdrawal. However, propranolol does not affect the associated anxiety or decrease the seizure risk.[76,84]

BENZODIAZEPINE DRUG INTERACTIONS

CASE 83-4

QUESTION 1: N.P., a 20-year-old female college student, has been taking alprazolam 1 mg tid PRN for treatment of GAD for the past 2 months. She states that alprazolam has been very helpful for her GAD, but reports feeling to her provider that she is feeling especially stressed. She is having trouble balancing the increased workload of higher level courses with her social life, which includes a new relationship. She has no medical illnesses, but states she has suffered from several episodes of heartburn recently, which may be stress related. She is also interested in starting an oral contraceptive. N.P. smokes two packs of cigarettes per day and drinks up to three 12-oz caffeinated sodas per day. An oral contraceptive (Yaz®) is prescribed, and ranitidine is recommended for treatment of heartburn.

What potential drug interactions with alprazolam are present in this case?

The most significant pharmacodynamic drug interactions involve other CNS depressants such as alcohol, opioids, or barbiturates. These combinations can lead to additive CNS and respiratory depressant effects that can be deadly. Most important pharmacokinetic drug interactions involve agents that either inhibit or induce benzodiazepine metabolism through cytochrome P-450 (CYP) 3A4 or CYP2C19.[85] One clinically significant drug interaction occurs with the use of azole antifungals in combination with benzodiazepines. Azole antifungals are potent CYP3A4 inhibitors that can cause a 170% increase in the area under the curve of alprazolam.[86] Therefore, the dosage of alprazolam should be reduced by about one-third in patients receiving this combination. Because benzodiazepines have a relatively wide margin of safety, elevated plasma levels or prolonged elimination half-lives are unlikely to cause serious toxicity. However, they can lead to increased sedative and psychomotor effects, which may be clinically significant in certain cases. Conversely, increased benzodiazepine metabolism by hepatic enzyme inducers may result in medication ineffectiveness. Refer to a drug interactions database, such as Facts & Comparisons (http://www.wolterskluwercdi.com/) for additional information.

In N.P.'s case, the most important drug interaction is between alprazolam and the newly prescribed oral contraceptive, Yaz®. Estrogen-containing oral contraceptives can inhibit the CYP3A4 metabolism of benzodiazepines such as alprazolam, potentially resulting in increased side effects.[87,88] Thus, a reduction in the benzodiazepine dosage may be needed when oral contraceptives are added to ongoing benzodiazepine therapy, as in N.P.'s case. The clearance of LOT benzodiazepines that undergo glucuronidation can be accelerated by oral contraceptives, but this interaction is probably clinically insignificant.[61,87]

Cigarette smoking increases the clearance of some benzodiazepines (clorazepate, lorazepam, oxazepam), but has no effect on others (diazepam, midazolam, chlordiazepoxide).[89] Overall, the effect of smoking is unpredictable and is most likely to be important in patients who either stop or start smoking while taking a benzodiazepine. N.P. should be urged to quit smoking for the sake of her general health and to prevent substantial risks of serious cardiovascular events occurring in smokers taking oral contraceptives. If N.P. does quit, careful monitoring will be needed to determine whether any alprazolam dosage reduction is necessary. N.P. should also be encouraged to decrease her soda consumption because caffeine can increase anxiety and may worsen heartburn.

BENZODIAZEPINE USE IN PREGNANCY AND LACTATION

Case 83-4, Question 2: At her clinic visit 2 years later, N.P. is doing very well. She has graduated from college, is happily married, and states that she and her husband have decided to start a family. N.P. has discontinued her oral contraceptive in the hope of becoming pregnant soon, and has successfully quit smoking. N.P. takes alprazolam 0.5 mg bid or tid as needed, and wonders whether she should also stop taking this drug before she becomes pregnant. What is the teratogenic potential of alprazolam? What alternative treatments are available for the management of N.P.'s anxiety?

Early reports implicated diazepam in causing several birth deformities, including cleft lip or cleft palate and limb and digit

malformations, but later studies failed to support this association.[90–94] Most benzodiazepine anxiolytics are classified as pregnancy category D. However, pregnancy categories are gradually being removed and replaced with more helpful information about medication risks as per the Pregnancy and Lactation Labeling Rule (PLLR), indicating there is some evidence of fetal risk, but the benefits of the medication may outweigh these risks in certain patients.[90,92] Available evidence suggests that benzodiazepine use during the first trimester increases the risk of oral clefts by ~2.4-fold, but the absolute risk is increased only 0.01%. Benzodiazepines have not exhibited strong teratogenic effects, but it is always advisable to avoid drug use during pregnancy when possible, especially in the first trimester.[92,94]

In patients such as N.P., the benzodiazepine should be tapered and discontinued before she becomes pregnant. Nondrug treatments for her GAD such as relaxation therapy, meditation, biofeedback, or cognitive therapy may be helpful. If necessary, single or repeated small doses of benzodiazepines during the second and third trimesters are unlikely to have important adverse effects on the fetus. In these instances, an agent with a short half-life, such as lorazepam, should be considered.[94] Chronic or large doses, especially of long-acting agents, should be avoided because they may accumulate in the fetus. Perinatal sequelae in newborns of mothers who took benzodiazepines during pregnancy include withdrawal symptoms, sedation, muscle weakness, hypotonia, apnea, poor feeding, low birth weight, and increased risk of preterm birth.[91,95]

The clinical situation of unexpected pregnancy in a female maintained on benzodiazepines can also arise. Benzodiazepine dosages should be tapered as quickly as possible to the lowest dosage necessary and discontinued if possible. The postpartum period is a time of heightened risk of recurrence of anxiety disorders, and new mothers should be monitored carefully for signs of relapse.[96] Benzodiazepines are excreted readily in breast milk, and they should be avoided by nursing mothers, when possible, but use is not absolutely contraindicated.[97] If benzodiazepines are used,

short-acting agents with no active metabolites are recommended to avoid sedation, poor feeding, withdrawal, and other effects in the infant.[91,98]

BENZODIAZEPINE OVERDOSE AND USE OF FLUMAZENIL

Benzodiazepine overdose is characterized by respiratory and CNS depression. Overdose with benzodiazepines as the sole ingested agent is rarely life-threatening, and full recovery is the usual outcome.[99] Flumazenil is a benzodiazepine receptor antagonist effective in reversing sedation associated with benzodiazepine intoxication. The primary use of flumazenil is in reversing benzodiazepine-induced conscious sedation (primarily with midazolam) in patients who have been sedated for minor surgical or diagnostic procedures. Flumazenil is also approved for treating benzodiazepine overdose, but this use is controversial because of potentially serious complications (eg, supraventricular arrhythmia, seizure), and questions about its cost-effectiveness.[100,101] Flumazenil administration does not appear to decrease mortality or length of hospital stay in cases of benzodiazepine overdose; therefore, its use for this purpose has become limited.[100]

The most common side effects include agitation, dizziness, nausea, general discomfort, tearfulness, anxiety, and a sensation of coldness.[99] Rapid or excessive infusion has been associated with tachycardia and hypertension. Flumazenil is contraindicated in overdoses of any agent that decreases the seizure threshold, such as TCAs. Toxicology screening and an electrocardiogram (ECG) should be performed before flumazenil is administered. Because of a risk of seizures, flumazenil should also be avoided in patients with increased intracranial pressure or a known history of seizures or head injury, in those who have been receiving chronic benzodiazepine therapy, and in patients with a history of recent illicit drug abuse (eg, cocaine, heroin). Administration of flumazenil should occur only when acute seizure management measures are available.

PHYSIOLOGIC VARIABLES INFLUENCING BENZODIAZEPINES

CASE 83-5

QUESTION 1: B.G., a 72-year-old male, is brought to the emergency department (ED) by his wife after being involved as the driver in a minor car accident. He has no physical injuries except for several small abrasions caused by the car airbag deployment. However, B.G. appears drowsy, is mildly confused, and has an unsteady gait. A toxicology screen reveals no alcohol or other substances, except for clonazepam, which his provider prescribed 10 months ago. B.G.'s wife states he has been taking clonazepam 0.5 mg bid, and it has been remarkably effective in improving his anxiety. B.G., who is 68 inches (172.72 cm) tall and weighs 250 pounds (113.39 kg), has moderate liver disease caused by years of heavy drinking. He has successfully maintained his sobriety for nearly 2 years. It is determined that B.G. is experiencing adverse effects of clonazepam, probably caused by drug accumulation.

What factors could be influencing disposition of clonazepam in this patient?

Benzodiazepine pharmacokinetics can be affected by various physiologic factors, such as aging, sex, obesity, liver disease, kidney disease, and ethnicity.[102-105] Pharmacokinetic and pharmacodynamic alterations may have clinically significant implications that have the potential to impact patient safety. Several of these factors are present in this case, and may have contributed to the accumulation of clonazepam with resulting adverse consequences.

B.G.'s age may influence clonazepam disposition. Reductions in both CYP3A4 and CYP2C19 activity have been reported to occur with aging. The glucuronidation metabolic pathways are minimally affected with age, so not such effect is seen with the LOT benzodiazepines.[61] Other factors contributing to longer benzodiazepine half-lives in the elderly include decreased hepatic blood flow and increased volumes of distribution of lipid-soluble compounds because of decreased muscle mass and increased fat. Increased volume of distribution can increase a drug's half-life in the absence of any clearance changes. As described in Case 83-5, Question 1, older patients are more sensitive to the sedative and psychomotor and, especially, cognitive impairing effects of benzodiazepines. For these reasons, benzodiazepines should be avoided in the elderly. In rare cases where use is necessary, the recommended benzodiazepine dosages for patients older than age

65 years are generally one-third to one-half of those used in healthy adults.

Sex also may influence benzodiazepine clearance, but studies yield mixed results.[87,106,107] Females have been reported to have higher CYP3A4 and CYP2C19 activities than do males, which may partially explain these findings. Increased CYP3A4 activity in females disappears after menopause, which may necessitate the use of lower benzodiazepine dosages during the postmenopausal period. Females have slower glucuronidation metabolic processes than do males, resulting in lower clearance of the LOT benzodiazepines.[61,87]

Obesity and liver impairment are other physiologic factors relevant to B.G.'s case. Obesity increases the volume of distribution of benzodiazepines and the extent of accumulation of long-acting agents. Significant changes in the elimination half-lives of lorazepam and oxazepam are not observed in patients with obesity. Liver dysfunction can reduce benzodiazepine elimination rates and prolong their half-lives, resulting in recommendations for decreased dosages. The pharmacokinetics of the LOT benzodiazepines are unaffected by liver disease.

Decreased protein binding of benzodiazepines can occur in patients with renal insufficiency, which may lead to increased free fractions of highly protein-bound agents. However, no significant changes in clearance or volume of distribution of free drug have been noted. Regarding ethnicity, up to 25% of Asians are CYP2C19 poor metabolizers. Decreased clearance of a variety of CYP2C19 substrates, including diazepam, has been reported in Asian patients.[108]

In summary, the physiologic factors that can alter benzodiazepine disposition in B.G. are his age, obesity, male sex, and liver disease. Accumulation of clonazepam owing to these combined effects probably led to his mental status changes. If continued benzodiazepine therapy is deemed necessary for B.G., lorazepam or oxazepam would be preferred agents for anxiety because they are less affected by aging, obesity, liver disease, or drug interactions.

Temazepam is also less affected by these factors, but is primarily a sedative/hypnotic.

Benzodiazepine dosage equivalencies, which are based on relative potencies, can be used to determine an equivalent dose for the selected agent (see Table 83-5). However, as mentioned earlier, these equivalencies are inexact, and dosing conversions should take patient variables and usual dosage ranges into consideration. For example, B.G. had been taking 1 mg/day of clonazepam, so the calculated equivalent lorazepam dosage is 2 mg/day. Because of his age and recent reaction at this dose, a somewhat lower initial dose of 0.5 mg bid or tid (1–1.5 mg/day) would be indicated, accompanied by careful monitoring for adverse effects or withdrawal symptoms.

However, switching to a nonbenzodiazepine agent would be a better treatment option for B.G. for several reasons. First, B.G. is older than age 65, and geriatric patients are more sensitive to the sedative, cognitive, and psychomotor effects of benzodiazepines compared to younger patients.[66] Second, given his history of alcohol misuse, prescribing B.G. a controlled substance should be avoided. Lastly, B.G. has been using his benzodiazepine as maintenance treatment for anxiety for 10 months. Benzodiazepines are indicated as bridging or rescue medications for short-term use (<12 weeks).

Buspirone Therapy

Case 83-5, Question 2: Several days after recovery from clonazepam intoxication, you discuss your concerns about benzodiazepine use with B.G. He agrees and expresses a desire to discontinue benzodiazepine use. He is especially concerned about the risk of getting into another car accident or falling and hurting himself. The decision is made to switch B.G. from clonazepam to buspirone. How does the clinical profile of buspirone compare with benzodiazepines?

Buspirone lacks CNS depressant effects, sedation, cognitive or psychomotor impairment, respiratory depression, and muscle relaxant or anticonvulsant effects.[49] This makes buspirone useful in older patients who may have a variety of chronic medical conditions.

Buspirone is generally well tolerated, and possible side effects include mild nausea, dizziness, headache, and initial nervousness.[109] Unlike many antidepressants, buspirone does not adversely affect sexual functioning and has actually improved sexual functioning in some patients with GAD.[50] Buspirone has minimal potential for abuse and is not classified as a controlled substance. It does not produce physical dependence or withdrawal syndromes on discontinuation, even after long-term therapy.[49,110] It also does not interact with alcohol or other CNS depressants and is relatively safe in overdose.[49]

Buspirone is as effective as benzodiazepines such as alprazolam, oxazepam, lorazepam, diazepam, and clorazepate in the treatment of GAD.[109,110] As with antidepressants, buspirone is more effective than are benzodiazepines in treating the cognitive symptoms of anxiety. However, the anxiolytic effects of buspirone are more gradual in onset than are benzodiazepines. Anxiolytic effects are observed within the first 7 to 10 days, but 3 to 4 weeks may be needed for optimal results. Buspirone must be taken on an ongoing basis if it is effective, and the drug should not be taken on an as-needed basis.

SWITCHING FROM BENZODIAZEPINE TO BUSPIRONE THERAPY

Case 83-5, Question 3: How should B.G. be switched from benzodiazepine to buspirone therapy?

Because buspirone does not bind to the benzodiazepine receptor to modulate GABA, it is not effective in preventing or treating benzodiazepine withdrawal. Thus, when patients are converted from benzodiazepine to buspirone therapy, the benzodiazepine must be discontinued gradually. Because it takes several weeks for the full therapeutic effects of buspirone to occur, it can be initiated before the benzodiazepine taper begins. This may indirectly ease

benzodiazepine withdrawal by providing extra anxiolytic coverage during the benzodiazepine taper period.[111]

Administration with food may significantly increase bioavailability by decreasing the first-pass effect. Therefore, it is recommended that buspirone dosages be lowered in patients with compromised renal or hepatic function and that use of the drug be avoided in cases of severe impairment. Buspirone is metabolized by CYP3A4, and coadministration of CYP3A4 inhibitors, including grapefruit juice, can result in significant increases in buspirone levels.[49] Because of buspirone's wide margin of safety, even large increases in its plasma levels may be tolerated. However, buspirone should be avoided in patients taking monoamine oxidase inhibitors (MAOIs) and used cautiously in combination with high-dose antidepressants because of the risk of serotonin syndrome.

B.G. has been taking clonazepam for several months, and the drug needs to be withdrawn gradually during a period of at least 4 to 8 weeks, although a longer taper may be better tolerated. B.G. can be started on buspirone during this taper. The usual recommended starting dosage of buspirone is 15 mg/day given in two to three divided doses, but a lower dosage (10 mg/day given as 5 mg bid) is indicated in B.G. because of his older age and liver disease. Twice-daily dosing is preferred to facilitate compliance, and is comparable in efficacy and tolerability to three-times-daily dosing.[112] The daily dosage may be increased in 5-mg/day increments at least every 3 to 4 days. Optimal anxiolytic doses generally range from 20 to 30 mg/day, with 60 mg/day being the recommended maximum. There are no specific guidelines for adjusting dosages in patients with liver impairment; therefore, dosage titrations in B.G. should be made slowly, according to his response and side effects.

PANIC DISORDER

Diagnostic Criteria

The hallmark characteristic of panic disorder is the occurrence of sudden and distinct panic attacks, which are marked by an overwhelming wave of symptoms and feelings, reaching their peak within 10 minutes. Symptoms are listed in **Table 83-8**. To meet diagnostic criteria, at least one of the attacks must be followed by four or more symptoms lasting at least 1 month, including persistent worry or concern about the consequences of the attack or significant behavior change related to the attack.[1] Experiencing less than the four required symptoms to fulfill diagnostic criteria is termed a *limited symptom attack*. Three types of panic attacks have been defined with regard to the context in which they occur: unexpected or uncued panic attacks (the attack is not associated with a situational trigger); situationally bound panic attacks (the attacks invariably occur on exposure to a situational trigger); and situationally predisposed panic attacks (the attacks are more likely to, but do not invariably, occur on exposure to a situational trigger).[1]

Table 83-8

Symptoms of Panic Disorder

Palpitations, pounding heart, or increased heart rate
Sweating
Trembling or shaking
Sensations of shortness of breath, smothering, or choking
Chest pain or discomfort
Nausea or abdominal distress
Feeling dizzy, unsteady, lightheaded, or faint
Derealization or depersonalization
Fear of losing control or going crazy
Fear of dying
Paresthesias
Chills or hot flushes

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. American Psychiatric Association; 2013.

Although panic attacks are the hallmark symptom of panic disorder, their occurrence can also be associated with depressive and other anxiety disorders.[1] For example, situationally predisposed panic attacks may occur in either panic or phobic disorders.

Nocturnal panic attacks, which awaken a person from sleep, are almost always indicative of panic disorder. Because panic attacks occur unpredictably, they often lead to generalized anxiety, constant fear of sudden attacks, or agoraphobia.

Epidemiology and Clinical Course

Although the estimated lifetime prevalence of panic disorder is 6.8%, ~10% of persons experience recurrent panic attacks that do not fulfill the diagnostic criteria for panic disorder, and nearly 30% experience a single isolated panic attack at some point in their lives.[15] The onset of panic disorder often occurs during stressful periods, usually in the late teens to mid-30s, with rare first onset in the elderly population.[8,87] Females are affected two to three times more often than are males.[87]

Panic disorder, similar to other anxiety disorders, is accompanied by marked degrees of psychiatric comorbidity. Common comorbidities include other anxiety disorders, affective disorders, personality disorders, and alcohol or substance use disorders, with the majority of patients suffering a major depressive episode at some point.[1,15,113,114] Patients with psychiatric and medical comorbidities have more severe symptoms, respond more slowly to treatment, have a lower chance of reaching remission, and have a greater suicide risk (particularly when depression or substance abuse are present) than those with panic disorder alone.[115] Although most patients experience episodic periods of remission and relapse, nearly one in five suffer almost continuously.[116]

Panic disorder is associated with very high rates of health care service utilization.[115] The vast majority of patients with panic disorder do not report feeling anxious, and report only physical symptoms, such as chest pain, GI problems, headache, dizziness, and shortness of breath, which contributes to misdiagnosis.[117] The poor recognition of panic disorder in primary care settings further increases use of medical services. Panic disorder is the underlying cause of symptoms in an estimated 10% to 30% of patients referred

to specialty vestibular, respiratory, or neurology clinics, and up to 60% of those referred for cardiology consultation.[1] It is not uncommon for patients to have been in the health care system for up to 10 years before they are correctly diagnosed.

Etiology and Pathophysiology

A neurobiologic model for panic disorder has been proposed in which the amygdala is the central hub of the fear circuit.[5,118] Various projections from the amygdala, including the hypothalamus and the LC, trigger autonomic and neuroendocrine responses resulting in anxiety and panic attacks. Patients with panic disorder have a heightened anxiety sensitivity (fear of anxiety-related sensations), and a variety of substances and situations may activate the anxiety and panic response.[118] Acute panic attacks are believed to be caused by dysregulated firing in the LC, as described previously (see section on Neurobiology of Anxiety), and hyperresponsiveness of the NE system may be an underlying cause for panic disorder.[119]

Other neurobiologic research suggests that patients with panic disorder have abnormal patterns of cerebral glucose metabolism in certain brain areas; abnormalities in GABA-A receptor, NE, 5-HT, and CCK functioning; decreased GABA-A benzodiazepine binding sites; abnormal regulation of neuroactive steroids that modulate GABA-A receptors; hyperactivation of the HPA axis; CCK-B receptor gene polymorphism; and are hypersensitive to carbon dioxide. These findings seem to predispose patients to panic attacks, although they require further study.[114,118-120]

Genetic and environmental influences both contribute to a familial pattern, in which people are 8 to 21 times more likely to develop panic disorder if they have a first-degree relative with the disorder.[1,18] Several studies have shown that distressing childhood events (eg, separation from parents and abuse) and behavioral inhibition during childhood (eg, excessive fear and avoidance of novel stimuli) are associated with markedly increased risks of developing panic disorder later in life.[118] No single biologic abnormality can explain

panic disorder, and further research is needed to define the complex interplay of the various pathophysiologic, genetic, and environmental findings in this illness.

Treatment of Panic Disorder

Approximately 70% to 90% of patients with panic disorder experience substantial relief with currently available treatments, which include both pharmacologic therapies and CBT.[1,114] Medications and CBT both are beneficial for reducing panic attacks initially, and their effects on phobic avoidance generally occur later. First-line medication treatments for panic disorder are SSRIs and venlafaxine XR. TCAs are generally considered second line, owing to decreased tolerability and more safety and drug–drug interaction concerns.[21,26,121,122] Benzodiazepines are no longer recommended as first-line treatment given their abuse liability, cognitive and psychomotor impairments, and risk of respiratory depression especially if used with other CNS depressants. The heightened anxiety sensitivity common in panic disorder makes patients especially vulnerable to initial antidepressant side effects, such as anxiety and agitation. For this reason, lower than usual starting doses of antidepressants are recommended in patients with panic disorder.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Paroxetine, sertraline, and fluoxetine are FDA approved for treating panic disorder, although other SSRIs (fluvoxamine, citalopram, escitalopram) are also effective in reducing the frequency of panic attacks, anticipatory anxiety, and associated depression.[21,26,122] Although low starting dosages are recommended (10 mg/day for paroxetine and citalopram, 25 mg/day for sertraline, 5–10 mg/day for fluoxetine and escitalopram) to minimize side effects, higher doses relative to antidepressant doses are usually required for response. The recommended target dosage range is 20 to 40 mg/day for

paroxetine, citalopram, and fluoxetine, 100 to 200 mg/day for sertraline and fluvoxamine, and 10 to 20 mg/day for escitalopram for panic disorder.[121]

Venlafaxine XR is also FDA approved for treating panic disorder. The initial dose of venlafaxine XR should be 37.5 mg/day with a recommended therapeutic dose of 150 to 225 mg/day.[121] Duloxetine is not FDA approved for this indication, although it has some evidence supporting off-label use.[123]

Response to SSRIs and other antidepressants in panic disorder occurs gradually, over the course of several weeks. Reduced frequency of panic attacks usually begins within 1 to 2 weeks. A trial period of at least 6 weeks should be allowed to fully assess response, and continued improvements may be seen during a treatment period of 6 months or longer.[121]

BENZODIAZEPINES

The benzodiazepines alprazolam and clonazepam are FDA approved for treating panic disorder, and are the most extensively studied agents of this class. However, lorazepam and diazepam, when used in equivalent doses, also appear effective.[117,121]

Benzodiazepines may be utilized short term, while waiting for antidepressant medications to reach full effect. Benzodiazepines may also be appropriate for some patients who have failed several antidepressants or with severe, refractory symptoms. Individuals with panic disorder may need higher doses of benzodiazepines for response than do patients with other anxiety disorders.[124] This may be related to reduced sensitivity of benzodiazepine binding sites in panic disorder.[125] An alprazolam dosage range of 4 to 6 mg/day is effective for most patients with panic disorder, but others may require up to 10 mg/day for optimal response. The total daily dose usually needs to be taken in three or four divided doses to minimize breakthrough anxiety or panic attacks before the next scheduled dose because of fluctuating serum levels given its relatively short duration of action. Patients with panic disorder are especially sensitive to benzodiazepine withdrawal effects. For these reasons,

using the longer acting benzodiazepine clonazepam (1–2 mg/day dosed bid) may be preferred over alprazolam.[124] The risks and benefits of benzodiazepine use should be carefully considered, especially in older adults, patients with a history of substance abuse, or patients with comorbid respiratory disease.

OTHER ANTIDEPRESSANTS

TCAs were the first medications widely used in the treatment of panic disorder. Imipramine (100–300 mg/day) and clomipramine (50–150 mg/day) are as effective as alprazolam, but are less well tolerated.[126] Evidence for most other TCAs is lacking.[21,26,121,122] Clomipramine appears to be more effective than are other TCAs for panic disorder, perhaps because of its greater serotonergic effects.[127] Despite using lower initial doses to minimize the anxiety-like side effect, many patients discontinue therapy because of poor tolerability.

Among the MAOIs, phenelzine is often heralded as being remarkably effective in the treatment of panic disorder, but this claim is based on studies conducted before the publication of the initial diagnostic criteria for panic disorder in 1980.[121] No recent MAOI studies are available to assess phenelzine's efficacy within the context of current diagnostic and treatment standards. It is generally an option of last resort for treatment-refractory cases because of the many clinical disadvantages of MAOIs relative to other antidepressants (see Chapter 86, Depressive Disorders).

Several open-label studies suggest that mirtazapine may also be beneficial in treating panic disorder.[21,121] Mirtazapine may be useful in patients who do not respond to SSRI therapy.[121] A recent open-label study of vortioxetine indicated potential benefit in panic disorder.[128] However, no randomized controlled studies (RCT) have been completed evaluating the efficacy of newer antidepressant agents, vortioxetine or vilazodone. The high medication cost is a potential barrier to their use.

MISCELLANEOUS AGENTS

Other medications that are reportedly effective in treating panic disorder include anticonvulsants (valproic acid, levetiracetam, gabapentin) and second-generation antipsychotics (primarily, risperidone and olanzapine) as either monotherapy or adjunctive therapy used in combination with an SSRI.[21,121] More information is needed before any of these can be routinely recommended for treating panic disorder.

NONPHARMACOLOGIC TREATMENTS

CBT, including exposure treatment and relaxation training, is also established as being effective in panic disorder.[114,121] The cognitive theory of panic disorder is based on the observed heightened anxiety sensitivity in these patients, and asserts that physical anxiety sensations are misinterpreted as being serious or life-threatening. These fears trigger a cycle of further worsening anxiety symptoms that finally progress to a panic attack. Reversing the cognitive component of this vicious cycle is an integral part of CBT, and is important in producing lasting therapeutic effects of treatment.[121] Breathing retraining and exposure to fear cues are key components of behavioral therapy. Some studies have found medications to be superior to CBT in the treatment of panic disorder, whereas others report opposite results.[121,129] Combining medication with CBT can be useful to increase response/remission rates in those with severe symptoms or a partial response and to improve relapse rates during pharmacotherapy discontinuation attempts.[21,124,130]

Clinical Presentation and Differential Diagnosis of Panic Disorder

CASE 83-6

Question 1: S.K., a 24-year-old female graphic artist, presents to the ED with chest pain, difficulty breathing, dizziness, and nausea. She describes feeling “as if my head is going off in space and I am outside my body.” These attacks often escalate quickly, peaking within 10 minutes and then start to subside within 30 minutes. She states she has been under extreme stress lately because of the

poor economy, and has conflicts with her landlord as a result of nonpayment of the rent on her art studio. S.K. fears she has had a heart attack or stroke brought on by her stressful life. S.K. recently visited her family provider for the same symptoms; however, a complete physical examination and laboratory workup yielded no abnormalities. She states her first “attack” occurred suddenly about 5 months ago while she was shopping for oil paints at the art supply store, and she can never predict when they will occur. Since then, her symptoms have become more severe and frequent, and she has started isolating herself in her studio for fear they will return when she is in public. S.K. uses marijuana “to relax” and occasionally drinks alcohol, less than weekly. She has suffered from depression in the past and was hospitalized for one severe episode 2 years ago. An ECG is performed and found to be normal. The provider’s diagnosis is panic disorder with agoraphobia.

What clinical features of panic disorder does S.K. display, and what are the important factors in the differential diagnosis of panic disorder?

S.K. exhibits many typical characteristics of panic disorder. As illustrated in this case, the first panic attack typically occurs without warning while the person is involved in a normal everyday activity and lasts 10 to 30 minutes. Panic attacks are extremely terrifying, and usually leave the sufferer feeling anxious and convinced something is medically wrong. As with S.K., it is not uncommon for patients to make ED visits after or during panic attacks, believing they have had a heart attack or any other serious event. Unfortunately, panic disorder is often not recognized in primary care settings, and no medical cause for the symptoms can be identified. Faced with findings that they are apparently healthy, patients may make repeated ED visits and consult different doctors and specialists in an attempt to uncover a physical explanation for their frightening symptoms.

S.K. exhibits the following target symptoms of panic disorder: chest pain, shortness of breath, dizziness, abdominal distress, and loss of control. Agoraphobia is present because she avoids leaving her studio because of her fear of having panic attacks. Other factors consistent with a diagnosis of panic disorder include her young age, female sex, and lack of abnormal physical findings. This case also illustrates the association between onset of panic disorder and stressful life events, its common association with depression, and

the frequent lack of recognition of panic disorder in primary care settings.

Because different substances or medical conditions can cause severe anxiety and panic, it is necessary to rule out these potential causes for panic attacks.[117] Notable triggers of panic attacks include caffeine, alcohol, nicotine, nonprescription cold preparations, cannabis, amphetamines, and cocaine (see Table 83-2).[117] S.K. uses marijuana, which can be associated with panic symptoms. Although chronic moderate-to-severe use of marijuana may complicate the treatment of panic disorder, it appears that infrequent marijuana use does not adversely affect treatment.[131,132] S.K. does not endorse chronic, severe marijuana abuse, but if she does not adequately respond to treatment, this might be further explored. Medical illnesses that can cause panic attacks include thyroid dysfunction, asthma, chronic obstructive pulmonary disease (COPD), mitral valve prolapse, and seizure disorders.[133] Panic attacks can also occur with other anxiety disorders. However, in these cases, the panic attacks usually occur on exposure to a feared object or situation (in phobic disorders), an object of obsession (in OCD), or a stimulus associated with a traumatic stressor (in PTSD). S.K. reports that her panic attacks occur unexpectedly, and situationally bound or predisposed attacks are not evident; therefore, the features are consistent with panic disorder.

Treatment Selection for Panic Disorder, Selective Serotonin Reuptake Inhibitor Dosing Issues, and Combination Selective Serotonin Reuptake Inhibitor–Benzodiazepine Therapy

Case 83-6, Question 2: S.K. is referred to a psychiatrist who decides to initiate treatment with paroxetine 20 mg every morning. Three days later, S.K. calls the doctor and states that her anxiety and panic attacks have greatly increased since she started taking paroxetine. The psychiatrist prescribes alprazolam 0.5 mg (tablets), and instructs S.K. to take one tablet as needed for the anxiety. What factors should be considered in the selection of an initial

medication treatment for panic disorder? Why is the prescribed treatment for S.K. inappropriate?

An SSRI is an appropriate first-line treatment for most patients with panic disorder.[21] In patients such as S.K. who have a history of depression, SSRIs may also help prevent relapse of depression. Patients with severe or distressing symptoms may initially require concurrent benzodiazepine therapy, which provides quick relief from anxiety and panic attacks until the therapeutic effects of SSRIs are evident. At that time, usually after several weeks, the benzodiazepine can be gradually discontinued. An SSRI–benzodiazepine combination is still a commonly prescribed initial treatment, even though guidelines recommend monotherapy unless initial anxiety is extremely high.[134] Although benzodiazepines are generally avoided in patients with a history of substance abuse, use of low doses for a limited time may be appropriate for some patients with disabling symptoms, as long as there is no current substance (especially alcohol or opioid) abuse.[21,75,121] Because of the levels of distress and impairment caused by S.K.'s panic disorder, combined SSRI–benzodiazepine therapy would have been a reasonable initial treatment. Because panic attacks peak quickly and generally last <30 minutes, an as-needed benzodiazepine is not helpful to prevent panic attacks. As such, scheduled benzodiazepine dosing is preferred over an as-needed dosing schedule during initial therapy.[121]

Paroxetine is an appropriate SSRI for the treatment of panic disorder, and may be less anxiety provoking than is a more activating SSRI such as fluoxetine.[27] Although paroxetine would not be the best initial choice in an older adult, owing to its anticholinergic effects, S.K. is only 24 years old, so this is a reasonable selection. However, when paroxetine is used for panic disorder, it should be started at a very low initial dose of 10 mg/day. In S.K.'s case, the prescribed 20-mg/day starting dose was too high. Also, scheduled versus as-needed benzodiazepine dosing would have been preferred. After 2 to 4 weeks, the benzodiazepine can be gradually discontinued while the SSRI therapy is continued and gradually

titrated to the target effective dose. The potential for drug interactions must also be kept in mind when SSRI–benzodiazepine combinations are used because certain SSRIs can inhibit benzodiazepine metabolism, leading to increased benzodiazepine side effects (see section on Benzodiazepine Drug Interactions).

Patient Counseling Information

Patients such as S.K. who are beginning SSRI therapy for the treatment of panic disorder should be counseled about possible increased anxiety during the first 1 or 2 weeks of treatment as well as other common SSRI side effects, including nausea, headache, sexual dysfunction, and either insomnia or sedation. Because these are dose-related effects, patients should inform their clinician of any problems, and a dosage reduction may be indicated. These adverse effects (with the possible exception of sexual dysfunction) usually subside after 1 to 3 weeks of continued treatment. It is also important to inform patients that it may take several weeks before beneficial effects of antidepressant treatment are seen, and 6 to 12 weeks or longer may be required for full response. Patients receiving benzodiazepines should be counseled about their use in providing anxiolytic coverage during the initial weeks of SSRI therapy, as well as their limited utility as long-term therapy. Other pertinent counseling information for benzodiazepine treatment should also be included (see Case 83-2, Question 4). The desired goals of therapy and likely duration of treatment should also be explained. Providing information about the nature of panic disorder, including reassurance that panic attacks are not life-threatening, is also important. Many clinicians recommend that patients keep a “panic diary” in which they record frequency of panic attacks, along with symptoms experienced during attacks.

Clinical Assessment and Goals of Therapy

Case 83-6, Question 3: Owing to her negative experience, S.K. refuses to continue paroxetine, so escitalopram is prescribed instead. After 1 week of escitalopram therapy at the initial dosage of 5 mg/day, S.K. is tolerating the medication well. The plan is to gradually increase escitalopram to 10 mg, then to 20 mg/day during the next several weeks. S.K. is also taking alprazolam, 0.5 mg bid to tid. What are the desired goals of treatment in this case, and how can S.K.'s response to treatment be assessed?

Five domains in panic disorder have been identified in which treatment outcomes should be assessed: (a) frequency and severity of panic attacks, (b) anticipatory anxiety, (c) phobic avoidance behaviors, (d) overall well-being, and (e) illness-related disability in various areas (work, school, family).[121] The treatment goals in this case are, first, to stop S.K.'s panic attacks, then to reduce her anticipatory anxiety, followed by reversal of phobic avoidance.[58] These outcomes should allow her to more comfortably leave her studio when required and, secondarily, improve her overall functioning and quality of life.

Several different instruments have been used to assess outcomes of treatment in panic disorder.[58] In addition to the panic diary, others include the Panic Appraisal Inventory, the Sheehan Patient-Related Anxiety Scale, the Panic and Agoraphobia Scale, and the Panic Disorder Severity Scale. The latter is currently considered by many experts to be the most useful because it evaluates outcomes in all five identified target domains of panic disorder.[58,121]

Course and Duration of Therapy

Case 83-6, Question 4: After 3 months of escitalopram therapy, S.K. reports that she has had no panic attacks in the past month and her functioning has improved dramatically. She is currently taking 20 mg/day of escitalopram, and gradually stopped taking the alprazolam 3 to 4 weeks ago. S.K. reveals she is painting regularly, selling some of her paintings, paying her rent, and she has begun dating again. S.K. is experiencing no significant side effects from escitalopram. She wonders how long she should continue taking it because she is doing so well. What is the recommended duration of treatment for panic disorder?

Long-term medication trials in panic disorder support the recommendation that treatment should continue for at least 6 to 12 months after acute response.[21,121] The benefits of maintenance pharmacotherapy in preventing relapse are well documented, although the optimal duration of treatment is a subject of continued debate among researchers of panic disorder. Maintenance treatment gives patients time to resume normal lifestyles and to reestablish daily activities after acute cessation of panic attacks.

Escitalopram therapy should be continued at the current dosage for 3 to 6 more months. After a successful period of full remission, a trial of medication discontinuation may be attempted to determine whether continued treatment is necessary. Medication should not be stopped in patients who are experiencing stressful life events or substantial residual problems in any of the five domains (frequency and severity of panic attacks, anticipatory anxiety, phobic avoidance behaviors, overall well-being, and illness-related disability in work, school, and family).[121] When a medication is discontinued, it should be withdrawn gradually over several months, regardless of the class. Because of the devastating impact panic disorder can have, reinstitution of drug treatment is indicated if relapse occurs. Long-term treatment with antidepressants, and benzodiazepines if necessary, is generally successful in maintaining treatment benefits without detrimental effects or dosage escalations.

SOCIAL ANXIETY DISORDER AND SPECIFIC PHOBIAS

Classification and Diagnosis of Phobic Disorders

The *DSM-5* includes two primary types of phobic disorders: specific phobia and social anxiety disorder (formerly social phobia), with symptoms presented in **Table 83-9**.[1] These disorders involve excessive or unreasonable fears and lead to avoidance behavior to minimize anxiety, for a duration of at least 6 months. The main

difference between specific phobias and social anxiety disorder is that the former involves fear and avoidance of specific stimuli and not a general fear of social situations.

Table 83-9

Symptoms of Social Anxiety Disorder (Social Phobia) (Items 1–5) and Specific Phobia (Items 2–5)

- Marked and constant fear of one or more social situations in which the person is exposed to unfamiliar people or possible scrutiny by others and the person fears humiliation or embarrassment
- Experiencing the situation causes an immediate anxiety response
- Feared situation is avoided or experienced with intense anxiety or distress.
- Feared situation exceeds the true risk associated with the social situation according to sociocultural norms.
- Fear or avoidance significantly interferes with the person's normal routine or activities or causes marked distress.

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. American Psychiatric Association; 2013.

SOCIAL ANXIETY DISORDER

Social anxiety disorder manifests as intense irrational fear, anxiety, or avoidance of scrutiny or evaluation by others in social situations because of concerns about humiliation or being made to appear ridiculous.[1] A defining feature is that the fears and anxiety are confined to social situations (eg, speaking to people, attending social gatherings, eating or drinking in public, using public restrooms, public speaking), and patients are usually symptom free when alone. If the fear is strictly confined to speaking or performing in public, a *performance-only* specifier is applied to the diagnosis. Common symptoms seen in social anxiety disorder include blushing, muscle twitching, and stuttering, in addition to other typical symptoms of anxiety. Panic attacks may also occur in either specific phobia or social anxiety disorder on exposure to the feared object or situation. However, social anxiety disorder is differentiated from panic disorder

in that it involves the fear of scrutiny by others, rather than the fear of having a panic attack.

SPECIFIC PHOBIAS

Specific phobias are coded by one of five specifiers: animal (eg, insects, dogs, spiders), natural environment (eg, heights, water, storms), blood–injection–injury (eg, blood, injury, medical procedures), situational (eg, flying, bridges, elevators), or other.[1] Significant impairment of functioning or marked distress must be present for a diagnosis of specific phobia to be warranted. For example, fear of flying might constitute a diagnosis of specific phobia in a person whose job requires airplane travel, but it would not impair functioning in someone who never has occasion to fly.

First-line management of specific phobias involves avoidance of the stimuli or exposure-based psychotherapy, such as CBT or virtual reality exposure. Medications are not generally considered beneficial, because pharmacotherapy for specific phobia is largely understudied and psychotherapy is extremely successful. Benzodiazepines effectively reduce anxiety associated with a phobic trigger, but they may also interfere with the efficacy of these exposure therapies.[21,26,122]

Social Anxiety Disorder

EPIDEMIOLOGY AND CLINICAL COURSE

In the United States, the lifetime and past-year prevalence of social anxiety disorder is ~13% and 7%, respectively.[15,135] The male-to-female prevalence ratio is ~2:3.[9] Social anxiety disorder usually begins early in life, with a mean onset between ages 14 and 16 years.[136] More than 50% of patients are affected before adolescence, and a history of shyness and behavioral inhibition throughout childhood is common.[136] Unless effectively treated, the clinical course is often chronic, unremitting, and lifelong, and only 20% to 40% of patients are reported to recover after 20 years of living with this condition.[135]

COMORBIDITY AND CLINICAL SIGNIFICANCE

Comorbidity in social anxiety disorder is high, with an estimated 70% to 90% of individuals having at least one other psychiatric disorder in their lifetime.[1,135,136] Common comorbid conditions include simple phobia, MDD, GAD, panic disorder, body dysmorphic disorder, and alcohol abuse. Because of its early onset, social anxiety disorder usually precedes the development of comorbid disorders. Alcohol is commonly used to decrease anxiety in social situations. The risk of suicide attempts is high, especially in those with both social anxiety disorder and another psychiatric illness, such as depression.[9]

Because social anxiety disorder usually begins during the teenage years, it can seriously interfere with development of normal social skills, achievement of full academic and career potentials, and abilities to form interpersonal relationships.[137] This leads to functional disabilities that may persist for a lifetime. Social anxiety disorder is associated with unemployment, lower levels of education, and dependence on public financial support systems.[9] People with social anxiety disorder are less likely to marry, and more than half report moderate-to-severe impairments in their abilities to carry out ordinary daily activities.[137]

ETIOLOGY AND PATHOPHYSIOLOGY

Social anxiety disorder is a familial disease, but the relative contributions of genetic versus environmental influences have not been differentiated.[18] Early factors predisposing to its development include anxious behavior modeling in parents and parental overprotection.[1] Shyness in children, which is associated with later development of social anxiety disorder, has been linked to a specific genetic polymorphism of the serotonin transporter promoter region.[138]

Biologic studies suggest that performance-only social anxiety disorder has a different underlying pathophysiology involving noradrenergic system dysfunction. Conversely, in nonperformance-only social anxiety disorder, there is substantial evidence for dopaminergic (decreased dopamine neurotransmission) and

serotonergic dysfunction (5-HT type-2 receptor hypersensitivity).[139-141]

TREATMENT OF SOCIAL ANXIETY DISORDER

Early detection and treatment of social anxiety disorder are vital in reducing lifelong functional consequences and may prevent development of comorbid disorders. Because of the nature of the disorder, some sufferers are reluctant to seek treatment resulting in an average treatment delay of 16 years.[142] Those who seek help, even in psychiatric settings, may not be diagnosed or treated appropriately.[136] Pharmacotherapy and CBT are both first-line options.[21] Although data do not support the routine use of combined modalities in the management of social anxiety disorder, clinicians should determine whether combined therapy would be useful on a case-by-case basis.[143]

Selective serotonin reuptake inhibitors and serotonin and norepinephrine reuptake inhibitors

As with other anxiety disorders, SSRIs, in addition to the venlafaxine XR, are considered the primary treatment option for most patients with social anxiety disorder,[136] for which paroxetine, sertraline, and venlafaxine XR are FDA approved.[143] Nonetheless, fluoxetine, fluvoxamine, citalopram, and escitalopram have also demonstrated efficacy in controlled clinical trials, although fluoxetine has negative evidence as well.[21,143] Preliminary evidence with duloxetine suggests this agent may be useful.[144]

Unlike patients with GAD and panic disorder, those with social anxiety disorder often tolerate standard antidepressant starting doses. Target doses for social anxiety disorder are typically within the normal antidepressant dosage ranges. It is thought that SSRIs exhibit a flat dose–response curve.[145] Although some individuals may require higher dosages, adequate time (2–4 weeks) should be allowed before the dosage is increased. Response to SSRIs occurs gradually, and an adequate medication trial to assess response should last at least 8 to 10 weeks. Many who experience minimal

response at week 8 may show a good response at week 12, and improvements have been found to continue throughout 16 weeks of treatment.[146]

Other antidepressants

The MAOIs, in particular phenelzine (60–90 mg/day), have also demonstrated marked efficacy for social anxiety disorder, but are reserved for SSRI nonresponders.[21,136,143] Case reports and open studies suggest that bupropion may be useful in treating social anxiety disorder, but controlled trials are needed to define its role.[136] Mirtazapine has conflicting evidence from small RCTs, but may be considered in SSRI nonresponders.[21] Imipramine is ineffective for social anxiety disorder, and TCAs (except clomipramine) are not among the recommended treatment options.[21,136,143] Likewise, nefazodone is not recommended given the risk of hepatotoxicity and conflicting evidence, including one negative RCT.[21]

Benzodiazepines

Benzodiazepines are generally considered second-line therapy for social anxiety disorder, because they have limited efficacy in treating psychiatric comorbidities and possess abuse/dependence potential. In clinical practice, benzodiazepines are commonly used in combination with SSRI therapy on an as-needed basis before participation in stressful social situations.[143] However, the efficacy of adjunctive benzodiazepines to decrease time to response or increase response rate is unclear.[147] The high-potency benzodiazepines may be useful as monotherapy in select patients. Clonazepam (1–3 mg/day) was markedly efficacious in one controlled study, whereas alprazolam (1–6 mg/day) showed only modest efficacy compared with placebo.[142]

β-Blockers and other miscellaneous agents

β-Adrenergic receptor blockers reduce peripheral autonomic symptoms of anxiety and, thus, are useful for performance-related

social anxiety disorder.[136] Propranolol (10–80 mg) and atenolol (25–50 mg) are the two recommended agents, and can be used on an as-needed basis (1–2 hours before the performance) to reduce performance anxiety symptoms such as tremors, palpitations, and blushing. A test dose should be tried before the actual occasion to assess tolerability.

Pregabalin is also considered to be an acceptable first-line agent, in the absence of comorbidities, that would benefit from an SSRI, based on placebo-controlled trials for acute management and relapse prevention.[21,148] It appears that a higher pregabalin dose (450–600 mg/day) may be necessary for effective treatment. In 2019, the FDA issued an alert warning of respiratory depressant effects with gabapentinoids in those taking other CNS depressant agents and/or with underlying respiratory impairment.[71] Other anticonvulsants, antipsychotics, and miscellaneous agents have also been reported to be effective in the treatment of social anxiety disorder, but they are considered second- or third-line treatments.[21,46,143] These include gabapentin, tiagabine, topiramate, valproate derivatives, olanzapine monotherapy, adjunctive aripiprazole, adjunctive risperidone, and atomoxetine.

Nonpharmacologic treatments

Several studies have demonstrated CBT to be comparable to medications in the treatment of social anxiety disorder.[149] Although medications may work faster, CBT is believed to result in longer lasting treatment gains, with effects persisting for 1 to 5 years. The cognitive therapy component changes maladaptive thought patterns, such as expectations of performing poorly and overconcern about negative evaluation by others.[149] The behavioral therapy component, as in other anxiety disorders, involves repeated exposure and practice performing in those feared situations. Social skills training can also be beneficial in improving interpersonal communication skills.

CLINICAL PRESENTATION OF SOCIAL ANXIETY DISORDER

CASE 83-7

QUESTION 1: S.H., an 18-year-old male, is brought for psychiatric consultation by his mother who reports that her son is extremely shy, and she is concerned about his ability to "fit in" at college. S.H. was referred to the psychiatrist by his primary care provider, who reports that S.H. is physically healthy. S.H.'s mother states he is a very bright young male who earned straight A grade in high school despite frequent absenteeism. He only has one close friend, and has never been on a date. S.H.'s mother says that during high school, S.H. rarely attended school social functions and spent much of his time in his room working on his computer. On graduation from high school, he received a full scholarship to a community college, but is quite anxious about going and is debating whether he should turn down the scholarship. When questioned by the psychiatrist, S.H.'s face turns bright red, and his voice shakes when he speaks. S.H. admits his behavior is not normal, but says he is afraid he might "do something stupid" when he is around people and becomes extremely embarrassed when he has to talk to anyone. He has wanted to ask a certain girl on a date for 3 years, but experienced severe anxiety attacks on the few occasions he tried to approach her. S.H. is afraid of being turned down, and believes no girl would ever want to date someone like him. The psychiatrist's diagnosis is social anxiety disorder.

What clinical features of social anxiety disorder are present in S.H.?

S.H. exhibits many characteristic features of the generalized type of social anxiety disorder. S.H. admits he does not like being around people for fear of embarrassment, and he generally avoids social situations, which are classic traits of social anxiety disorder. Symptoms of blushing and shaking voice are also common in social anxiety disorder, as well as other typical anxiety symptoms such as palpitations, trembling, sweating, tense muscles, dry throat, hot/cold sensations, and a sinking feeling in the stomach. S.H. also displays hypersensitivity to rejection and low self-esteem, and he realizes his behavior and fears are unreasonable. These symptoms and S.H.'s young age are consistent with a diagnosis of social anxiety disorder.

S.H.'s case illustrates the substantial disability that can result from this illness. S.H.'s anxiety disorder has deprived him of normal social development, making friends, dating, participating in social functions regularly, and pursuit of higher education. Future impairments throughout S.H.'s life are likely to be significant unless his anxiety is treated successfully.

TREATMENT SELECTION FOR SOCIAL ANXIETY DISORDER

Case 83-7, Question 2: The provider decides to initiate sertraline 50 mg every morning for S.H. Is the prescribed pharmacotherapy appropriate in this case?

Because S.H.'s generalized social anxiety disorder is severely affecting his life, medication treatment is indicated. SSRIs are first-line therapy for treating social anxiety disorder, and sertraline is a good choice because it is FDA approved for this indication. Although not applicable in this case, sertraline is also effective for many other psychiatric disorders commonly seen in patients with social anxiety disorder. The sertraline starting dose of 50 mg/day is appropriate for S.H., and 50-mg increment dosage increases can be made every 4 weeks according to response, up to a maximum of 200 mg/day. Escitalopram or paroxetine would also be reasonable choices. Signs of response may be seen within 2 to 4 weeks, but 8 to 12 weeks is usually required for optimal results. Patients with social anxiety disorder may be uncomfortable or reluctant to mention medication side effects such as sexual dysfunction, so providers should make it a point to ask about this. If available, CBT may also be combined with pharmacotherapy for S.H.

GOALS AND DURATION OF TREATMENT

Case 83-7, Question 3: What are the goals of treatment in this case, and how can S.H.'s response to treatment be objectively assessed? How long should effective therapy be continued?

Three principle domains of treatment outcomes have been defined for social anxiety disorder: symptoms, functionality, and overall well-being.[58] It is recommended that all three of these areas are assessed because even if all anxiety symptoms disappear, treatment is not clinically significant unless functioning also improves. The clinician-rated Liebowitz Social Anxiety Scale and the patient-rated

Sheehan Disability Scale can be used for measuring improvements in symptom and functional ability domains, respectively.[58] In S.H.'s case, the desired outcomes of treatment include reducing fear and avoidance of social situations, enabling him to comfortably interact socially and attend college, and improving his quality of life.

Several studies have examined relapse rates after double-blind discontinuation of effective treatment in social anxiety disorder.[143,146,149] Long-term studies have shown that sertraline, paroxetine, escitalopram, fluvoxamine CR, venlafaxine XR, pregabalin, and clonazepam prevent relapse of social anxiety disorder during continuation treatment.[21] Therefore, pharmacotherapy should be continued for at least 1 year after response.[136,143] After that time, a gradual medication discontinuation trial may be attempted with vigilant monitoring for signs of relapse.

POSTTRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

Diagnostic Criteria

PTSD and acute stress disorder occur in people who have experienced a severely distressing traumatic event. These disorders are characterized by symptoms of intrusive reexperiencing, avoidance features, autonomic hyperarousal, and negative cognitions and mood symptoms.[1] In addition to war veterans, PTSD also occurs in persons exposed to events such as natural disasters, serious accidents, criminal assault, rape, PHYSICAL or sexual abuse, and political victimization (eg, refugees, concentration camp survivors, hostages). The trauma does not have to involve physical injury to the PTSD victim. Witnessing someone else being injured or killed, being diagnosed with a life-threatening illness, and experiencing the unexpected death of a loved one are common types of trauma that may lead to PTSD.[1]

Symptoms of PTSD are presented in **Table 83-10**.[1] According to diagnostic criteria, the person must have exposure to actual or threatened death, serious injury, or sexual violence via directly experiencing the event, witnessing the event in person, learning the event occurred to a close family member or friend, or experiencing extreme exposure to aversive details of an event.[1] Specifiers indicate whether PTSD is delayed (after 6 months) onset in relation to the trauma and/or whether it is associated with dissociative symptoms.[1] Symptoms must persist for at least 1 month to meet the criteria for PTSD. *Acute stress disorder* is a separate diagnostic category in the *DSM-5*, and refers to cases in which symptoms last <1 month (but at least 3 days).[1] It involves many of the same clinical features as PTSD, and as with PTSD, symptoms must be severe enough to interfere with functioning.

Table 83-10

Symptoms of Posttraumatic Stress Disorder for Individuals Ages 6 Years or Older

1. Intrusion (eg, memories, dreams, dissociative reaction [such as flashbacks], intense distress that is experienced on exposure to stimuli associated with the traumatic event, or physiologic reactions to internal or external cues that reflect the event)
2. Avoidance (eg, avoidance of or efforts to avoid distressing memories, thoughts, or feelings or external reminders such as places, people, conversations about or related to the event)
3. Increased arousal including at least two of the following:
   - Sleep disturbances
   - Irritability or anger outbursts
   - Difficulty concentrating
   - Hypervigilance
   - Exaggerated startle response
   - Reckless or self-destructive behavior
4. Persistent negative alterations in cognition or mood associated with the event including at least two of the following:
   - Amnesia surrounding the event
   - Negative beliefs or expectations about oneself, others, or the world

- Distorted cognitions about the cause or consequence of the event where the individual blames themselves or others
- Negative emotional state
- Diminished interest or participation in activities
- Detachment or estrangement
- Lack of ability to experience positive emotions

Epidemiology and Clinical Course

In the United States, PTSD is associated with a lifetime prevalence of ~10% in the general population, and up to 24% among deployed serviceman from Iraq and Afghanistan.[150] PTSD is twice as common in females, although, overall, males are exposed to trauma more often.[153] An estimated 80% to 90% of individuals in the United States today will experience at least one event during their lifetime traumatic enough to lead to PTSD.[151]

Most people who are exposed to a traumatic event do not develop PTSD; ~90% of individuals experience a normal acute stress response to trauma and fully recover.[151] Risk factors for the development of PTSD include experiencing assaultive violence, more severe and chronic traumas, a history of depressive or anxiety disorders, lack of social support after the trauma, and experiencing dissociative or other intense symptoms during or soon after the trauma.[150-152] Previous exposure to trauma also increases the risk of developing PTSD after later traumas, and survivors of childhood sexual or physical abuse have been found to be especially vulnerable.[152,153]

Overall, 79% to 88% of patients with PTSD also suffer from other disorders in their lifetime, including MDD, alcohol or other substance abuse, GAD, panic disorder, and phobic disorders.[150,151,153-155] The risk of suicidality in PTSD is high and likely influenced by comorbid MDD.[156] Recent studies have also found associations with PTSD and coronary heart disease, traumatic brain injury, and sexual dysfunction.[157-159] PTSD causes significant functional disability and

has been associated with school failure, teenage pregnancy, unemployment, marital instability, legal problems, and impaired performance in the workplace.[160]

The course of PTSD is highly variable. Most patients who meet criteria for PTSD 1 month after trauma show spontaneous recovery within 6 to 9 months.[154] PTSD continues for years in an estimated 10% to 25%, and some patients experience a lifelong course of illness.

Etiology and Pathophysiology

Psychological trauma, especially that which occurs early in life or is chronic in duration, can cause persistent changes in various aspects of brain functioning and in neurobiologic responses to stress.[161] Evidence of altered NE, 5-HT, glutamatergic, GABA system, HPA axis, neuroendocrine, substance P, and opioid system functioning has been found in PTSD.[162-165] Stress-induced hyperactivity of central noradrenergic systems is believed to lead to the generalized anxiety and autonomic hyperarousal associated with PTSD.[163] Neurobiologic consequences of stress and trauma result in both structural and functional changes in the brain, including reduced hippocampal volume and excessive activation of the amygdala.[166] Genetic factors may also play a role in influencing vulnerability to the damaging effects of stress.[167]

Treatment of Posttraumatic Stress Disorder

Recent guidelines emphasize the importance of trauma-focused psychotherapies in the treatment of PTSD, even above pharmacotherapy. Non–trauma-focused psychotherapies may also be beneficial. Medications can also be useful in treating PTSD, and may be required alone or in combination with nonpharmacologic treatments, especially for patients with moderate or severe illness.[26,152,153,160,168,169] When assessing various treatment options for PTSD, it is important to consider effects on all four core symptom

clusters (reexperiencing or intrusive symptoms, avoidance, hyperarousal, or negative cognitions and mood symptoms). Not all PTSD treatments are effective for each domain.

The preferred first-line medications in PTSD are SSRIs or venlafaxine XR, but various other antidepressants may also be useful. Response to pharmacotherapy occurs very gradually, taking 8 to 12 weeks or longer. Partial response at 12 weeks of treatment may be followed by full remission after several more months of therapy; therefore, an adequate period should be allowed to fully determine response to a particular medication. Lack of improvement after 4 weeks of therapy indicates nonresponse, so alternative treatment strategies should be tried in these cases.[170] Although further research is needed, prevention of PTSD using various pharmacologic strategies has been evaluated in adults.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Sertraline and paroxetine are currently the only FDA-approved SSRIs for PTSD. Large controlled studies have demonstrated that both agents are effective and superior to placebo, as well as fluoxetine and venlafaxine XR.[171] They also have beneficial effects on depression and general anxiety symptoms, and have been associated with improvements in overall functioning and quality of life.[170,171] Citalopram, escitalopram, and fluvoxamine have shown efficacy in the treatment of PTSD in open trials, but randomized, double-blind, placebo-controlled studies have yielded negative results.[170,172] Finally, one small, naturalistic study in treatment-resistant males suggests that duloxetine may be effective in managing comorbid depression and PTSD.[173] However, in another small, prospective study in military veterans suggests that additional studies are warranted.[174]

OTHER ANTIDEPRESSANTS

Several open-label studies and case reports suggest nefazodone or mirtazapine is effective in treating core symptoms of PTSD.[165,175]

Nefazodone is not commonly used in practice, since the addition of an FDA black box warning for rare but serious, potentially fatal liver injury.[176] Although supporting evidence for mirtazapine is not as strong, it may be considered an appropriate alternative to SSRIs or venlafaxine in certain patients, such as patients with comorbid insomnia or sexual dysfunction from first-line antidepressants. The TCAs amitriptyline and imipramine and the MAOI phenelzine have also been found to be effective for PTSD in controlled trials. However, these agents are generally not recommended because of their poor tolerability and safety profiles.[153] Because of the relatively high risk of suicide in PTSD, TCAs can be especially dangerous in this population.

MISCELLANEOUS AGENTS

Various other medications have been used successfully in limited numbers of PTSD cases. Anticonvulsants carbamazepine, valproate, topiramate, tiagabine, gabapentin, oxcarbazepine, vigabatrin, pregabalin, levetiracetam, and lamotrigine have been studied with inconsistent results, mostly in case series and open-label trials.[21,26,171,175] These agents may be effective in certain patients, and can be useful for reducing irritability, impulsivity, and anger or violent outbursts, particularly in patients with bipolar disorder.[177] Anticonvulsants may also be effective for intrusive, reexperiencing, and hyperarousal symptoms. Atypical antipsychotic agents have been used effectively to treat PTSD-related psychotic symptoms and sleep disturbances, although evidence is limited, and side effect burden often outweighs potential benefit. Evidence is most substantial for risperidone and olanzapine, although there are studies showing benefit with aripiprazole and quetiapine as well. A recent meta-analysis suggests that these agents may help target symptoms of intrusion.[178] Conflicting evidence exists for the use of the β-adrenergic antagonist, propranolol, which has been studied in blocking memory consolidation, and therefore may prevent PTSD if administered within hours of the traumatic event.[179] Larger studies are needed to determine whether this is a useful preventive option.

Preliminary evidence supports the use of hydrocortisone for this indication, although additional studies are needed.[180] Benzodiazepines are generally ineffective in treating PTSD, and use of these agents is not recommended.[181] Benzodiazepine use during trauma-focused therapy is also associated with worse outcomes and should be avoided.[182]

The α_1-adrenergic antagonist, prazosin, dose at bedtime may decrease nightmares, increase sleep time, and reduce other core symptoms in patients with PTSD.[165,183] However, a recent study in veterans found no statistically significant difference in distressing dreams or sleep quality between prazosin and placebo groups.[184] Nonetheless, prazosin is still the most commonly used agent for PTSD nightmares, primarily because alternatives for treatment of nightmares are scarce. Alternatively, the α_2-adrenergic agonist clonidine has been studied for PTSD-related nightmares or symptoms of hyperarousal; however data are limit.[185]

NONPHARMACOLOGIC TREATMENTS

Trauma-focused psychotherapies are first-line options for PTSD.[186] These include trauma-focused CBTs (eg, cognitive processing therapy, prolonged exposure therapy) and eye movement desensitization and reprocessing (EMDR). Cognitive therapies teach patients how to reframe negative thinking, and seem to be most effective for symptoms of demoralization, guilt, and shame. Exposure therapies have patients confront traumatic memories or situations, and are better for reducing intrusive thoughts, flashbacks, and avoidance behaviors. EMDR involves patients recalling traumatic memories while being exposed to external stimuli. Studies are needed to further investigate the utility of virtual reality exposure therapy and transcranial magnetic stimulation in PTSD.[187,188] Trials of combined psychosocial therapies and medication are inconclusive, and require further investigation to determine superior effectiveness compared with either treatment strategy alone, but may be warranted in more severe cases.[189]

Clinical Presentation of Posttraumatic Stress Disorder

CASE 83-8

QUESTION 1: D.D. is a 42-year-old female who was attacked and raped 1 month ago in the driveway of her home as she was getting out of her car at night. She did not seek medical treatment at the time and waited several days before reporting the incident to anyone, including her family. She presents to her provider and reports that she cannot sleep, and she is irritable, anxious, and depressed. When asked about any recent stressors in her life, she finally tells her doctor about the rape. D.D. has no history of psychiatric illness, admits that her symptoms have appeared since the attack, and says she has never had any psychiatric problems until now. She states she has nightly nightmares, and becomes extremely anxious every time she gets out of her car when it is dark outside. She avoids driving in the evenings when possible. She is startled when the phone rings or when someone approaches her unexpectedly, and she freezes if she sees a male who bears any physical resemblance to her attacker. D.D. also states that memories of the rape often flash through her mind for no reason, although she tries hard not to think about it. The assailant has not been caught, and D.D. feels extremely guilty for not promptly reporting the crime. Her symptoms are interfering significantly with her ability to work, and have put a strain on her marriage.

What clinical features of PTSD does D.D. display?

Individuals with PTSD often present with nonspecific symptoms indicative of a generalized anxiety, depression, or substance use disorder. They may not realize or want to reveal an association between their symptoms and the trauma experienced. Careful evaluation by the clinician is required to elicit a pattern suggestive of PTSD. D.D. displays many target symptoms of PTSD, including reexperiencing/intrusive symptoms (eg, nightmares, recurrent memories), avoidance of the activity reminding her of the trauma (ie, driving at night), symptoms of increased arousal (eg, sleep difficulties, irritability, exaggerated startle response), and negative alterations in cognition (eg, guilt). In addition, she is experiencing feelings of depression, distress, marital problems, and impairment in occupational functioning as a result of her symptoms. The lack of any previous psychiatric illness combined with the temporal

relationship between the attack and her symptoms supports the presence of PTSD as opposed to another anxiety or depressive disorder. Because her trauma occurred 1 month ago, her condition would be classified as acute-onset PTSD.

Treatment Selection and Selective Serotonin Reuptake Inhibitor Dosing

Case 83-8, Question 2: What factors are important in the selection of an initial treatment for D.D.?

Trauma-focused psychotherapy is considered the preferred first-line treatment for PTSD, although there are also several first-line medication options. The pros and cons of the various trauma-focused psychotherapies and medication should be discussed with the patient. Provide the patient with information about the availability, time commitment, and therapy style of trauma-focused psychotherapy as well as potential medication side effects. Because D.D. is exhibiting moderate-to-severe PTSD symptoms, combining psychotherapy and pharmacotherapy may also be warranted. Patient preference and availability of trauma-focused therapy options are also important factors to consider when determining best initial treatment.

D.D. informs her provider that she does not want to initiate any type of psychotherapy and prefers medication treatment alone. An SSRI is the preferred initial medication treatment for most patients.[171] Sertraline is an appropriate choice of treatment in this case, and is FDA approved for PTSD. Low initial SSRI doses are recommended in PTSD, so sertraline can be started at 25 mg/day and gradually increased to the target dosage range of 100 to 150 mg/day, according to response and tolerability.[175]

Clinical Assessment and Goals of Therapy

Case 83-8, Question 3: What are the goals of treatment in this case, and how can D.D.'s symptoms be objectively assessed?

The first goal of treatment of PTSD is to reduce the core symptoms of reexperiencing/intrusion, avoidance, hyperarousal, and negative alterations in mood and cognitions. In D.D.'s case, these target symptoms include nightmares, intrusive memories, avoidance behaviors, irritability, hyperarousal, sleep difficulties, and guilt. Improvements should begin within the first 2 weeks and gradually continue over the course of 2 to 3 months. Secondary goals in this case include improving D.D.'s stress tolerance, decreasing her work- and marriage-related disability, and improving her quality of life. Other general treatment goals in PTSD include decreasing detrimental behaviors (use of alcohol or substances, risky activities, violence) and treating comorbid psychiatric conditions.

Several different rating scales have been developed to assess response to treatments in PTSD.[58] The most commonly used clinician-rated scales are the Clinician Administered PTSD Scale and the shorter Treatment Outcome PTSD Scale. The Clinician Administered PTSD Scale is most often used in clinical PTSD trials. The Sheehan Disability Scale is often used to assess functional impairment attributable to PTSD.

Case 83-8, Question 4: D.D. returns 3 months later, stabilized on sertraline 150 mg/day. She has had a significant reduction in flashbacks, and is able to drive at night again with only mild anxiety. Her relationship with her husband has improved, and she feels less irritable and depressed. However, D.D. continues to have nightly nightmares of her rape, which make it difficult to fall back asleep. She is only sleeping 3 to 4 hours a night. What treatment options can be offered to address her nightmares?

As long as D.D. does not have low blood pressure at baseline, prazosin is a reasonable off-label medication option for the treatment of PTSD nightmares, although evidence supporting efficacy is mixed. The recommended initial dosing for prazosin is 1 mg orally at bedtime. Prazosin doses >16 mg/day are not typically used in clinical

practice.[190] Prazosin maximum dosing is often further limited by dose-dependent hypotension. Females may be more sensitive to the effects of prazosin, and therefore doses >10 mg/day should be used with caution.[185] Start prazosin 1 mg orally at bedtime. Titration schedules vary, although it would be reasonable to titrate the prazosin in increments of 1 mg/day, with dose increases no sooner than every 3 to 4 days. Blood pressure monitoring is recommended with dose increase. Alternatively, D.D. may consider behavioral therapies such as CBT or EMDR.[191]

Course and Duration of Treatment

Treatment response in PTSD is more likely to occur when treatment is started within 3 months of the trauma.[153,160] There is no well-established definition of response in PTSD, but a decrease in symptoms by 30% to 50%, along with substantial functional improvement, is commonly used in clinical trials. Full recovery during treatment of PTSD is fairly uncommon, and partial responders to either medication or psychosocial therapies may benefit from adding another treatment modality. When an initial SSRI trial is ineffective, the patient may be switched to another SSRI or another antidepressant shown to be effective in PTSD.[21] Partial responders may benefit from the addition of a second medication, depending on which core symptoms predominate (see section on Treatment of Posttraumatic Stress Disorder).

For patients who respond, treatment should be continued for an additional 6 to 12 months for acute cases (when symptoms were present >3 months before treatment) and 12 to 24 months for chronic cases (when symptoms lasted >3 months before treatment).[153] Long-term SSRI treatment can prevent relapse of PTSD, especially in those who show good response during the first 3 months of therapy.[181] When pharmacotherapy is discontinued, it should be withdrawn gradually over the course of 1 to 3 months.

OBSESSIVE–COMPULSIVE DISORDER

Diagnostic Criteria

OCD is characterized by repetitive thoughts (obsessions) that cannot be ignored or suppressed voluntarily and/or repetitive behaviors (compulsions). The compulsions are designed to reduce anxiety associated with obsessions or to prevent some future event or situation; however, they are not actually connected to the obsessions in any realistic way or are excessive. Obsessions and compulsions result in marked distress, are time-consuming (>1 hour/day), or significantly impair functional ability.[1] Both obsessions and compulsions are unpleasant and disturbing to the sufferer, and are not associated with pleasure or gratification. This feature distinguishes OCD from certain other behaviors (eg, excessive gambling or shopping) often described as "compulsive."

OCD is a clinically heterogeneous disorder involving a broad range of symptoms with four primary OCD symptom dimensions: symmetry obsessions and repeating, counting, and ordering compulsions; contamination obsessions and cleaning compulsions; hoarding obsessions and compulsions; aggressive, sexual, and religious and related compulsions. Although specific symptoms in an individual may change with time, they usually remain within the same dimension.[192]

Epidemiology and Clinical Course

OCD is one of the least common mood–anxiety disorders with a lifetime risk and 12-month prevalence between 2% and 3%.[15] Although onset of illness ranges from very early childhood to adulthood, the mean onset of illness is 20 years, which is later than are most anxiety disorders. Males tend to have an earlier onset of illness (childhood) than do females (adulthood). Approximately one-fourth of patients experience symptoms by age 14, and onset after 30 years of age is rare.[1] Childhood-onset OCD may be a distinct

illness subtype.[195] There is usually a gradual onset of symptoms, although abrupt onset may occur during stressful periods and pregnancy.[1,193]

The course and severity of OCD are highly variable and unpredictable. The majority of patients with OCD will have a chronic course that waxes and wanes rather than an intermittent or episodic course. Fewer than 10% of patients will have a deteriorating course.[194] A 40-year naturalistic study found that although 83% of patients had improved at the end of the follow-up period, only 20% experienced full remission.[194]

OCD can have seriously detrimental effects on function such as abilities to socialize, study, work, make friends, and maintain good relationships with family and friends given the time spent obsessing and performing compulsions as well as avoiding situational triggers.[1,195] It is estimated that each person with OCD loses an average of 3 years' wages during his or her lifetime.[195] Quality-of-life ratings in patients with OCD indicate marked impairments, and are similar to those observed in patients with depression.

Although several effective treatments are currently available for OCD, there is an average delay of 7.5 years between onset and seeking medical evaluation for OCD.[195] This may be because most patients with OCD realize their symptoms are senseless, so they attempt to hide their disorder because of embarrassment. People with OCD often carry out their rituals privately, and may be very successful at concealing their symptoms from others. Initial treatment for OCD is commonly sought outside psychiatric settings, and the obsessive–compulsive symptoms are often missed. Clinicians across the health care system can incorporate four simple OCD screening questions into their practice to improve detection: Do you have to wash your hands over and over? Do you have to check things repeatedly? Do you have recurrent distressing thoughts you cannot get rid of? Do you have to complete actions again and again or in a certain way?[196]

Psychiatric Comorbidity and Obsessive–Compulsive Spectrum Disorders

Identification of comorbid conditions with OCD is important because it can influence treatment decisions. As with other anxiety disorders, OCD is often accompanied by psychiatric comorbidity in 60% to 90% of patients; affective disorders (eg, depression, bipolar disorder), anxiety disorders, and tic disorders being common.[1,21,26,194] Tics occur in 20% to 30% of patients with OCD. These individuals are believed to represent a distinct subtype of illness, where patients are more likely to be male, have an earlier onset (before age 10 years), experience more severe symptoms, and have a poorer response to SSRIs than do those with OCD alone.[197] Distinguishing OCD from obsessive–compulsive personality disorder (OCPD), a personality pattern characterized by rigid and inflexible preoccupation with rules, lists, order, and perfectionism, can be difficult. OCD and OCPD co-occur in a small percentage of patients. OCPD, however, does not involve distressing obsessions and compulsions.

OCD is classified as an illness within obsessive–compulsive and related disorders.[1] Other related disorders included are body dysmorphic disorder (preoccupation with an imagined or slight defect in appearance), trichotillomania (recurrent impulses to pull out one's hair), excoriation disorder (skin-picking), and hoarding disorder. As with OCD, many patients with these conditions have shown good response to treatment with serotonergic antidepressants such as SSRIs or clomipramine.[198]

Etiology and Pathophysiology

Because OCD displays such clinical heterogeneity, there may be several distinct etiologies for different subtypes of illness. Structural and functional brain imaging suggests that OCD is a neurologic disorder characterized by a hyperfunctioning circuit involving the frontal lobe and basal ganglia regions termed the *frontostriatal circuit*.[192] Abnormalities therein imply potential dysfunction in

glutamatergic, dopaminergic, and serotonergic neurotransmission. In support of this hypothesis, these abnormalities normalize after successful treatment of OCD with SSRI monotherapy and antipsychotic augmentation. Preliminary evidence with glutamatergic agents suggests a role in treatment. Furthermore, neuromodulation therapies (eg, deep brain stimulation, cycloserine-enhanced CBT) and neurosurgical techniques interrupting this circuit are often effective in the treatment of OCD. Aberrant activity in this system may lead to impaired executive function, decision-making, and memory because these cognitive domains are mediated by this system.

Besides biologic factors, twin and family studies support genetic influences, particularly in early-onset OCD cases.[18,199] Genetic studies have found associations between OCD and specific polymorphisms in the glutamatergic (high-affinity neuronal/epithelial excitatory amino acid transporters), dopaminergic (catechol-*O*-methyltransferase and dopamine D_4-receptor genes), and serotonergic (5-HT type 1Dβ and 5-HT type-2A receptor genes) pathways.[200-202] The heritability of OCD is estimated at 40%, with the remaining variation purportedly mediated by environmental factors (eg, perinatal events, trauma, stress, neuroinflammation).[192] An example of this is the autoimmune disease, called PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection). Reports describe children who developed sudden and severe tics and obsessive–compulsive symptoms after strep throat infections.[203] These children may be better treated with antibiotics or immunomodulatory therapies. The possibility of a PANDAS correlation should be considered in any child who develops abrupt onset of obsessive–compulsive symptoms and/or tics and has a history of pharyngitis within the past 6 months.

Treatment of Obsessive–Compulsive Disorder

Both medications and behavioral therapies are effective in the treatment of OCD. Behavioral therapy is vitally important for OCD,

and the combination of drugs plus behavioral therapy provides optimal treatment. All medications consistently effective as monotherapy are potent inhibitors of serotonin reuptake. These include the SSRIs, clomipramine, and the SNRI venlafaxine.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

SSRIs are the only first-line medication treatments for OCD, of which fluvoxamine, fluoxetine, paroxetine, and sertraline are FDA approved based on double-blind, placebo-controlled studies.[204] Citalopram and escitalopram also are effective, but with less evidence to support their use. No single SSRI is considered to be more effective than are the others in treating OCD, but some patients may respond to or tolerate one agent better than another.[204] Drug interactions may also influence SSRI choice. Fluvoxamine is a strong CYP1A2 and CYP2C19 inhibitor, which may increase concentrations of CYP1A2 substrates (olanzapine, clozapine, tizanidine, caffeine) or CYP2C19 substrates (omeprazole, diazepam). Fluoxetine and paroxetine are strong CYP2D6 inhibitors that may increase concentrations of CYP2D6 substrates such as atomoxetine, aripiprazole, tramadol, or dextromethorphan.[205]

Usual SSRI starting dosages can be used in OCD, but at least 4 weeks should be allowed before exceeding the targeted minimally effective dosages (fluvoxamine 200 mg/day, fluoxetine 40 mg/day, paroxetine 40 mg/day, and sertraline 100 mg/day).[204] SSRIs are generally considered to have a dose–response relationship such that higher SSRI doses may be required to effectively treat OCD.[26] In addition, several controlled studies support the efficacy of venlafaxine in the treatment of OCD.[206] Although other SNRIs (duloxetine, desvenlafaxine, milnacipran, or levomilnacipran) may ultimately show efficacy in the treatment of OCD, additional well-controlled studies are needed.[207]

CLOMIPRAMINE

Clomipramine was the first drug FDA approved for OCD treatment in 1989, and was considered the standard treatment for several years, until the SSRIs gained popularity. Many large well-controlled studies have documented that clomipramine is superior to placebo and significantly improves OCD symptoms in ~60% to 70% of patients.[194,206] Clomipramine is the only TCA recommended for OCD treatment, because others have not proved efficacious,[21,26,122,194,208] although there is some evidence to the contrary.[209] The efficacy of clomipramine is attributed to its more potent effects on 5-HT reuptake inhibition compared with other TCAs. Clomipramine is often referred to as an SRI (serotonin reuptake inhibitor), not an SSRI, because its major active metabolite, desmethylclomipramine, is a potent inhibitor of NE reuptake. Clomipramine also blocks adrenergic, histaminergic, and cholinergic receptors, resulting in an adverse effect profile similar to that of other TCAs (see Chapter 86, Depressive Disorders).

Although direct comparison studies have shown clomipramine to be similar in efficacy to various SSRIs in treating OCD, several meta-analyses have concluded that clomipramine is superior to SSRIs overall.[206,210] Nonetheless, clomipramine is currently reserved as a second-line treatment option for patients who do not respond adequately to SSRI therapy given its less desirable tolerability profile (eg, sedation, orthostatic hypotension, weight gain, and anticholinergic side effects).[206] Details about the clinical use of clomipramine are discussed in Case 83-10, Question 1.

AUGMENTATION STRATEGIES

Other than venlafaxine XR, no other miscellaneous agents studied in OCD have demonstrated impressive efficacy as monotherapy. However, several agents appear to be useful as augmentation therapy to boost response to SSRIs or clomipramine in partial responders.[211] The combination of an SSRI plus clomipramine is one such option for patients who show partial response, although attention must be paid to potential drug interactions, which may lead to clomipramine toxicity (see Case 83-10, Questions 2 and 3).

Antipsychotic agents are the most studied pharmacologic augmentation strategy in OCD, and may improve response in 30% of patients.[212] They may be particularly effective in four scenarios: treatment-refractory OCD, OCD with poor insight (often treatment refractory), comorbid tic disorders, and comorbid schizophrenia.[213] Several meta-analyses have been conducted on antipsychotic effectiveness.[212,214-216] Risperidone (0.5–4 mg/day) is generally considered to have the highest evidence base for antidepressant augmentation in OCD. Other reasonable agents include aripiprazole and haloperidol (of which haloperidol is less tolerated compared to second-generation antipsychotics). Conversely, quetiapine (up to 600 mg/day) and olanzapine (2.5–20 mg/day) use is controversial based on inconsistent evidence supporting their use in well-designed trials. Preliminary evidence suggests paliperidone may not be more effective than placebo, and ziprasidone may be less effective than quetiapine.[217,218] Recent evidence suggests antipsychotics are less effective than augmenting with CBT with exposure–response prevention (ERP) and, thus, may not be a preferred augmentation strategy.[219,220] In addition, the use of antipsychotics must be weighed against tolerability and safety concerns such as metabolic dysfunction and extrapyramidal symptoms.

Besides antipsychotics, other medications (eg, topiramate, memantine, pindolol, pregabalin, ondansetron, mirtazapine, buspirone) may also be considered as augmentation agents, although the evidence is limited to lower quality studies.[21,221,222] As such, this strategy should be one of last resort, unless otherwise clinically indicated.

MISCELLANEOUS AGENTS

Benzodiazepines, although typically useful in other anxiety disorders, are generally not beneficial in treating OCD. There are several reports of clonazepam being effective as adjunctive therapy or monotherapy, which may be explained by its serotonergic properties; however, double-blind placebo-controlled trials have been negative.[223] As such, clonazepam is not recommended by treatment

guidelines.[194] The MAOI phenelzine was one of the first medications studied for OCD. Early case reports of its use were favorable, but more recent findings suggest phenelzine is largely ineffective for OCD.[194] A few cases and short-term studies have explored the use of the dietary supplement *N*-acetyl cysteine (NAC) for OCD, with mixed efficacy results, but a mild side effect profile. Long-term, randomized, placebo-controlled trials are needed to determine whether NAC is an effective treatment option for OCD.[224]

NONPHARMACOLOGIC TREATMENTS

Cognitive behavioral therapies

CBT is an extremely important component of OCD treatment and should be incorporated into the treatment plan whenever possible. The combination of psychotherapy and medication is generally superior to pharmacotherapy alone, but not to CBT alone.[21,194] CBT alone may be appropriate for mild OCD or in cases in which it is desirable to avoid medication (eg, pregnancy, medical conditions). Treatment gains achieved with CBT often are maintained long after its discontinuation, which is an advantage versus pharmacotherapy, likely improving relapse prevention.[196] The cognitive therapy component of CBT is aimed toward changing the detrimental thought patterns in OCD, and is most helpful for obsessions such as scrupulosity, moral guilt, and pathologic doubt. The behavioral therapy aspect, ERP, involves exposure to feared objects or situations followed by prevention of the usual compulsive response. This type of therapy is most beneficial for patients with contamination fears, hoarding, and rituals involving symmetry, counting, or repeating. Because ERP is anxiety provoking and can be very distressing, patients may refuse to participate.[225]

Procedures and devices

Neurosurgical treatment of OCD has been practiced since the 1950s, and is considered an option of last resort in treatment-refractory patients. Anterior cingulotomy and anterior capsulotomy are the most commonly used surgical procedures. Indications for

neurosurgery include severe disability from symptoms and failed treatments (drugs and behavioral therapies) that have been tried systematically for at least 5 years.[226] Neurosurgery success rates range from 35% to 70%. Complications (including potential infections, personality changes, cognitive impairment, and epilepsy) appear to be rare, and limited long-term follow-up studies indicate the benefit is maintained with mild-to-moderate impairments in neuropsychological performance.[226,227] A deep brain stimulation device received FDA approval in 2009 for adjunctive use to medications in chronic, severe, treatment-resistant OCD (three or more failed medication trials) under the Humanitarian Device Exemption (HDE).[228] The device is surgically implanted in the brain and provides electrical stimulation. However, evidence of effectiveness is not required for devices approved under the HDE. Along with the risks of surgical implantation, possible side effects include negative changes in mood, increased anxiety, worsening of OCD symptoms, hypomania, paresthesia, shocking sensation, muscle weakness/contraction, or dizziness.[229] More recently, in 2018, the FDA expanded the indications for the Brainsway Deep Transcranial Magnetic Stimulation (TMS™) System to include OCD. TMS is a noninvasive treatment option that uses a magnetic field to stimulate specific areas of the brain. Side effects of TMS are generally mild, including headache, neck, face or jaw pain, or muscle twitching/spasms.[230] The FDA permits marketing of TMS for treatment of obsessive–compulsive disorder.

Defining Response to Therapy

Response to medication treatment in OCD is gradual and often delayed. Initial improvements usually begin to appear within the first month. Patients with unsatisfactory response by weeks 4 to 9 should have their SSRI dosages gradually increased to the manufacturer's recommended maximum. A trial of 8 to 12 weeks at maximal tolerated medication dosages is recommended before assessing

therapeutic benefit, and maximal response may take as long as 5 to 6 months.

Because complete elimination of symptoms is rare with current treatments, the primary goal of OCD treatment is to minimize functional impact of symptoms.[231] Most clinical trials in OCD define clinical response as a 25% to 35% reduction in Yale–Brown Obsessive–Compulsive Symptom Checklist (Y-BOCS) scores. Therefore, even those classified as responders may be left with 65% to 75% of their original symptoms, and this may or may not result in significant improvements in functioning or quality of life. The Y-BOCS is an objective tool in the initial evaluation of those who present with symptoms of OCD. It is a 10-item scale with a maximal possible score of 40; a score of >15 is generally considered to represent clinically significant obsessive–compulsive symptoms.[232] This scale is a standard tool for evaluating drug efficacy in OCD clinical trials; and is often used in clinical practice to assess response to treatments, with a version designed for administration with children.

STRATEGIES FOR MANAGING NONRESPONSE AND PARTIAL RESPONSE

Approximately 40% to 60% of patients show clinically meaningful improvements during an initial (SSRI or clomipramine) medication trial, but only a small percentage exhibit marked response.[206] Predictors of poor response include poor insight; hoarding, sexual, religious, and symmetry dimension symptoms; prepubertal onset of illness; and presence of comorbid personality, mood, or eating disorders.[21] For nonresponsive patients, it is usually recommended to pursue a second SSRI trial, because ~20% of initial nonresponders will respond with a subsequent trial. Given this and tolerability concerns, clomipramine is typically reserved as a third-line treatment option, although its use second line would be reasonable given its efficacy in SSRI nonresponders.[196,206] Patients with partial response to an initial SSRI trial may be better served by adding an augmentation agent to preserve therapy benefits rather than switching to a new medication and risk losing any improvement

already gained. In addition, per the American Psychiatric Association (APA), using SSRI doses beyond those FDA approved may be beneficial for poor responders if tolerability is acceptable.[194,233-235] Monitor closely for serotonin syndrome. Caution is warranted if exceeding FDA-approved maximum doses of citalopram, escitalopram, or, to a lesser extent, fluoxetine, given the dose-dependent risk of QTc prolongation.

Clinical Presentation and Assessment

CASE 83-9

Question 1: R.G. is a 25-year-old female whose husband reports that she spends 1.5 hours a day cleaning the stove and takes four showers each day. The unusual behavior began about 1 year ago after the birth of their son but has continued to worsen, and R.G.'s husband states that he cannot deal with her "odd habits" any longer. R.G. recently lost her job as a secretary because of tardiness (it took her 3 hours to get ready for work) and spending too much time away from her desk in the ladies' room. R.G. admits that it is silly, but she has irresistible urges to make sure both she and her surroundings are completely free of germs so that her child will not get sick. She also confines herself to one floor of their three-level house because she is afraid that she will fall down the stairs while carrying her son. R.G. also states that she constantly has "what if" thoughts about horrible things happening to her family, which are very disturbing. The provider's diagnosis is OCD.

What clinical features of OCD does R.G. display, and how can her symptoms be objectively evaluated?

R.G. displays many characteristic symptoms of OCD. The most commonly encountered clinical presentation of OCD involves excessive fear of contamination with dirt, germs, or toxins and repeated washing of hands or cleaning objects or surroundings. These persons also typically avoid touching possibly dirty objects (eg, doorknobs, money) or shaking hands with people. Another common clinical presentation of OCD is the patient with pathologic doubt who constantly worries something bad will happen because of his or her negligence. Individuals can be afraid they have failed to lock the door, turn off the stove, shut the refrigerator door, or secure

the medicine cabinet from children. As a result, they continuously check and recheck their actions.

R.G. displays obsessions of contamination and pathologic doubt, and compulsions of excessive cleaning and washing. These symptoms are time-consuming, cause significant distress, and have led to her unemployment and marital difficulties. As seen in this case, most persons present with a mixture of various obsessions and compulsions. R.G. also realizes her thoughts and behaviors are "silly," which most often is the case in OCD. This case also illustrates the onset of OCD during times of stressful or significant life events. Pregnancy, death of a relative, and marital discord have been identified as precipitating factors in the onset of OCD.[193,231,236]

Selective Serotonin Reuptake Inhibitor Treatment of Obsessive–Compulsive Disorder

Case 83-9, Question 2: On assessment, R.G.'s Y-BOCS score is found to be 33. Her provider prescribes fluvoxamine IR tablets, and instructs R.G. to take 100 mg every morning for 1 week and then 200 mg every morning thereafter. He also refers R.G. to a psychologist to receive CBT. Is this initial choice of therapy appropriate?

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selection and dosing

SSRIs such as fluvoxamine are considered the best choice of initial pharmacotherapy for OCD. The primary differences between SSRIs involve pharmacokinetic properties and potential for drug interactions (see Chapter 86, Depressive Disorders). Because there are no overall differences in SSRI efficacy, fluvoxamine is a suitable selection for R.G. However, the prescribed dosing instructions for R.G. are not appropriate. The initial recommended dosage for fluvoxamine IR in adults is 50 mg/day (25 mg in children), and it is best taken in the evening because it tends to be sedating. Using higher than necessary dosages can increase both adverse effects and medication costs, and these factors can lead to early termination

of therapy. The dosage can be increased by 50-mg increments every 3 to 4 days according to patient tolerability, up to the initial targeted dose of 200 mg/day and a maximum of 300 mg/day.[204] Daily doses exceeding 100 mg should be given in two divided doses if once-daily dosing is not well tolerated. Fluvoxamine extended-release (XR) capsules are also available, for once-daily administration and possibly improved tolerability. However, the cost of fluvoxamine ER versus IR can be a barrier to use.

ADJUNCTIVE COGNITIVE BEHAVIORAL THERAPY

R.G.'s Y-BOCS score of 33 indicates extremely severe symptom severity, which supports using a combined treatment approach. The overall efficacy of these nonpharmacologic treatments is estimated to be 50% to 70% when used alone, and their use to complement pharmacotherapy is considered vital.[196] For R.G., ERP therapy might involve covering her hands with dirt and not allowing her to wash them for a certain time period. These behavioral techniques cause extreme anxiety and discomfort, which often lead to dropout from therapy or noncompliance with "homework assignments" (which involve continuation of the therapy principles outside the clinical setting), but are highly effective if the patient can adhere to treatment.

SELECTIVE SEROTONIN REUPTAKE INHIBITOR ADVERSE EFFECTS AND PATIENT COUNSELING

Case 83-9, Question 3: What patient counseling information should be provided to R.G. in conjunction with the prescribed treatments?

All patients with OCD beginning treatment should be counseled that medication response occurs gradually and several weeks may elapse before beneficial effects become noticeable. It is important to emphasize that maximal response may take ≥3 months and complete elimination of all symptoms is unlikely. Inform patients that

a variety of other medications exist for those who do not respond adequately to an initial trial.

R.G. should be educated about possible fluvoxamine side effects, including nausea, sedation or insomnia, and headache. Medication should be taken with food to decrease these effects. Side effects are most common during the initial weeks of therapy, are usually dose related, and often subside with continued treatment. Other aspects of SSRI therapy, including additional adverse effects and their management and drug–drug interactions, are discussed in Chapter 86, Depressive Disorders. Patients should be encouraged to report any problems to their treatment provider. The importance of adhering to prescribed therapies, both pharmacologic and behavioral, should also be stressed.

Case 83-9, Question 4: After 4 weeks, R.G. is taking fluvoxamine 200 mg/day (100 mg bid) and tolerating the medication well. She states that she has not noticed much improvement, and her Y-BOCS score is slightly decreased at 30. R.G. has been to the cognitive behavioral therapist twice, but is reluctant to return because the therapy was so stressful. R.G. requests to be switched to a more effective medication, and she also asks to be given some alprazolam to help calm her anxiety during behavioral therapy sessions. What is the best course of action for R.G. at this point?

Switching to another medication is not recommended at this point because not enough time has elapsed to assess fluvoxamine's efficacy. R.G. is tolerating fluvoxamine well and has shown a mild improvement, so this medication should be continued for at least another 4 weeks. Additional counseling information should be provided to R.G. to emphasize this fact. An increase in fluvoxamine dosage, up to 250 or 300 mg/day, may be considered after several more weeks because some patients may respond better to higher dosages. If R.G.'s symptoms continue to cause significant functional impairment after 10 to 12 weeks of higher dose fluvoxamine therapy, a change in treatment (eg, switching to another SSRI or augmentation therapy) will be indicated.

R.G. should be encouraged to continue CBT to optimize the chance for successful treatment. An anxiety response is integral to

the therapeutic benefits of behavioral therapies; because benzodiazepines can blunt this response, they may reduce their efficacy. Therefore, alprazolam should be avoided, and a temporary reduction in the intensity of behavioral therapy may be indicated instead.

Course and Duration of Therapy

Case 83-9, Question 5: After 5 months of treatment, taking fluvoxamine IR 150 mg bid (300 mg/day), R.G. is happy to report her OCD is much improved (Y-BOCS score of 11). She still has intermittent obsessions related to contamination and doubting, but they are less intense than before. She is usually able to resist urges to clean and wash excessively, and is using the stairs in their home with only mild discomfort. Her previous employer has agreed to let her return when she is ready, and she plans to do so soon. R.G.'s husband is extremely pleased with her progress. Their primary question at this visit is whether treatment can be discontinued now because R.G. is doing so well. What recommendations should be provided regarding the long-term course of therapy for R.G.?

This case illustrates a common outcome of OCD treatment, in which some symptoms persist (as evidenced by a Y-BOCS score of 11 = mild symptoms), but significant improvements in functioning occur. It is currently recommended that effective treatment for OCD be continued for at least 1 year after response to reduce the risk of relapse.[232,237] Therefore, continued drug treatment for at least 7 more months is indicated. Results from several studies suggest decreased medication doses (with SSRIs and clomipramine) during maintenance therapy are comparably as effective as full doses in preventing relapse.[232] If R.G. was experiencing any fluvoxamine-related problems, a slow decrease to the minimally effective dose (150 mg/day) during maintenance therapy might be recommended.

After a 1-year maintenance period, discontinuation of medication may be considered by carefully weighing the possible risks and benefits. When medication therapy for OCD is withdrawn, the dosage should be gradually decreased by ~25% every 1 to 2 months. Continuous monitoring for signs of relapse is required

during this period. Gradual discontinuation also lessens the chance of the withdrawal syndrome often occurring after abrupt discontinuation of SSRI or TCA therapy (see Chapter 86, Depressive Disorders). Long-term or even lifelong maintenance pharmacotherapy is usually recommended after two to four severe relapses or three to four less severe relapses.

Clomipramine Treatment

DOSING GUIDELINES

CASE 83-10

Question 1: K.T. is an 18-year-old Asian male who was diagnosed with OCD ~2 years ago and also suffers from moderate depression. His provider plans to start him on clomipramine therapy because he has failed previous trials with paroxetine and fluvoxamine.

Is clomipramine an appropriate choice of therapy for this patient? What recommendations can be made regarding initiation of clomipramine treatment?

Current guidelines recommend clomipramine be reserved for patients with OCD who fail at least two SSRI trials; therefore, its choice for this patient could be appropriate.[194] One precaution relevant to this case is that clomipramine, similar to other TCAs, is highly dangerous in overdose situations. Because K.T. is depressed, he should be evaluated carefully for any suicidal thoughts before starting clomipramine. If suicidal ideation is detected, it would be preferable to try another SSRI or venlafaxine XR. This case also illustrates the common comorbidity of depression with OCD. Fortunately, most drug treatment can be beneficial for both conditions. Nevertheless, the responses of depression and OCD to treatment are independent of one another, so depression may respond completely to a certain medication while OCD symptoms persist.[232]

Clomipramine is typically initiated at a low dosage of 25 mg/day administered with meals. Divided daily doses are sometimes used

initially to minimize side effects, but the total daily dose can be given at bedtime after dose titration given its average elimination half-life of 24 hours.[204,238] The clomipramine dosage should be increased to an initial target range of 150 to 200 mg/day during 2 to 4 weeks, guided by patient tolerability. The maximal recommended daily dosage of clomipramine is 250 mg/day because of the sharply increased risk of seizures (2.1%–3.4%) with higher dosages as compared with the risk with dosages <250 mg/day (0.24%–0.48%).[239] Longer duration of clomipramine therapy may also increase the risk of seizures. As such, use with caution in persons with a history of seizures, head injury, or other factors might lower the seizure threshold.

Side effects and monitoring guidelines

Case 83-10, Question 2: What guidelines should be recommended for monitoring the outcomes (both therapeutic and adverse) of clomipramine therapy?

Clomipramine is less well tolerated than are the SSRIs, and can cause a number of significant adverse effects, especially during the first few weeks of therapy. The most common side effects, reported in more than half of those taking clomipramine, include sedation, dry mouth, dizziness, and tremor.[239] Constipation, nausea, blurred vision, insomnia, and headache also occur frequently. K.T. should be advised that these usually subside with continued treatment.

Many patients receiving long-term clomipramine (and other TCA) therapy gain substantial amounts of weight. As with the SSRIs, sexual dysfunction can be a problem in both males and females. In males, clomipramine can cause ejaculation abnormalities, which can impair fertility. Patients taking clomipramine should also be counseled about the additive CNS depressant effects with alcohol and to be cautious about the possible sedative effects while driving or performing other potentially hazardous activities.

As with other TCAs, an ECG should be performed before starting clomipramine in individuals at risk for heart disease and in pediatric

patients. Elevations in liver enzymes have been observed frequently during the first 3 months of clomipramine treatment, and baseline liver function tests should also be obtained before initiating treatment. The liver enzyme changes are reversible on discontinuation of clomipramine therapy.

Clomipramine metabolism exhibits interpatient variability, and it is difficult to accurately predict the resulting clomipramine level from any given dose. The initial hepatic metabolism of tertiary TCAs such as clomipramine involves demethylation through various isozymes, including CYP1A2, CYP2C19, and CYP3A4.[238,240] Both the parent drug and the primary active metabolite (*N*-desmethylclomipramine or norclomipramine) then undergo CYP2D6-mediated hydroxylation. Therefore, the metabolism of clomipramine will be affected by combination with any agent inhibiting CYP1A2, CYP2C19, CYP3A4, or CYP2D6. Clinically significant drug interactions are possible with several of the SSRIs, including fluoxetine, paroxetine, fluvoxamine, and sertraline (see Chapter 86, Depressive Disorders). Monitoring plasma levels may be clinically useful in certain patients to guide dosing and minimize drug toxicity. No therapeutic range for plasma drug concentrations has been firmly established for clomipramine in OCD. However, a trough level of 230 to 450 or 500 ng/mL of total (clomipramine plus *N*-desmethylclomipramine) has been suggested as a therapeutic range. Based on the half-life of clomipramine and *N*-desmethylclomipramine, steady state may not be reached until ~2 weeks after dose adjustment. Although various studies have failed to find a correlation between clomipramine plasma level and clinical response, the ratio of clomipramine to *N*-desmethylclomipramine (typically 1:2 or 1:2.5) may be important.[241] Higher levels of *N*-desmethylclomipramine relative to clomipramine have been associated with poorer clinical response.[242,243]

Asian patients such as K.T. have been found to have significantly decreased clearance of clomipramine and higher clomipramine to *N*-desmethylclomipramine ratios compared with Whites, which may necessitate use of lower doses.[244] This is probably caused by a genetic polymorphism of either CYP2C19 or CYP2D6, which results in decreased metabolic capacity via these metabolic pathways in the

Asian population. Careful monitoring for possible signs of toxicity should accompany dose increases, and the clomipramine plasma level should be checked in all patients who show unexpected effects with usual doses. An opposite effect has been described in ultrarapid CYP2D6 metabolizers, in which unusually high clomipramine dosages may be required for therapeutic efficacy.

Augmentation

Case 83-10, Question 3: After 10 weeks of taking clomipramine 100 mg at bedtime, K.T. has shown partial response. He continues to experience mild-to-moderate anticholinergic side effects and frequent daytime fatigue. His total plasma clomipramine and *N*-desmethylclomipramine level taken 20 hours after his last dose is relatively high for the given dose at 453 ng/mL.[245] The provider decides to add another drug to augment treatment. Considering K.T.'s current medication regimen and the evidence supporting the different augmentation strategies, which drug would be the best choice for K.T.?

When adding an SSRI to a TCA, the potential for drug interactions should always be considered. Clomipramine is metabolized by CYP1A2, CYP3A4, CYP2C19, and CYP2D6.[238,240,246,247] The CYP2D6 pathway is particularly important because it is the rate-limiting metabolic pathway for elimination of both clomipramine and *N*-desmethylclomipramine. Fluvoxamine, paroxetine, and fluoxetine are all strong inhibitors of clomipramine metabolism, whereas sertraline is a weak-to-moderate inhibitor. Alternatively, escitalopram and citalopram would not be likely to cause a significant drug interaction, but evidence for escitalopram as an augmenting agent in combination with clomipramine is lacking.[248]

A combination less likely to be associated with a drug interaction is the combination of clomipramine and a second-generation antipsychotic; however, most trials combined antipsychotics with SSRIs rather than with clomipramine. Nonetheless, antipsychotic augmentation with agents demonstrating more consistent efficacy in well-designed trials (eg, risperidone and aripiprazole) is a reasonable strategy in patients requiring more improvement, as previously

discussed. Haloperidol would not be the optimal choice in K.T.'s case because it inhibits clomipramine metabolism, and as a first-generation antipsychotic, it is associated with numerous side effects. Aripiprazole may be preferred over risperidone given its lower risk of QTc prolongation, orthostasis, sedation, and weight gain/metabolic syndrome.[216]

Sleep Disorders

Devon A. Sherwood and Anna K. Morin

CORE PRINCIPLES		CHAPTER CASES
INSOMNIA AND RESULTING DAYTIME SLEEPINESS		
1	Asking the right questions to investigate the type of insomnia (ie, trouble falling asleep, staying asleep, or early morning awakening), possible causes (lifestyle issues, drugs), resulting impairment, and concomitant conditions are essential to determine proper management.	**Case 84-1 (Questions 1, 2), Table 84-4, Figure 84-2**

CORE PRINCIPLES		CHAPTER CASES
2	Nonpharmacologic treatments such as cognitive-behavioral interventions are recommended first-line therapy for managing insomnia in a variety of patients owing to high efficacy and avoidance of medication side effects.	**Case 84-1 (Questions 3, 4), Table 84-1**
3	Pharmacologic treatments for insomnia are selected based on their efficacy, tolerability, onset and duration of effect, potential for next-day hangover, and abuse potential.	**Case 84-1 (Questions 5–10), Table 84-2**
4	Insomnia concurrent with medical illness is frequently chronic (>1 month) and, if left untreated, may affect recovery from the medical condition. Treating both conditions at the same time is recommended.	**Case 84-2 (Questions 1–4), Table 84-4, Figure 84-2**
5	Insomnia concurrent with psychiatric illness requires optimization of psychiatric maintenance medications and the judicious use of hypnotic medications based on the type of sleep problem and substance abuse history.	**Case 84-3 (Questions 1–4), Figure 84-2**

CORE PRINCIPLES		CHAPTER CASES
6	Managing insomnia in an elderly individual involves consideration of age-related pharmacodynamic and pharmacokinetic changes and counseling regarding realistic treatment expectations. Medication doses lower than those used in younger individuals should be prescribed.	**Case 84-4 (Questions 1–5), Table 84-2**
SLEEP APNEA		
1	Sleep apnea leads to excessive daytime sleepiness (EDS), fatigue, and increased risk of cardiovascular and cerebrovascular disease. Effective treatment with continuous positive airway pressure or surgical interventions can improve overall functioning, quality of life, and morbidity and mortality. Excessive somnolence may be managed by medications with stimulant properties.	**Case 84-5 (Questions 1, 2), Table 84-5**
2	It is essential to avoid sedating medications in patients with sleep apnea because these agents interfere with mini-arousals that keep the patient alive.	**Case 84-5 (Question 3)**
NARCOLEPSY		
1	Narcolepsy is an incurable neurologic disease characterized by sleep attacks and cataplexy.	**Case 84-6 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
2	Stimulants can help decrease sleep attacks and promote daytime alertness, although they do not help with cataplexy or nocturnal insomnia. Sodium oxybate is effective for cataplexy and improves nocturnal sleep, but has high abuse potential and has been associated with psychiatric side effects. Newer agents solriamfetol and pitolisant are effective for EDS and EDS and cataplexy, respectively.	**Case 84-6 (Questions 3, 4), Table 84-5**

INTRODUCTION

Approximately one-third of the adult life is expended on sleep. The innate necessity of sleep is present in almost all mammals, although all the functions of sleep are not fully understood.[1,2] Naturally with the human physiology devoted to sleep and the numerous factors that can disrupt this process, sleep disorders are remarkably common. Sleep deficiency, including insufficient sleep duration, irregular timing of sleep, poor sleep quality, and sleep or circadian rhythm disorders, is highly prevalent and threatens public safety.[3,4] Decades of scientific findings associate sleep deficiency with increased disease risk, including cardiovascular and metabolic disease, psychiatric illness, substance use disorder, pregnancy complications, and impaired neurobehavioral and cognitive impairment.[4,5] At least 10% of the American population is reported to have a sleep disorder that is clinically significant and a public health concern.[3] Major sleep disorders in the United States include insomnia ranging from 15% to 35%,[6,7] sleep apnea at 6% to 24%,[8,9]

periodic limb movements in sleep (PLMS, previously known as nocturnal myoclonus), restless leg syndrome (RLS) ranging from 3% to 15%,[10,11] and narcolepsy at 0.025% to 0.05%.[12] Of note, RLS and PLMS are considered sleep disorders but are reviewed under Chapter 59, Parkinson Disease and Other Movement Disorders. Untreated sleep disorders, including chronic insomnia, sleep apnea, PLMS, and narcolepsy, are all associated with diminished mental and physical functioning and poor quality of life.[3,4,7]

Nightmares, nocturnal leg cramps, and snoring are more benign sleep disorders. Nightmares occur in 5% to 30% of children ages 3 to 6 years, and ~2% to 6% of adults have weekly nightmares.[13] Sleepwalking occurs in 1% to 2% of the population. Complex sleep behavior disorders, such as driving or eating while still asleep, are uncommon to rare. These behaviors are more common in people taking hypnotics, and medication counseling should be provided for patients prescribed any sleep medication.[13,14]

CIRCADIAN RHYTHM AND SLEEP CYCLES

Sleep is a dynamic process with a cyclical recurrence and varying stages. The endogenous sleep–wake pattern of humans is based on the solar day–night cycle called the *circadian rhythm*. The circadian rhythm is controlled by both internal and external factors and sets the sleep–wake cycle at 24.2 hours. Sensory input (visual and acoustic) or other external factors modify the “internal clock” to a 24-hour day through working with the internal network and signaling brain centers to either wake or sleep. Thus, darkness is a visual cue that prepares the brain for sleep. Similarly, bright light serves to prepare the brain for wakefulness.[1,2]

Once sleep is initiated, it alternates between the two phases of rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. These phases vary in length throughout the sleep cycles. During a normal night of sleep, a person generally has four to six

cycles of sleep that last an average of 90 minutes (vary 70–120 minutes).[15] See **Figure 84-1** for normal sleep cycles by age.

Figure 84-1 Normal sleep cycles.

Polysomnography

Each sleep stage serves a physiologic function and can be monitored in sleep laboratories by polysomnography (PSG). *PSG* is the term used to describe three electrophysiologic measures: the electroencephalogram (EEG), the electromyogram, and the electrooculogram of each eye. It may also include an electrocardiogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitoring. The pattern of brain waves, muscle tone, and eye movements measured can be used to categorize the various sleep stages.[15,16]

Nonrapid Eye Movement Sleep

NREM sleep is divided into four stages, with different quantities of time and functions in each stage. Stage 1 is a transition between sleep and wakefulness known as *relaxed wakefulness*, which generally makes up ~2% to 5% of sleep. The function of stage 1 is to initiate sleep. Approximately 50% of total sleep time is spent in stage 2, which is rapid-wave (theta) or lighter sleep. Stage 2 provides rest for the muscles and brain through muscle atonia and low-voltage brain wave activity. Arousability from sleep is highest during stages 1 and 2. Stages 3 and 4 are slow-wave (delta) or deep sleep. Stage 3 occupies an average of 5% of sleep time, whereas stage 4 constitutes 10% to 15% of sleep time in young, healthy adults. In contrast to stages 1 and 2, it is difficult to awaken someone during stages 3 and 4, or delta sleep.[15] Delta sleep, also known as *restorative sleep*, is enhanced by serotonin, adenosine, cholecystokinin, and interleukin (IL)-1. The ability of IL-1 to promote slow-wave sleep supports a widely held theory linking deep sleep to the augmentation of immune function. Some hormones (eg, somatostatin, growth hormone) are released mainly during slow-wave sleep. Deep sleep is most abundant in infants and children and tends to level off at ~4 hours a night during adolescence. At age 65, deep sleep accounts for only 10% of sleep, and at age 75, it is often nonexistent.[1,15–17]

Rapid Eye Movement Sleep

NREM sleep is necessary for rest and rejuvenation, whereas the purpose of REM sleep is not fully understood. It appears important for certain types of learning and memory, but this may change throughout the lifespan.[18] REM sleep is greatest in infants, accounting for about 50% of total sleep time. As aging occurs before 2 years and throughout adulthood, REM sleep is usually 20% to 25% of sleep. This percentage of total REM sleep is maintained into healthy old age, but can decline markedly in the presence of organic brain dysfunctions of the elderly. REM sleep is also called *paradoxical sleep* because it has aspects of both deep sleep and light sleep. Body and brainstem functions appear to be in a deep sleep state as muscle and sympathetic tone drop dramatically. In contrast, neurochemical processes and higher cortical brain function appear active. Dreaming is associated closely with REM sleep, and when a person is awakened from REM, alertness returns relatively quickly.[15]

Numerous physiologic functions are altered during REM sleep. Breathing is irregular, consisting of sudden changes in respiratory amplitude and frequency corresponding to bursts of REM. Temperature control is lost and the body temperature typically lowers. REM sleep brings on variability in heart rate, blood pressure (BP), cerebral blood flow, and metabolism. Cardiac output and urine volume decrease. Blood may become thicker as a result of autonomic instability and temperature changes.[1,15–17]

REM duration varies throughout the night but increases each cycle. In the last half of the night, REM becomes notably longer and more intense when body temperature is at its lowest, around 5:00 AM. When deprived of REM sleep, whether through poor sleep, drugs, or disease states, the brain and body try to catch up. REM rebound occurs and may result in vivid dreams or an overall less restful sleep.[15–19]

NEUROCHEMISTRY OF THE SLEEP–WAKE CYCLE

Wakefulness- and Sleep-Promoting Neurochemicals

A basic understanding of brain neurochemistry is essential in understanding sleep disorders and the clinical use of hypnotics. Hypnotics exert their effects by modulating brain neurotransmitters and neuropeptides (eg, serotonin, norepinephrine, acetylcholine, histamine, adenosine, and γ-aminobutyric acid [GABA]). The neuronal systems in which neurotransmitters and neuropeptides act to control the sleep–wake cycle lie in the brainstem, hypothalamus, and basal forebrain, with connections in the thalamus and cortex. Noradrenergic, histaminergic, and acetylcholine-containing neurons promote wakefulness because they modulate cortical and subcortical neurons.[19] Excitatory amino acids, such as glutamate and stimulating neuropeptides (eg, substance P, thyrotropin-releasing factor, corticotropin-releasing factor) also promote wakefulness.[19] Hypocretin 1 and 2, also known as orexin A and B, are neuropeptides that modulate the sleep–wake cycle. Hypocretin 1 and 2 are deficient in people with narcolepsy and primary hypersomnia.[15,19–21]

Wakefulness and sleep are antagonistic states competing for control of brain activity. Sleep takes over as the wakefulness-maintaining neuronal systems weaken and sleep-promoting neurons become active. Serotonin-containing neurons of the brainstem raphe dampen sensory input and inhibit motor activity, promoting the emergence of slow-wave sleep.[15,16,19] Opiate peptides (eg, enkephalin, endorphin) and GABA, an inhibitory neurotransmitter, also promote sleep.[15,22]

Drug-Induced Effects on Neurochemicals

The neurochemistry of sleep also can be understood by considering the effect of hypnotic drugs on specific neurotransmitters. GABA is facilitated when a benzodiazepine compound attaches to the GABA–chloride ionophore complex and causes chloride channels to open and inhibit overexcited areas of the brain.[23,24] GABA-facilitating hypnotics, such as benzodiazepines, induce sleep and decrease arousals between stages, providing more continuous stage 2 sleep.[19,23,25] Benzodiazepines, however, also may decrease stage 4 slow-wave sleep and suppress REM, leading to REM sleep rebound on abrupt discontinuation.[15,23,25] Antihistamines that promote sleep do so by blocking histamine-containing neurons involved in maintaining wakefulness. The excitatory effects of caffeine and other methylxanthines are attributed to their antagonism of adenosine receptors. Adenosine is a sleep-promoting neurotransmitter or neuromodulator.[19,21]

Neurotransmitter alteration may or may not affect REM sleep. Drug-induced noradrenergic and serotonergic modulation usually decreases REM sleep. An increase in dopaminergic neurotransmission can increase wakefulness but has no direct effect on REM sleep. In contrast, increased cholinergic neurotransmission triggers REM sleep.[19] It is useful to think of the brain centers, neurochemicals, and neuropeptides involved as an interactive network regulating our sleep–wake cycle. Hence, drugs or disease states that alter neurotransmission can have a significant impact on the sleep–wake cycle.

Diagnosis

The International Classification of Sleep Disorders, Third Edition (*ICSD-3*)[26] and the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*)[27] are the latest editions of guides used for classification and diagnosis of sleep disorders. Both *ICSD-3* and *DSM-5* categorize sleep disorders largely based on pathophysiology and presumed etiology rather than numbers of hours of sleep.

INSOMNIA

During the course of a year, approximately one-third (30%–36%) of the population will experience insomnia, and 10% to 15% will consider the problem severe because of daytime consequences.[26] Sleep research also shows that chronic insomnia (ie, insomnia >1 month) can predict untreated illness or may contribute to injury and illness.[2,28,29] Children, adolescents, and adults with persistent insomnia are twice as likely to develop anxiety and four times as likely to develop depression when compared to people without insomnia.[28] Chronic insomnia is also more common in individuals with high BP, breathing difficulties, gastrointestinal (GI) disorders, cancer, and chronic pain, among other conditions.[28–30] Insomnia and excessive daytime sleepiness (EDS) in the elderly are leading predictors of institutionalization.[31]

To meet the criteria for insomnia disorder according to *ICSD-3* and *DSM-5*, the sleep disturbance must cause significant distress or impairment in important areas of functioning (ie, social, occupational, educational, academic, behavioral) and occur at least three nights per week over a 3-month period despite adequate opportunity for sleep.[26,27] The insomnia disorder can be further classified based on duration as follows: episodic (1–3 months), persistent (>3 months), and recurrent (two or more episodes in 1 year). Insomnia with a duration <1 month, previously referred to as transient insomnia, would be classified as “other specified insomnia disorder.”[26]

Patient Assessment

When first assessing a patient, it is important to determine whether the sleep problem is related to difficulty falling asleep, maintaining sleep, early morning awakening, nonrestorative–quality sleep, EDS, or a combination of these problems. Answers to the questions, “How long does it take you to fall asleep” and “How many hours do you sleep?” should be compared with the patient’s normal sleep pattern to determine how it varies. Questions such as “How do you feel

during the day: well rested, sleepy, or something else?" can help assess functional impairment. In addition, the patient's sleep schedule, including bed time, sleep-onset latency, number and length of nighttime awakenings, time to sleep reinitiation, and total wake and sleep time should be reviewed.[32]

The next step involves investigating the possible causes of the sleep disorder and any concomitant conditions. All coexisting medical, psychiatric, drug, environmental, and social causes must be considered and treated along with the sleep disorder. Impact of the sleep disturbance on daytime functioning should be assessed to evaluate the severity of the disorder. A sleep diary in which the patient records bed and wake times, estimated time to fall asleep, number and duration or awakenings, time and type of medication/substance ingestion, time and duration of any naps, and sleep quality can help elucidate the type of sleep disorder.[32]

In addition to assessing patient symptoms and determining the cause of insomnia, it is important to discuss patient expectations. Not all patients need the same amount of sleep, and too much sleep can be as problematic as too little sleep.[27]

Nonpharmacologic Treatment

The first-line treatment for chronic insomnia should be psychological and behavioral therapies. Cognitive-behavioral therapies (CBTs) are effective, long-lasting interventions for insomnia and considered the standard of care.[33,34] They may be more effective than is pharmacotherapy for sleep-onset latency and sleep efficiency.[35,36] The sleep benefits of these interventions are not immediate and can take several weeks to successfully implement. Results vary depending on the individual and the severity and chronicity of insomnia.[35] **Table 84-1** lists established cognitive and behavioral interventions with brief descriptions in addition to important sleep hygiene strategies to include in patient counseling.[33]

Table 84-1

Nonpharmacologic Treatments for Insomnia

1. Cognitive-behavioral therapy: Modify behavioral and cognitive factors that lead to sleep disturbances.
   Cognitive: Identify and stop thought patterns that interfere with sleep.
   Behavioral: stimulus control, sleep restriction, relaxation, paradoxical intention
   a. Stimulus control: Train the brain to reassociate the bed and bedroom with sleep and reestablish a consistent sleep–wake schedule.
   b. Sleep restriction: Create "sleep debt" by limiting amount of time in bed to only the total number of hours actually spent sleeping, then increasing time in bed as sleep efficiency improves.
   c. Relaxation therapy: Target physiologic hyperarousal resulting from stress and tension (eg, meditation, progressive tensing/relaxing of muscles, yoga, stretching).
   d. Paradoxical intention: Encourage the patient to engage in most feared behavior, "staying awake," to reduce performance anxiety associated with falling asleep.
2. Sleep hygiene: useful adjunctive treatment, not effective monotherapy
   Avoid caffeine, stimulants, heavy meals, and alcohol at bedtime; exercise early in the day before dinner to relieve stress and prime brain for sleep; turn face of the clock away from view; establish before-bedtime ritual; use bedroom only for sleep and intimacy; make sure bedroom is dark, quiet, and comfortable; avoid daytime napping.

Pharmacologic Treatment

Pharmacotherapy is indicated for a variety of reasons. These include when nondrug interventions fail or cannot be implemented, sleep disturbances produce significant distress or impairment and immediate symptom relief is required, patient preference is for drug therapy, or if insomnia is comorbid with another medical, sleep, or psychiatric disorder.[33] Patients often do not seek treatment for insomnia from their health care provider when pharmacologic

treatment is warranted. Instead, alcohol or over-the-counter (OTC) sleep aids with unfavorable results that can worsen insomnia or next-day functioning are used.[36–38]

The ideal hypnotic has a rapid onset of effect (within 20 minutes, the natural time to fall asleep), helps the patient sleep throughout the night, does not cause daytime impairment, and carries no abuse potential. Currently, there are no ideal hypnotics. Hypnotics that are benzodiazepine receptor agonists come closest to the ideal.[36,39] Available agents vary in onset, duration, and potential for daytime impairment, mostly because of their individual pharmacokinetic profiles (**Table 84-2**).[40] The selection of an appropriate hypnotic should consider the type of insomnia to be treated and the physiologic characteristics of the patient. For example, if someone cannot fall asleep but has no trouble staying asleep and wants to prevent next-day carryover effects, a rapid-acting hypnotic with a short half-life and no active metabolites is desirable.[36,39,40] Age, sex, socioeconomic status, and comorbidities also influence the hypnotic prescribed.[38–41] Refer to **Figure 84-2** for the treatment algorithm for insomnia.

Table 84-2

Sedative-Hypnotic Agents FDA Approved for Treatment of Insomnia

Generic* (Brand Name)	Dose (mg)		Onset (Minutes)	Half-Life (Hours)	Duration of Action[11]	Insomnia Indication
	Healthy Adults	Elderly/ Hepacic Impaired				
Benzodiazepines						
Estazolam (generics)	1–2	0.5–1	60–120	10–24	Intermediate	Sleep onset and sleep maintenance'
Flurazepam (generics)	15–30	NR	60–120	>100"	Long	Sleep onset and sleep maintenance[1]
Quazepam (Dora!*, generics)	7 5–15	NR	30–60	47–100"	Long	Sleep onset and sleep maintenance[1]
Temazepam (Restoril®, generics)	7.5–30	7.5	60–120	3.5–18.4	Intermediate	Sleep onset and sleep maintenance[1]
Triazolam (Halcion®, generics)	0.125–0.25	0.125	15–30	1.5–5.5	Short	Sleep onset[1]
Nonbenzodiazepine Receptor Agonists						
Zaleplon (Sonata*)	10–20	5–10	30	1	Short	Sleep onset[1]
Zolpidem						
Oral tablet (Ambien*)	5–10*	5	30	1 4–4.5	Short	Sleep onset*

Sublingual tablet[8] (Intermezzo®)	1 75–3.5"	1.75	20–38	1 4–3.6	Short	Middle-of-the-night-awakeningn
Sublingual tablet[8] (Edluar®)	5–10"	5	30	I 57–6 73	Intermediate	Sleep onset"
Mucous membrane spray (Zolpimist®)'	5–10"	5	10	2 7–3	Short	Sleep onset[1]
Eszoplclone (Lunesta*)	1–3 (start at 1 in all patients)	1–2	30	6	Intermediate	Sleep onset and sleep maintenance'
Dual Orexin Receptor Antagonists						
Lemborexant (Dayvigo")	5–10 (start at 5 in all patients)	51	30	17–19	Intermediate	Sleep onset and maintenance*
Suvorexant (Belsomra*)	10–20 (5–10 moderate CYP3A4 inhibitor)	10–20'	30	12	Intermediate	Sleep onset and maintenance*
Daridorexant (Quviviq*)	25–50	25'	30	8	Intermediate	Sleep onset and maintenance*
Melatonin Agonist						
Ramelteon (Rozerem*)	8	8	30	1–5"	Short	Sleep onset"
Antidepressants						
Doxepln (Silenor®)	6	3	30	15 3 (31")	Intermediate	Sleep maintenance'

CR, controlled release; CYP, cytochrome P450; ER, extended release; FDA, U.S. Food and Drug Administration; NR, not recommended.

[a]Dispense with a product-specific Medication Guide.

[b]Time the patient feels the effects after a single dose; usually approximates half-life with multiple doses; individual variability exists; and tolerance may develop with continued use, lessening the duration; short = 1 to 5 hours; intermediate = 5 to 12 hours; long = >12 hours.

[c]FDA approved for short-term (7–10 consecutive days) treatment of insomnia.

[d]Half-life includes the parent compound and its active metabolites.

[e]In females, start with the lower dose.

[f]Not limited to short-term use.

[g]To be dissolved under the tongue and not swallowed whole.

[h]Take only if 4 hours remaining before planned wake time.

[i]To be sprayed over the tongue immediately before bedtime.

[j]Severe hepatic impairment only = NR (not recommended).

[k]Take only if 7 hours remaining before planned wake time.

[l]Not a controlled substance.

INSOMNIA IN A NORMALLY HEALTHY PATIENT

CASE 84-1

QUESTION 1: L.A., a 36-year-old female, is requesting a medication for treatment of her sleep disorder. She returned to Boston, Massachusetts, from a month-long business trip to California 2 days ago. She is now having difficulty falling asleep. When she initially arrived in California 4 weeks ago, she went to sleep immediately at 7:00 PM and awoke at 3:00 AM. Her sleep pattern adjusted during her 4-week visit in California, but upon returning to Boston, it now takes her 2 to 3 hours to fall asleep. She has difficulty awakening in the morning and, as a result, sleeps past 9:00 AM. She needs to be able to wake up by 6:00 AM and be alert during the day in her job as an accountant.

What information provided by L.A. is important in the assessment of her sleep disorder? What additional information should be obtained from L.A. to assist in the assessment of her sleep disturbance?

L.A. describes a circadian rhythm sleep–wake disorder, specifically sleep phase syndrome related to a time-zone shift (previously referred to as *jet lag*). Her major problem is difficulty falling asleep and awakening later than desired because she reports no trouble staying asleep or awakening too early. It is important for L.A. not to be sedated during the day so that she can fulfill her job obligations. Additional information needed from L.A. includes the duration of insomnia, methods already tried to relieve insomnia and their efficacy, concomitant medications, coexisting medical conditions or psychiatric disorders, alcohol use, caffeine use, and current life stressors. L.A. should be advised that assessing all of the aforementioned information is necessary in treating her sleep problem.

CASE 84-1, QUESTION 2: In response to your additional questions, you learn that L.A. has no medical problems and takes no prescription medications. She has been taking pseudoephedrine at night for nasal congestion since returning from California. She denies drinking alcoholic beverages and coffee but admits to recently increasing her cola intake from infrequent consumption of 1 to 2 cans between lunch and bedtime to try to stay awake. She denies a long history of sleep disorder, but adds, “I have not been able to sleep as well since

traveling; I don't know why." What factors could be contributing to L.A.'s problems?

Several factors are contributing to L.A.'s type of sleep disorder. Her circadian rhythm has been disrupted because of travel, but she also takes a stimulating decongestant (ie, pseudoephedrine) and drinks caffeine-containing beverages (ie, an average can of cola has about 35 mg of caffeine; L.A. consumes 35–70 mg/day). In addition, she sleeps in new surroundings that may require time for adjustment. All these factors can contribute to difficulty in falling asleep. Circadian rhythm sleep disorder results from a mismatch between the sleep–wake schedule required by a person's environment and the circadian sleep–wake pattern.

NONPRESCRIPTION SLEEP AIDS

Case 84-1, Question 3: L.A. would like to purchase a nonprescription sleep medication. What would you recommend?

An individual risk-versus-benefit assessment is essential before recommending any medication, including OTC products. Although OTC products (ie, antihistamines, melatonin, valerian, and other herbals) are commonly advertised as sleep aids, data supporting the use of these products are limited. Antihistamines can cause drowsiness and may help patients fall asleep. The ability to cause sedation does not necessarily lead to hypnotic efficacy. Some patients do not feel well rested the next day after taking an antihistamine, but instead feel slow, lethargic, and not mentally sharp. This "hangover effect" can be significant and may be related to the lipid solubility and central histaminic (H_1) and muscarinic blocking effects of the antihistamine.[36,42] Antihistamines with low lipid solubility (eg, cetirizine, loratadine) do not cross the blood–brain barrier readily and should not cause sedation. Although diphenhydramine is the most common antihistamine found in

nonprescription sleep medications, some preparations contain doxylamine.

Case 84-1, Question 4: What additional counseling is needed for L.A.?

Tolerance can develop to sedative effects of antihistamines after 3 to 7 days of continued use.[36–38,42] Because of a high incidence of daytime sedation and risk of cognitive psychomotor impairment,[34] antihistamines are a poor choice for L.A., an accountant who must stay alert and functional throughout the day. Any attempt to manage L.A.'s sleep disorder should start with nonpharmacologic interventions before initiating any drug therapy.

TIME-ZONE SHIFT: NONPHARMACOLOGIC TREATMENT VERSUS TRIAZOLAM OR NONBENZODIAZEPINE RECEPTOR AGONISTS

Case 84-1, Question 5: L.A. wants to know when she should ask her doctor for a prescription for the treatment of her insomnia. What would you recommend?

L.A. should be informed about the likely causes of her sleep disturbances (ie, time-zone shift, caffeine-containing beverages, pseudoephedrine, new surroundings). She also should understand that it may take 1 to 3 weeks for her system to readjust after traveling.[43] The importance of nonpharmacologic interventions to improve sleep, particularly those that pertain to reestablishing a desired sleep–wake cycle and sleep hygiene education (Table 84-2), should be emphasized. In addition, an hour of bright light in the morning can serve as an environmental stimulus, normalizing the circadian rhythm.[43] If L.A.'s sleep disturbances persist despite adhering to cognitive-behavioral interventions, an insomnia medication may be necessary.

Short-acting hypnotics (**Table 84-3**)[33,38,42,44] are effective in treating time-zone shifts to induce and regulate sleep if the stay will be

relatively short (<5 days) and if critical activities must be accomplished during the first 48 hours after arrival at the destination.[43] Females may be more susceptible to the adverse effects of hypnotics than do males, possibly due to greater oral bioavailability.[36,42] Nonbenzodiazepine receptor agonist (NBRA) hypnotics (also known as Z-hypnotics) such as zaleplon, zolpidem, and eszopiclone have fewer reports of rebound insomnia and anterograde amnesia at recommended doses because of selectivity for the α_1-receptor subunit and also lack significant anxiolytic and muscle relaxant effects compared with triazolam.[44]

Table 84-3

Potential Causes and Contributing Factors for Each Chronic Sleep Problem

Difficulty Falling Asleep (DFA)
Learned or conditioned activation (primary insomnia): restless legs syndrome (RLS)
Medications: methylphenidate, modafinil, fluoxetine, bupropion, steroid, β-blocker
Substances: caffeine, guarana, alcohol
Psychiatric disorders: schizophrenia, depression, anxiety disorder, bipolar disorder
Medical disorder: chronic pain, neuropathy, gastrointestinal disorder, cardiopulmonary disorders (particularly if in recumbent position)
Difficulty Maintaining Sleep (DMA)
Excessive time in bed
Psychiatric disorder: major depression, anxiety or bipolar disorder, substance abuse disorder
Sleep-disordered breathing: sleep apnea, acute respiratory distress syndrome
Cardiac disease: atrial fibrillation, heart failure, angina
Neurologic disorder: dementia, Parkinson disease, multiple sclerosis
Early Morning Awakening
Major depression
Advanced sleep phase syndrome: learned or conditioned activation (primary insomnia)

Difficulty Falling Asleep (DFA)
Forced to get up because of family or work obligations
Excessive Daytime Sleepiness
Medications: clonidine, antihistamines, antipsychotic, antidepressant, benzodiazepine, chloral hydrate, opioid, anticonvulsant, α_1-adrenergic blockers
Obstructive sleep apnea, central sleep apnea, narcolepsy
Chronic sleep deprivation

MELATONIN

Case 84-1, Question 6: L.A. would like to try melatonin for improved sleep but wonders whether it is safe and effective. What information is available on the safety and efficacy of melatonin for circadian rhythm or other types of sleep disorders?

Melatonin is a naturally occurring hormone secreted by the pineal gland, located in the center of the brain. The pineal gland is connected to the retina via a nerve pathway that runs through the suprachiasmatic nucleus of the hypothalamus, the body's circadian clock. The pineal gland produces melatonin (a by-product of serotonin metabolism) only during the nocturnal phase of the circadian cycle and only in the presence of relative darkness.[42,45]

Studies in adults show that melatonin has at least mild sleep-promoting properties when administered before the period of natural increase in endogenous melatonin (~10:00 PM to midnight). It causes significantly more sleepiness when taken at 8:00 PM compared with 11:30 PM, theoretically because the brain's receptors are already saturated with melatonin late at night.[42,45] Doses between 0.5 and 5

mg taken close to the target bedtime in the new time zone can decrease sleep disturbances. A systematic review of 10 clinical trials showed melatonin was more effective for travel eastward crossing multiple time zones.[45] Melatonin 0.5 to 10 mg has been found effective for entraining the circadian rhythms in blind people, alleviating insomnia in developmentally disabled, handicapped, or children and adults with autistic spectrum disorders, and treating short-term, initial insomnia in children with attention deficit hyperactivity disorder (ADHD).[42,45,46] The safety and effectiveness of melatonin for long-term use or other sleep disorders has not been established. Consumers selecting melatonin products OTC should be advised that the purity of melatonin is not regulated by the U.S. Food and Drug Administration (FDA). Although doses of 0.5 to 5 mg of melatonin are well tolerated, side effects include sleepiness, headache, and nausea.[42,45,46] Melatonin use has been associated with reports of depression, liver disease, and vasoconstrictive, immunologic, and contraceptive effects.[42,45]

RAMELTEON

Case 84-1, Question 7: L.A.'s doctor gave her a prescription for ramelteon 8 mg at bedtime. How does ramelteon compare with melatonin?

Ramelteon is a highly selective melatonin agonist at melatonin 1 and 2 receptors (MT1, MT2). MT1 regulates sleepiness and MT2 adjusts circadian rhythms and regulates phase shifts from day to night.[47,48] Ramelteon is approved by the FDA for insomnia characterized by difficulty falling asleep. Clinical studies on primary insomnia show it decreases the time to fall asleep by 10 to 19 minutes, and it increases total sleep time by 8 to 22 minutes.[47–49] One controlled trial showed it was superior to placebo in decreasing time to fall asleep during a 6-month period, although ramelteon's onset was 15 minutes faster than was placebo after week 1 but only 9 minutes faster at 6 months.[48] Its half-life ranges from 1 to 2.6 hours. The half-life of its active metabolite, M II, is 2 to 5 hours.

Ramelteon undergoes hepatic metabolism by cytochrome P450 (CYP) isoenzyme CYP1A2. Increases in serum concentration occur even with mild liver disease, so caution is recommended for patients who have at least moderate liver disease. Fluvoxamine is a strong inhibitor of CYP1A2, and given with ramelteon, dramatically increases its serum concentration. Coadministration with fluvoxamine or any potent CYP1A2 inhibitor should be avoided. The most common adverse events observed with ramelteon include headache (7%), dizziness (5%), somnolence (5%), fatigue (4%), and nausea (3%).[48,49]

In clinical trials, no evidence of cognitive impairment, rebound insomnia, withdrawal effects, or abuse potential was demonstrated even at doses up to 20 times the usual treatment dose.[50] These results were markedly different from the abuse potential and side effects of triazolam at treatment doses and doses up to three times higher than usual.[47,48,51] Of note, no study has directly compared ramelteon and another hypnotic for insomnia management.[51] Ramelteon is a reasonable option for patients with initial insomnia with no abuse potential and little to no risk of next-day impairment.

NONBENZODIAZEPINE RECEPTOR AGONISTS (ZOLPIDEM, ZALEPLON, AND ESZOPICLONE)

Case 84-1, Question 8: It has been a month since her return and L.A. continues to have difficulty falling asleep. What alternative medications (aside from ramelteon) offer rapid onset, have a low risk of daytime sedation, and can be administered safely for weeks to months if necessary?

Considering their rapid onset of action, NBRA medications (zaleplon, zolpidem, and eszopiclone) are all potential alternatives for L.A. They have varying degrees of selectivity for the α_1-subunit on the $GABA_A$ receptor. This selectivity imparts hypnotic efficacy with no significant anxiolytic, muscle relaxant, or anticonvulsant effects. Consequently, NBRAs have a lower risk of abuse, withdrawal, and tolerance compared with older nonselective benzodiazepines. These

attributes make NBRAs more desirable for the treatment of chronic insomnia. Both zolpidem controlled release (CR) and eszopiclone are FDA approved for chronic insomnia and are effective for up to 3 to 6 months of therapy.[39] Zolpidem has been studied up to 12 months and was not associated with rebound insomnia or withdrawal symptoms.[52] In addition, eszopiclone was studied for 12 months of nightly administration and found to be well tolerated with no tolerance observed.[53] Another potential advantage of NBRA α_1-subunit selectivity is little to no change in sleep architecture or sleep stages. Benzodiazepines increase the percentage of stage 2 sleep but can suppress REM and stages 3 and 4 deep restorative sleep. In contrast, NBRAs do not interfere with these sleep stages and have lower rates of uncomfortable REM rebound (vivid dreams, increased autonomic instability) on discontinuation.[39,54]

The NBRAs differ with respect to pharmacokinetics and adverse events. Zolpidem, the first NBRA, was marketed in the United States in 1991. It is absorbed rapidly, reaches peak serum levels in 1.5 hours, and is eliminated rapidly with an average half-life of ~2.5 hours.[43] For faster sleep onset, zolpidem should be taken on an empty stomach because of a more rapid absorption. A food-effect study demonstrated that administration of a zolpidem 10 mg tablet 20 minutes after a meal resulted in a decrease in area under the curve (AUC) and maximum serum concentration (C_{max}) of 15% and 25%, respectively, and an increase in the time to maximal concentration (T_{max}) from 1.4 to 2.2 hours.[55] Zolpidem is metabolized by the oxidative CYP3A4; therefore, drug interactions should be considered when zolpidem is coadministered with CYP3A4 inhibitors. Zolpidem has no active metabolites, and it has a low risk of residual daytime sedation in recommended doses.[39,44] Zolpidem CR has no clear advantage over zolpidem, except that it may provide a slightly longer duration of sleep. Zolpidem CR is a bilayered tablet with a first layer that dissolves quickly to induce sleep and a second layer that releases zolpidem more gradually to improve sleep maintenance. Serum concentrations peak in 2 hours compared with 1.5 hours for immediate-release zolpidem, with an

associated longer latency to effect.[40] Of note, zolpidem has been approved as oral spray to help with sleep onset. Owing to buccal absorption, it has a rapid onset of action of 10 minutes.[56] Gender metabolism differences exist where females metabolize zolpidem slower than do males, resulting in blood levels nearly twofold higher. As a result, in females or the elderly, the recommended starting dose is 5 mg of zolpidem immediate release or 6.25 mg zolpidem extended release (ER).[57] In 2019, the FDA added a boxed warning for risk of serious injuries secondary to complex sleep behaviors, including sleepwalking, sleep driving, and engaging in other activities while not fully awake, associated with all NBRAs.[14] For females, the elderly, or patients such as L.A. who express concern that a medicine may be too strong, the starting dose should be 5 mg at bedtime.

Zaleplon offers a shorter elimination half-life (~1 hour) and duration of effect than does zolpidem (see Table 84-3). It is the least likely of all hypnotic agents to cause residual daytime sedation and has the least effect on memory and psychomotor performance. An assessment of psychomotor performance, arousal, memory, and cognitive functioning with zaleplon revealed no cognitive impairment.[39,44] The most common adverse effects of zaleplon include dizziness, headache, and somnolence.[58] In dose escalation studies using up to 60 mg, symptoms appear at ~30 minutes after dosing, peak at 1 to 2 hours, and are no longer evident after 4 hours. It can be taken in the middle of the night as long as the individual has 4 hours left in bed. Zaleplon is metabolized primarily via aldehyde oxidase, CYP3A4 is a secondary route of metabolism, and there are no active metabolites. It has less potential for drug or food interactions compared with zolpidem or eszopiclone.[42]

Eszopiclone maintains efficacy with no evidence of tolerance after 6 months of continuous use, resulting in FDA approval for long-term use.[59–62] Hypnotic efficacy has been demonstrated for up to 6 months in younger patients taking 2 to 3 mg nightly, and in elderly patients taking 1 to 2 mg nightly, although only the higher range of doses significantly improved sleep maintenance. As with zolpidem and zaleplon, eszopiclone has a rapid onset of effect, but differs in

that it has a longer duration of effect (see Table 84-3). T_{max} is delayed up to 1 hour when eszopiclone is administered after a high-fat meal, potentially delaying the onset of sleep.[59,60]

Eszopiclone has less receptor selectivity than does either zaleplon or zolpidem, potentially resulting in some anxiolytic, amnestic, and anticonvulsant activity.[61] Among the three Z-hypnotic drugs, eszopiclone has a dose-related unpleasant bitter taste noted by 16% to 34% of patients.[59,60] Headache and dizziness were reported more commonly with eszopiclone than with placebo, and at higher doses, next-day confusion and memory impairment were reported in up to 3% of patients.[39,60] Eszopiclone is primarily metabolized by CYP3A4, so drugs that induce or inhibit this isoenzyme can have an impact on metabolism and clinical effects.[60]

L.A. needs a medication that will hasten sleep onset but does not need continued drug effect later in the night. Both zolpidem and zaleplon are useful alternatives for L.A. because of their efficacy for her sleep-onset difficulty. However, zaleplon may be preferred because of quick onset and short half-life to mitigate the risk of next-day hangover. Among the NBRAs, eszopiclone has the longest half-life and the greatest risk for next-day impairment.

Case 84-1, Question 9: Zolpidem 5 mg is prescribed because of its low cost and less risk for next-day impairment. L.A. expresses concern about possible adverse effects owing to its labeling as a Schedule IV controlled substance and the FDA boxed warning of complex sleep behaviors such as night eating and night driving.[63] How should L.A.'s concerns be addressed?

Patient counseling is most effective when it is interactive, with both patient and practitioner actively listening to each other while exchanging information. It is best to begin by emphasizing the benefits of zolpidem to improve her sleep and daytime functioning. Next, L.A. should be reassured that zolpidem is generally well tolerated and she will be prescribed the lowest dose to minimize the likelihood of adverse effects. Counseling should include a discussion of common and potentially serious adverse effects along with management strategies. Common possible adverse effects include

headache (28%), drowsiness (26%), fatigue (17%), and dizziness (14%).[39,58] Anaphylactoid reactions and nightmares have been reported in postmarketing studies. All NBRAs are contraindicated in patients who have experienced an episode of complex sleep behaviors after taking them. In addition, L.A. should be encouraged to report both effectiveness and all adverse effects to her clinician. Alcohol should not be consumed together with zolpidem or any NBRA because it can cause excessive side effects and interfere with L.A.'s sleep.

To address L.A.'s concern regarding complex sleep behaviors, a reasonable response would be "rarely, individuals taking sleeping medication have been reported to be making phone calls, eating, having sex, or driving while half asleep. The risk for these potentially dangerous effects increases if consumers take a higher than the recommended dose, or drink alcohol, or mix hypnotics with other sedating medications."[14,63] Another rare allergic reaction is facial swelling (angioedema). All manufacturers of hypnotic medication are required to include this information in their package inserts.[14,63]

Although the abuse potential of NBRAs is less than that of benzodiazepines, they are problematic in active substance use disorders. NBRAs are Schedule IV controlled substances with more potential for abuse than do ramelteon or sedating antidepressants, such as trazodone.[47] Tolerance and withdrawal associated with NBRAs are unlikely but reported with abrupt discontinuation, and patients should be counseled of this possibility, particularly at high doses.

Case 84-1, Question 10: L.A. asks about a newer sleep medication, suvorexant, and whether she could use this to help her sleep. What information can you provide L.A. regarding the safety and efficacy of suvorexant for insomnia?

Suvorexant is a dual orexin A and orexin B receptor antagonist (DORA) approved for the treatment of insomnia characterized by difficulty falling asleep and/or maintaining sleep.[64] The orexin signaling pathway promotes wakefulness and arousal; antagonism of

orexin receptors can promote sleep. Studies show that suvorexant can decrease latency to onset of sleep and wake after sleep onset without disrupting the sleep architecture.[65] The initial recommended daily dose is 10 mg within 30 minutes of bedtime and with at least 7 hours of sleep time available.[64] Suvorexant should be taken on an empty stomach because time to sleep onset may be delayed by 1.5 hours if taken with or soon after a meal. If needed, the dose can be increased in 5 mg increments to the maximum recommended daily dose of 20 mg at bedtime.[64] Suvorexant is a CYP3A4 substrate and a dose reduction of 5 mg daily is recommended when administered concurrently with a moderate CYP3A inhibitor; concurrent administration with a strong CYP3A inhibitor is not recommended.[66] No rebound insomnia or withdrawal symptoms have been observed following abrupt discontinuation.[67] When compared to zolpidem, suvorexant is associated with less abuse potential, although still classified as a Schedule IV medication.[65] However, individuals with a history of substance abuse disorder may be at increased risk for abuse with suvorexant.[65,66] The most commonly reported adverse effect in clinical trials evaluating suvorexant in patients with insomnia was daytime somnolence.[65]

Lemborexant is the second DORA approved for the treatment of insomnia characterized by difficulty falling asleep and/or maintaining sleep.[68] In placebo-controlled trials, lemborexant significantly improved objective and subjective measures of sleep onset and sleep maintenance and promoted NREM sleep with no effect on REM sleep.[65] The most common adverse event reported in clinical trials with lemborexant was somnolence. In a study evaluating the respiratory safety of lemborexant, patients with mild obstructive sleep apnea (OSA) did not experience worsening of sleep apnea.[69] The recommended dosing of lemborexant is 5 mg taken immediately before going to bed and with at least 7 hours remaining before the planned awakening time.[68] The dose may be increased to a maximum of 10 mg, based on clinical response and tolerability. The initial and maximum dose of lemborexant should be decreased to 5 mg when administered concomitantly with weak CYP3A4 inhibitors or in patients with moderate hepatic impairment. Concomitant use of

lemborexant should be avoided with moderate-to-strong CYP3A4 inducers and inhibitors and in patients with severe hepatic impairment.[68]

In January 2022, the FDA approved daridorexant, another DORA, for the treatment of insomnia. Daridorexant is approved for adults at 25- or 50-mg doses taken once daily 30 minutes before bedtime and at least 7 hours remaining before planned awakening.[70] Approval is based on two phase three multicenter randomized, double-blind, placebo-controlled, parallel-group trials evaluating daridorexant in 1854 adults with insomnia. One study evaluated 50 mg, 25 mg, or placebo and the other study evaluated 25 mg, 10 mg, or placebo once daily in the evening for 3 months. The 10-mg dose is not an approved dose. Daridorexant was associated with significant improvements versus placebo in daytime function, particularly in sleepiness and mood, sleep onset and sleep maintenance, and patient-reported total sleep time. Daridorexant was not associated with rebound insomnia or withdrawal effects. The most commonly reported adverse events were headache, somnolence, or fatigue. The maximum recommended dose in patients with moderate hepatic impairment or with concomitant use of a moderate CYP3A4 inhibitor is 25 mg. Daridorexant is not recommended in patients with severe hepatic dysfunction and should not be taken concomitantly with strong CYP3A4 inhibitors or moderate or strong CYP3A4 inducers. Taking daridorexant with or soon after a meal may delay the time to sleep onset. The FDA has recommended that daridorexant be classified as a controlled substance and scheduling is pending. Daridorexant cannot be compared with other DORAs because there are no head-to-head trials.[70]

Complex sleep behaviors, suicidal ideation, sleep paralysis, hallucinations, and cataplexy-like symptoms have been reported with DORAs. Because individuals with narcolepsy lack or have a decreased number of orexin receptors in the hypothalamus, DORAs are contraindicated in patients with narcolepsy. Studies comparing DORAs to other hypnotic agents, such as the NBRAs, are lacking.

BENZODIAZEPINES

The pharmacologic properties of benzodiazepines, including sedation, anterograde amnesia, antianxiety and anticonvulsant activity, muscle relaxation, and ethanol potentiation, occur as a result of interaction with various $GABA_A$ receptor subunits. The sedative effects of benzodiazepines are primarily mediated via activity at the α_1-subunit of the $GABA_A$ receptor.[71]

Although effective as hypnotics, benzodiazepines pose more disadvantages than do NBRA agonists, including the impairment in new learning or anterograde amnesia and the potential for complex sleep behaviors (eg, eating, sleeping, driving, or other activities while asleep). These effects can interfere with daytime functioning and result in the inability to remember new information. Patients should be cautioned regarding tolerance to the hypnosedative effects and physiologic dependence that can occur with long-term use of a benzodiazepine and the potential for rebound insomnia with abrupt discontinuation.[36,38,42] In addition, benzodiazepines are generally avoided in elderly patients because they increase the risk of cognitive impairment, delirium, falls, fractures, and motor vehicle crashes because of drug accumulation risks (prolonged half-lives).[72]

Although several are available, only five benzodiazepines carry an FDA indication to treat primary insomnia (estazolam, quazepam, flurazepam, triazolam, and temazepam). Both lorazepam and clonazepam are commonly used, but indicated only for insomnia associated with anxiety. Many approved benzodiazepines, including estazolam, quazepam, and flurazepam, are no longer recommended because of oversedation caused by long half-lives from parent or active metabolites. For example, flurazepam has intermediate fat solubility but depends on the plasma concentrations of its metabolite, *N*-desalkylflurazepam, for most of its activity (T½ flurazepam 2.3 hours, *N*-desalkylflurazepam 47–100 hours).[42] *N*-desalkylflurazepam concentrations take ~24 hours to accumulate and induce sleep, but also accumulates during chronic dosing and can affect daytime cognition in patients.[42] Triazolam is also not recommended often, owing to a short half-life. Triazolam is most commonly associated

with rebound insomnia (ie, daytime nervousness, jitteriness, and insomnia worse than before) if abruptly stopped after >7 to 10 days of continuous use and exhibits withdrawal problems.[44,54,71]

Among FDA-approved benzodiazepines to treat primary insomnia, temazepam is most often recommended likely due to its intermediate duration of action (T½ ~8.8 hours). It has moderate fat solubility, but a longer dissolution time caused by its large particle size, and takes 1.5 to 2 hours to reach peak plasma concentrations. The longer dissolution has a notable lag time for efficacy, and thus should be taken 45 to 60 minutes before bedtime.

INSOMNIA IN AN ILL PATIENT

Insomnia and Effect on Sleep Stages

CASE 84-2

Question 1: A.T., a 42-year-old female with a 5-year history of hypothyroidism and a 2-year history of hypertension and chronic lower back pain, was just transferred from the intensive care unit (ICU) into a medical unit. Her cardiac status is considered "stable" 2 days after a myocardial infarction (MI). She is 69 inches (175.26 cm) tall and weighs 158.73 pounds (72 kg). She is receiving aspirin 81 mg (enteric coated), levothyroxine 112 µg, and nifedipine ER 30 mg all taken by mouth 1 hour before breakfast every day. Her main problem is insomnia, including difficulty falling asleep, difficulty maintaining sleep, and early morning awakenings. A.T. reports insomnia for 6 weeks before admission, which worsened during the hospitalization.

What type of insomnia does A.T. have, and how might the insomnia affect her health?

A.T.'s insomnia is considered chronic because she experienced it for >1 month before hospital admission. It is severe because it involves difficulty falling asleep, maintaining sleep, and early morning awakening. Careful monitoring and effective treatment of A.T.'s sleep disturbance is crucial; studies show disrupted sleep can increase the

risk of another adverse cardiac event, owing to worsening autonomic instability and poor perfusion to the myocardium.[73]

Because normal sleep moves through all the stages of NREM and REM in a continuous cycle, a patient deprived of continuous sleep may not receive sufficient time in each sleep stage. When stage 2 is diminished, muscles have insufficient opportunity to rest and rejuvenate. If NREM stages 3 and 4 are eliminated, immune function and the healing process can be disrupted. If REM sleep is deprived or excessive, neurotransmitter function may be altered and physiologic homeostatic processes can be disrupted.[15,16,29]

Drug or Disease Etiologies

Case 84-2, Question 2: What individual drug or disease-state factors should be assessed in A.T. before developing a treatment plan?

The insomnia treatment algorithm in Figure 84-2 is useful in systematically addressing A.T.'s sleep problem. It calls for thoroughly evaluating all concomitant conditions and the type of insomnia in each patient. Numerous medical disorders and primary sleep disorders are associated with difficulty falling asleep and maintaining sleep (**Tables 84-4** and **84-5**).[5,29,73] First, A.T. should be assessed for sleep apnea because untreated sleep apnea is a known etiology of cardiac disease and hypnotics can be dangerous in untreated sleep apnea (see Case 84-5, in the section on Sleep Apnea). Second, A.T.'s pain management should be assessed for optimal efficacy. Acute post-MI pain adds to A.T.'s chronic lower back pain. Of patients with lower back pain, 50% experience chronic poor sleep patterns.[29,73] Third, A.T. was just transferred out of the ICU. Sleep deprivation in an ICU is common and is attributed to the continuous lighting, noise, and constant interventions. Sleep deprivation may prolong or worsen a disease process through diminished natural killer cell activity and decreased stages 3 and 4 of NREM sleep (when healing occurs).[42,74,75] Medications also may be contributing to A.T.'s insomnia (Table 84-4). Levothyroxine can overstimulate the

central nervous system (CNS) if given in excessive doses. A.T.'s thyroid status should be reevaluated to ensure appropriateness of the thyroid dose, especially considering her post-MI status.[76] Calcium channel blockers have been associated with occasional sleep disturbances; therefore, nifedipine should be evaluated as a potential contributing factor.[76] See Table 84-3.

Table 84-4
Potential Causes of Chronic Sleep Disorders

Psychiatric Disorders	
Anxiety disorders	Depressive disorders
Bipolar disorder	Psychotic disorders
Personality disorders	Somatoform disorders
Organic mental disorders	Substance abuse disorder
Medical and Neurologic Disorders	
Angina pectoris	Dementia
Bronchitis	Peptic ulcer disease
Chronic fatigue	Hyperthyroidism and hypothyroidism
Cystic fibrosis	Asthma
Huntington disease	COPD
Parkinson disease	Epilepsy
Hypertension	Gastroesophageal reflux
Arthritis	Renal insufficiency
Cardiac disease	Connective tissue disease
Chronic pain	
Cancer	
Sleep Disorders	
RLS	Sleep apnea (obstructive or central)
PLMS (nocturnal myoclonus)	Primary snoring

Psychiatric Disorders	
Circadian rhythm sleep disorder (jet lag, shift work, delayed sleep phase)	Narcolepsy
Drugs Associated With Sleep Disturbance	
Insomnia	Hypersomnia
Alcohol	Alcohol
Bupropion	Benzodiazepines
Fluoxetine	Antihypertensives
Sertraline	Clonidine
MAO inhibitors	α-Adrenergic blockers
TCA	ACE inhibitors
Thyroid supplements	β-Blockers
Calcium channel blockers	Anticonvulsants
Decongestants	Analgesics
Appetite suppressants	Chloral hydrate
Theophylline	Antipsychotics
Corticosteroids	Antihistamines
Dopamine agonists	Opioids

ACE, angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; MAO, monoamine oxidase; PLMS, periodic limb movements during sleep; RLS, restless legs syndrome; TCA, tricyclic antidepressants.

Table 84-5
Agents for the Treatment of Sleep Apnea or Narcolepsy

Generic (Brand Name)	Recommended Dosage Range (mg)	Indication
Armodafinil (Nuvigil®)	150–250 mg once daily	EDS with narcolepsy or OSA
Dextroamphetamine (Dexedrine®) Dextroamphetamine/amphetamine salts (Adderall®)	5–60 mg/day divided doses	EDS with narcolepsy
Methylphenidate (Ritalin®)	10–60 mg/day divided doses	EDS with narcolepsy
Modafinil (Provigil®)	200–400 mg once daily	EDS with narcolepsy or OSA
Sodium oxybate (Xyrem®) Sodium oxybate salts (Xywav®)	4.5–9 g/night in two divided doses	EDS or cataplexy with narcolepsy
Solriamfetol (Sunosi®)	75–150 mg once daily[a] 37.5–150 mg once daily[b]	EDS with narcolepsy or OSA
Pitolisant (Wakix®)	9–36 mg once daily	EDS or cataplexy with narcolepsy

EDS, excessive daytime sleepiness; OSA, obstructive sleep apnea.

[a]Narcolepsy dosage.

[b]Obstructive sleep apnea (OSA) dosage.

Another clue to a possible cause of A.T.'s sleep problem is her description of early morning awakening, which could be related to hospital activity during these hours or to the presence of a major

depressive disorder. A.T. requires psychiatric evaluation to rule out depression, which occurs in about one-third of patients after an MI.[77] In general, patients with chronic illnesses are at increased risk for experiencing major depression, which typically presents with insomnia or hypersomnia. Interestingly, medical outcome studies of other chronic illnesses (cardiovascular, pulmonary, renal, and neurologic disease) show a high prevalence of sleep disturbance even in those not suffering from depression.[29,73] Chronic insomnia related to multiple causes can be resistant to treatment; however, treatment of underlying causes increases the likelihood of insomnia resolution (see Table 84-4).

Comparing Available Hypnotics

Case 84-2, Question 3: A.T.'s pain is now under control; her levothyroxine dose is appropriate; and nifedipine-induced sleep disturbance, sleep-disordered breathing, RLS, and PLMS have all been ruled out. A psychiatric evaluation finds that A.T. does not have major depression, but she is anxious about "life after a heart attack." She meets the criteria for primary insomnia and adjustment disorder with anxiety. She continues to have trouble falling asleep and staying asleep. She will be discharged in 2 days. The psychiatric consultation suggests an adjunctive medication with anxiolytic properties that may also help with sleep. Which hypnotic is best for A.T., considering her individual clinical characteristics?

The ideal hypnotic for A.T. should act quickly and continue working throughout the night to provide her with uninterrupted sleep. A hypnotic that is not metabolized in the liver would have a lower potential for drug interactions and lessen the opportunity for systemic accumulation. If daytime drug concentrations are needed to calm anxiety, however, a hypnotic with slowly eliminated active metabolites may be desirable. The comparable doses of the hypnotic medications are listed in Table 84-2. When considering available hypnotic medications, differences in pharmacodynamic and pharmacokinetic properties should be considered (Table 84-2).

Onset of effect is related to lipophilicity, receptor binding affinity, and T_{max}.[40,42]

For A.T., a nonselective benzodiazepine hypnotic is preferable because of the need for anxiolytic properties in addition to hypnotic efficacy. NBRAs are not effective anxiolytic agents. Temazepam is an appropriate choice for A.T. Of the five approved benzodiazepine agents approved for insomnia (see Table 84-2), temazepam's advantages are intermediate duration of activity that would keep her asleep throughout the night, offer anxiolytic benefit, and present a lower risk of daytime impairment owing to no known active metabolites.[42,78] A.T. may require a hypnotic for longer use. She has difficulty moving around during the day because of her chronic lower back pain, and oversedation from drug accumulation may impair her daytime functioning. A potential advantage of using temazepam in A.T.'s case is its lack of hepatic oxidative metabolism and intermediate duration of action of 8 to 12 hours. It does not interfere with the metabolism of other hepatically metabolized drugs and it does not accumulate, minimizing the potential for daytime impairment.[42,78] The long onset of action may be of concern, although A.T. could take temazepam an hour before bedtime to optimize timing for sleep.

Benzodiazepine Dependence and Tolerance

Case 84-2, Question 4: In further discussion with A.T., who prefers to try cognitive-behavioral interventions for anxiety reduction and sleep induction, temazepam 15 mg at bedtime is prescribed on an as-needed basis. A.T. will be monitored regularly as an outpatient for efficacy and tolerability. As A.T. is preparing to leave the hospital, her daughter expresses concerns about the potential for physical dependence on temazepam versus other sleep medications, and the risk of A.T. "becoming addicted." How would you respond to her concerns?

Fear of dependence and addiction to medications is a concern among the general public. Television station "medical experts" and popular magazine "health sections," while providing information, may

increase the potential for confusion, erroneous impressions, and misinformation. For health care practitioners, it becomes even more crucial to provide sound drug information in common, easy-to-understand terms.

An example of the practitioner's response may be, "I'm glad you have expressed a concern; it gives us a chance to discuss temazepam therapy before your mother leaves the hospital. Temazepam has been prescribed for a medical reason, to improve her sleep and aid in her healing process. One therapeutic benefit of temazepam is an 8-hour duration of effect. Your mother will be able to sleep throughout the night so that she is well rested during the day. It also may decrease her anxiety over not sleeping, and that puts less stress on her heart."

Possible side effects of temazepam include sedation, unsteadiness, dizziness, and, with long-term use, the possibility of permanent cognitive deficits including reduction in short-term memory. She should let her doctor know if she experiences any adverse effects. Right now, it is unclear how long A.T. will be taking temazepam. Duration of therapy needs to be assessed on an ongoing basis. If A.T. takes temazepam every night for >4 weeks, two things could happen: (a) she may develop a tolerance and it may not help her sleep anymore, or (b) she may develop a dependence in which she may have worse insomnia if she does not take it. The primary concern is not addiction but the possible dependence. This means A.T. should not change her dose or stop on her own. Any changes in dose or stopping must be done slowly and with her doctor's involvement. These two scenarios do not always occur and are not likely because your mother will be taking it on an as-needed basis. If one or the other does happen, other interventions may be tried to help with her sleep, or the temazepam dose can be gradually decreased to prevent withdrawal problems. It is important to advise A.T. to avoid alcohol, and report any decrease in effectiveness or any adverse effects to her health care practitioner.

Patients taking benzodiazepines for >1 year tend to be older, medically ill, chronically dysphoric, and have panic disorder or chronic insomnia. Most chronic use appears to be medically

appropriate and does not lead to dose escalation or abuse. Among patients with chronic dysphoria, the indications are less clear, and dose escalation is noted sometimes without notable therapeutic benefit. Benzodiazepine hypnotics rarely are taken alone for pleasure and generally are not likely to be abused. Among patients with substance use disorders, however, they frequently are taken as part of a polysubstance abuse pattern with alcohol and narcotics, methadone, and cocaine users. In these groups, abuse is highly prevalent. Benzodiazepines are used to augment euphoria (narcotics and methadone users), to decrease anxiety and withdrawal symptoms (alcohol use), and to ease the "crash" from stimulant-induced euphoria (cocaine users).[79,80]

Physiologic dependence on benzodiazepines, resulting in a withdrawal and abstinence syndrome, develops usually after 2 to 4 months of daily use of the longer half-life benzodiazepines. Shorter half-life benzodiazepine use can result in physiologic dependence earlier (days to weeks) and may be associated with more withdrawal problems.[42,54] See Table 84-2 for a comparison of pharmacokinetic properties of hypnotics.

INSOMNIA AND PSYCHIATRIC DISORDERS

Stepwise Approach to Selecting a Hypnotic

CASE 84-3

Question 1: M.B., a 33-year-old female, is hospitalized after a suicide attempt in which she tried to overdose on sertraline, ibuprofen, and diphenhydramine. Before the suicide attempt, M.B. had been sober for 3 years. She is diagnosed with major depression and alcohol use disorder. After completing an interview with M.B., you learn she was doing well until 3 months ago when depression symptoms worsened during her divorce. Two weeks before admission, her outpatient primary care doctor prescribed sertraline for depression and omeprazole for acid reflux. She went on a drinking binge 5 days ago that ended with a suicide attempt. Her target symptoms include early morning awakening, trouble falling asleep, 15-pound (6.80-kg) weight loss, apathy, social withdrawal,

depressed mood, hopelessness, and anhedonia. Medications continued in the hospital include sertraline 100 mg daily and omeprazole 20 mg daily. M.B. currently reports feeling restless and sleeping only 3 to 4 hours a night. Use Table 84-2 and Figure 84-2 to compare the clinically significant differences between available hypnotics and to demonstrate how such information can be used to develop a patient-specific treatment plan.

What is the best approach to solving M.B.'s sleep problem?

The insomnia treatment algorithm outlined in Figure 84-2 serves as a useful guide for the assessment and management of M.B.'s sleep problem. Concomitant conditions and the type of insomnia (difficulty falling asleep, difficulty maintaining sleep, early morning awakening) are assessed simultaneously. Possible causes or contributing factors are identified and treated. The type of insomnia can aid in treatment selection. Cognitive-behavioral interventions can be implemented if M.B. is willing and able to participate.

Factors to consider in the drug selection process include substance use history, the need for rapid onset, and duration of effect. For example, agents with long-acting metabolites (eg, flurazepam) may accumulate or cause daytime hangover. If the hypnotic has no hepatic metabolism, it will not be subject to drug interactions with other agents that are hepatically metabolized. Also, if insomnia is chronic and resistant to hypnotic treatment, or if a low abuse potential agent is desired (eg, for a person with an existing substance use disorder such as M.B.), trazodone or another sedating antidepressant may be selected.

Sleep Disturbance of Depression

Case 84-3, Question 2: What type of insomnia does M.B. have? How is it different from other types of insomnia?

M.B. has trouble falling asleep and early morning awakening, and sleep time has decreased to 3 or 4 hours a night. She is diagnosed with major depression, and sleep difficulty is part of the disorder. Generally, initial insomnia and early morning awakening are

associated with depression, although difficulty maintaining sleep and next-day fatigue are common as well. M.B. is most bothered by trouble falling asleep, early morning awakening, and next-day fatigue. Up to 65% of outpatients with major depression report one or more symptoms of sleep disturbance, whereas 90% of inpatients with depression such as M.B. report insomnia.[81]

The insomnia of depression is likely related to a dysregulation of neurotransmitters, such as serotonin, norepinephrine, and dopamine, in addition to dysregulation of the hypothalamic–pituitary axis. All are involved in regulating mood and the sleep–wake cycle.[16,66] Neurotransmitter activity is modified by the effects of antidepressants on REM sleep. Most pro-serotonergic antidepressants suppress REM, causing increased REM latency and decreased total REM time.[81,82] Indeed, REM sleep deprivation can elevate mood.[81,83] Patients who are depressed and deliberately deprived of REM sleep have had a reduction in depressive symptoms. In addition to effects on REM, antidepressants redistribute slow-wave sleep to more physiologically natural patterns, with increased intensity in the first half of the night.[83] Sedating antidepressants with serotonin 2 (5-HT_2) antagonist properties, such as trazodone and mirtazapine, alleviate insomnia and improve sleep architecture.[81]

Treatment

Case 84-3, Question 3: M.B. and the treatment team ask you what factors other than depression (ie, medications, alcohol) may contribute to M.B.'s insomnia. How can her sleep problem be solved?

The treatment for M.B.'s insomnia should begin with patient education. She should be informed that >90% of patients who are depressed have some sleep disturbance, either too little or too much, and her sleep should improve as depressive symptoms improve (in 2–8 weeks). Counseling on cognitive-behavioral interventions to improve sleep may be appropriate when M.B.'s

depression begins to clear and she is more motivated to improve her sleep hygiene. In the meantime, the potential contribution of sertraline causing restlessness or insomnia should be assessed by confirming the drug is dosed in the early morning to minimize this effect.[78] A sedating antidepressant such as mirtazapine may be preferred unless M.B.'s history includes a positive response with sertraline that would justify ongoing treatment. M.B. also was using alcohol before admission. Alcohol disrupts sleep and can increase arousal when its sedative effects wear off, leading to more fragmented sleep.[38,84] All patients with sleep issues should be counseled to minimize or eliminate alcohol altogether.[84] M.B. should avoid alcohol given her history of substance use. Drug and alcohol withdrawal and the lingering "abstinence syndromes" often are associated with insomnia, although sometimes hypersomnia is the predominant symptom.[38,85]

HYPNOTICS

Prescribing a hypnotic short-term or a sedating antidepressant is recommended for patients who are depressed with insomnia because a good night's sleep can improve treatment adherence and daytime functioning until antidepressant effects become apparent.[73,74] All antidepressants, including selective serotonin reuptake inhibitors (SSRIs), such as sertraline, can improve sleep as the depression lifts; however, most antidepressants such as SSRIs, serotonin norepinephrine reuptake inhibitors (eg, venlafaxine, desvenlafaxine, duloxetine), bupropion, and monoamine oxidase inhibitors can cause insomnia as well.[76,81] Analysis of residual symptoms in partially treated patients who are depressed taking SSRIs shows continuing insomnia is present in 44%, requiring additional interventions such as trazodone or mirtazapine.

Hypnotics that act at benzodiazepine receptors are not recommended for M.B. because of her drug use history and recent alcohol use. Older nonselective benzodiazepines such as temazepam can have a euphoric effect, are cross-tolerant with alcohol, and are likely to be misused by patients with alcohol and

substance use problems.[42] Abuse, dependence, and withdrawal reactions have been reported with newer $GABA_A$ receptor α_1-subunit selective NBRAs (zolpidem, zaleplon, eszopiclone); therefore, neither class of drugs is appropriate for M.B.[39,58]

Antidepressants

Case 84-3, Question 4: What is the evidence for trazodone's use in managing insomnia? What other antidepressants are used in the treatment of insomnia? Discuss the advantages and disadvantages of using sedating antidepressants for the treatment of insomnia in M.B.

If the clinician determines that sertraline treatment is preferred, then trazodone may be added to alleviate insomnia.[86] The addition of trazodone to fluoxetine, bupropion, or monoamine oxidase inhibitors decreased time to sleep and increased duration of sleep but caused intolerable sedation in a few patients who received fluoxetine. Tolerance did not develop to the sedative effects of trazodone in short-term studies (>6 weeks) used adjunctively for depression; however, decreased benefit with time has been reported.[86] The 5-HT_2 antagonist properties of trazodone at low dosages, in addition to its antagonism at histamine-1 and α_1 adrenergic receptors, provide the rationale for its efficacy as a sedating agent.[87]

Trazodone is not thought to be a highly effective antidepressant medication because most people cannot tolerate an effective depression dose (300–600 mg/day). Owing to its sedating properties, low-dose trazodone (50–200 mg/day at bedtime) has become a commonly prescribed adjunctive medication to induce sleep while awaiting the onset of another primary antidepressant's effect.[86] Trazodone has a half-life of ~6.4 hours in younger adults and 11.6 hours in the elderly. It undergoes hepatic metabolism via CYP2D6 and CYP3A4; thus, inhibitors of these isoenzymes can increase blood levels and worsen side effects. The most common side effects of trazodone include drowsiness (29.1%), dizziness (21.9%), and dry mouth (17.7%). Cardiac arrhythmias are possible at

doses >200 mg/day, as is priapism, a painful prolonged erection that occurs in 1 of 1000 to 10,000 males. Although priapism is considered rare, it can lead to impotence if untreated; therefore, males should be counseled about priapism at any dose of trazodone.[86]

In the only placebo-controlled trial of trazodone conducted in primary insomnia, investigators compared the hypnotic efficacy of trazodone and zolpidem with placebo in 306 adults (21–65 years of age). Subjects were randomly assigned to receive trazodone 50 mg, zolpidem 10 mg, or placebo nightly for 2 weeks. Sleep parameters were assessed using a subjective sleep questionnaire, which patients completed each morning and at weekly office visits. Trazodone was found to be as effective as zolpidem for the first week of treatment, but during the second week, only zolpidem was more effective than was placebo.[86] Tricyclic antidepressants (TCAs; eg, amitriptyline, doxepin) were used to treat primary insomnia for years based on case reports describing efficacy in doses of 10 to 75 mg/night.[42,81] TCAs, however, increase the risk of cardiovascular problems and anticholinergic side effects in a dose-related manner (see Chapter 86, Depressive Disorders).

Ultralow-dose doxepin (a TCA) 3- and 6-mg tablets are available for the treatment of insomnia characterized by difficulties with sleep maintenance. Doxepin is not a controlled substance, so it may be of value in patients with a history of substance use. Four clinical trials conducted in slightly >1000 patients demonstrated ultralow-dose doxepin's efficacy and safety in both younger adults and the elderly.[88] Doxepin demonstrated improved sleep efficiency during the final third of the night and in the seventh and eighth hours of sleep. Doxepin was well tolerated, with residual sedation and anticholinergic effects no different than that for placebo. There were no significant effects on next-day alertness, memory, or psychomotor function. Hypnotic efficacy with doxepin was demonstrated for up to 3 months.

For M.B., a TCA raises additional safety concerns. M.B. has a history of substance use and prior suicide attempts. Both are risk factors for future suicide attempts. TCAs are more toxic in overdose

when compared with trazodone, and there are multiple reports of TCA plasma levels increasing to toxic levels when administered in combination with CYP450 2D6 inhibitors (see Chapter 86, Depressive Disorders).

Switching to mirtazapine as an antidepressant that offers more sedation is a reasonable consideration for M.B. If M.B. has a partial but significant response to sertraline at maximal tolerated doses and good tolerability except for insomnia at 4 weeks, mirtazapine can be added to facilitate remission. Mirtazapine has 5-HT_2 antagonist and antihistamine effects, which impart sedation, and it is safer than are TCAs in overdose.[81] Mirtazapine is not associated with priapism, but it can cause metabolic disturbances including weight gain and dyslipidemia.

INSOMNIA IN THE ELDERLY

CASE 84-4

Question 1: S.D., a 77-year-old male, is seen for his initial geriatrics primary care clinic visit. Vital signs include temperature, 98.8 °F (37.11 °C); heart rate, 58 beats/minute; respiratory rate, 18 breaths/minute; BP, 166/69 mm Hg; height, 63 inches (160.02 cm); and weight, 109 pounds (49.44 kg). He was referred from an emergency department (ED) visit 4 days earlier with reports of palpitations and anxiety. Before his ED visit, his medications included atenolol 50 mg daily, lorazepam 1 mg at bedtime, and saw palmetto 320 mg daily. At his ED visit, he stated he had taken lorazepam for sleep for >1 year, but did not take it the prior 2 nights and started feeling palpitations and anxiety. His electrocardiogram showed normal sinus rhythm at 67 beats/minute, and S.D.'s head computed tomography scan result was negative for any hemorrhage. S.D. was told not to restart the lorazepam, but instead to take diphenhydramine 50 mg at bedtime. He took only one dose because it makes him feel "terrible" and fatigued for the next 2 days. On further questioning, he states that he falls asleep without difficulty, usually awakens two to three times each night to urinate, and often has difficulty falling back to sleep. In the past, lorazepam was helpful for his sleep difficulty.

What considerations are important for the assessment and treatment of insomnia in an elderly patient such as S.D.?

Treatment of insomnia in the elderly represents a therapeutic dilemma. Evidence supports an increased need to treat insomnia in the elderly to reduce its potentially serious complications, yet many drug treatment options have potential for harm that may outweigh their benefit. In a large epidemiologic study of sleep problems in 9282 individuals 65 years and older conducted by the National Institute on Aging, 57% of subjects indicated at least one sleep problem occurring most of the time, 19% had difficulty falling asleep, 30% reported awakening at night, and 19% reported of awakening too early.[89] Despite such a high frequency of sleep problems, they are primarily thought to be more a marker of poor physical and mental health rather than caused by aging itself.[89,90]

Historically, it was accepted that age-related sleep changes begin in early adulthood and progress steadily across the adult lifespan.[91] However, in a meta-analysis of 65 studies of quantitative sleep parameters across the lifespan of individuals from ages 5 to 102 without sleep problems, most changes in sleep were found to occur by age 60.[81] Changes in sleep latency are small and subtle, with an overall increase between 20 and 80 years of <10 minutes. Increases in percentages of stages 1 and 2 sleep, as well as decreases in total sleep time, percentage of slow-wave and REM sleep, and REM latency, were significant with aging up to age 60, but only minimal changes were seen after age 60. Only sleep efficiency was found to continue to significantly decrease after age 60. Therefore, identifying factors underlying sleep problems in the elderly is critical and can lead to appropriate diagnosis and treatment. Elderly patients need not be resigned merely to getting the sleep that they do because they are "getting older."[91]

Case 84-4, Question 2: What are the more common underlying causes of sleep problems in the elderly?

Common precipitants of acute insomnia in the elderly include acute medical illnesses, hospitalization, changes in the sleeping environment, medications, and acute or recurring psychological

stressors. Chronic or long-term insomnia may be associated with a variety of underlying medical, behavioral, and environmental conditions, as well as medications.[92] Identification of treatable underlying causes should be the first step in the management of insomnia, based on a medical and medication history, physical and mental status examination, and laboratory investigations including thyroid function, serum chemistry panel, and cardiopulmonary studies if indicated.[92,93] Special attention should be directed to chronic pain from any cause, pulmonary disease, chronic renal disease, neurologic disorders, and polyuria from urinary, prostate, or endocrine disorders. Medical conditions with a strong association with insomnia include heart disease, hypertension, diabetes, stomach ulcers, arthritis, migraine, asthma, chronic obstructive pulmonary disease (COPD), neurologic problems, menstrual problems, depression, and bipolar disorder.[94,95] Primary sleep disorders are RLS, sleep apnea, and circadian rhythm disorders.[73,90,95] The potential contribution of medications to the sleep problem needs to be evaluated, and changes in medication or timing of administration should be considered. Many drugs with CNS effects can alter patterns of sleep and wakefulness, both during their use and withdrawal.[37,89,95] Both prescribed and OTC medications must be evaluated. The more common drugs of concern include stimulants (caffeine, nicotine, and amphetamines), alcohol, activating antidepressants (eg, SNRIs and bupropion), pseudoephedrine, bronchodilators, β-blockers, calcium channel blockers, corticosteroids, and dopamine agonists. Evening administration of drugs such as diuretics may also contribute to nighttime awakenings and sleep problems.

Psychological Versus Drug Treatments for Insomnia

Case 84-4, Question 3: Which nondrug therapy treatment options might be appropriate for S.D.?

CBT is an effective and safe alternative to drug therapy for insomnia and has also been shown to be an effective augmenting treatment with drug therapy.[35,36] CBT limitations include that it is little known, not widely available, and more time consuming than is drug therapy. Both pharmacologic and nonpharmacologic approaches are effective for the short-term management of insomnia in late life, and current evidence suggests that sleep improvements are better sustained over time with behavioral treatment.[35] A comparative meta-analysis of 21 studies of pharmacotherapy and behavior therapy for persistent insomnia in adults found that both treatments similarly produced moderate-to-large improvements in number of awakenings, wake time after sleep onset, total sleep time, and sleep quality.[96] Behavior therapy, however, resulted in a greater reduction in sleep latency than did pharmacotherapy. CBT was compared with pharmacotherapy (zolpidem) and its combination in 63 young and middle-age adults with chronic sleep-onset insomnia.[35] There was a significant difference in percentage change in improved sleep-onset latency (CBT 52%, combination therapies 52%, zolpidem 14%, placebo 17%). No significant differences were found among the groups in total sleep time. The authors concluded that CBT, alone or in combination with pharmacotherapy, was more effective than was pharmacotherapy alone or placebo for the treatment of sleep-onset insomnia. Avoidance of medications with their associated costs, adverse effects, and drug interactions are the primary advantages of CBT. Disadvantages of CBT include possible longer time to effective treatment, higher initial cost, and relative paucity of trained providers in many areas.[97]

Case 84-4, Question 4: What are the concerns about the use of lorazepam or another benzodiazepine in S.D.?

Specific concerns need to be addressed about the risks most associated with benzodiazepines in the elderly regarding dependence, risk of falls, cognitive dulling, and memory loss.[72] Concern about dependence and the nontherapeutic use of

benzodiazepines has been an important factor in limiting the long-term treatment of insomnia with hypnotic drugs.[98] In patients with insomnia specifically, the risks of dependence and recreational use of benzodiazepines are relatively low. Dose escalation appears to occur only when treatment is ineffective or when the patient has a history of substance use disorder or anxiety. Although still controversial, the risk of dependence and abuse associated with the newer nonbenzodiazepine drugs may be lower than that associated with benzodiazepine hypnotic drugs. An even greater concern with benzodiazepine use in the elderly is the risk of falls and subsequent hip fractures. Using 42 months of Medicaid health care claims data in New Jersey for >125,000 individuals older than 65 years, the association between hip fractures and benzodiazepine use was evaluated.[99] Compared with not being exposed to a benzodiazepine, exposure to any benzodiazepine was associated with a 54% higher rate of hip fracture, and after adjusting for potential confounding variables, benzodiazepine use was associated with a 24% higher rate of hip fracture. Use of short half-life benzodiazepines was found to be no safer than the use of long half-life benzodiazepines, and the risk of hip fracture was highest during the first 2 weeks after starting a benzodiazepine. These findings support the usual recommendation that the elderly should be given doses lower than that for their younger adult counterparts, but they challenge the suggestion that only long half-life drugs should be avoided in the elderly owing to clearance concerns. Elderly patients should also be monitored closely to prevent cognitive decline caused by benzodiazepines and avoid use when possible.[100]

Case 84-4, Question 5: What are the concerns about the use of diphenhydramine in S.D.?

Sedating antihistamines are not recommended for treating insomnia in the elderly because there is no evidence of sustained benefit and they pose significant risk of anticholinergic effects, notably cognitive impairment, dry mouth, urinary retention, and

constipation.[37,72,97,101] Duration of sedative effect efficacy from antihistamines is also problematic, with tolerance to sedative effects developing quickly (3–7 days).[102,103]

S.D.'s primary sleep problem is related to his nocturia. He is self-treating his urinary symptoms with saw palmetto, which he did not mention at his ED visit (perhaps because no one asked whether he used any OTC or herbal medications). His primary treatment, therefore, must be directed at assessing and more successfully treating his nocturia. S.D. also likely experienced lorazepam withdrawal symptoms. The many potential risks associated with benzodiazepines in the elderly led to a valid decision to discontinue lorazepam. However, the choice of diphenhydramine was poor not only because of limited short-term efficacy but also because of its potential to worsen both urinary symptoms and memory impairment. Clinicians must ask patients about OTC and herbal medications they may be using to self-treat their symptoms. The best treatment of sleep problems in elderly persons is to identify any underlying treatable cause, review and identify any sleep hygiene issues, and avoid using benzodiazepines or sedating antihistamines, whose risks often outweigh any benefit. Ramelteon may be considered as an option for elderly patients with sleep-onset insomnia who have an increased risk of falls and in patients with a history of COPD or substance use disorder.[48]

PEDIATRIC INSOMNIA

Typical sleep needs in children vary from 12 to 14 hours in children ages 1 to 3 years to between 8.5 and 9.5 hours in adolescents.[104] All major sleep disorders can occur in youth, and therefore evaluation for insomnia, RLS, PLMS, sleep apnea, and narcolepsy are needed whenever symptoms warrant. Trouble initiating and maintaining sleep are more common in children with ADHD (25%–50%) and autism spectrum disorders (44%–83%). Of infants and toddlers, 10% to 30% have bedtime sleep resistance that can be managed

behaviorally with parental education. Inconsistent bedtime, falling asleep away from bed, fears, and psychiatric and medical conditions can all contribute to poor sleep in children.[104]

At least 5% to 10% of high school students have delayed sleep phase syndrome, a physiologic condition in which they do not fall asleep until between 1:00 and 3:00 AM and they awaken between 9:00 AM and noon. School schedules dictate earlier awakening, resulting in chronic sleep deprivation. Poll data indicate that 28% of high school students fall asleep in school at least once a week, and 14% are late or miss school because of oversleeping.[104]

Behavioral interventions to promote good sleep habits (eg, consistent bedtime and wake time, before-bedtime ritual) should be initiated during childhood and continued throughout adolescence to promote a lifetime of healthy sleep. No hypnotics are FDA approved for insomnia in children and adolescents, and significant data are lacking to guide clinicians on medications to improve sleep in youth. Diphenhydramine, clonidine, and melatonin are commonly used in children and some adolescents; however, the use of Z-hypnotics is also increasing, although this class has not been well studied in this population.[105]

PREGNANCY AND LACTATION

Pregnant patients have insomnia symptoms more often than do their nonpregnant counterparts, and many ingest hypnotic or sedating medications. Despite frequent usage of hypnotics, health care providers are often reluctant to prescribe medications to pregnant females for fear of teratogenicity. Doxylamine is FDA pregnancy category A, although this indication is derived from the treatment of hyperemesis gravidarum and not insomnia.[106] Diphenhydramine is in FDA pregnancy category B and is generally considered the safest sleeping medication in pregnancy.[103] Nevertheless, a pregnant patient should only use it on an as-needed basis. Sedating antihistamines are not compatible with breast-feeding because they

have the potential to dry up milk supply because of anticholinergic effects.[107] Melatonin, ramelteon, suvorexant, and lemborexant should not be used because of unknown risks to the fetus.[108,109]

Regarding the most commonly prescribed hypnotic, zolpidem, the American Academy of Pediatrics considers it compatible with breast-feeding, but the risk versus benefit should be considered on an individual basis.[107,108] Other Z-hypnotics and DORAs do not have sufficient data in pregnancy and lactation to make recommendations.[1]

Benzodiazepine hypnotics are pregnancy category D or X. They should be avoided in pregnancy because of the risk of respiratory depression, neonatal flaccidity, infant feeding difficulties if given in the second and third trimesters, and the controversial risk of cleft palate if given in the first trimester.[110] Benzodiazepines are not recommended in breast-feeding because the risks outweigh the benefits in most cases.[107]

SLEEP APNEA

Clinical Presentation

CASE 84-5

Question 1: E.S., a 52-year-old male, presents to an ambulatory care clinic with chronic fatigue, low energy, excessive snoring, and overall less restful sleep. When asked what prompted E.S. to come to the clinic, he answers: "My wife and I have been sleeping in separate bedrooms for the past 6 months. She says my loud snoring and gasping to breathe keeps her awake. I'm tired all day and find myself nodding off a lot." His symptoms have worsened during the past year since early retirement. He has gained weight (220 pounds [99.79 kg]; he is 72 inches [182.88 cm] tall and his body mass index is 29.8 kg/m^2) and has developed hypertension. E.S.'s current BP reading is 145/92 mm Hg. Medications include lisinopril 10 mg and aspirin 81 mg, both taken in the morning.

What are the possible causes of E.S.'s sleep disorder and why is it important for E.S. to have his problem evaluated in a sleep laboratory?

E.S. reports diminished sleep quality, excessive snoring, gasping for air, and weight gain. Although a number of causes could be responsible for E.S.'s symptoms, one of the most serious is sleep apnea. Sleep apnea is a neurologic disorder characterized by mini-episodes of breathing cessation lasting about 10 seconds. These mini-episodes generally occur multiple times in an hour. If there is a reduction in airflow but no cessation of breathing, it is termed *hypopnea.* The brain responds to episodes of apnea and hypopnea with mini-arousals, waking the individual to stimulate breathing.[111,112] These frequent mini-arousals prevent the individual from obtaining quality sleep by not allowing sufficient time in deep, slow-wave sleep, or REM. OSA, the most common type, may be induced when extra body weight (note E.S.'s weight gain) places pressure on the throat and uvula, narrowing the space into which air must travel; this results in the difficulty or cessation of breathing and excessive snoring. An estimated 3% to 7% of males and 2% to 5% of females meet the criteria for OSA.[112,113]

The apnea/hypopnea index (AHI), measured using PSG (ie, EEG, electrooculogram, electromyogram), represents the number of episodes per hour. The AHI score accompanied by symptoms of EDS is used to diagnose OSA as follows: >5 to 14 (mild), 15 to 29 (moderate), and >30 (severe).[112]

Risk factors for OSA include age 65 years and older, obesity (BMI >30), male gender, craniofacial anatomy that alters mechanical and neural properties of the upper airway, genetic predisposition, cigarette smoking, alcohol consumption before sleep, and comorbid conditions such as hypertension, diabetes mellitus, polycystic ovary syndrome, hypothyroidism, and pregnancy.[113] Hypertension and weight gain may be contributing to E.S.'s sleep difficulty. Untreated OSA is associated with an increased risk of hypertension, coronary artery disease, and cerebrovascular disease.[114–116] Although sleep apnea occurs in ~5% of females and 15% of males in the general population, it occurs in up to 40% of patients with hypertension.[114] Treatment of OSA can improve BP control and lead to more restful sleep. Of note, OSA also occurs in nonobese individuals and in all ages, including infants.[113,115] Sleep-disordered breathing, including

snoring, is a significant risk factor for hypertension even in young individuals of normal weight.[114]

Overnight evaluation using PSG in a sleep laboratory would confirm or rule out sleep apnea and allow distinction between OSA and the less-common central sleep apnea.[112,115] Central sleep apnea results when breathing repeatedly starts and stops during sleep because the brain does not send proper signals to the muscles that control breathing (ie, the diaphragm does not move in attempts to take in air).[116] Treatment of central sleep apnea requires continuous positive airway pressure (CPAP) as opposed to being alleviated through weight loss or anatomic manipulations. Central sleep apnea can occur along with OSA.

Drug Treatment Considerations

Case 84-5, Question 2: Results from the sleep laboratory study clearly document E.S.'s sleep problem as OSA. He experiences an average of 65 apneic episodes per hour. E.S.'s weight gain and inactivity probably contribute to the problem. Both are serious, potentially life-threatening conditions. Why should E.S.'s sleeping difficulties not be treated with a hypnotic medication?

Hypnotics, alcohol, or any CNS depressant can be lethal for patients with sleep apnea and should not be prescribed for E.S. CNS depressants interfere with the mini-arousals required to stimulate breathing once it has stopped. In this case, the sleep laboratory study may have saved E.S. from a potential life-threatening breathing disorder that could have been exacerbated by a hypnotic with CNS depressant activity.

OSA can be treated by tracheostomy, nasal surgery, tonsillectomy, uvulopalatopharyngoplasty, and either nasally or orally administered CPAP.[112] Weight loss and CPAP therapy are the most effective treatments and must be maintained for continued therapeutic efficacy.[112,115] In CPAP, the patient wears a lightweight mask to bed each night, and a constant flow of air is provided mechanically to prevent breathing cessation and to allow for more restful sleep.

Although CPAP is effective for both OSA and central sleep apnea, the results are short-lived, and apneic episodes typically reappear when CPAP therapy is stopped. Preliminary studies in individuals with nocturnal bradycardia and sleep apnea show that insertion of a permanent cardiac pacemaker significantly improved bradycardia and sleep apnea.[117] At this time, the best treatment for E.S.'s hypertension and sleep apnea is weight loss and CPAP.

Case 84-5, Question 3: If weight loss, surgery, and CPAP are all ineffective or impractical, what drug treatments are potentially effective for E.S.'s sleep apnea?

Drug treatments indicated for OSA are primarily geared toward improving EDS, and thus have stimulant properties that should be used with caution in patients with cardiovascular conditions. Solriamfetol, a selective dopamine and norepinephrine reuptake inhibitor (DNRI), has recently been approved by the FDA to treat EDS in patients with both OSA and narcolepsy.[118] It is typically dosed starting at 37.5 mg orally once daily upon awakening, and the dose based on efficacy and tolerability can be doubled every 3 days up to 150 mg/day. The most common side effects seen when treating EDS in patients with OSA were decreased appetite, nausea, anxiety, irritability, and insomnia. In addition, solriamfetol has been associated with dose-dependent increases in BP and heart rate.[118] Designated as schedule IV in the United States, solriamfetol is associated with an abuse potential similar to or lower than that of phentermine.[119] Similarly, modafinil and armodafinil are also approved to treat EDS associated with OSA, narcolepsy, and shift work sleep disorder. These agents are often best used as an adjunct to nightly CPAP usage and morning administration of modafinil 200 to 400 mg or armodafinil 150 to 200 mg.[120,121] For E.S., solriamfetol, modafinil, and armodafinil would only be considered if his hypertension was controlled as an adjunct to CPAP. He should be cautioned to monitor his BP carefully if any stimulant medication is used.

NARCOLEPSY

Narcolepsy is an incurable neurologic disorder characterized by the sudden onset of EDS. Although not specific to narcolepsy, EDS is a requirement for diagnosis and can be present with or without cataplexy. Cataplexy, present in 60% to 90% of patients with narcolepsy, involves the loss of muscle tone in the face or limb muscles and is often induced by strong emotions or laughter.[122] Cataplexy can present as subtle, with the patient limp or not moving, or dramatic, with the patient collapsing to the floor.[123] Hypnagogic hallucinations and sleep paralysis are other secondary symptoms not present in all persons with narcolepsy. Hypnagogic hallucinations are perceptual disturbances (ie, auditory, visual, tactile) that occur while experiencing a sleep attack. The patient may see imaginary objects, hear sounds, or feel sensations. Sleep paralysis is a terrifying, benign, and brief (lasting >10 minutes) experience that can occur when falling asleep or when awakening and can last several minutes. Patients are unable to move their limbs, to speak, or even to breathe deeply. Between 10% and 20% of patients experience the tetrad of symptoms that include EDS, cataplexy, hypnagogic hallucinations, and sleep paralysis. Except for EDS, these symptoms are thought to be expressions or partial expressions of REM sleep.[13,111,122]

Narcolepsy is classified into two types: narcolepsy type 1 (NT1) and narcolepsy type 2 (NT2).[26,122] In addition to EDS, NT1 criteria include the presence of cataplexy, whereas NT2 criteria include NT1 symptoms without cataplexy. Symptoms of narcolepsy often begin at puberty, but patients are usually not diagnosed until the late teens or early 20s. Early symptoms consist of EDS and poor sleep quality. The sleep cycle becomes progressively more erratic with frequent bursts of REM and decreased regularity of deep or slow-wave sleep. PSG in a sleep laboratory is ideal to confirm narcolepsy. Sleep architecture is notably different. Instead of the 90-minute delay before REM, individuals with narcolepsy progress directly into REM sleep.[111,122] A cerebrospinal fluid hypocretin 1 level of <110 pg/mL is

also diagnostic for narcolepsy. Postmortem brain studies of patients with narcolepsy show an 85% to 95% decrease in hypocretin-containing neurons.[123]

An autoimmune response of unknown origin is thought to damage hypocretin/orexin-secreting cells in the hypothalamus. Without functional hypocretin/orexin cells, the sleep–wake cycle is disrupted. Hypocretin/orexin is also involved in control of body weight, water balance, and temperature.[111,122]

Comparing Treatments

Optimal treatment of narcolepsy involves treating both sleep attacks and cataplexy. Schedule II controlled substances, methylphenidate and dextroamphetamine, were the first drugs used to treat narcolepsy, with 65% to 85% of patients deriving significant improvements in wakefulness. Mixed amphetamine salts are also FDA approved for narcolepsy.[111] The mechanism of action of methylphenidate and amphetamines is related to increasing neurotransmission of dopamine and norepinephrine. Modafinil, a Schedule C-IV controlled substance, is an effective treatment with less abuse potential. Its exact mechanism of action is not fully understood, but it is thought to increase wakefulness through noradrenergic, adrenergic, histaminergic, GABA-modulating, glutamatergic, and hypocretin/orexin-stimulating mechanisms.[111,122] Armodafinil is the dextroenantiomer of modafinil. Its therapeutic effect, side effect profile, half-life, and abuse potential are similar to those for modafinil.[122] In summary, these stimulating drugs decrease the number of sleep attacks, improve task performance, and increase the time to fall asleep, but they cannot eliminate sleep attacks altogether. Research is underway exploring the possible use of immunosuppression at the time of narcolepsy onset. One hypothesis suggests that the destruction of orexin neurons is immune mediated and immunosuppression therapy during a period of pathologic immune response could prevent or reduce damage to

the hypocretin system that otherwise would lead to the development of narcolepsy.[102,111,123,124]

Newer classes of compounds targeting EDS in narcolepsy include pitolisant, a selective histamine H_3-receptor inverse agonist that acts presynaptically to activate histamine neurons and enhance endogenous histamine release, and solriamfetol, a DNRI.[125,126] Pitolisant is considered a first-line treatment for EDS, as monotherapy or add-on treatment with other narcolepsy medications and also effective in the treatment of cataplexy.[127] At recommended once-daily morning doses ranging from 9 to 36 mg, pitolisant is generally well tolerated, with adverse events that include insomnia, headache, nausea, anxiety, and irritability. Pitolisant is associated with low abuse potential, significantly lower than that of phentermine and similar to that of placebo.[128] Solriamfetol is effective in improving wakefulness in adults with EDS associated with narcolepsy at doses of 75 to 150 mg once daily upon wakening.[118] The most common adverse effects with solriamfetol in narcolepsy studies at the FDA-approved doses were headache, nausea, decreased appetite, anxiety, insomnia, dry mouth, constipation, and palpitations.

Cataplexy does not respond to psychostimulants or modafinil; rather, sodium oxybate and antidepressants remain the first-line strategy. TCAs (imipramine and clomipramine) were the first antidepressants used, but protriptyline, desipramine, SSRIs (fluoxetine, sertraline, and paroxetine), and SNRIs (venlafaxine and duloxetine) are also used.[111] SSRIs and protriptyline offer the advantage of less daytime sedation, compared with tertiary TCAs. The effectiveness of antidepressants for the treatment of cataplexy is thought to be related to REM-suppressant effects. A Cochrane Database Review concluded that insufficient evidence exists to recommend antidepressants as effective treatments for cataplexy, given that most studies are small and uncontrolled.[129] However, it should be recognized that large-scale studies on such a rare disorder are difficult to conduct.[111] Antidepressants are not considered effective in decreasing sleep attacks.[111,122,129]

Sodium oxybate (Xyrem®; Xywav®), a salt form of the CNS depressant γ-hydroxybutyrate, is FDA approved for treatment of cataplexy and EDS in narcolepsy.[130,131] Its therapeutic effects are related to decreased REM, improved sleep consolidation, and increased stages 3 and 4 slow-wave sleep.[111] Sodium oxybate must be administered twice during the night while the patient is in bed to consolidate 6 to 8 hours of sleep. In two randomized, double-blind, placebo-controlled trials, sodium oxybate 9 g/night (ie, 450 mg at bedtime, then 450 mg 2–4 hours later), but not 3 or 6 g/night, significantly reduced the median frequency of cataplexy attacks by 69% in patients with narcolepsy, whereas 4.5 to 9 g for 8 weeks significantly reduced the median frequency of cataplexy attacks by 57% to 85% in a dose-related manner. Both trials showed a 6% to 30% reduction in EDS as measured on the Epworth Sleepiness Scale and a 20% to 43% reduction in daytime sleep attacks.[123] Because of a significant risk of CNS depression and abuse potential, sodium oxybate is a Schedule III controlled substance. It is only available through restricted distribution, the Xyrem® or Xywav® Risk Evaluation and Mitigation Strategy Program, which uses specifically certified pharmacies in the United States for dispensing.[130,131]

Mixed Amphetamine Salts and Fluoxetine

CASE 84-6

Question 1: G.B., a 23-year-old male with narcolepsy, has been taking mixed amphetamine salts ER 60 mg in the morning for sleep attacks associated with narcolepsy, and fluoxetine 20 mg daily will be started to treat cataplexy.

What are the potential risks of using both mixed amphetamine salts and fluoxetine to treat G.B.?

Anorexia, GI problems (abdominal pain, nausea, vomiting, diarrhea), anxiety, irritability, insomnia, and headaches are common side effects of stimulant drugs.[111] Although rare, psychotic reactions can occur in patients with narcolepsy taking stimulants at any dose; however, psychosis generally resolves when the stimulant is

discontinued. Stimulants, even at high dosages (eg, 80 mg methylphenidate), usually do not bring a patient to a normal level of alertness, and sometimes nocturnal sleep is disrupted. To prevent stimulant-induced insomnia, doses should be taken before 3:00 PM. Tolerance to the therapeutic effects of stimulants may develop in some patients with narcolepsy.[111,122,132] Drug holidays may allow the patient to recapture therapeutic benefit; however, many patients opt for an increased stimulant dose instead. Exceeding maximal recommended doses of stimulant significantly increases the risk of psychosis, substance abuse disorder, psychiatric hospitalization, tachyarrhythmia, and anorexia according to a case–control study in 116 patients with narcolepsy taking stimulants.[111,132] Seizures have also been reported.[132]

Fluoxetine may improve cataplexy, but it can worsen nocturnal insomnia and contribute to restlessness, headache, nausea, and sexual side effects including anorgasmia.[81,129] In addition, fluoxetine is a potent CYP2D6 inhibitor resulting in higher levels of amphetamine.[133] G.B. should be monitored closely during the initiation of fluoxetine therapy, and the amphetamine dose should be lowered by 30% to 60% to minimize side effects and prevent toxicity. The optimal therapeutic dose of fluoxetine to manage cataplexy has not been established, but low doses may be effective and minimize the risk of side effects.

Modafinil and Sodium Oxybate

Case 84-6, Question 2: G.B. experiences intolerable nervousness, irritability, and nocturnal insomnia on mixed amphetamine salts and fluoxetine. There is no improvement in cataplexy with the addition of fluoxetine. He asks about switching to modafinil and sodium oxybate. Does the combination of modafinil and sodium oxybate offer any advantage for G.B.?

Modafinil's efficacy relative to other CNS stimulants has not been adequately assessed in controlled clinical trials; however, it has less potential for insomnia and adverse CNS reactions at recommended

dosages between 200 and 400 mg/day administered in the morning.[134] It also has less abuse potential compared with stimulants and is a Schedule IV controlled substance. Headache was the only adverse experience rated significantly higher than was placebo in 283 patients taking the recommended dose of either 200 or 400 mg/day of modafinil. Anorexia, nervousness, restlessness, and pulse and BP increases are dose-related side effects to discuss during counseling. The maximum tolerable single daily dose may be 600 mg/day because 800 mg/day produced increased BP and pulse in one tolerability study.[135] Gradual dosage titration improves tolerability. Armodafinil, an active stereoisomer of modafinil, is effective at usual doses between 150 and 250 mg/day. It has an adverse effect profile similar to that of modafinil.[122,134]

Improved daytime wakefulness is an advantage of sodium oxybate compared with antidepressants. A controlled trial involving 278 patients showed an increase in slow-wave sleep (stages 3 and 4) and decreased nightly sleep disruption in patients taking sodium oxybate with modafinil compared with modafinil alone.[136] Sodium oxybate can be administered safely with stimulants and modafinil; however, coadministration with other CNS depressants, including hypnotic medication, is contraindicated because of the risk of respiratory depression.[123]

Case 84-6, Question 3: What counseling should G.B. receive as he switches to modafinil and sodium oxybate?

People taking modafinil should receive counseling regarding the potential for drug interactions. Modafinil induces CYP3A4 metabolism primarily in the gut and inhibits CYP2C19. Decreased levels of triazolam and ethinyl estradiol have been associated with modafinil coadministration.[137] Monitoring for drug interactions is crucial because modafinil and armodafinil are increasingly used for other indications, including daytime sleepiness associated with Parkinson disease, shift work, fibromyalgia, sleep apnea, fatigue associated with multiple sclerosis, and ADHD.[138–140]

Sodium oxybate should not be given to those with sleep-disordered breathing, sleep apnea, or an alcohol or substance abuse disorder.[130,131] Adverse effects include nausea, headache, dizziness, and enuresis. Safe coadministration of modafinil and sodium oxybate has been described in clinical trials[136]; however, cases of severe side effects including panic, psychosis, depression, and new-onset suicidal ideation have been described.[141] The risk of serious side effects versus benefits in managing cataplexy and nocturnal insomnia should be discussed with G.B. and his family. Close monitoring, particularly during the first weeks and months of treatment and when dosages are adjusted up or down, should be advised.[141,142] G.B. should be instructed how to properly administer sodium oxybate, drinking half the dose on an empty stomach immediately before bedtime and then setting his alarm for 4 hours later to take the midnocturnal dose.

Naps and Other Behavioral Interventions

Case 84-6, Question 4: The benefits, possible risks, and importance of regular physician assessment have been explained to G.B., and he agrees to report efficacy and adverse effects to his primary care provider regularly. G.B. is reminded to take the medicine at regular intervals along with daytime naps. Why are naps helpful in the treatment of G.B., and what other behavioral interventions are useful in treating narcolepsy?

Strategically timed 15- to 20-minute naps taken at lunch and then again at 5:30 PM can be refreshing for patients with narcolepsy and increase their time between sleep attacks. Narcolepsy support groups are available and may help G.B. better cope with such a life-changing chronic illness. It also is important for G.B. to avoid alcohol and to regulate his bedtime and wake-up time in the attempt to normalize his sleep habits.[111,122,134]

Schizophrenia

Richard J. Silvia, Robert L. Dufresne, and Justin C. Ellison

CORE PRINCIPLES		CHAPTER CASES
1	Schizophrenia is a persistent, heterogeneous syndrome that includes both positive and negative symptoms. Together, these symptom clusters can have variable effects on patient quality of life, functional recovery, and prognosis. Prodromal symptoms preceding the first episode of psychosis may go unnoticed for many months. Onset of an acute psychotic episode can be an acute or insidious process that causes a significant impact on function and ability to perform activities of daily living.	**Case 85-1 (Questions 1, 2)**

	CORE PRINCIPLES	CHAPTER CASES
2	Treatment goals will vary based on the stage of the patient. During an acute phase, stabilization and safety are primary. During a stable phase, maintaining stability and improving functional recovery are the main goals. Treatment modalities should include both pharmacologic and nonpharmacologic methods.	**Case 85-1 (Questions 3–5)**
3	Many factors need to be considered in selecting an appropriate medication regimen for a patient with schizophrenia. Patient factors such as comorbidities, targeted symptoms, adherence history, personal and family history of medication response, and others need to be assessed. Medication-related factors include efficacy, safety profile, pharmacokinetics and drug interactions, and economic considerations.	**Case 85-1 (Questions 6, 7, 10, 11, 14, 15, 22, 26, 27, 30, 33)**

	CORE PRINCIPLES	CHAPTER CASES
4	Adverse effects of antipsychotics are varied. They may include acute and chronic extrapyramidal movement disorders, metabolic disturbances such as weight gain and alterations in serum glucose and lipids, and other adverse effects such as sedation and orthostasis. Monitoring and appropriate interventions for adverse effects should be ongoing throughout all stages of illness to ensure continued safety and avoid medication discontinuation.	**Case 85-1 (Questions 8, 9, 15–25, 27–30)**
5	Patients who do not respond to an adequate antipsychotic trial should be assessed for adherence. Long-acting injectable antipsychotics may be an option to help maintain adherence. Clozapine is the treatment of choice in patients who are refractory to at least two adequate trials of antipsychotic medications. However, clozapine does require strict adherence to blood monitoring because of the risk of agranulocytosis and carries a significant adverse effect burden.	**Case 85-1 (Questions 12–14, 26, 30–32)**

CORE PRINCIPLES		CHAPTER CASES
6	Treatment of female patients of childbearing age may require special consideration. Untreated psychosis can result in poor self-care for the mother and inadequate prenatal care. There is also the concern regarding substance use, dangerous behaviors, and even suicide. Therefore, the risks and benefits of ongoing antipsychotic treatment should be carefully weighed by both the patient and the treatment team.	**Case 85-1 (Question 34)**
7	Early recognition of symptoms of first-episode psychosis (FEP) and referral to appropriate multidisciplinary, comprehensive treatment services are crucial to long-term functional recovery. This population is highly sensitive to adverse effects. Antipsychotics should be titrated to the minimum effective dose to decrease the duration of untreated psychosis and improve long-term prognosis.	**Case 85-1 (Question 35)**

INTRODUCTION

Schizophrenia is a psychiatric illness that can lead to lifelong effects on a patient's functioning. Manifesting primarily as a thought disorder, patients often have problems with perception, maintaining

contact with reality, thought processing, and behavior. These symptoms can lead to a variety of impairments across many domains, including social, occupational, and emotional. Owing to these symptoms, patients may require hospitalizations to help maintain or restore functionality. Treatment of schizophrenia encompasses multiple modalities, all targeted at improving a patient's symptoms and functioning, decreasing hospitalizations, and preventing morbidity and mortality.

EPIDEMIOLOGY

Schizophrenia is a heterogeneous, genetically linked "spectrum" disorder that affects 0.7% of the population.[1] It is the ninth leading cause of disability in the world,[2] being found in all cultures and races. Although often incorrectly assumed to be more common in males, there is no gender difference in the incidence of the illness. However, the onset of schizophrenia tends to occur between ages 18 and 25 in males and from 26 to 45 years old in females and usually persists for a lifetime.[3] Overall, more severe symptoms are generally seen in males versus females.

ECONOMIC BURDEN

The economic burden of this devastating disease and its treatment is enormous.[4–7] In one estimate from 2002, U.S. costs for schizophrenia totaled $62.7 billion. This included $30.3 billion in direct health care costs (of which medications accounted for $5.0 billion) and $32.4 billion in indirect costs, such as lost productivity and other costs incurred to the health care system. Although progress has been made in treating the symptoms of schizophrenia and restoring moderate levels of functioning, there is as of yet no cure. Because many patients present with an early age of onset, the

lifetime burden of illness can be great. Many patients will need repeated hospitalizations, and when not hospitalized will require significant outpatient services and treatment. In addition, many patients require supportive living situations, either in facilities designed for these services or with family members, increasing the financial burden on their families as well.

ETIOLOGY

Multiple neurotransmitter and physiologic mechanisms have been hypothesized to explain the complex etiology of schizophrenia. Many theories on the role that aberrant neurotransmitter systems play in schizophrenia are derived from the pharmacologic actions of the medications used to treat the illness in addition to direct analysis from biologic samples. Findings on neurologic scans and other measurements of neuroanatomy are also not consistent across patients to allow for these methods to be reliably employed in making a diagnosis of schizophrenia. Genetic markers have more recently been explored with advances in genetics, but these too are not all encompassing. In this section, the chemical, biologic, and environmental basis of schizophrenia are presented.

Genetic and Environmental Risk Factors

A genetic component to schizophrenia has been hypothesized since the observation that family members of patients are more prone to develop schizophrenia than is the general population. Rates of schizophrenia among family members vary (anywhere from 2% to 50%) based on the relationship to the patient with schizophrenia.[1] Children born to parents who both have schizophrenia are affected in 40% to 60% of cases. Siblings of patients with schizophrenia, including dizygotic twins, are also affected in 10% to 15% of cases. However, monozygotic twins develop schizophrenia ~50% of the time if their twin also has the illness. Second- and third-degree

relatives of patients more closely approximate the general population, but still develop the illness ~2% to 5% of the time. Many genes are thought to play a role in schizophrenia, but no one gene has been found to be universal across patients. This finding suggests that multiple genes may be involved in the etiology of schizophrenia. Although a genetic role appears to exist, it does not explain how all patients develop the illness. Approximately two-thirds of patients have no known familial history of the illness; therefore, other factors must play a role in these patients.[1] Certain environmental exposures in early development are associated with the development of schizophrenia. Maternal infections, in particular influenza, stress, and malnutrition during the first and second trimesters, have shown a link to the child developing schizophrenia. Fetal or infant hypoxia during delivery or in the first few months of life has been shown to double the risk of schizophrenia. Childhood trauma and substance abuse have also been linked to the development of schizophrenia.

Pathophysiology

The actual nature of the pathophysiology of schizophrenia is both unknown and complex. It may be more appropriate to conceptualize it as a syndrome that may involve many different underlying disease mechanisms.[8] Although numerous deviations in brain structure and physiology have been noted, such as decreased gray matter volume, whole-brain volume, and enlarged ventricle size,[9] most treatments focus on antagonism of presupposed increased activity at dopamine-2 (D_2) receptors. The potency of typical antipsychotic medications has correlated with their antagonism of these receptors, although some atypical antipsychotics, such as clozapine, are extremely effective with a lesser degree of D_2 receptor blockade.[10] The initial *dopamine hypothesis* of schizophrenia theorized that positive symptoms of schizophrenia (eg, conceptual disorganization and hallucinations) result from abnormally increased activity in the mesolimbic dopamine neurons and that negative and affective

symptoms of schizophrenia result from subnormal mesocortical dopamine neuronal activity.[11] This remains a clinically useful, albeit simplistic, conceptual framework because many dopamine agonists tend to increase positive symptoms and oppose the effects of antipsychotics. The relation of negative symptoms to dopamine neurotransmission is even more complex. Some suggest that decreased dopamine in frontal areas is linked to negative symptoms and that increased dopaminergic neurotransmission in striatal areas results in positive symptoms.[12] To explain the efficacy and lack of movement adverse effects, prolactin elevation, or secondary negative symptoms of antipsychotics such as clozapine and quetiapine, one theory proposes that they have a faster dissociation from the D_2 receptor than do other antipsychotics.[13] It has also been suggested that 65% of D_2 receptor occupancy predicted response and 78% predicted extrapyramidal adverse effects.[14]

More recent thinking suggests involvement of glutamate and γ-aminobutyric acid (GABA), which are intertwined with the disturbances in dopaminergic neurotransmission.[15] Although speculation that glutamate was involved in the pathophysiology of schizophrenia started in the 1980s, the demonstration that *N*-methyl-D-aspartate (NMDA) receptor antagonists best replicated all the major schizophrenic symptoms such as the positive, negative, and cognitive ones in healthy subjects lent credence to the "NMDA receptor hypofunction hypothesis." Because negative symptoms and cognitive deficits are not treated by D_2 receptor antagonists nor worsened by dopamine agonists, a theory that involves early disruption of glutamine transmission in schizophrenia is an appealing hypothesis. Also, unlike subcortical dopaminergic dysfunction, pathologic brain changes such as widespread dendritic and spine dysplasia along with cortical atrophy could possibly relate to NMDA receptor hypofunction.[16] Excitatory neurotransmission in the brain is predominantly glutamatergic, and glutamate dysfunction could possibly relate to dopamine dysfunction both in its prodrome and later on in the course of the illness.[17] In schizophrenia, it can be considered that dopaminergic changes are a final end mechanism

where antipsychotics work, in which increased mesocortical dopamine turnover and overactive mesolimbic dopaminergic overactivity result from other preceding neurotransmitter changes.[10]

Gradual progressive NMDA receptor hypofunction would also be consistent with the altered neuroanatomy of schizophrenia.[18] Decreased brain volume in schizophrenia has been noted since the 1920s, and there are more recent findings to believe that there are changes in brain structure with reductions in the volume of certain areas of the brain as well as changes in connectivity.[8] Enlargement of cerebral ventricles is a typical finding in schizophrenia, and reduced dendritic spine density in cerebral cortical pyramidal neurons where NMDA subtypes of glutamate receptors are present have been noted.[19] Some of these neuroanatomic differences include impaired white matter integrity and reduced volume of gray matter in the inferior parietal, prefrontal, superior, and medial temporal, thalamic, and striatal regions.[20] There are also a number of studies suggesting the importance of these white matter abnormalities in schizophrenia to dysconnectivity between functional tracts.[21]

CLINICAL PRESENTATION

Historical Concept of Schizophrenia

Schizophrenia was first characterized as “dementia praecox” by early psychiatrists Arnold Pick and Emil Kraepelin in the late 19th century,[22] and was described by Bleuler as a “disintegration of psychic functions.”[23] Historically, schizophrenia has been a disease characterized by progressive deterioration of the brain. Although modern findings seem to corroborate this viewpoint, few patients with schizophrenia show the progressive incremental loss of function that is characteristic of neurodegenerative illnesses.[24] The demonstrated effectiveness of dopamine receptor antagonists in the treatment of schizophrenia[25] resulted in the disorder being

conceptualized as a heterogeneous syndrome characterized by D_2 receptor hyperfunction[26] predominately in the mesolimbic regions of the brain.

Diagnosis and Differential Diagnosis

The diagnosis of schizophrenia in the recently introduced *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) requires that an individual has at least two persistent symptoms such as delusions, hallucinations, or disorganized speech or behavior over a 6-month period.[3] Also, in the *DSM-5* subtypes of schizophrenia, such as paranoid or undifferentiated, have been removed. These distinctions were not clinically useful because patients often displayed characteristic symptoms from each subtype at various times in their illness, or even concurrently.[3] Patients presenting with either manic or depressive symptoms concomitantly with their typically schizophrenic ones are still diagnosed as having schizoaffective disorder (**Table 85-1**).

Table 85-1
***DSM-5* Criteria for Schizophrenia**

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3: 1. Delusions 2. Hallucinations 3. Disorganized speech (eg, frequent derailment or incoherence) 4. Grossly disorganized or catatonic behavior 5. Negative symptoms (ie, diminished emotional expression or avolition)
B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if

successfully treated) that meet Criterion A (ie, active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (eg, odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiologic effects of a substance (eg, a drug of abuse, a medication) or another medical condition.

F. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are present for at least 1 month (or less if successfully treated).

Numerous disorders are characterized by psychosis during exacerbation. Schizophrenia differs in its presentation from bipolar disorder in that there are prominent signs of conceptual disorganization and hallucinations (**Table 85-2**). Prominent "negative" symptoms such as apathy, avolition, poverty of speech, and emotional blunting may also be present. Schizoaffective disorder, bipolar type may pertain to patients who present with both positive schizophrenic symptoms and either mania or depression. It is not uncommon for patients with schizophrenia to suffer from secondary depression at various times during the course of their illness as well.[27] Suicide in these patients is not uncommon.[28]

Table 85-2

Differential Diagnosis for Schizophrenia

Drug-Induced Psychoses

Drug-Induced Psychoses
Alcohol (or other sedative-hypnotics)
Amphetamine (or other stimulant)
Cocaine
Cannabis (marijuana)
Phencyclidine (PCP)
Lysergic acid diethylamide (LSD)
Anticholinergics (especially in overdose)
Anabolic and corticosteroids
Other Psychiatric Disorders
Major depressive or bipolar disorder with psychotic features
Schizoaffective disorder
Schizophreniform disorder and brief psychotic disorder
Delusional disorder
Paranoid, schizoid, or schizotypal personality disorder
Obsessive–compulsive disorder and body dysmorphic disorder
Posttraumatic stress disorder
Autism spectrum disorder or communication disorders

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. American Psychiatric Association; 2013.

In new-onset psychosis, the treating clinician should be careful to rule out drug-induced (eg, amphetamines, cocaine, “k2” synthetic cannabinoids, anticholinergics, lysergic acid diethylamide [LSD], phencyclidine) causes. Corticosteroids may induce a manic type of psychosis, whereas anabolic steroids may provoke a more aggressive type of psychotic presentation. Obtaining a toxicology screen may be prudent. A patient can have a brief psychotic disorder that comes on suddenly, last for up to 1 month, and remit with no recurrence of symptoms. A patient presenting with signs and symptoms of schizophrenia between 1 and 6 months is said to have a schizophreniform disorder. Furthermore, depression can present with mood-congruent auditory hallucinations (often deprecatory) and

delusions. Finally, patients with cluster A personality disorders can show some isolated symptoms such as paranoia or blunted affect, but do not meet the full criteria of schizophrenia.[29]

Hallmark/Target Symptoms

The symptoms of schizophrenia are generally organized into two main domains: positive and negative (**Table 85-3**). Positive symptoms are usually what the public perceives when thinking about schizophrenia: hallucinations, delusions, and disorganization. Hallucinations can affect any of the five senses, but auditory ones are the most common. Delusions are fixed false beliefs that are persistent despite evidence to the contrary. Delusional subtypes include persecutory, erotomanic (eg, delusion of love), delusions of grandeur (having special abilities), or somatic (eg, delusion of being pregnant in the context of negative pregnancy test results). Disorganization can manifest in the patient's speech, thought patterns, or behaviors. For example, a patient wearing a winter coat in the summer or having an unprovoked agitation would constitute disorganized behavior. Negative symptoms of schizophrenia include apathy, avolition, blunted affect, and poverty of speech.[30] A decreased ability to experience pleasure (known as *anhedonia*) and social withdrawal can lead to significant functional impairment, even when positive symptoms are relatively absent in a patient. During acute episodes, positive symptoms may predominate, whereas over the long term it may be negative symptoms that are more troubling and disabling to a patient. A third domain of cognitive symptoms can also present in schizophrenia. Symptoms include concrete thinking, inattention, problems with memory, learning and executive function, as well as conceptual disorganization.[31] When these cognitive symptoms are combined with negative symptoms over the patient's lifespan, significant impairment in function may result. Comorbid depression is also common in schizophrenia,[32] can be difficult to treat,[29,33,34] and symptoms can be predictive of relapse.[35,36] Depressive symptoms may be overlooked in the face of

overwhelming positive symptoms, or confused with negative symptoms.

Table 85-3
Positive and Negative Symptoms of Schizophrenia

Positive	Negative
Hallucinations (auditory, visual, or other senses)	Diminished emotional expression (body language)
Delusions (persecutory, paranoid, grandiose, etc)	Avolition/psychomotor retardation
Disorganized thinking/speech	Alogia (decreased speech)
Grossly disorganized or abnormal motor behavior (including catatonia)	Anhedonia (decreased ability to feel pleasure)
Unusual behavior	Asociality (lack of socialization)
Combativeness, agitation, and hostility	Affective flattening
Ideas of reference	

CASE 85-1

QUESTION 1: J.J., a 26-year-old, single female college student, was brought to the emergency department of the local hospital by her school's campus security at 3:00 AM after she was found running naked through the campus screaming, "They're after me and won't leave me alone! They keep telling me to run and hide!" J.J.'s roommate has accompanied her with the security officers.

History of Present Illness: J.J. is not a good historian, but her roommate is willing to provide information to help. When asked questions, J.J. provides indirect, tangential answers, repeating her concerns of "they are after me." When asked who is after her, she responds "the FBI of course! They think I'm a spy, but I am a spy for the CIA!" Various times during the interview, J.J. is found talking to someone not in the room. When asked about that, she says she hears the voice of her CIA supervisor through the "transmitter in my head" and needs to respond. She said the transmitter also allows her to read other people's minds, which is how she spies for the CIA. J.J.'s roommate states that J.J. has been acting erratic for the past couple semesters, but she thought it was just from an online video game they had been playing. Once, she returned to their dorm room and J.J. had barricaded the door from the inside with furniture so no one would find her. She states that J.J. is often up late at night on her computer, which she says is to "look for traces of the enemy spies."

Medical History: J.J. has no significant medical or psychiatric history. She has never been hospitalized or treated for any psychiatric condition in the past. Her roommate has known her since they started college together 3 years ago, and they have been roommates for the past 2 years. The roommate says J.J. was fairly normal-quiet and shy, getting good grades until the unusual behavior started almost a year ago after they returned from summer break. She says J.J.'s behavior has gotten increasingly unusual and erratic since then.

Psychosocial History: A call to J.J.'s mother finds that her father has a history of alcoholism and domestic violence, which led to their divorce when J.J. was 14. J.J.'s paternal uncle has been diagnosed with schizophrenia and has been hospitalized multiple times over his lifetime. J.J.'s mother says she has always been a very good student, but not very social when in high school, tending to isolate from her classmates. She screamed at them one day in school saying she would defend herself if they carried out their plans and the police were called. No charges were filed and J.J. was entered into the school's anger management program, to which she never showed up. J.J.'s roommate states she only drinks socially at occasional parties and denies any illicit substance abuse.

Physical Exam/Lab Tests: J.J.'s physical exam shows no significant or contributory findings other than some bruising on her knuckles from punching the walls. J.J. states this is from "fighting off the FBI agents" when they find her. Lab tests, including complete blood count (CBC), serum chemistry panel, and liver and thyroid function test results all return normal. A urine drug screen returns negative results. No other tests were ordered.

Mental Status Exam: *Appearance and Behavior*: J.J. is a tall, average-build, neat but casually dressed young female who appears her stated age. She shows signs of paranoia and agitation because she is constantly looking around the room and pacing. She constantly asks to be released "before they find me." *Mood:* J.J. is anxious and concerned that the "FBI will find me" and prevent her from completing her mission. Affect is animated because of her level of agitation. She does not report any depressive ideation. *Memory:* Long-term memory appears to be intact (confirmed by roommate), but the patient will not cooperate with recall tests of immediate and short-term memory because "this is a waste of time and I need to be released." *Orientation:* J.J. is oriented to person, place, time, and situation. *Thought Content:* J.J. is fixated on needing to leave in order to complete her mission. She is convinced that the longer she stays, the more likely the FBI will find her here and she will "need to fight my way out." She also states she is trying to use her implanted transmitter to read the thoughts of the people in the room. She denies any suicidal or homicidal ideation. She accuses you of keeping her there to help the FBI. *Thought Process:* J.J.'s speech is highly disorganized such that she can be difficult to comprehend. *Perception:* J.J. is clearly responding to internal stimuli and most likely to auditory hallucinations. She also keeps asking the staff if something is burning and where the smell is coming from. *Insight and Judgment:* J.J. has

poor insight into her symptoms and mental state, and will most likely require inpatient hospitalization for psychosis.

Provisional Diagnosis: psychotic episode, most likely due to schizophrenia

What hallmark symptoms of schizophrenia is J.J. presenting with at this time? How might these symptoms be used in monitoring treatment?

J.J. currently presents with a number of hallmark symptoms of schizophrenia. She has olfactory and auditory hallucinations (hearing her CIA supervisor and others), delusions (she works for the CIA and the FBI is after her, having a transmitter in her head), and magical thinking (she can read people's thoughts). She shows conceptual disorganization in her speech. She is also agitated and uncooperative and has acted out on her delusions by getting into arguments with people she feels are from the FBI. These symptoms should begin to decrease and subside with time as effective medication treatment is utilized, allowing us to determine if J.J. is responding appropriately.

Case 85-1, Question 2: What information from J.J.'s history also contributes to a diagnosis of schizophrenia? What is the prognosis for J.J.?

Although J.J. has had no previous psychiatric treatment, she is in the age range for an initial psychotic episode of schizophrenia (late teens to mid-20s). J.J. has been showing increasingly unusual behavior for >6 months and possibly up to a year, according to her roommate, with more drastic changes more recently. Before this, J.J. did show some prodromal symptoms, most notably some difficulty interacting with peers while in high school and isolating herself. There is also a family history of schizophrenia (paternal uncle) and alcoholism (father). J.J.'s prognosis is variable because her young age of onset, family history of schizophrenia, and unstable home environment at a young age indicate a poor prognosis, but her relatively high baseline functioning and intelligence (she did very well in high school and is currently in college) would increase the chances for a better long-term outcome. Because J.J. is early in her

illness, it will take time to better determine her long-term prognosis more clearly.

Typical Course of the Illness and Prognosis

The course of schizophrenia can vary between individuals. However, a common pattern entails a premorbid phase with possible signs of cognitive, motor, and social deficits in childhood at 12 years old or younger, a prodromal phase during adolescence and young adulthood (12–18 years old) including a functional decline with brief or attenuated positive symptoms, and then an active phase that includes florid positive symptoms as part of psychosis.[20,37] An improved prognosis is associated with female gender, a preponderance of positive and mood symptoms versus negative symptoms, rapid onset of symptoms, older age at symptom onset, and high premorbid functioning.[38,39]

Generally, the negative (or deficit) and cognitive symptoms of schizophrenia predominate earlier in the development of the disorder. Florid positive symptoms usually emerge between ages 18 and 25 years in males and 20 and 30 years in females.[23] During the prodromal phase, patients may show what resembles negative symptoms: blunted affect, decreased motivation and energy, social withdrawal, and others. Cognitive symptoms may also present, such as poor concentration and memory, which may manifest as declining school or work performance. Low-level positive symptoms may also be seen, mostly in the form of disorganized thinking. Other symptoms such as depression, anxiety, or irritability may also present. Often, these symptoms will go unrecognized in adolescents and may be mistaken for anything from puberty, relationship problems, or drug abuse. This phase may last from weeks to years and often is not attributed to schizophrenia until the first psychotic episode. In many instances, patients will convert to a full schizophrenia diagnosis with more significant positive symptoms and go months or more before receiving treatment. This delay may affect the long-term prognosis of the illness because early treatment can

decrease later morbidity and because the response to treatment in first-episode schizophrenia is critical.[40]

After an active phase of schizophrenia, which can last a large part of adulthood, patients usually enter a residual phase of chronic disability. Later in this phase, symptoms may become somewhat similar to that of the prodromal phase. As the disease progresses, residual symptoms may increase between episodes and make normal day-to-day functioning difficult. As the patient ages, the medical complications of schizophrenia, treatment-emergent metabolic syndrome, and effects of tobacco use increasingly take hold.[37] Patients with schizophrenia have a life expectancy of 9 to 10 years less (or more by some estimates) than that in the average population.[41] The disease often becomes characterized by a preponderance of negative symptoms and cognitive deficits in those living into the later years.[3] However, with early intervention and support, many patients can achieve symptom control and lead meaningful and fulfilling lives.

TREATMENT

Schizophrenia is generally considered a chronic, lifelong illness consisting of varying periods of illness severity, with resulting effects on patient functionality. Although pharmacotherapy can have positive effects on reducing symptoms of the illness and improving functionality, there are often symptoms that may not respond adequately to treatment. In addition, despite adequate treatment, patients may have relapses of their illness, leading to acute psychotic episodes needing more intensive treatment. Treatment is, therefore, usually lifelong and is often multidisciplinary in its approach, consisting of pharmacotherapy, psychosocial therapy, case management, and other methods.

Goals of Treatment

The overall goal for the treatment of schizophrenia is to reduce the symptoms of the illness to improve patient functionality and quality of life. Depending on the patient's current level of acuity, the specific goals for the patient at that time may vary. Although similar pharmacotherapy and nonpharmacotherapy methods may be employed across the spectrum of severity of schizophrenia, they may be utilized differently. Patients are generally described as being in one of three treatment phases according to the American Psychiatric Association (APA): acute, stabilization, and stable.[3] These phases are not static, and patients can move between these phases frequently over the course of their illness.

ACUTE PHASE

The primary goal of treatment in the acute phase of illness is to reduce the threat of harm to the patient or others. Patients experiencing acute psychosis will present with prominent positive symptoms and exhibit disorganized speech and/or behaviors. Negative symptoms and suicidal ideation may also be more pronounced and severe. This will often require a higher level of care than the outpatient setting can provide and necessitate inpatient psychiatric hospitalization while the patient is stabilized. Medications, including short-acting injectable antipsychotics and benzodiazepines, are usually required to target agitation in acute psychosis. However, psychosocial interventions and collaboration with family and caregivers for collateral information are also crucial in this phase of illness.[42] Antipsychotics should be initiated as soon as clinically possible to decrease the duration of untreated psychosis and improve long-term prognosis.[43]

The reason for psychiatric decompensation should be ascertained through patient report and collateral information (eg, caregiver insight, pharmacy fill records). Schizophrenia has a variable course. Exacerbations can occur even on a therapeutic regimen in the context of psychosocial stressors, illicit substance use, and other reasons. However, if the exacerbation was due to nonadherence, the reasons should be explored with the patient. If the patient was

nonadherent owing to intolerable adverse effects, a lower dose or an alternative medication could be considered. If difficulty remembering to take medication was the issue, a long-acting injectable (LAI) formulation could be considered. In either scenario, the decision to initiate or change the antipsychotic should be based on patient preference, prior history of response, tolerability, and relevant medical comorbidities.

STABILIZATION PHASE

The aim during the stabilization phase is to promote continued recovery, maintain symptom control, begin facilitating referrals for supportive outpatient services, and reduce adverse effects and the likelihood of future relapse. The patient and involved caregivers should be educated on the timeline of symptom response, possible medication adverse effects and their management, importance of adherence, and recognizing early signs of symptom recurrence. Risk of relapse is highest in the first 6 months post the initial psychotic episode. Therefore, medications should be maintained for at least 6 months at the dose found to be effective in reducing positive symptoms during the acute phase.[44] Patients and caregivers should be counseled that partial response, such as decreased volume, intensity, or frequency of auditory hallucinations, should not be considered a failure of treatment. Residual symptoms can persist beyond the acute and stabilization phases but may remit with maintenance treatment.

STABLE PHASE

The main focus of the stable phase is quality of life and functional recovery. This is achieved through ensuring optimized treatment of symptoms, minimizing the risk of adverse effects, and psychosocial interventions. The question of how long antipsychotics need to be continued is often raised by patients. Antipsychotics have been shown to significantly reduce rates of relapse at 1 year versus placebo.[45] Therefore, maintenance antipsychotic treatment should be continued for at least 1 year in all patients recovering from a

psychotic episode. Caveats to this include intolerable adverse effects to the antipsychotic or uncertainty of the diagnosis of schizophrenia. Lifelong treatment is recommended in patients who have experienced multiple episodes of psychosis, at least two episodes within 5 years, or those who pose a significant risk to themselves or others when symptoms are left untreated. A slow, cautious taper off of antipsychotics can be considered after 1 year in patients recovering from a first episode with close follow-up established.[44] Routine monitoring for adverse effects, especially extrapyramidal syndromes (EPSs) and metabolic syndrome, is recommended during the stable phase. Patients may not connect an adverse effect to their medications, particularly a somatic symptom, when the main therapeutic target of their medication is in the central nervous system (CNS), so education and close follow-up are needed. The nonpharmacologic aspects of treatment are an important adjunct to pharmacologic management in functional recovery. Psychosocial interventions include assertive community treatment teams for high-risk patients, vocational training or supported employment, and cognitive-behavioral therapy. Adjunctive treatments for comorbid conditions, such as depression and anxiety, should also be addressed during this phase.

Nonpharmacologic Interventions

In addition to medication-based treatments, there are a variety of nonpharmacologic treatments that have also been found to be useful in the treatment of schizophrenia. Most patients will benefit from a combination, multidisciplinary approach to treatment. Treatment guidelines for schizophrenia recommend a treatment plan that includes both pharmacologic and nonpharmacologic treatment.[44] Nonpharmacologic interventions may include individual or group psychological therapy as well as family therapy, cognitive skills training, vocational skills training, and others. When utilized, these interventions have increased patient understanding of their illness,

decreased patient symptoms and relapse rates, and improved social and occupational functioning.

Selection of one of these interventions is based on the patient's level of acuity and specific needs, but should be considered during all phases of the illness. For example, a patient having an acute episode of psychosis might not be appropriate for cognitive or vocational skills training, but might benefit from individual therapy to help develop insight into their illness and understand why they are being treated. During an acute phase, other more simplistic interventions can also play a key role. For example, inpatient settings may utilize techniques to minimize stimulation or stress for patients, particularly those who are agitated or potentially aggressive. Group therapy sessions can assist patients with social interaction, something that might be difficult for many patients.

As the patient moves from an acute phase into a stabilization or stable phase, addition of skills training could be considered. Many patients will have lingering negative and cognitive symptoms that might not fully respond to pharmacotherapy. Cognitive skills training can assist with both of these areas, helping patients to overcome functional deficits arising from these symptoms. Vocational skills training can teach patients a variety of skills to prepare them to reenter the workforce, even if only in a minor role.

Family therapy can be helpful for both patient and family. Many families are greatly affected when a family member is diagnosed with schizophrenia. Improving family understanding of the illness and how to interact appropriately with the patient can be of great impact to all involved. In addition, the stress on the family can be mitigated through family therapy and assistance programs.

Pharmacists can also play a role in nonpharmacologic treatment by assisting with patient education (particularly in regard to medications) and patient adherence to medication. Assistance with adverse effects to medications is also an area in which pharmacists can play a role.

Case 85-1, Question 3: What are the management goals for J.J.?

First and foremost is to ensure J.J.'s safety. Although not serious, she has already injured herself by punching her walls. She is also very argumentative because of her paranoia, which could inadvertently lead to an altercation. A reduction in J.J.'s symptoms is also desired, ideally leading to an improvement in her functionality and insight into her illness. In light of J.J.'s symptoms and lack of insight into her illness, she will most likely require hospitalization to both ensure her safety and effectively treat her symptoms.

Case 85-1, Question 4: What nonpharmacologic treatment would you recommend for J.J. at this time?

During the acute phase, especially while J.J. still displays prominent positive symptoms, nonpharmacologic treatment should center on stress reduction and education on her illness. By reducing her stress, the goal is that J.J.'s paranoia and agitation will decrease, allowing her to more meaningfully engage in treatment. Illness education can be accomplished through both individual and group therapy and education sessions. As J.J. moves from an acute phase into a stabilization phase, more specific interventions can be started, such as vocational skills training, depending on her need and her level of functionality at that time.

J.J. would also benefit from medication education, such as from a pharmacist, once she is more stable in order to better understand her medications and any potential adverse effects.

Case 85-1, Question 5: How should J.J. be best communicated with by the staff treating her at this time? What recommendations would you provide her family and friends for communicating with her, both currently and once she is sent home?

The staff should attempt to use methods of communication that will not agitate J.J. or increase her paranoia. This includes both verbal and nonverbal ("body language") communication. If J.J. does become paranoid or agitated, she should be approached with

calmness in an attempt to deescalate the situation. Directly challenging her hallucinations and delusions will most likely only increase her paranoia, so this should be avoided. If possible, speak to J.J. during times when she is calm and having fewer symptoms and inquire about what methods she would prefer employed to calm her down when she does become agitated, such as being put in a room alone to relax, listening to music, conversing with a staff member, and so on.

J.J.'s family and friends should be educated about her illness to help them understand how to avoid upsetting her and potentially increasing her symptoms, especially during the acute phase. Avoidance of topics that would make her upset would also be appropriate. Once J.J. is sent home, they should interact with her as they normally would, but being aware that her symptoms could return at any time and they should be vigilant for this. If they observe any significant change in her status, they should attempt to get J.J. to a medical provider to evaluate her situation.

Assessment

The issues and conducting a differential diagnosis of schizophrenia have been previously discussed. Patients are assessed for the severity of their symptomatology after diagnosis using information from direct assessment via patient interview, discussions with family and friends of the patient as well as treatment staff, and review of the medical records. There are no laboratory tests to measure progress in schizophrenia at this time. It is important to obtain laboratory baseline monitoring tests that can be relevant for the differential diagnosis and for the monitoring of adverse effects of medications. First, it is important to obtain a complete psychiatric and medical history including all past medications. It is suggested that patients receive a physical exam and that clinical laboratory tests of thyroid, liver, and renal function be obtained. A CBC count with differential as well as a urinalysis and urine toxicology screen (if drug abuse is suspected) should be obtained. A fasting blood glucose and serum

hemoglobin (Hb) A_{1C} level is useful considering the high rate of type 2 diabetes prevalent in patients with schizophrenia. Obtaining an electrocardiogram (ECG) is also useful, especially if the patient is older than age 40 years or likely to receive a medication with significant QT_c prolongation effects.

The most prevalent way to record the results of a clinical assessment in the patient with schizophrenia would be via the mental status examination.[46] If a patient is to be treated in a clinical study, schizophrenic symptomatology may be assessed using the Positive and Negative Symptoms Scale (PANSS),[47] the Brief Psychiatric Rating Scale (BPRS),[48] and the Clinical Global Impression (CGI) scale. Adverse effects to antipsychotic treatment can be assessed using instruments such as the Abnormal Involuntary Movements Scale (AIMS) or the Dyskinesia Identification System Condensed User Scale (DISCUS) for tardive dyskinesia (TD),[49] or the Simpson-Angus Rating Scale for drug-induced parkinsonism, and general adverse effects can be recorded via the Treatment Emergent Symptoms Scale (TESS).[50] These are all scales suitable to measure the severity of these symptoms, but are not used as diagnostic instruments.

Pharmacotherapy Interventions

ANTIPSYCHOTICS

Classification and nomenclature of the antipsychotics

The first effective antipsychotic medication used in Western medicine was chlorpromazine, a low-potency sedating “typical” antipsychotic first developed in 1951 to augment anesthesia and was termed by its inventor Laborit to be a *vegetative stabilizer*.[51] Although its introduction resulted in a sharp decrease in the number of hospitalized patients with schizophrenia, it was imperfect in that it caused adverse effects such as drug-induced parkinsonism, acute dystonias, sedation, anticholinergic effects, and orthostasis. The knowledge that D_2 antagonism was key in making effective agents for treating schizophrenia led to the development of a plethora of

new agents, some of which were much more specific in selectively antagonizing these receptors. The medications with greater dopamine specificity tended to have fewer effects on other neurotransmitter systems (**Fig. 85-1**). Therefore, these “high-potency” first-generation antipsychotics (FGAs), such as haloperidol or fluphenazine, were less likely to cause related adverse effects such as sedation, increased appetite, dry mouth, constipation, and orthostasis than were “low-potency” agents, such as chlorpromazine and thioridazine. However, high-potency FGAs have a greater propensity to cause acute dystonias and drug-induced parkinsonism than do the low-potency agents. The middle-potency agents, such as loxapine, molindone, and perphenazine, have more moderate adverse effects. These medications have other unique properties that differentiate them. For example, molindone was found to induce modest weight loss,[52,53] and loxapine was thought to be somewhat atypical in its effects on serotonergic receptors. These recognized properties helped lead to the development of second-generation antipsychotics (SGAs) or “atypical antipsychotics.”[54]

Figure 85-1 Four dopamine pathways in the brain. The neuroanatomy of dopamine neuronal pathways in the brain can explain both the therapeutic effects and the side effects of the known antipsychotic agents. (1) The nigrostriatal pathway projects from the substantia nigra to the basal ganglia and is thought to control movements. (2) The mesolimbic pathway projects from the midbrain ventral tegmental area to the nucleus accumbens, a part of the limbic system of the brain thought to be involved in many behaviors, such as pleasurable sensations and the powerful euphoria of drugs of abuse, as well as delusions and hallucinations of psychosis. (3) A pathway related to the mesolimbic pathway is the mesocortical pathway. It also projects from the midbrain ventral tegmental area, but sends its axons to the limbic cortex, where it may have a role in mediating positive and negative psychotic symptoms or cognitive side effects of neuroleptic antipsychotic medications. (4) The fourth dopamine pathway of interest is the one that controls prolactin

secretion, called the *tuberoinfundibular pathway*. It projects from the hypothalamus to the anterior pituitary gland.

The first SGA, clozapine, differed dramatically in its pharmacology from previous agents. It is a very potent antagonist of serotonin-2a (5-HT_{2a}) and serotonin-2c (5-HT_{2c}) receptors. It was later determined that the ability to antagonize serotonergic receptors was critical to creating other new "atypical" agents that could act in a manner similar to clozapine, but without its critically serious adverse effect profile. Clozapine was shown to have robust effectiveness in treating resistant schizophrenia,[55] but it causes agranulocytosis in about 1% to 2%,[56] induces seizures in 6% of those taking it at higher dosages,[57] besides possessing nuisance side effects such as sialorrhea and constipation, and even being associated with myocarditis.[58–60] Because clozapine is restricted to only the patient who is resistant to treatment or intolerant to antipsychotics, newer agents that were introduced, such as risperidone, olanzapine, quetiapine, and ziprasidone, were used with initial excitement. This excitement was tempered with caution when it was discovered that these agents could also be associated with obesity, hypertriglyceridemia, and even the onset of type 2 diabetes mellitus. Later, somewhat unique agents were introduced with possible advantages such as aripiprazole, lurasidone, paliperidone, iloperidone, asenapine, brexpiprazole, and cariprazine. The terms FGA and SGA are utilized for clarity throughout the chapter.

General differentiating characteristics of antipsychotics

It is sometimes useful to conceptualize the different antipsychotic medications in terms of their action at different receptor subtypes or by potency (**Table 85-4**). The SGAs are more potent at blocking 5-HT_{2a} serotonergic receptors than they are at blocking D_2 receptors. The SGAs are generally less likely to cause drug-induced parkinsonism and TD than do first-generation medications, but some of these agents may be more prone to cause metabolic issues than do the FGAs.[61] Low-potency antipsychotics are often given in

hundreds of milligrams per day and tend to have greater antihistaminic, anticholinergic, and α-1 antagonist effects than do their high-potency (roughly 1–20 mg daily) counterparts.

Table 85-4
Clinical Effects of Receptor Antagonism by Antipsychotics

Receptor (Subtype)	Clinical Effect of Antagonism
Dopamine (D_2)	*Mesolimbic pathway* (basal ganglia): treatment of positive symptoms *Mesocortical pathway* (prefrontal cortex): may worsen negative symptoms *Nigrostriatal pathway* (substantia nigra): extrapyramidal symptoms (EPSs) *Tuberoinfundibular pathway* (hypothalamus–anterior pituitary): increased prolactin release
Serotonin (5-HT_{2a})	Treatment of negative symptoms; increased dopamine release in prefrontal cortex; may reduce mesolimbic dopamine release
Serotonin (5-HT_{2c})	Implicated in antipsychotic-associated weight gain
Muscarinic (μ_1)	Anticholinergic side effects (dry mouth, constipation, urinary retention, blurred vision, hot/dry skin, memory impairment); sedation
Histamine (H_1)	Increased appetite, sedation
Alpha (α_1)	Orthostatic hypotension

Typical Antipsychotics or First-Generation Antipsychotics

Low-potency phenothiazine antipsychotics include the prototype antipsychotic chlorpromazine as well as thioridazine and its metabolite mesoridazine. Low-potency typical antipsychotics are strong histamine-1 blockers and are associated with more weight gain than are the high- potency ones. They also tend to be strong blockers of α-1, inducing orthostasis, and muscarinic receptors, which results in dry mouth, blurred vision, and constipation. Thioridazine is distinctive in that it can cause retinopathy in doses

>800 mg daily. Moreover, it has received a black box warning because it can cause prolonged QT_c intervals that can be clinically significant, especially if a 2D6 P450 isoenzyme antagonist (which increases its serum levels) is also being used.[62] Use of thioridazine is restricted to patients who are resistant to treatment because these proarrhythmic effects and use in clinical practice are uncommon.

Common middle-potency typical antipsychotics include molindone, loxapine, and perphenazine. Molindone is the only antipsychotic that has been associated with weight loss in some reports.[52,53] Loxapine is regaining use because of its inhalation dose form, and perphenazine has had a resurgence in the use of sorts owing to it being the chosen typical antipsychotic in the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE)-1 trial.[63] These agents tend to fall in between the high- and low-potency agents in terms of adverse effects.

The high-potency typical antipsychotics are very selective for D_2 receptor blockade; thus, they cause fewer adverse effects related to antihistaminic, anticholinergic, or α-1 receptor blocking effects. However, they are more likely to induce adverse extrapyramidal effects such as dystonia, drug-induced parkinsonism, and akathisia than do the lower potency typical agents. Their availability as long-lasting depot injections of haloperidol and fluphenazine and reduced rate of adverse metabolic effects encourage their continued use. Other, less often utilized high-potency agents include thiothixene and trifluoperazine (**Table 85-5**).

Table 85-5
First-Generation Antipsychotics

Medication Name (Generic/Brand); Potency—Chlorpromazine Equivalents; Class	Dosage Forms	Adult Dosing Schedules	Dose Adjustments
Haloperidol (Haldol®) High: 2 Butyrophenone	*Tablet:* 0.5, 1.2. 5. 10. 20 mg *PO solution:* 2 mg/mL *Injectable (immediate releasc)* 5 mg/ml	*Initial*: 0.5–5 mg bid or tid (depend· Ing on symptom severity) *Usual range.* 5–40 mg	*Rcnal* No specific recommendations *Hepatic* No specific recommendations
Fluphenazine (Prolixin*) High: 2 Phenothiazine	*Tablet*: 1.2.5. 5. 10 mg *PO Clixir* 2.5 mg/rnL *PO solution:* 5 mg/mL *Injectable (immediate release):* 2.5 mg/mL	*Initial* 2.5–10 mg q 6–8 hours *Usual range* I–40 mg/day	*Rcnal* Use with caution (nondialyzable). *Hcpatic* Use with caution.
Thiothixene (Navane®) High 4 Thioxanthene	*Capsule:* 1.2. 5. 10 mg	*Initial* 6–10 mg daily (divided doses) *Usual range:* 5–60 mg/day	*Rcnal:* Use with caution (nondialyzable). *Hcpatic* Consider dose reduction
Trifluoperazine (Stelazine*) High 5 Phenothiazine	*Tablet* 1.2. 5. 10 mg	*Initial:* 2–5 mg bid *Usual range:* 15–20 mg/day	*Rcnal* Use with caution (nondialyzable). *Hepatic:* Consider dose reduction
Rsrphenazine (Trilafon*) Mid 8–10 Phenothiazine	*Tablet* 2. 4. 8. 16 mg	*Initial:* 4–8 mg tid *Usual range:* 8–64 mg/day	*Renal* No specific recommendations *Hcpatic* Consider dose reduction.
Loxapine (Loxitane®, Adasuve®) Mid: 10 Dibenzoxazeplne	*Capsulc* 5. 10. 25. 50 mg *Inhalation powdcr* 10 mg	*Initial:* 10 mg bid *Usual range:* 20–250 mg/day (PO)	*Rcnal* No specific recommendations *Hepatic* No specific recommendations
Chlorpromazine (Thorazine®) Low: 100 Phenothiazine	*Tablet:* 10. 25. 50. 100, 200 mg *Injection (immediate rc-lease):* 25 mg/mL	*Initial* 100–200 mg/day in divided doses. increase 20–50 mg/day q 3–4 days as indicated	*Renal* No specific recommendations *Hcpatic* Consider dose reduction.
Thioridazine (Mellarll®) Low: 100 Phenothiazine	*Tablet* 10. 25. 50. 100 mg	*Initial* 50–100 mg tid with gradual dose Increases *Usual range* 50–800 mg/day	*Renal* Use with caution (nondialyzable). *Hepatic* Consider dose reduction.

Note: Information on long-acting injectable (LAI) versions of these medications can be found in Table 85-8.

Atypical or Second-Generation Antipsychotics

SGAs are agents that exert more effects on antagonism of 5-HT_{2a} subreceptors than on D_2 receptors and cause dramatically less drug-induced extrapyramidal symptoms. The SGAs clozapine, quetiapine, and olanzapine are more likely to induce metabolic disorders, such as weight gain,[64] hypertriglyceridemia,[65–69] and, possibly, glucose dysregulation[70] than do other antipsychotic medications. Atypical antipsychotics are thought by many to have greater efficacy in the treatment of negative and cognitive symptoms of schizophrenia and a reduced risk of TD.[61]

Clozapine has a unique pharmacology, which makes it the only agent found to be effective in treatment-resistant schizophrenia and suicidality in schizophrenia.[55,61] Clozapine is associated with a higher incidence of agranulocytosis and neutropenia relative to other antipsychotics that require frequent serum monitoring. This agent is discussed more in the section Inadequate Response. Risperidone (Risperdal®) is considered to be an atypical antipsychotic that is effective and less likely to cause extrapyramidal system adverse effects at doses <6 mg/day. Akathisia can be a problem especially in the elderly. Paliperidone (Invega®), or 9-hydroxyl risperidone, is the active metabolite of risperidone and has shown itself to be as effective as the parent drug.[71] Paliperidone is a controlled-release OROS® oral (PO) dosage form that utilizes osmotic pressure to deliver the medication in a controlled manner. Patients should be counseled not to be alarmed if the insoluble outer tablet shell is found in their stool. The long-acting injectable dosage forms of paliperidone and its parent compound risperidone are discussed in the section on Long-Acting Injectables.

Olanzapine (Zyprexa®) is an atypical antipsychotic that is very effective, but it can cause significant weight gain with related glucose dysregulation as well as increased serum triglycerides.[66,72] Olanzapine doses may need to be adjusted in smokers because of the induction of the cytochrome P450 (CYP) 1A2 isoenzyme system by the polycyclic aromatic hydrocarbons (PAHs) in cigarette smoke.[73] An olanzapine–samidorphan combination (Lybalvi®) has been FDA approved, which appears to retain the efficacy of olanzapine in

schizophrenia with a reduction in long-term weight gain.[74] This is due to the effects of samidorphan, which is a μ-opioid receptor antagonist with partial agonist activity at κ and δ opioid receptors. Owing to the samidorphan, this medication should not be given to patients dependent on opioids. This combination dose form contains 10 mg of samidorphan per tablet and either 5, 10, 15, or 20 mg of olanzapine.[75]

Quetiapine (Seroquel®) is a low-potency D_2 antagonist.[63] Owing to its minimal risk of drug-induced movement disorders, it is often utilized in patients with psychosis in Parkinson disease before the use of clozapine.[76] It is recommended that patients be counseled regarding diet and exercise before and during the use of these agents and clozapine. Ziprasidone (Geodon®) should be administered with at least 500 calories to ensure sufficient absorption.[77] It causes little weight gain or dyslipidemia and has minimal anticholinergic or extrapyramidal adverse effects. Although there were initial warnings about cardiac conduction delays (prolonged QT interval), there have been sparse reports linking the medication to death because of this concern.[78–80] An ECG before and during treatment is advised.[81]

Aripiprazole (Abilify®) should be dosed in the morning because it may be activating in some patients owing to its partial D_2 receptor agonism. Typical adverse effects include nausea, vomiting, and insomnia in the first weeks of treatment. It has a lower risk of weight gain, dyslipidemia, QT delays, and can actually cause decreases in serum prolactin and triglycerides. In fact, it has been used as augmentation to remedy hyperprolactinemia induced by other antipsychotics.[82–84] It also seems to have a low risk of EPS. Although aripiprazole's unique differential effect on dopaminergic systems can be beneficial, dopamine-3 (D_3) partial agonism may induce an increase in risky, reward-based behaviors, such as gambling.[85,86] Brexpiprazole (Rexulti®) is a recent addition to the antipsychotic armamentarium that showed superiority to placebo in both key clinical trials (at 4 mg daily) with pharmacologic and therapeutic similarities to aripiprazole.[87,88] It is a partial agonist at D_2 receptors

and serotonin 5-HT_{1a} and antagonist at 5-HT_{2a} and noradrenergic α-1b and α-2c receptors.[89] It is metabolized by both 2D6 and 3A4 hepatic isoenzyme systems, and dose reductions (DRs) are recommended if these systems are inhibited.[90] Cariprazine (Vraylar®) is pharmacologically similar to aripiprazole and brexpiprazole in that it is a partial agonist at the D_2, D_3, and 5-HT_{1A} receptors and an antagonist at 5-HT_{2A} receptors. However, it has about a 10-fold greater affinity for the D_3 receptor than for the D_2 receptor.[91] It is unclear what therapeutic differences result from its stronger effects on D_3 receptors.[92–94]

Iloperidone (Fanapt®) is less likely to cause drug-induced parkinsonism, akathisia, and hyperprolactinemia than do the typical antipsychotics, but has a risk of moderate weight gain, orthostasis, and the potential to cause QT interval prolongation that can be of concern in some patients.[95,96] Asenapine (Saphris®) needs to be administered sublingually for rapid and adequate absorption. It has an absolute bioavailability of 35% when taken sublingually and <2% when swallowed. The patient should be counseled not to eat or drink for 10 minutes after the sublingual administration. There is also a 24-hour patch formulation of asenapine (Secuado®) available. Patients should be counseled to avoid the application of external heating sources (ie, heating pads or electric blankets) to the patch because this may increase exposure to asenapine by up to 3.9-fold. The most common adverse reactions with asenapine (≥5% and at least twice the rate of placebo) are somnolence, dizziness, extrapyramidal symptoms other than akathisia, and weight gain.[97] Lurasidone (Latuda®) is an effective agent with a low propensity to cause drug-induced parkinsonism, metabolic complications, or QT_c prolongation. It needs to be taken with food (about ≥350 calories) for adequate absorption. The most common adverse events associated with lurasidone treatment are nausea, vomiting, akathisia, dizziness, and sedation (**Table 85-6**).[98]

Table 85-6
Second-Generation Antipsychotics

Medication Name (Generic/Brand)	Dosage Forms	Adult Dosing Schedules	Dose Adjustments
Aripiprazole (Abilify®)	*Tablet*: 2, 5, 10, 15, 20, 30 mg *ODT*: 10, 15 mg *Injectable (short acting)*: 9.75 mg/1.3 mL *Oral solution*: 1 mg/mL	*Initial*: 10–15 mg/day, titrate at 2-week intervals *Usual range*: 15–40 mg *Max*: 30 mg/day	*Renal/hepatic*: No dose adjustment necessary
Asenapine (Saphris®, Secuado®)	*SL tablet*: 5, 10 mg *Transdermal 24-hour patch*: 3.8, 5.7, 7.6 mg	*Initial*: 5 mg bid (no benefit demonstrated with higher doses); 3.8-mg patch q daily and increase as needed weekly	*Renal/hepatic*: No renal dose adjustments necessary; use not recommended in severe hepatic impairment Warn patient not to swallow SL tablet.
Brexpiprazole (Rexulti®)	*Tablet*: 0.25, 0.5, 1, 2, 3, 4 mg	*Initial*: 1 mg days 1–4; 2 mg days 5–7; 4 mg day 8 *Usual range*: 4 mg daily	*Renal*: 3 mg max in CrCl <60 mL/minute *Hepatic*: 3 mg max in Child–Pugh score ≥7
Cariprazine (Vraylar®)	*Capsule*: 1.5, 3, 4.5, 6 mg	*Initial*: 1.5 mg day 1, increase to 3 mg day 2, increase in 1.5- to 3-mg increments as needed *Usual range*: 1.5–6 mg	*Renal*: Not recommended in CrCl <30 mL/minute *Hepatic*: Not recommended in severe impairment (Child–Pugh score 10–15)
Clozapine (Clozaril®, FazaClo ODT®, Versacloz®)	*Tablet*: 12.5, 25, 50, 100, 200 mg *ODT*: 12.5, 25, 100 mg *Oral suspension*: 50 mg/mL	*Initial*: 12.5–25 mg/day, titrate by 25–50 mg/day to target of 300–450 mg/day. *Usual range*: 350–600 mg *Max*: 900 mg/day	*Renal/hepatic*: No specific recommendations
Iloperidone (Fanapt®)	*Tablet*: 1, 2, 4, 6, 8, 10, 12 mg	*Initial*: 1 mg bid, increase by 2 mg/day to target dose of 12–24 mg/day. *Max*: 24 mg/day	*Renal*: No adjustments necessary *Hepatic*: Use not recommended
Lurasidone (Latuda®)	*Tablet*: 20, 40, 80, 120 mg	*Initial*: 40 mg daily taken with food *Usual range*: 40–160 mg/day *Max*: 160 mg/day	*Renal*: Initial dose of 20 mg/day and max of 80 mg/day in moderate-to-severe impairment *Hepatic*: Initial dose of 20 mg/day and max of 80 mg/day in moderate impairment and max of 40 mg in severe impairment
Lumateperone (Caplyta®)	*Capsules*: 42 mg	*Initial*: Take one capsule by mouth daily with food. No titration required	*Hepatic*: Use not recommended in moderate-to-severe hepatic impairment No adjustment necessary in mild impairment
Olanzapine (Zyprexa®)	*Tablet*: 2.5, 5, 7.5, 10, 15, 20 mg *ODT*: 5, 10, 15, 20 mg *Injection (short acting)*: 10 mg/vial (5 mg/mL after reconstitution)	*Initial*: 2.5–10 mg/day *Usual range*: 20–40 mg/day *Max*: FDA recommended max is 20 mg/day.	*Renal*: Initial dose of 5 mg/day should be considered. *Hepatic*: Child–Pugh classes A and B, no adjustment necessary
Olanzapine/Samidorphan combination (Lybalvi®)	*Tablets*: 5, 10, 15, or 20 mg of olanzapine with 10 mg of samidorphan	*Initial*: 5 mg/10 mg or 10 mg/10 mg of olanzapine/samidorphan *Usual range*: 5 to 20 mg daily of olanzapine with 10 mg of samidorphan	*Renal*: Use is not recommended in patients with end-stage renal disease.

Rallperidone (Invega*)	*Tablct (ER)*: 1.5, 3, 6, 9 mg	*Initial*: 6 mg/day, increases should not exceed 3 mg every 5 days. *Usual range*: 9–12 mg *Max*: 12 mg/day	*Renal*: CrCl 50–79 mL/minute: Initiate at 3 mg, max 6 mg/day. CrCl 10–49 mL/minute: Initiate at 1.5 mg, max 3 mg/day. CrCl <10 mL/minute: use not recommended *Hepatic*: Child–Pugh classes A and B, no adjustment required
Quetiapine (Seroquel*)	*Tablet (IR)*: 25, 50, 100, 200, 300, 400 mg *rablet (ER)*: 50, 150, 200, 300, 400 mg	*Initial (IR)*: 25 mg bid, titrate In 25- to 50-mg increments, given tid to tid, to a target range of 300–400 mg/day by day 4; further adjustments at 25-to 50-mg increments with at least 2 days between adjustments: usual range 300–750 mg/day *Initial (ER)*: 300 mg/day: target 400–800 mg/day *Max*: 800 mgfday	*Rcnal*: No specific recommendations *Hepatic*: Initiate IR tablets at 25 mg/day and increase by 25–50 mg/day Increments/day; initiate ER tablets at 50 mg/day and Increase by 50 mg/day increments.
Risperidone (Risperdal®)	*Tablet*: 0.25, 0.5, 1, 2, 3, 4 mg OO7: 0.5, 1.2, 3, 4 mg *Oral solution*: 1 mg/mL	*Initial*: 1–2 mg/day: usual 4–6 mg/day *Usual range*: 4–8 mg/day *Max*: 16 mg/day	*Renal/hcpatic*: Recommend initial dose of 0.5 mg bid, may increase dose 0.5 mg bid: increases above 1.5 mg bid should be compieted over 1-week Intervals.
Ziprasldone (Geodon*)	*Capsule*: 20, 40, 60, 80 mg *Injectablc (short aettng)*: 20 mg/mL	*Initial*: 20 mg bid with food: dose adjustments at a48-hour intervals *Max*: 80 mg bid	*Renal*: No adjustments necessary in mlld-to-moderate Impairment Use IM with caution. *Hepatic*: No adjustments necessary in mlld-to-moderate Impairment

Note: Information on long-acting injectable (LAI) versions of these medications can be found in Table 85-8.

Lumateperone (Caplyta®) is a newer atypical antipsychotic FDA approved for use in schizophrenia at a dosage of 42 mg daily. The other doses studied in clinical trials did not reach statistical significance when compared to placebo. Lumateperone is a strong antagonist of 5-HT_{2A} receptors and is both a full antagonist at postsynaptic D_2 receptors and a partial agonist at presynaptic D_2 receptors.[99] It is relatively unique for an antipsychotic in that it inhibits serotonin reuptake and also indirectly modulates glutamatergic activity; the relevance of these properties to its clinical effects is not clearly established. Lumateperone is a substrate of CYP3A4 and uridine glucuronyl transferase (UGT) and subject to possible drug interactions induced by drugs affecting these systems.[100] In a pooled analysis of late-phase controlled clinical trials, the treatment-emergent adverse effects that presented at twice the rate of placebo and ≥5% for lumateperone were dry mouth and somnolence/sedation.[101]

Mechanism of drug action

All antipsychotic medications currently approved for the treatment of schizophrenia have at least some D_2 antagonistic effects. These antipsychotic medications have been divided into two major classes depending on whether they substantially antagonize 5-HT_{2a} receptors and dopaminergic ones. Although activity in attenuating dopamine transmission in the mesolimbic pathway is seen as being beneficial in decreasing the severity of positive schizophrenic symptomatology, decreased activity of dopamine receptors in mesocortical pathways (sometimes owing to antipsychotic medication) may relate to the severity of negative symptoms. Antagonism of 5-HT_2 receptors in the striatum by SGAs may balance decreased dopaminergic neurotransmission and decrease their relative propensity to cause TD.[102]

Selection of an Antipsychotic

Antipsychotic choice is based on a number of factors, many of which are patient specific. In making a selection, consider such patient factors as treatment history (if any), medical comorbidities and concurrent medications, patient preferences, and potential cost concerns. If the patient has a known history of being treated with antipsychotics, this can help guide current selection. Previous positive response to an antipsychotic is a good indicator of future response, just as previous lack of response would recommend against trying that agent in the future. History of adverse effects to particular agents is useful also. If a patient is known to have had an adverse event to a specific agent in the past that would preclude them from receiving this agent again (including a patient's stated preference for this reason), then this will help guide current medication selection. In addition, if an adverse effect led to medication discontinuation or poor adherence in the past, an antipsychotic that has a minimal risk of causing that adverse effect in the future should be selected. If information about a patient is not available, particularly in newly diagnosed patients with no prior treatment, medication history for a first-degree relative with schizophrenia may be useful in selecting an agent for the patient in a similar manner.

One area of debate has been selecting between FGAs and SGAs. Studies comparing the two classes head-to-head have shown similar efficacy rates between them.[103,104] Although the older agents are more prone to cause movement disorders, such as EPSs, the newer agents are thought to be more prone to causing metabolic disturbances in patients. Although SGAs are widely considered first choice in clinical practice,[105] most treatment guidelines now consider either FGAs or SGAs (other than clozapine) as potential first-line choices for treatment, depending on the patient factors described earlier.[106,107]

Case 85-1, Question 6: Which type of antipsychotic medication would you recommend for J.J. at this time? What factors would you use to select a

treatment regimen for her?

Because J.J. has never been treated with an antipsychotic before, almost any type is potentially viable as a treatment. Atypical antipsychotics would most likely be preferable. Typical antipsychotics, although efficacious, might lead to significant extrapyramidal or other adverse effects that she might not tolerate well, possibly leading to nonadherence. Also, with chronic usage, typical antipsychotics (FGAs) are more likely to cause TD than do SGAs. Because she is young and fairly healthy, we would also want to select an atypical antipsychotic with minimal long-term risks of metabolic adverse effects, such as weight gain and glucose irregularities. Pharmacoeconomic considerations should also be taken into account because some of the atypical antipsychotics are available generically and some are not.

Case 85-1, Question 7: What pharmacologic agents should be considered first to treat J.J. considering her acute symptoms?

In light of J.J.'s acute psychotic symptoms and agitation, a combination of both antipsychotics and adjunctive agents should be considered at this time. Although antipsychotics are generally the mainstay of schizophrenia treatment, they may not reduce symptoms quickly enough. Benzodiazepines may also be useful, especially during periods of increased agitation. Use of adjunctive medications to treat any adverse effects, such as EPSs, may also be needed. Depending on J.J.'s compliance with PO medications or during any periods of increased agitation, intramuscular (IM) injections of medications, including antipsychotics, benzodiazepines, and side effect medications, may need to be utilized acutely.

EFFICACY

Although there are numerous studies demonstrating the efficacy of current antipsychotic medications in comparison to placebo and accepted treatment, more attention has been paid of late to

effectiveness studies comparing currently available antipsychotics. These effectiveness trials are intended to show the comparative value of these agents in situations that are more comparable to routine clinical care by utilizing less stringent eligibility criteria, longer duration, prospective design, and large sample size.[108] Still, they are randomized double-blind trials using intent-to-treat analysis just as if they were efficacy studies. Interpreting these studies is a help in bridging the chasm between studies in ideal populations and routine clinical care.

One of the landmark effectiveness trials comparing antipsychotic agents is the National Institutes of Mental Health (NIMH)-funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) trial. The first phase of the CATIE trial compared the SGAs quetiapine (N = 329), ziprasidone (N = 183), risperidone (N = 333), and olanzapine (N = 330) with the middle-potency FGA perphenazine (N = 257). The main outcome variable was time to discontinuation of the antipsychotic for any cause. Overall, 74% of the patients discontinued treatment over the 18-month course of the study. This study showed significantly less medication discontinuation ($P < .001$) in patients treated with olanzapine (64%) than in those receiving quetiapine (82%) or risperidone (74%). After adjusting for multiple comparisons, the difference in using olanzapine with ziprasidone or perphenazine did not reach significance. When analyzed separately, the discontinuation rates due to intolerability were substantially higher in the patients treated with olanzapine, but there was a significantly greater time to discontinuation with olanzapine compared to quetiapine, risperidone, and perphenazine. The lower number of patients in the ziprasidone group reduced the power (and thus the chance to find the difference) for comparisons with this agent and the others. The 18-month duration of the study could not yield information on the long-term effects of these agents in causing TD or metabolic disorders.[63]

Patients who discontinued treatment were eligible for enrollment in phase two of the CATIE trial to receive a different antipsychotic if they dropped out primarily for lack of tolerance or efficacy. Those primarily not responding in the earlier phase could instead enter the

phase two trial in which there was a clozapine treatment arm.[109] In the lack of tolerability arm, patients assigned to olanzapine (N = 68) or risperidone (N = 70) showed a longer time to discontinuation rates than those receiving either quetiapine (N = 63) or ziprasidone (N = 135).[110] In the poor responder study arm, patients receiving clozapine (N = 45) showed a significantly lower ($P < .05$) time to discontinuation of treatment than did those receiving either olanzapine (N = 17), quetiapine (N = 14), or risperidone (N = 14).[111] The third phase of the CATIE trial involved the 270 patients who discontinued treatment in the earlier phases, who went on to receive aripiprazole, clozapine, olanzapine, perphenazine, quetiapine, or risperidone. The lack of power made it difficult to show any differences in effectiveness between these agents, and in this open trial, few patients received either perphenazine (N = 4) or fluphenazine decanoate (N = 9).[112] Of note, at each subsequent phase of CATIE, statistical power was reduced as compared to the original study because of subject attrition, thereby increasing type II error.

Another often cited study is the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS 1) in which 227 patients were randomized to receive either FGAs (N = 118) or to be treated with an SGA (N = 109). This pragmatic, non–industry-funded study was powered only to compare the overall differences between the FGA and SGA groups and not the individual antipsychotics themselves. The hypothesis that second-generation medications would have an advantage on any quality of life measures over first-generation medications was disproved.[113] The CUtLASS 2 study was similarly designed and compared clozapine to other SGAs in patients who did not respond sufficiently to two prior treatments. Patients on clozapine showed significant improvements on PANSS scores ($P < .01$), felt they did much better ($P < .05$), and there was a trend for improvement ($P = .08$) on their quality of life as measured on the Quality of Life Scale (QLS).[113,114]

SGAs have also shown better response and remission rates than haloperidol in patients recovering from a first episode.[115] Meta-analyses and related techniques have been utilized to attempt to

overcome limitations of low power in comparative antipsychotic efficacy trials. One meta-analysis looked at 150 double-blind randomized controlled trials (RCTs) in >20,000 patients and found only amisulpride (not available in the United States), clozapine, olanzapine, and risperidone to be more effective than the FGAs. The SGAs showed fewer EPSs and, with the notable exception of aripiprazole and ziprasidone, caused more weight gain than did haloperidol. However, there were no significant differences in weight gain between the low-potency typical antipsychotics such as chlorpromazine and the second-generation agents.[116]

One controversial topic not clearly covered by effectiveness trials or meta-analysis is the use of combinations of antipsychotic medications.[117] Although combination use is a relatively common practice,[118] it is not recommended owing to the paucity of evidence for its safety and efficacy[119,120]; in fact, combination antipsychotic therapy is often targeted by quality improvement programs.[121] Although there are situations (eg, adding aripiprazole for a patient stabilized on risperidone to attenuate hyperprolactinemia) in which this use can be logical and beneficial,[27,117,122,123] there are other times when patients resistant to treatment should receive alternative approved effective pharmacotherapy with clozapine.[124]

DOSAGE FORMS

Antipsychotics are commercially available in a variety of dosage forms to allow for the need for different treatment situations and settings. The most common forms consist of orally administered products such as tablets/capsules (both short- and long-acting forms), orally disintegrating tablets (ODTs), and PO liquid solutions/suspensions; and one medication is also available as a topical patch. Many antipsychotics are also available as injectables, some as short-acting IM forms and some as long-acting IM forms. Selection of an appropriate dose form can depend on factors such as the severity of the patient's illness and risk of imminent harm to themselves or others, willingness or ability to take medications, and treatment setting.

Alternative oral dose forms

Although almost every antipsychotic is available as a traditional tablet or capsule, many are available in other PO dosage forms. In an effort to help with adherence, several antipsychotics are available as PO liquids, ODTs, or patch formulations. The SGAs aripiprazole, risperidone, and ziprasidone are available as PO liquids, which may be useful in patients who have a hard time swallowing traditional tablets (or will not swallow them) or to achieve more specific dosing, such as might be needed for pediatric or geriatric patients. ODTs are formulated to dissolve rapidly when placed on the tongue, needing only for the patient to swallow their own saliva to obtain medication absorption in the gut. This formulation is particularly useful in the inpatient setting when “cheeking” or nonadherence is suspected. Aripiprazole, clozapine, olanzapine, and risperidone are available as ODTs. Asenapine is available as a sublingually dissolving tablet or 24-hour patch.

Short-acting injectables

The short-acting injectable formulations of antipsychotics are frequently utilized in the acute phase of illness. Patients presenting to psychiatric emergency services are often in crisis and can be at risk for harm to themselves or others. If nonpharmacologic deescalation techniques fail and the patient refuses PO medication, short-acting IM injections are effective in rapidly targeting agitation related to psychosis. IM formulations avoid first-pass metabolism and thus are approximately two to four times as potent as PO formulations and reach peak concentrations within 30 to 60 minutes.[125] The FGAs haloperidol, fluphenazine, and chlorpromazine, as well as the SGAs olanzapine, ziprasidone, and aripiprazole are currently available in short-acting IM formulations.

There are currently no head-to-head trials comparing the efficacy of the available short-acting IM SGAs. However, their efficacy and safety were evaluated in a review of nine double-blind, RCTs. Data were extracted to compare olanzapine, ziprasidone, and aripiprazole to either placebo or the active comparator (haloperidol or lorazepam)

to calculate the number needed to treat (NNT) and the number needed to harm (NNH).[126] All three of the agents demonstrated superior efficacy to placebo and the NNT was lowest for olanzapine and ziprasidone. Olanzapine 10 mg demonstrated superiority compared to haloperidol 7.5 mg (NNT = 5). A low dose of aripiprazole 1 mg IM was shown to be less effective compared to haloperidol 7.5 mg IM (NNT = −5).[126] The available RCTs for ziprasidone IM did not have an active comparator such as haloperidol or lorazepam IM. The adverse effect profiles of the SGAs differed significantly in terms of NNH, although all three agents were associated with less EPSs than was haloperidol. Olanzapine was associated with an NNH of 50 for treatment-emergent hypotension.[126] This is in line with the manufacturer's recommendation to avoid concomitant administration with benzodiazepines. In one of the studies, aripiprazole demonstrated an NNH of 47 for akathisia when compared to placebo.[126] Data were not available to evaluate QT_c-prolonging effects of ziprasidone IM in terms of NNH. The manufacturer's guidance states that ziprasidone IM is contraindicated in patients with a known history of QT prolongation, recent acute myocardial infarction (MI), or with uncompensated heart failure. Caution should be taken when given with other medications known to increase the QT interval (eg, classes Ia and III antiarrhythmics, thioridazine, chlorpromazine, moxifloxacin) and in patients with renal insufficiency due to the clearance of the cyclodextrin excipient through the kidney.[127]

Haloperidol short-acting IM is commonly the preferred agent on hospitals' acute agitation protocols because of its proven efficacy, low risk for orthostasis, and its ability to be administered with IM lorazepam, if necessary. The cost of haloperidol may also be advantageous versus the SGAs, but the cost of IM anticholinergics (eg, benztropine) must be taken into account with its higher risk of EPS. Overall, the short-acting IM dosage forms of the antipsychotic agents are a crucial piece of the treatment team's armamentarium and key to ensuring the safety of a patient with agitation related to acute psychosis (**Table 85-7**).

Table 85-7
Agents Used to Treat Acute Agitation

Medication	Dosage Form	Dosing Schedule (As Needed)	Onset (Minutes)	Max Dose/ 24 Hours	Duration of Action (Hours)
Lorazepam	PO (tablet), IM, IV	1–2 mg	60–90 (PO); 15 (IM)	10 mg	8–10
Typical Antipsychotics					
Haloperidol	PO (tablet), IM	5–10 mg every 0.5–2 hours	30–60 minutes	30 mg	Up to 24
Fluphenazine	PO (tablet), IM	1–2.5 mg every 6 hours (tablet); 1.25 mg every 6 hours (IM)	Not available	10 mg	6–8
Chlorpromazine	PO (tablet), IM	50 mg (IM); 100 mg (PO) every 1–4 hours	15–60	200 mg	Not available
Atypical Antipsychotics					
Olanzapine	PO (tablet), IM, ODT	5–10 mg every 2–4 hours	15–45	30 mg (IM), 20 mg (ODT)	24
Risperidone	PO (tablet, liquid), ODT	1–2 mg every 0.5–2 hours	60	4 mg	Not available
Ziprasidone	PO (tablet), IM	10–20 mg every 2–4 hours	30–60	40 mg	4
Aripiprazole	PO (tablet, liquid), IM, ODT	10–15 mg (tablet); 9.75 mg (IM) every 2 hours	1–3 hours	30 mg	Not available

IM, intramuscularly; IV, intravenously; ODT, oral disintegrating tablet; PO, orally.

Long-acting injectables

Long-acting injectable antipsychotics (LAIAs) are an option for patients with a history of medication nonadherence or in those patients who prefer LAIAs over once-daily PO antipsychotics. LAIAs allow the patient the option to decrease the frequency they need to make a decision to take medications. PO antipsychotics require daily recommitment to be adherent versus biweekly, monthly, or even longer with LAIAs. Lapses in adherence are also more apparent and early interventions can be initiated if a patient fails to show up for an injection appointment. Effectiveness and tolerability of the PO counterpart to an LAIA should be established before conversion to the LAIA. Equivalent doses of LAIAs do not pose a greater risk of adverse effects than does the PO antipsychotic with the exception of injection site pain.[128] LAIAs take months to reach steady-state concentration; therefore, making dose adjustments to acutely target symptoms or manage adverse effects is inefficient.

A number of large-scale RCTs failed to demonstrate a significant benefit of LAIAs over PO antipsychotic medications in relapse prevention in schizophrenia.[129,130] A meta-analysis including a total of 5176 patients enrolled in 21 RCTs of at least 6 months' duration found LAIAs did not reduce relapse compared to PO antipsychotics.[131] This finding may be due in part to the selection of a population of subjects with greater engagement in treatment, more insight, and high adherence to PO medications relative to the real-world patient population. Increased clinician contact, implicit or explicit efforts to monitor adherence, and free study medication also reduce the ability of RCTs to reflect relapse rates in more patients who are unstable and often prescribed LAIAs.[132] A 2-year, double-blind RCT, conducted by Rosenheck and colleagues, enrolled 369 patients with schizophrenia who were at risk for psychiatric hospitalization.[133] The patients were assigned to LAI risperidone or a PO antipsychotic of the clinician's choice. No significant differences in psychiatric hospitalization rates, symptoms of psychosis, or measures of social functioning were found between groups. Mirror-image studies, which compare periods of treatment with PO antipsychotics and LAIAs in the same patient, have been proposed as a better method to capture the real-world effectiveness of LAIAs.

A systematic review and meta-analysis examined 25 mirror-image studies of 5940 patients with schizophrenia >12 months (>6 months each of PO and LAIA treatment). LAIAs were superior to oral antipsychotics in preventing hospitalization (16 studies, risk ratio [RR] = 0.43; 95% confidence interval [CI], 0.35–0.53; $P < .001$) and decreasing number of hospitalizations (15 studies, RR = 0.38; 95% CI, 0.28–0.51; $P < .001$). These results should be interpreted with caution as mirror-image studies can have intrinsic expectation bias and return to a stable status may reflect the natural course of illness.[129]

Patients with recent-onset schizophrenia have inherently less understanding of the importance of treatment and adherence and may benefit from treatment with LAIAs. This is also a crucial period to improve patient quality of life, reduce the impact on educational or early career goals, and reduce relapse rate to improve long-term prognosis. One RCT of LAI risperidone versus oral risperidone in 86 patients with recent-onset schizophrenia demonstrated lower rates of relapse in the LAI risperidone group (5% vs 33%).[134] More recently, Kane and colleagues conducted a cluster randomized, multicenter trial that examined the effect of aripiprazole monohydrate LAI versus treatment as usual on time to first psychiatric hospitalization in a population of patients with early-phase schizophrenia. They demonstrated a mean survival time of 613.7 days (95% CI, 582.3–645.1 days) for LAI and 530.6 days (95% CI, 497.3–563.9 days) for treatment as usual. This translated to a hazard ratio of 0.56 (95% CI, 0.34–0.92; $P = .02$) favoring LAI over treatment as usual and NNT of 7 with LAI to prevent an additional hospitalization.[135] These data merit discussion with the patient to determine preference of LAI versus oral agents, particularly in the early phases of illness.

Two high-potency FGAs, fluphenazine and haloperidol, are available as decanoate ester LAI formulations. Conversion to the LAI formulation of haloperidol can be achieved either by administering 10 times the oral dose the patient is stabilized on or by administering 20 times the oral dose for a loading dose regimen.[136] The loading dose regimen more rapidly achieves therapeutic serum levels of haloperidol and allows for earlier discontinuation of oral

medication.[128,136] The standard conversion requires oral overlap with the current dose of oral haloperidol for at least 1 month before being gradually tapered.[128] Fluphenazine decanoate is released faster than is the haloperidol decanoate and achieves time to maximal concentration (T_{max}) in ~24 hours. It is recommended that the oral medication be decreased by 50% upon administration of the first injection and discontinued after the second injection.[128,137] There is not enough data to support a loading dose regimen for fluphenazine decanoate. The standard oral to LAI conversion is 1.25 times the oral dose administered every 2 to 4 weeks.[137] A double-blind study reported no difference in relapse, symptoms, or adverse effects between groups stabilized on every 2-week versus every 6-week injection intervals.[138] These results suggest that dosing intervals longer than the usual 2 to 4 weeks may be an option to reduce antipsychotic exposure without risk of relapse. Both decanoate ester formulations require utilizing the "Z-track technique" for administration. This prevents loss of medication, abscess formation, or subcutaneous (SC) lumps. However, it is more painful than are standard injections.

SGAs currently available in LAI formulations are aripiprazole (Abilify Maintena® and Aristada®), risperidone (Risperdal Consta® and Perseris™), paliperidone (Invega Sustenna®, Invega Trinza®, and Invega Hafyera®), and olanzapine (Zyprexa Relprevv®). Aripiprazole monohydrate (Abilify Maintena®) requires a 14-day oral overlap and is dosed monthly. Aripiprazole lauroxil (Aristada®), a prodrug of aripiprazole, can have an extended dosing interval, between 4 and 8 weeks, as determined by the oral equivalent dosage.[139] It is initiated in one of two manners: given as Aristada Initio® 675-mg injection with a 30-mg single dose of oral aripiprazole or given as the calculated maintenance injectable dose with a 21-day overlap of the current oral dosage. The normal starting dose of aripiprazole monohydrate for most patients will be 400 mg IM monthly. However, patients with renal impairment or concomitant administration with strong CYP3A4 and 2D6 inhibitors or inducers for >14 days require dose adjustments, which are detailed in **Table 85-8**. Dosing of

aripiprazole lauroxil is converted from the oral dose requirement of each individual (eg, 10-mg oral aripiprazole equates to a 441-mg injection).

Table 85-8
Long-Acting Injectable Antipsychotics

	Available Dosages	PO to LAI Conversion	Dosage	Interval	Loading Dose	PO Overlap
Fluphenazine decanoate	25 mg/mL (5 mL multidose vial)	10 mg PO = 12.5 mg q 3 weeks IM	*Initial*: 12.5–25 mg *Target*: 12.5–50 mg	q 2–4 weeks	No	Decrease PO by 50% after first injection; d/c PO after second injection
Haloperidol decanoate	50 mg/mL; 100 mg/mL (1 mL single-dose vial and 5 mL multidose vial)	10–20 × PO dose	10–15 × PO dose administered monthly; max 100 mg first injection if naive to haloperidol decanoate	q 4 weeks	20 × PO dose first injection, then 10× PO dose maintenance	Continue PO × 2–3 injections if loading dose not used.
Aripiprazole monohydrate (Abilify Maintena®)	300- and 400-mg kits	400 mg IM q month	*Initial*: 400 mg IM monthly; 300 mg IM monthly (poor CYP2D6 metabolizers, concomitant strong CYP2D6 or 3A4 inhibitors, or side effects at higher dose); 200 mg monthly (poor CYP2D6 metabolizers taking CYP3A4 inhibitors, concomitant strong CYP2D6 and 3A4 inhibitors)	q month	No	Continue PO for 14 days
Aripiprazole lauroxil (Aristada®, Aristada Initio®)	441, 662, 882 mg 675 mg (Initio®)	*PO dose* / *IM dose* 10 mg / 441 mg 15 mg / 662 mg ≥20 mg / 882 mg	*Initial*: 441, 662, or 882 mg monthly depending on PO dose 882 mg may be given q 6 weeks	q 4–6 weeks	No	21 days-*OR*-Aristada Initio® 675 mg for first injection with single 30-mg PO dose
Olanzapine pamoate (Zyprexa Relprevv®)	210-, 300-, and 405-mg kits	*PO dose* / *IM dose first 8 weeks* / *IM dose maintenance* 10 mg/day / 210 mg q 2 weeks or 405 mg q 4 weeks / 150 mg q 2 weeks or 300 mg q 4 weeks 15 mg/day / 300 mg q 2 weeks / 210 mg q 2 weeks or 405 mg q 4 weeks 20 mg/day / 300 mg q 2 weeks / 300 mg q 2 weeks	*Initial*: 150–300 mg IM q 2 weeks or 405 mg q 4 weeks *Target*: 300 mg q 2 weeks or 405 mg q 4 weeks	q 2 weeks or q 4 weeks	Yes	Not required
Paliperidone palmitate (Invega Sustenna®)	39-, 78-, 117-, 156-, and 234- mg kits	Initiate with 234 mg IM on day 1 and 156 mg IM on day 8 (both deltoid). Mild renal impairment (CrCl ≥50 mL/minute and <80 mL/minute): Initiate with 156 mg IM on day 1, then 117 mg IM on day 8.	*PO dose* / *IM dose* 3 mg/day / 39–78 mg 6 mg/day / 117 mg 12 mg/day / 234 mg Mild renal impairment / 78 mg	q 4 weeks	Yes	Not required
Paliperidone palmitate (Invega Trinza®)	273, 410, 546, 819 mg	Convert from Invega Sustenna® dosage (minimum 4 months of treatment)	*Sustenna®* / *Trinza®* 78 / 273 117 / 410 156 / 546 234 / 819	q 3 months	No	Not required
Paliperidone palmitate (Invega Hafyera®)	1092, 1560 mg	Convert from Invega Sustenna® (minimum 4 months of treatment) or Trinza® dosage (minimum 3 months of treatment)	*Sustenna®/Trinza®* / *Hafyera®* 156/546 / 1092 234/819 / 1560	q 6 months	No	Not required
Risperidone long-acting injection (Risperdal Consta®)	12.5-, 25-, 37.5-, 50-mg dose packs	*PO dose* / *IM dose* 2–3 mg / 25 mg 4–5 mg / 37.5 mg 6 mg / 50 mg	*Initial*: 25 mg IM q 2 weeks with PO overlap × 3 weeks *Target*: 25–50 mg IM q 2 weeks	q 2 weeks	No	Continue PO for 3 weeks.
Risperidone long-acting injection (Perseris®)	90, 120 mg	*PO dose* / *SC dose* 3 mg / 90 mg 4 mg / 120 mg Note: These doses are approximate. Doses <3 mg/day or >4 mg/day may not be appropriate to convert to the SC injection.	Initial: 90 mg or 120 mg (per dose conversion) and maintain on monthly schedule.	q monthly	No	Not required

CrCl, creatinine clearance; CYP, cytochrome P450; IM, intramuscular; LAI, long-acting injectable; PO, orally; q, every; SC, subcutaneous.

LAI risperidone is administered IM every 2 weeks and requires an oral overlap of 3 weeks because of delayed release of risperidone from suspension in copolymer microspheres. Less than 1% of the risperidone is released within the first 3 weeks postinjection. The SC formulation of risperidone (Perseris™) is administered by monthly abdominal injections and does not require oral overlap or a loading dose regimen. Candidates are limited to those stabilized on 3- or 4-mg oral risperidone, which equate, respectively, to 90 and 120 mg of the SC injection. Paliperidone palmitate (Invega Sustenna®) is dosed monthly and does not require oral overlap with the recommended loading regimen. In patients without renal impairment, the initial loading regimen consists of a 234-mg deltoid injection on day 1 followed by a 156-mg deltoid injection on day 8. Paliperidone palmitate should be avoided in severe renal impairment (creatinine clearance [CrCl] <50 mL/minute). Paliperidone palmitate is also available in formulations administered every 3 months (Invega Trinza®) or every 6 months (Invega Hafyera®) for patients stabilized on the monthly formulation for a minimum of 4 months. Patients can also be converted from Trinza® to Hafyera® after a 3-month dosing cycle on either 546 or 819 mg. The dose of the 3-month formulation is 3.5-fold higher than is the last dose of the monthly formulation.

However, there is minimal difference in injection volume between the two formulations (1.5 mL for Invega Sustenna® 234 mg vs 2.625 mL for Invega Trinza® 819 mg). Invega Hafyera® is supplied as 1092 mg/2.5 mL and 1560 mg/5 mL and must be administered as a gluteal IM injection over a 30-second period.

LAI olanzapine (Zyprexa Relprevv®) has an associated risk evaluation and mitigation strategy (REMS) because of the risk of postinjection delirium/sedation syndrome (PDSS). PDSS results from supratherapeutic levels of olanzapine caused by accidental intravascular placement of the injection and rapid dissolution of olanzapine pamoate. Symptoms mimic olanzapine overdose and can include sedation, coma, and delirium. The administering facility must have available access to emergency response services and monitor the patient for at least 3 hours postinjection for signs and symptoms of PDSS. The risk of PDSS is 0.2% per injection and history of prior tolerability does not translate to a lower risk of PDSS for future injections. LAI olanzapine distribution is restricted to the Zyprexa Relprevv Patient Care Program that requires the prescriber, facility, patient, and pharmacy be enrolled before releasing the injection. The high administrative burden placed on the facility and patient to coordinate the postinjection monitoring limits its use in clinical practice.

PHARMACOKINETICS AND DRUG INTERACTIONS

Pharmacokinetics (PKs) and potential for drug–drug interactions are necessary considerations for the safe and effective dosing of antipsychotic medications. One key point to keep in mind is the difference between the time to therapeutic effect and time to steady-state plasma concentration. Response of positive symptoms of schizophrenia can be seen within days of treatment initiation. However, it may take ≥4 to 7 days depending on the half-life of the antipsychotic to achieve steady-state plasma concentrations. The half-life of an antipsychotic may also be misleading in determining dosing frequency. Most oral antipsychotics should be dosed once daily, with the exception of asenapine and ziprasidone owing to

issues with absorption. Ability to dose these agents once daily is in part due to higher concentration and longer receptor occupancy in the CNS as well as longer duration of pharmacologic effect than is reflected by the serum concentration.[140] During initial titration, split-day dosing is appropriate when targeting acute agitation or while the patient develops tolerance to peak concentration-dependent adverse effects (eg, sedation and orthostatic hypotension). Once the patient can safely tolerate the medication, the dose can be consolidated to help reduce pill burden and increase patient adherence.[141]

Antipsychotic drug interactions can be mediated through direct PK interactions or by additive pharmacodynamic (PD) effects. PK interactions usually involve phase I oxidative metabolism through the CYP system; however, interactions can occasionally involve phase II metabolism (eg, glucuronidation). Many antipsychotics undergo metabolism through CYP1A2, 2D6, and 3A4 hepatic isoenzymes (see **Table 85-9**). The inhibition or induction of these CYP enzymes can result in clinically relevant changes in antipsychotic serum levels. For example, inhibition of CYP1A2 by the antidepressant fluvoxamine can cause a significant elevation in clozapine serum level and place the patient at risk for serious adverse effects, such as seizures. The reverse would be true for CYP1A2 induction. To use the same example, if a patient were to begin taking a CYP1A2 inducer, such as carbamazepine or phenytoin, the clozapine serum level would drop and place the patient at risk for recurrence of psychotic symptoms. A common CYP1A2 inducer that deserves special mention is cigarette smoke and the PAHs contained within that smoke. PAHs, not nicotine, are responsible for the induction; therefore, it is important to note that when an inpatient is stabilized on an agent metabolized by CYP1A2 (eg, clozapine, olanzapine, asenapine), the serum level can drop by up to 50% if they resume smoking upon discharge. Many antidepressants and mood stabilizers also have potent effects on CYP metabolism, so caution should be taken when adding them to an antipsychotic regimen,[142,143] PD interactions occur when an additional agent that enhances the effect of the antipsychotic activity at the receptor site without directly affecting the serum level of the antipsychotic is added to a patient's

regimen. For example, adding the potent anticholinergic agent benztropine to an SGA with anticholinergic properties, such as olanzapine or clozapine, will compound anticholinergic adverse effects such as constipation.

Table 85-9

Pharmacokinetic Comparisons of Antipsychotics

Antipsychotic Agent		Mean Half-Life (Hours)	Major Metabolic Pathway
First-generation antipsychotics	Chlorpromazine	30	CYP 2D6
	Fluphenazine	14–16	CYP 2D6
	Haloperidol	14–37	CYP 2D6, CYP 3A4
	Loxapine	19	None (minor—CYP 1A2, CYP 2D6, and CYP 3A4)
	Perphenazine	9–12	CYP 2D6
	Thioridazine	5–27	CYP 2D6
	Thiothixene	34	CYP 1A2
	Trifluoperazine	3–12	None
Second-generation antipsychotics	Aripiprazole	75–94	CYP 2D6, CYP 3A4
	Asenapine	24	UGT1A4, CYP 1A2
	Brexpiprazole	91	CYP 2D6, CYP 3A4
	Cariprazine	48–96	CYP 3A4 (minor—CYP 2D6)
	Clozapine	12	CYP 1A2 (primary), CYP 2C19, CYP 2D6, CYP 3A4
	Iloperidone	18–33	CYP 2D6, CYP 3A4
	Lumateperone	18	CYP 3A4, CYP 2C8, CYP 1A2
	Lurasidone	18–40	CYP 3A4
	Olanzapine	21–54	CYP 1A2, CYP 2D6
	Paliperidone	23	Limited CYP 2D6, CYP 3A4
	Quetiapine	6–7	CYP 3A4
	Risperidone	3–20	CYP 2D6
	Ziprasidone	7	Aldehyde oxidase, CYP 1A2, CYP 3A4

CYP, cytochrome P450; UGT, .

PHARMACOECONOMIC CONSIDERATIONS

When the SGAs were first introduced in the 1990s, there was great concern over their higher cost compared to the older antipsychotics.

Because the FGAs were all available in cheaper generic forms, the newly marketed SGAs were still under patent protection and, therefore, anywhere from 10 to 100 times higher the cost than were their older counterparts.[144] From 1997 to 2007, the amount spent on outpatient antipsychotic prescriptions in the United States (not including the Veterans Affairs system) increased from $1.7 billion/year to $7.4 billion/year.[145] This represents a large percentage of overall U.S. mental health expenses over this time period. As the SGAs have slowly become available in generic forms, the concern about their higher costs has decreased slightly, but cost differences still remain.

Although actual medication cost is commonly scrutinized when examining schizophrenia treatment, it needs to be balanced against other costs associated with the illness. Factors such as hospitalization rates, outpatient service utilizations, and patient functionality also need to be considered. One study examining the outcomes of formulary restrictions of SGAs in >100,000 Medicaid patients with schizophrenia found that from 2001 to 2008, these restrictions increased hospitalization rates by 13%, inpatient costs by 23%, and total Medicaid expenditures by 16%, while only reducing medication expenses by 4%.[146] In selecting an antipsychotic, medication costs should be considered, especially in light of the costs to overall public health, along with other factors mentioned previously such as efficacy and adverse effect profile.

ADVERSE DRUG REACTIONS

One of the main factors in selecting an antipsychotic includes the adverse effect profile of the agents being considered. Although many of these adverse effects are common across most, if not all, antipsychotics, the incidence of these effects can vary greatly. The common, class-wide adverse effects seen with these agents include EPSs, anticholinergic effects, cardiovascular effects, metabolic effects (including hyperprolactinemia), and others.

As in treating any illness, a careful balance must be maintained between efficacy and tolerability. When an adverse effect is

discovered in a patient, evaluation of the benefit-to-risk ratio of the medication should take place. Medication factors such as the degree of benefit to the patient, the severity and frequency of the adverse effect, and level of discomfort or distress to the patient should all be considered. In any situation, the patient should be included in any decision regarding adverse effect management. Unresolved adverse effects that significantly bother a patient can lead to nonadherence and potential treatment failure.

If an adverse effect is determined to be fairly mild and cause minimal patient distress, then it may not require any intervention beyond close monitoring to ensure it does not worsen over time. Many adverse effects may be little more than a slight annoyance and can be approached in this way. As an adverse effect becomes more severe or distressing to a patient, it may require more direct intervention. A reduction in antipsychotic dose may be needed or the addition of a secondary medication to treat a particular adverse effect (described subsequently) may be required. If truly warranted, the antipsychotic may need to be changed to another agent where the likelihood of the adverse effect might be lower. One potential factor to consider is the risk of decompensation when changing antipsychotics. Antipsychotics share similar pharmacologic effects and have similar efficacy rates, but not all antipsychotics may be effective for a given patient.

When determining that a change in antipsychotics is warranted, due to adverse effects, poor efficacy, or both, there are several methods that can be employed for switching. In instances where the change needs to be abrupt, perhaps due to a serious or life-threatening adverse effect, an immediate discontinuation of the old agent and initiation of the new agent should be considered. When more time can be given to the change of agents, a cross-titration from one agent to the other can be performed. In these instances, the new agent can either be increased over time as the old agent is simultaneously reduced or the new agent initiated at a therapeutic dose followed by a downward taper of the old agent over time. The rates of these medication increases and decreases are determined

by the clinical presentation and concerns for patient safety (**Table 85-10**).

Table 85-10

Relative Incidence of Antipsychotic Adverse Effects

	Sedation	EPS	Anticholinergic	Orthostasis	Weight Gain
Typical—Low Potency					
Chlorpromazine	+++	++	++	+++	++
Thioridazine	+++	++	+++	+++	+
Typical—Mid Potency					
Loxapine	+	++	+	+	+
Perphenazine	++	+++	+	+	+
Typical—High Potency					
Fluphenazine	+	++++	+	+	+
Haloperidol	+	++++	+	+	+
Thiothixene	+	+++	+	+	+
Trifluoperazine	+	+++	+	+	+
Atypicals					
Aripiprazole	0 to +	+	0	0 to +	0
Asenapine	+	+	0	+	+
Brexpiprazole	0 to +	+	0	0 to +	0
Cariprazine	0 to +	++	0	0 to +	0 to +
Clozapine	+++	0	+++	+++	++++
Iloperidone	0 to +	+	0	+++	+
Lurasidone	+	++	0	0 to +	0 to +
Olanzapine	++	+	++	++	++++
Paliperidone	0 to +	+	+	+	++
Quetiapine	++	0 to +	+	++	++
Risperidone	+	++	0	++	++
Ziprasidone	+	++	0	++	0 to +

0, no effect; +, low; ++, moderate; +++, high; ++++, very high; EPS, extrapyramidal side effects.

Extrapyramidal adverse effects and tardive syndromes

The blocking of D_2 receptors in the striatum by antipsychotics can also cause acute adverse reactions such as dystonias (involuntary contractions of skeletal muscles) and drug-induced parkinsonism (pseudoparkinsonism). Restoring the balance between acetylcholine and dopamine in the striatum can reduce EPSs, which is why low-potency FGAs with appreciable anticholinergic activity (eg, chlorpromazine and thioridazine) can be less problematic than the

high-potency ones in this regard. This can also be done using anticholinergics such as benztropine or trihexyphenidyl, by using amantadine, by lowering the dose of the antipsychotic, or by using an SGA instead. However, some evidence suggests that changing patients to an SGA will not always lead to the improvement in these movement disorders to the degree expected.[147]

Dystonia

Acute dystonias are uncomfortable, sustained muscle contractions that can occur as torticollis (involving the neck), the trunk, the tongue, or as an oculogyric crisis (where the patient's eyes appear to roll up in the head). Oculogyric crises and dystonias tend to present in the first few days of treatment. Symptoms are treated using anticholinergic medications via IM administration for rapid efficacy (eg, benztropine 2 mg IM stat). Scheduled PO administration of the chosen anticholinergic agent is continued after acute symptom resolution. However, this rapid treatment often does not help the attitude of affected patients toward their caregivers when clinicians are trying to develop a therapeutic alliance with a patient who may already be prone to suspicion or paranoia.[148]

Parkinsonism

Drug-induced parkinsonism is the most common and reversible of adverse movement effects. It consists of rigidity, masked face, slowed gait, and tremor. These symptoms are short-lived and easily treated. These occur most often in the first 3 months of treatment. Drug-induced parkinsonism is a separate entity from idiopathic Parkinson disease, which is a distinct illness on its own.

The high-potency FGAs are more likely to induce drug-induced parkinsonism than do the low-potency agents. Increased dosages of FGAs in higher risk patients (eg, medication naive, female, advanced age) increase this risk. SGAs are, on the whole, less likely to induce this syndrome. Clozapine and quetiapine are the least likely to induce drug-induced parkinsonism, and often can be used without worsening the underlying movement disorder in patients with

idiopathic Parkinson disease.[149–151] However, although clozapine has been robustly effective in these patients, reports with quetiapine are conflicting.[76]

Strategies for reducing or eliminating antipsychotic-induced parkinsonism include lowering the dose of antipsychotic, switching to an atypical antipsychotic (with the lowest risk choices being quetiapine or clozapine), or treating the patient with antiparkinsonian medication. The antiparkinsonian medications often used are anticholinergic agents such as benztropine (Cogentin®; given from 0.5 mg bid to 2 mg tid), trihexyphenidyl (Artane®), biperiden (Akineton®), diphenhydramine, or the novel agent amantadine (Symmetrel®; given from 100 to 400 mg daily in divided dosages). The anticholinergic agents add to adverse effects and pill burden and continuation is often not necessary after 3 months. Amantadine causes less of these problems and works by an alternate mechanism of action; however, it is not as effective as the anticholinergics in many patients.[148] Anticholinergic adverse effects are discussed in greater detail in the section on Anticholinergic Effects.

Akathisia

Akathisia can present alone or in combination with drug-induced parkinsonism, or TD.[152,153] It presents as an inability to remain still combined with an intense feeling of internal restlessness that can make the patient appear quite agitated.[154] In the unfortunate event that akathisia is incorrectly interpreted as agitation, increased or “as-needed” antipsychotic doses to target agitation will worsen the syndrome. Akathisia is best treated by a small reduction in antipsychotic dosage, addition of low-dosage β-adrenergic blockers (eg, propranolol 10 mg bid or tid), or addition of anticholinergic agents (especially if drug-induced parkinsonism is also present). Benzodiazepines can also be used in patients not responsive to the aforementioned strategies (**Table 85-11**).

Table 85-11
Agents to Treat Antipsychotic-Induced Parkinsonism and Akathisia

Medication	Equivalent Dose (mg)	Dose/Day (mg/day)
Anticholinergic		
Benztropine (Cogentin®)[a]	0.5	1–8
Biperiden (Akineton®)[a]	0.5	2–8
Diphenhydramine (Benadryl®)[a]	25	50–250
Procyclidine (Kemadrin®)	1.5	10–20
Trihexyphenidyl (Artane®)	1	2–15
Dopaminergic		
Amantadine	—	100–300
GABAminergic		
Diazepam (Valium®)	10	5–40
Clonazepam (Klonopin®)	2	1–3
Lorazepam (Ativan®)[a]	2	1–3
Noradrenergic Blockers		
Propranolol (Inderal®)	—	20–60 (max = 120)

[a]Oral dose or intramuscular injection can be used.

Case 85-1, Question 8: J.J. is eventually stabilized on brexpiprazole 2 mg daily while hospitalized. During the admission, the staff notice that her psychotic symptoms have decreased but that her agitation has slowly increased over time. She is constantly pacing around on the unit, and when she does sit down, she is always fidgety and unable to sit still. She says she feels uncomfortable most of the time. The unit staff have had to continue to give her lorazepam 1 mg several times a day for this agitation. What form of an EPS might J.J. be experiencing at this time? What information in her presentation supports this finding?

J.J. is most likely experiencing akathisia. Because her symptoms decreased when brexpiprazole was initiated, it is unlikely that it is

agitation due to her schizophrenia that is causing the restlessness. Antipsychotics, even those that are D_2 partial agonists such as brexpiprazole, are known to cause akathisia as an adverse effect. Her symptoms also appear to be akathisia: constant pacing/movement, always fidgety, and feeling of inner restlessness. Although lorazepam would be expected to treat agitation, it is also a potential treatment for akathisia.

Case 85-1, Question 9: What would be the appropriate treatment for J.J.'s akathisia?

First and foremost, it should be determined whether J.J. can be stabilized on a lower dose of her medication. Often, a reduction in antipsychotic dose will resolve any EPS symptoms. If this is not possible and J.J. would destabilize as a result, then an additional medication will be needed to manage the problem. Although lorazepam would serve this purpose, the concerns about chronic daily administration of benzodiazepines must be considered. Because J.J. may have akathisia with brexpiprazole as long as she is on the medication, she could require treatment for akathisia this entire time. Another option for treating this problem would be propranolol, the nonselective β-blocker. Propranolol has been found to be helpful in alleviating akathisia in low, subcardiac doses such as 10 to 20 mg bid. If this treatment is selected, then her blood pressure and heart rate should be monitored accordingly.

Case 85-1, Question 10: When arranging her discharge, the pharmacy that is called for her prescriptions informs you that her insurance plan will not pay for brexpiprazole. What medication would be appropriate to switch J.J. to at this time?

Ideally, we would keep J.J. on the medication that stabilized her during her hospitalization. It might be possible to contact her insurance to obtain prior authorization for this medication. If that cannot be done, then they should be asked if aripiprazole is

available for use with J.J. Aripiprazole is also a D_2 partial agonist, such as brexpiprazole, so theoretically it should work in a manner similar to that of brexpiprazole. If her insurance will not pay for aripiprazole, then another atypical antipsychotic with a similar adverse effect profile should be considered. Because brexpiprazole has lower rates of EPS and metabolic adverse effects, an agent such as ziprasidone might be considered because it has similar rates of EPS and metabolic effects but is available as a generic medication.

Case 85-1, Question 11: J.J. has been stabilized on ziprasidone 40 mg bid with meals while in the hospital. When should her target symptoms start to respond to the medication? What else can be done to help improve J.J.'s prognosis once she is discharged?

Although J.J.'s symptoms should start to decrease within a few days of starting the medication, it may take a week or longer to see significant improvement. At this point, she may be stable enough for discharge from the hospital, but still show some functional deficits. It may take several more weeks, possibly months, for her to return to her baseline before her symptoms start, and she may never fully reach this point. The utilization of nonpharmacologic methods, including individual and group therapy modalities, could also help J.J.'s continued improvement and stabilization. Education for both her and her family could also be of benefit.

Case 85-1, Question 12: J.J. returns home to her family, taking a leave from college for the remainder of the semester. She returns to school the following semester to resume classes, but notices she has a hard time focusing in class, which she attributes to the ziprasidone. Because she has not had any psychotic symptoms since being released from the hospital ~5 months ago, she thinks she is cured and no longer needs to take the medication. She contacts her psychiatrist about stopping the medication. Should J.J. discontinue her medication at this time? What do practice guidelines state regarding J.J.'s treatment needs at this time?

J.J. should not stop her medication at this time. Although a medication adjustment might be needed, depending on the nature and cause of her concentration, that is not a reason to stop the medication altogether. Most treatment guidelines recommend a minimum of 6 months, and preferably 1 year, of treatment after a psychotic episode. Because she has only been symptom free for 5 months, J.J.'s risk of relapse is very high without medication treatment.

Case 85-1, Question 13: Ultimately, J.J. decides to stop taking her ziprasidone and stops going to her psychiatrist appointments. In less than a month, she is brought to the emergency room (ER) by her parents because she has relapsed into another psychotic episode and is admitted back into the hospital. Is J.J. a candidate for LAIAs at this time?

J.J. is not a candidate for an LAIA currently because she has never tried an oral formulation of any of them to this point. Recommendations for use of an LAIA require, at a minimum, repeated dosages of the oral form of the medication to ensure a lack of an allergy to the medicine, or, in some instances, for the patient to be stable on an oral dose of the medication and then converted to the LAIA form. However, she might benefit from the use of an LAIA if she truly intends to be nonadherent with oral forms of antipsychotics. Because she has only shown nonadherence to one medication trial owing to a potential misunderstanding of her illness and her treatment, she could benefit from education in these areas to improve her adherence. In addition, her family could be educated to help J.J. maintain her medication adherence as well.

Case 85-1, Question 14: While on the inpatient unit for this most recent episode, J.J. continues to remain nonadherent to oral medication. She eventually agrees to receive an LAIA, but after speaking with her insurance, the only atypical antipsychotic LAIA they will pay for is risperidone LAIA. Is this an appropriate agent for J.J., and why or why not?

Assuming that J.J. has been administered oral risperidone in the past, which ensures a lack of an allergy to the medication, it still would not be an appropriate option at this time. Owing to the unique PK parameters of risperidone LAIA, it requires 3 weeks of overlap of oral medication (risperidone or otherwise) because the initial dose does not begin releasing medication until this time. Assuming J.J.'s nonadherence to oral medications will continue, this could lead to a poor outcome, especially if she is discharged from the hospital. J.J.'s insurance should be contacted to attempt to find an alternative atypical antipsychotic LAIA.

Tardive Dyskinesia

One of the more troubling potential adverse effects from chronic treatment with antipsychotics is the development of persistent choreoathetoid (sometimes described as snakelike) movements of the tongue, hands, feet, and, in severe cases, even the trunk of the patient.[155] Chronic blockade of striatal D_2 receptors by antipsychotics results in these receptors becoming supersensitive to available dopamine. Changes in interconnected neurotransmitter systems, such as GABAergic or muscarinic,[156] can result in dyskinesias that can often appear on withdrawal of antipsychotics, upon lowering of the dosage, or when a patient is changed to clozapine or quetiapine treatment from another antipsychotic. If these withdrawal dyskinesias persist, then the condition of persistent dyskinesia or TD can result. TD can also present without any change in medication dose after many years of treatment. FGAs are considered to have a much greater risk (5% yearly incidence in long-term use in adults) of causing TD than do the SGAs, but reported incidences vary appreciably between studies.[157] Risk of developing TD increases with cumulative lifetime dosage and duration of antipsychotic treatment, increased age, comorbid diabetes mellitus, traumatic brain injury, having an affective disorder, anticholinergic medication use, a history of drug-induced parkinsonism, and female gender.[158–161] Although the incidence rate for patients treated with typical

antipsychotics is more substantial,[157] the atypical antipsychotics also carry this risk albeit at a lower, but still not negligible, rate.[162]

Although all dyskinetic movements seen on withdrawal of antipsychotic medication are not necessarily persistent dyskinesia or *TD*, there are those cases of patients who do retain the potentially stigmatizing movements long after antipsychotic medications are tapered or changed. When this occurs, it is often very difficult to remediate these movements. Medication changes that decrease the effects of dopamine on striatal receptors tend to cause immediate improvement followed by long-term worsening of dyskinetic symptoms. Few double-blind studies show any benefit of augmenting with various agents, and agents that often have shown promise in early case reports and open studies (ie, diazepam, donepezil, branched chain amino acids) often do not bear up to the scrutiny of a double-blind trial.[163–165] Even accepted strategies such as lowering antipsychotic dosages (or stopping them when possible) or changing to less offending second-generation agents such as clozapine or quetiapine do not always yield the desired outcome. Some limited evidence suggests that clonazepam and ginkgo biloba may prove helpful.[165] Recently, a new class of medications called *vesicular monoamine transporter (VMAT)* type 2 inhibitors has been developed to help treat the symptoms of TD. VMAT collects monoamines within vesicles in the presynaptic neuron before release into the synapse. Inhibition of VMAT2 prevents the release of dopamine (and other monoamines) into the synapse within the CNS, reducing the overstimulation of dopamine receptors causing dyskinetic movements. Historically, the old antihypertensive reserpine was discovered to be an irreversible VMAT2 inhibitor (as well as VMAT1 in the PNS),[166] and more recently tetrabenazine (Xenazine®) was developed as a reversible VMAT2 inhibitor for the treatment of Huntington chorea. Although neither of these agents is FDA approved for the treatment of TD, the newest irreversible VMAT2 inhibitors, valbenazine (Ingrezza®)[167–169] and deutetrabenazine (Austedo®),[170] are approved for this purpose (**Table 85-12**). Both agents have shown benefits in decreasing the severity of dyskinesia as measured by the AIMS up to a year of

treatment, but long-term benefits beyond a year are still unknown at this time. Considering the significant costs of both of these medications, more long-term benefits would confirm their utility in clinical practice. One 3-year open-label unpublished trial did demonstrate continued improvements in dyskinetic movements with deutetrabenazine.[171] In addition, both agents have potential concerns for QTc prolongation, especially in combination with other risk factors for this adverse effect, including concurrent medications. Increases in serum prolactin and liver function tests, as well as depression and suicidality, have also been noted with both agents. A potentially better course of strategy appears to do what we can to prevent the occurrence of TD by strategies such as keeping antipsychotic dosages as low as possible and using medications that are less likely to induce this syndrome,[156,157,172] and incorporating close monitoring for the development of symptoms utilizing the AIMS exam. However, we do have the option to tailor our medication choice to the vulnerability of the patient. Because the severity and prevalence of TD is apparently on the decline,[156] there may be cause to be optimistic.

Table 85-12

Agents to Treat Antipsychotic-Induced Tardive Dyskinesia

Medication	Starting Dose (mg)	Dose Range (mg)	Notes
Valbenazine (Ingrezza®)	40 mg daily	40–80 mg daily	Use half-dose with 2D6/3A4 inhibitors, do not use with 3A4 inducers.
Deutetra-benazine (Austedo®)	6 mg daily	6–48 mg (doses >12 mg/day must be bid)	Take with food, max of 36 mg/day in 2D6 poor metabolizers

bid, twice daily.

Sources: Ingrezza (valbenazine). Package insert. Neurocrine Biosciences Inc; April 2021; Austedo (deutetrabenazine). Package insert. Teva Neuroscience Inc; June 2021.

Anticholinergic effects

The low-potency FGAs and certain SGAs, particularly olanzapine and clozapine, are potent muscarinic receptor antagonists. The resultant anticholinergic effects can range from bothersome to potentially life-threatening. These effects include dry mouth, blurred vision, mydriasis, tachycardia, urinary retention, constipation, paralytic ileus, confusion, and delirium. Something that may appear merely bothersome, such as dry mouth, can have more serious consequences if not addressed. Dry mouth can lead to dental caries or weight gain if thirst is quenched with sugary beverages. Additional sugar, in the form of gum or liquids, can also increase the risk of oral fungal infections. Patients can utilize sugar-free hard candies or gum, or saliva substitute products if anticholinergic medication dosage cannot be reduced.[173] In general, patients with schizophrenia should be encouraged to connect with regular dental services. Another often-overlooked anticholinergic adverse effect is constipation. Patients may not draw the connection between constipation and a medication that they are taking for their mental health. Consistent monitoring of patient's bowel habits and recommendation of a proper bowel regimen (eg, diet, physical activity, bulk-forming laxatives, stool softeners) can be the difference between a week of unaddressed bowel discomfort progressing to paralytic ileus and patient expiration due to bowel rupture or aspiration of gastric contents.[174]

The patient's overall anticholinergic burden is often increased by the addition of anticholinergic medications, such as benztropine, for EPS prophylaxis or treatment. Indication for use of anticholinergic agents should be reevaluated periodically during treatment and upon transitions in care. Failure to taper unnecessary anticholinergic medications can lead to decreased quality of life and preventable adverse effects.[175]

Cardiovascular effects

Antipsychotic medications are thought to exert cardiovascular effects through direct antagonism of adrenergic and cholinergic receptors, as well as through indirect central autonomic effects and baroreceptor reflexes.[176] Three common antipsychotic-induced cardiovascular effects, orthostasis, tachycardia, and QT_c prolongation, are described here.

Orthostatic Hypotension

Orthostatic hypotension occurs in up to 40% of patients treated with antipsychotic medications.[176] It occurs frequently during the initial dose titration and disproportionately affects elderly patients. Orthostasis results from the blockade of vascular α_{1A}-adrenoceptors, which makes it difficult for patients to adapt to positional changes in blood pressure. Tolerance to orthostasis will usually develop within 2 to 3 weeks of antipsychotic initiation or dose increase. Antipsychotic agents with high affinity for α_{1A}-adrenoceptors relative to D_2 receptors (eg, clozapine, risperidone) clinically display greater rates of orthostasis than do agents with low α_{1A} affinity relative to D_2 affinity (ie, haloperidol).[176] The risk of falls secondary to orthostasis can be mitigated by (a) slowing the rate of titration, (b) splitting the dose, and (c) counseling the patient to make slow transitions from prone and seated positions. Increasing fluid and salt intake and using support stockings are other nonpharmacologic interventions that may help alleviate orthostasis while the patient adapts to a change in dosage. More persistent orthostasis resulting from clozapine treatment can be managed with fludrocortisone or ephedrine if nonpharmacologic interventions are not clinically feasible.[177]

Tachycardia

Antipsychotic-associated tachycardia can occur as a direct effect of anticholinergic activity on vagal activity or as a compensatory mechanism related to orthostatic hypotension. Patients treated with

clozapine tend to have a dose-related increase in heart rate of 20 to 25 bpm.[176] Dose reduction, slower titration, or addition of a low-dose, preferably cardioselective, β-blocker can be considered if tachycardia is bothersome to the patient or symptomatic.[177,178]

Electrocardiographic Changes

Prolongation of the QT interval, or QT_c interval when corrected for heart rate, is a variable risk associated with all antipsychotics. QT_c interval prolongation increases the risk of torsade de pointes (TdP), a malignant polymorphic ventricular tachycardia that is associated with syncope and sudden cardiac death.[176] The potential mechanism for this effect is believed to be mediated through blockade of the rapidly activating delayed rectifying current (I_{Kr}), which conducts potassium out of the cardiomyocytes to cause cardiac repolarization.[176,179] However, there are insufficient data to establish the direct causal relationship between antipsychotic-induced QT_c prolongation and sudden cardiac death.[176,179]

The Pfizer 054 study, developed in consultation with the FDA, demonstrated QT_c prolongation as a class effect for SGAs.[180] This prospective, randomized, parallel-group study conducted by Harrigan and associates examined the effect of steady-state peak plasma concentrations of haloperidol 15 mg/day (N = 27), thioridazine 300 mg/day (N = 30), ziprasidone 160 mg/day (N = 31), quetiapine 750 mg/day (N = 27), olanzapine 20 mg/day (N = 24), or risperidone 6 to 8 mg/day increased to 16 mg/day (N = 25/20) on the QT_c interval in the presence or absence of metabolic inhibitors in patients with stable psychotic disorders. No patients were observed to have a QT_c interval >500 ms, and mean QT_c changes from baseline were similar for monotherapy and with concomitant administration of a metabolic inhibitor. The antipsychotics associated with the greatest change in mean baseline QT_c were thioridazine (30.1 ms) and ziprasidone (15.9 ms). Haloperidol, quetiapine, risperidone 6 to 8 mg/day, risperidone 16 mg/day, and olanzapine were associated with mean QT_c changes of 7.5, 5.7, 3.9, 3.6, and

1.7 ms, respectively.[181] To add context, the mean diurnal variation in QT_c is ~75 to 100 ms and this may vary further based on sleep, diet, obesity, electrolyte disturbances, endocrine dysfunction, gender, and age.[176,179] No cases of TdP were observed in the 4571 patients treated with ziprasidone included in the Pfizer 054 study and the ziprasidone database.[180] One of the newer SGAs, iloperidone, has also demonstrated a dose-dependent and drug interaction–dependent risk of QT_c prolongation similar to that of ziprasidone in both short- and long-term randomized trials.[182]

In clinical practice, concomitant administration of QT_c-prolonging agents should be avoided. If coadministration is necessary in a patient with no underlying cardiac abnormalities or risk factors for TdP, the patient should be monitored closely. A work group of members from the APA and American College of Cardiology (ACC) recommended in a recent resource document that no absolute QTc interval threshold should preclude a trial of any particular psychiatric medication. Instead, they suggest conducting a comprehensive risk–benefit analysis for the individual patient that should include, "Assessment of pharmacologic and nonpharmacologic risks for TdP versus the risk of failure to control high-risk psychopathology or of psychiatric decompensation."[183] Use of antipsychotics with higher risk of QT_c prolongation, chlorpromazine or ziprasidone, should be avoided in patients with underlying cardiac issues, electrolyte abnormalities (hypokalemia, hypocalcemia, or hypomagnesemia), congenital long-QT syndrome, or those comedicated with agents affecting cardiac function (particularly antiarrhythmics of class Ia, disopyramide, procainamide, and quinidine and class III, amiodarone, dofetilide, and sotalol).

Case 85-1, Question 15: After intensive education about her illness and need for treatment, as well as enlisting the help of her parents in ensuring she will take her medications, J.J. eventually agrees to take oral medications and is restabilized on risperidone 2 mg bid. After discharge, her outpatient psychiatrist notes that J.J. is still responding to internal stimuli, and confirms she is still having some auditory hallucinations. J.J.'s parents confirm she is taking her doses, so the dose is increased to 3 mg bid. Within a few weeks at her next

appointment, J.J.'s parents inform her psychiatrist that she can barely move, and she "walks like an old lady" at times. The psychiatrist examines J.J. and notes she has some mild stiffness in her extremities, a mild tremor in her hands, and when she walks her gait is abnormally short and almost shuffling in appearance. However, her hallucinations have subsided. What is the probable cause of J.J.'s abnormal neurologic findings at this time? What information in her presentation supports this finding?

J.J. is most likely suffering from drug-induced parkinsonism, a type of EPS. All the abnormal findings noted in J.J. at this time—stiffness, tremor, and shuffling gait—are characteristic findings of drug-induced parkinsonism. Although risperidone, as an atypical antipsychotic, is less likely to cause this problem compared to the older, conventional antipsychotics, it can still cause it. One risk factor of parkinsonism with risperidone is increasing the dose, which occurred in J.J. recently. Although she was fine on the lower dose, the increase in dose to 6 mg/day caused enough D_2 receptor blockade in the nigrostriatal pathway to induce this EPS type.

Case 85-1, Question 16: How can J.J.'s drug-induced parkinsonism be treated?

Ideally, the first choice would be to decrease the dose of the offending agent. Because J.J.'s dose of risperidone was just increased to 6 mg/day owing to lingering symptoms, this is most likely not an option because it is highly likely those symptoms would return. A change in antipsychotics could also be considered, but it appears that other than the EPS, J.J. is currently stable on this medication and dose. The only other option would be to add another medication to treat her parkinsonism. Some options include the use of anticholinergic medications, such as benztropine, or the use of amantadine.

Case 85-1, Question 17: J.J.'s drug-induced parkinsonism resolves with the addition of benztropine 0.5 mg bid. Will J.J. need to stay on this medication indefinitely?

J.J. should be maintained on benztropine for at least 3 months once her parkinsonism resolves. If there are no other changes in her clinical status or her medication treatment for her schizophrenia, then the use of benztropine should be reexamined at that time. If the medication is then removed and her parkinsonism does not return, then she should not need the medication any longer. Should the EPS return, however, then she may need continued anticholinergic treatment.

Case 85-1, Question 18: What are some other adverse effects that should be monitored for in J.J., both specific to risperidone and for antipsychotics in general?

Any patient receiving an antipsychotic should be monitored for all types of EPS, including parkinsonism. Other EPS types, such as dystonia and akathisia, should be watched for as well as the development of any TD. Although the risk of these concerns is lower with an atypical antipsychotic, such as risperidone, it is still possible. J.J.'s weight and serum glucose and lipids should also be monitored regularly both during the initiation of antipsychotic treatment and periodically throughout. Risperidone also can cause drug-induced orthostasis, so she should be monitored for dizziness, especially upon standing.

Metabolic effects

Hyperprolactinemia

Prolactin is a polypeptide hormone secreted by lactotroph cells in the anterior pituitary. Dopamine acts as an inhibitor of prolactin release in the tuberoinfundibular dopamine tract that projects from the hypothalamus to the anterior pituitary. Blockade of D_2 receptors within this pathway leads to increased release of prolactin and potential effects on multiple organ systems and gene expression throughout the body. Agents that cause more potent D_2 blockade are associated with a greater risk of hyperprolactinemia.[184] A multiple-treatment meta-analysis by Leucht and associates stratified select

antipsychotics based on their effect on the standardized mean difference in prolactin from baseline as follows: paliperidone (highest), risperidone, haloperidol, lurasidone, ziprasidone, iloperidone, chlorpromazine, olanzapine, asenapine, quetiapine, and aripiprazole (lowest/decreased prolactin).[185] Guidelines recommend baseline prolactin monitoring at the discretion of the clinician, screening for symptoms of excess prolactin at every visit for the first year of treatment and annually thereafter if symptoms are stable, and follow-up prolactin levels only if clinically indicated.[44,186,187] The upper limit of normal prolactin levels is 18 to 20 ng/mL in males and 24 ng/mL in females who are not pregnant or lactating.

Clinical sequelae from excess prolactin release include sexual dysfunction, gynecomastia, galactorrhea, amenorrhea, hypogonadism, and potential bone mineral density changes with long-term elevations. However, prolactin levels do not directly correlate with these adverse events and patients may remain asymptomatic. Considerations for treatment should only be addressed in actively symptomatic patients.[84,185] In symptomatic patients, dose reduction or switching to an agent with less potent D_2 blockade would be recommended first line. If these strategies fail to improve the symptoms or cannot be undertaken for clinical reasons, a dopamine agonist, such as bromocriptine, cabergoline, or amantadine, may be considered. However, the risk of potential exacerbation of psychosis must be weighed against potential benefit.[44,184,187,188] There is also growing evidence to support the use of adjunctive aripiprazole, a partial D_2 agonist, to improve hyperprolactinemia in patients who cannot be switched from a more potent agent.[82,84,189–191]

Case 85-1, Question 19: Over time, J.J.'s dose of risperidone is increased to 4 mg bid because of lingering symptoms. At one of her follow-up appointments, J.J. asks if it is safe to take the medication while she is pregnant. During the conversation, J.J. tells her psychiatrist that she is pregnant because she has not had her menstrual period in nearly 2 months, and her breasts have become larger and she has noticed she lactates periodically. The psychiatrist orders a pregnancy blood test that comes back with a negative result, but her serum

prolactin level is 115 ng/mL. What could explain why J.J. believes she is pregnant?

The negative pregnancy test result proves J.J. is not pregnant (assuming no error by the lab). Her symptoms are indicative of hyperprolactinemia, another potential adverse effect of D_2 receptor antagonism from antipsychotic therapy. As her prolactin level increased, it caused J.J. to become amenorrheic and caused her to lactate. Although not a common adverse effect of most atypical antipsychotics, both risperidone and paliperidone are similar to the typical antipsychotics in their propensity to increase serum prolactin.

Case 85-1, Question 20: How should J.J.'s hyperprolactinemia be treated?

Ideally, the treatment of antipsychotic-induced hyperprolactinemia involves a DR of the offending agent. Because J.J. was increased to 4 mg bid owing to an insufficient response to a lower dose, this may not be possible. If a DR cannot be done safely, then a change in antipsychotic to one with a lower risk of hyperprolactinemia should be considered. If this too is not clinically appropriate for the patient, then addition of a dopaminergic agonist may be considered, such as amantadine. This should be done cautiously because a strong dopaminergic agonist, such as bromocriptine, may exacerbate her psychosis. There are also data available on using aripiprazole augmentation to treat hyperprolactinemia from antipsychotics, but this might be considered after other agents have been tried, unless J.J. appears to need a stronger antipsychotic regimen.

Weight Gain

Although the development of the SGAs was supposed to free us from the concern of the extrapyramidal adverse effects of the FGAs, many of the newer agents such as clozapine, olanzapine, quetiapine, and risperidone showed a tendency to, just like the low-potency typical first-generation agents, cause substantial weight gain.[64] This substantial weight gain tended to occur to the greatest

extent in the first few months of treatment, with a certain segment of those treated gaining >20 pounds (9.07 kg).[192] One study showed that 15.4% of those patients treated with olanzapine had weight gain ≥7% of their body weight in the first 6 weeks of treatment.[193] It soon became apparent that clozapine and these newer SGAs had the potential to increase body weight, serum triglyceride levels,[64–67] and thereby potentially cause glucose dysregulation as well.[70,194,195] Patients suffering from schizophrenia are already prone to an earlier death than are patients who are not mentally ill because of their physical health and inherent sedentary lifestyle; therefore, weight gain may be an even more critical issue than is the potentially stigmatizing occurrence of TD.[162,196]

Numerous mechanisms have been theorized to explain the weight gain induced by the SGAs. These include histamine (H_1) receptor antagonism,[197,198] serotonin antagonism at 5-HT_{2c} with a possible genetic predisposition in some,[199,200] muscarinic antagonism that could possibly lead to increased consumption of sugary beverages or "thirsty" calories,[201] and impairments in plasma leptin secretion.[202–204] Concomitant medications, such as valproic acid, lithium, mirtazapine, some antihistamines, and tertiary tricyclic antidepressants can also increase body weight by synergistic pharmacologic effects.[69,205]

Hyperglycemia and Diabetes Mellitus

It is unclear if there are direct actions by SGAs involved in the development of diabetes mellitus. However, it is clear that weight gain, increased triglycerides, or decreased insulin sensitivity due to SGAs may cause an increased frequency or earlier onset of this endocrine disorder.[70,194,206–208] An early study showed a moderate correlation (R = .60, P = .03) between serum insulin and clozapine levels,[209] whereas Lund and associates showed an ~2.5 times greater risk of diabetes mellitus and hyperlipidemia in patients ages 20 to 34 years old treated with clozapine versus FGAs.[210] Other retrospective studies in veterans also suggested a slightly greater prevalence of diabetes in patients younger than 40 years old on the

SGAs clozapine, olanzapine, quetiapine, or risperidone (odds ratio [OR] = 1.09; CI = 1.03–1.15) than in those on FGAs[194] and an incidence of diabetes mellitus ~1.5 times greater in patients treated with olanzapine, risperidone, or quetiapine than with typical, mostly low-potency, antipsychotics.[70] Guidelines stress the need to monitor these patients routinely for glucose dysregulation, weight gain, and hyperlipidemia.[206,211]

Dyslipidemia

Treatment-emergent increases in both serum triglycerides and total serum cholesterol may occur with the use of antipsychotics. The initial reports were of increased serum triglycerides with clozapine,[65,67,212] a notation of this phenomenon in the package insert for quetiapine, and reports of this occurring in patients taking olanzapine.[66] Risperidone does not raise serum triglycerides as severely as does clozapine[212] and ziprasidone has negligible effects on serum triglycerides.[213,214] Aripiprazole resulted in lowered serum triglyceride levels compared to placebo in pooled double-blind trials.[215] Average serum triglycerides with clozapine, olanzapine, or quetiapine tended to increase by ~60 to 70 mg/dL between studies.[65–67,69] Extreme elevations in serum triglycerides (>1000 mg/dL) have been noted in some patients and were often associated with acute pancreatitis (**Table 85-13**).[68]

Table 85-13

Metabolic Monitoring Protocol for Antipsychotics[a]

	Baseline	Week 4	Week 8	Week 12	Week 16	Week 20	Week 24	Quarterly	Annually
Personal or family history	X								X
Weight (BMI)[b]	X	X	X	X	X	X	X	X	
Waist circumference	X								X
Blood pressure	X			X					X
Fasting plasma glucose	X	X (once during this period)		X			X	X (for first year)	X
Fasting lipid profile	X			X			X		X

BMI, body mass index.

[a]More frequent assessments may be warranted based on clinical status.

[b]Some references recommend weekly monitoring for first 6 weeks after initiation to determine patients at risk for more significant long-term weight gain, especially with agents with higher risk of causing weight gain.

Case 85-1, Question 21: What other metabolic effects need to be monitored in J.J. while she is receiving antipsychotic treatment? What are the risks of these effects in patients receiving these medications?

J.J., as with all patients receiving antipsychotics, is at risk for developing potentially significant weight gain, glucose irregularities including diabetes mellitus type 2, and dyslipidemia, especially hypertriglyceridemia. The risk varies among the agents, with SGAs generally thought to be at a higher risk than are the FGAs. Risperidone, which J.J. is currently receiving, is often considered to be at a midlevel risk of these effects compared to some of the other SGAs. Other possible risk factors include the patient's diet and exercise, family history of diabetes and cholesterol problems, and others.

Case 85-1, Question 22: The psychiatrist decides to change J.J. from risperidone to an agent with a lower risk of hyperprolactinemia. He starts J.J. on olanzapine, titrating up to 20 mg/day while removing the risperidone. What would be the appropriate monitoring for J.J. upon initiation of olanzapine?

Because olanzapine has a high risk of causing metabolic adverse effects in patients, J.J. should be monitored closely for the

development of these effects. Her weight should be checked very closely, especially at baseline and over the first few months of treatment. Monthly, if not more frequently, weights should be measured during this time. In addition, her serum glucose and/or HbA_{1C} along with her serum lipid panel should be checked at baseline and then in 3 months for any changes, with an interim serum glucose measurement around 1 to 2 months. Her blood pressure should also be monitored for any changes, especially if her weight increases significantly. If any increases or abnormalities are noted in these parameters, they should be addressed appropriately before becoming a medical concern.

Case 85-1, Question 23: After 2 months on olanzapine, J.J. returns to the clinic reporting that she is always eating and does not fit into her clothes from last summer. Her weight today is 151 pounds (68.49 kg). Body mass index (BMI) is 25.9 kg/m^2, an increase from her weight before olanzapine of 139 pounds (63.05 kg; and BMI of 23.9 kg/m^2). J.J.'s parents are also concerned because they have never seen her eat this much in her life. She is currently doing well on the medication, with no psychotic symptoms noticed over this time. They ask if the appetite and weight gain are from the olanzapine, and if there is anything that can be done about it. They ask about a "new form of olanzapine" that they read about online that has less weight gain. Would it help J.J. lose weight?

Olanzapine could certainly be the cause of her recent weight gain because it has one of the higher risks of causing weight gain among the SGAs. A 12-pound (5.44-kg) weight gain is certainly possible with this medication. Because J.J. and her parents have noticed an increase in her appetite since starting the medication, this makes it even more likely olanzapine is involved. Although there are no proven treatments for antipsychotic-induced weight gain, there are some interventions that could be implemented. J.J. should be given an appointment with a nutritionist to review her diet, and she should also be encouraged to increase her exercise on a regular basis, whether at a gym or even by adding 20- to 30-minute walks 4 to 5 days a week. Switching to the combination olanzapine–samidorphan medication at this time would likely have little benefit for J.J. It has

only been found to prevent weight gain from olanzapine at baseline, not reverse weight gain from an existing olanzapine regimen.

Case 85-1, Question 24: A month later, J.J. returns to the clinic. Blood work done a few days ago shows her fasting serum glucose to be 214 mg/dL, which is an increase from 132 mg/dL 4 months ago. Her HbA_{1C} has also increased from 5.9% to 7.1% over this time. A serum lipid panel shows her total cholesterol is 256 mg/dL, her direct low-density lipoprotein (LDL) cholesterol is 117 mg/dL, her high-density lipoprotein (HDL) cholesterol is 34 mg/dL, and her triglycerides are 997 mg/dL. Are these changes potentially related to J.J.'s antipsychotic treatment, and, if so, how should they be managed?

Increases in serum glucose and lipids, especially triglycerides, are possible with SGAs, and olanzapine in particular. Because her glucose and HbA_{1C} have increased since starting the medication, this makes it highly likely this is the cause. Although J.J.'s LDL and HDL cholesterol measurements are not ideal, they are not as concerning as her very elevated triglyceride level. At this high a level of triglycerides, there is the concern of possible pancreatitis. J.J. should be asked about any upper abdominal pain or other possible symptoms.

Although we could treat her increased serum glucose and lipids with appropriate medications for each concern, another consideration would be to change J.J. from olanzapine to another SGA with a lower risk of metabolic problems. This would need to be done after considering the risk of J.J.'s possible psychiatric decompensation from changing her antipsychotic treatment.

Medical Comorbidity

Currently, metabolic syndrome is seen as a major concern when treating schizophrenia, and it is recommended that patients receiving SGAs must be routinely monitored for weight gain, changes in fasting serum lipids, or signs of glucose dysregulation.[206,211,216] Some estimates of the prevalence of metabolic syndrome in patients with schizophrenia range from 18.8% to ~40% of those tested.[217] Because patients who are medication naive are already at a high risk

for developing metabolic syndrome,[218] we should strive to minimize the chance of worsening their situation. Furthermore, because weight gain with antipsychotic medication and its secondary metabolic complications tend to occur rapidly, patients should receive more frequent assessments for this when they are first started on or switched to a new antipsychotic medication. Medication use evaluations to make sure this necessary monitoring is performed may be helpful.[219]

Moreover, effective pharmacotherapy carries with it a potential for serious adverse metabolic effects such as obesity, hypertriglyceridemia, and resulting glucose dysregulation, as well as movement disorders such as akathisia, drug-induced parkinsonism, and TD. One study showed that metabolic disorders occur more than three times (3.7; 95% CI = 1.5–9.0) as much in patients with schizophrenia as compared to nonpsychiatrically ill controls.[220] In fact, cardiovascular disorders are the main reason patients with schizophrenia tend to die at a younger age than do their peers.[221]

Another concern is that, along with known genetic factors,[222] metabolic syndrome issues such as increased weight, serum leptin, lipids, and glucose are known risk factors for venous thromboembolism (VTE), which also may occur in association with antipsychotic pharmacotherapy.[223,224] The most established link is to the use of clozapine,[225] which is one of the most metabolically problematic agents. However, even more metabolically benign antipsychotics may eventually be linked to the increased occurrence of VTE.[226] Pulmonary embolism is a well-documented variant occurring with antipsychotics.[227,228] Because VTE related to antipsychotics is likely rare, the benefit-to-risk ratio should be kept in perspective.[229]

Other cardiovascular effects can be problematic when utilizing antipsychotic pharmacotherapy. Of concern, olanzapine, risperidone, and quetiapine have been associated with a threefold increased likelihood of cerebrovascular accidents (CVAs) and transient ischemic attacks during the first 6 months of treatment in elderly patients.[230,231] Other antipsychotics have also been implicated.[232] Such events could relate to the slightly higher risk of death in elderly

patients receiving these medications.[233] As a result, all antipsychotics have a black box warning from the FDA regarding an increased risk of CVAs in elderly patients taking these medications.

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome (NMS) is a rare, but potentially fatal, complication of antipsychotic therapy that can occur because of treatment with any antipsychotic or abrupt cessation of a dopamine agonist. Therefore, early recognition and management are crucial. There are numerous diagnostic scales to ensure accurate diagnosis of NMS for research purposes, but the most widely utilized in clinical practice is the *DSM-5* criteria. NMS is associated with high fever (103–104 °F [39.44–40 °C]), muscular rigidity, altered consciousness, and highly elevated creatinine phosphokinase (CPK), often >1000 µg/L. Other signs are drooling, difficulty swallowing, fast heart rate (>100 beats/minute), profuse sweating, incontinence, and labile blood pressure. It is treated by immediate cessation of antipsychotic therapy, supportive care, and the administration of medications such as dantrolene sodium, biperiden, or bromocriptine. Combination antipsychotic therapy was found in 39% of all NMS cases.[234] Some believe that physical exhaustion and dehydration predispose a patient to develop NMS, so it is important that patients on antipsychotics be cautioned to take proper caution in hot weather. Also, the effects of antipsychotics on the hypothalamus (which regulates temperature and food intake, among other activities) and the "body-secretion" drying activities of anticholinergic medications increase the danger of heat exhaustion in these patients.[235]

Case 85-1, Question 25: J.J.'s psychiatrist decides that in light of her weight gain and worsening glucose and lipid profiles, he is going to change her from olanzapine to lurasidone, titrating her up to 80 mg/day. She did well with the medication change. A few weeks after starting the lurasidone, her parents take J.J. into the ER one evening concerned that she has meningitis because she feels feverish, is sweating, seems confused, and has a stiff neck. The ER exam shows J.J. has a fever of 103.1 °F (39.5 °C), blood pressure of 176/98 mm Hg,

pulse of 136 bpm, respiratory rate of 36 bpm, a stiff neck that is not painful, and is sometimes incoherent when answering questions, but shows no outward signs of psychosis. She also is sweating profusely despite the air conditioning in the ER. Lab work is ordered and results return a couple of hours later. J.J.'s chemistries are normal except for a CPK of 5960 μg/L, a normal CBC, and normal serum glucose. Repeat vital signs 2 hours after she comes to the ER show a fever of 103.2 °F (39.56 °C), blood pressure of 96/62 mm Hg, pulse of 146 bpm, and a respiratory rate of 39 bpm. What is the most likely cause of J.J.'s presentation at this time and why? How should J.J. be managed?

J.J. is most likely suffering from NMS from lurasidone. Although NMS can occur at any time during treatment with any antipsychotic, the timing of this episode shortly after beginning the medication makes it more likely. Because she does not have pain in her neck or an elevated white blood cell (WBC) count, it is not likely meningitis as her parents feared (although this should be definitively ruled out). The high fever, labile blood pressure, tachycardia, sweating, confusion (without psychosis), and highly elevated CPK are indicative of NMS. J.J. will need to be admitted to the hospital because NMS can be life-threatening. Because she will need to stop taking all antipsychotics for up to 2 weeks, she will most likely require hospitalization during this time because her psychosis is likely to return. During the acute treatment period, she will likely need treatment for the NMS with either dantrolene (for the fever) or bromocriptine (a dopamine agonist), as well as other measures as needed for her fever, elevated blood pressure, and so on. During the longer period without antipsychotic treatment while waiting for the NMS to resolve, J.J. will likely need treatment with sedatives such as benzodiazepines because we cannot actively treat her schizophrenia.

Case 85-1, Question 26: During the subsequent admission for her episode of NMS, J.J. is eventually started on aripiprazole for her schizophrenia. A few days into titrating the medication to an effective dose, she develops some mild stiffness in her arms, most likely some mild parkinsonism. Fearful that this is the NMS returning, J.J. now refuses to take any antipsychotics. Her psychiatrist decides to start her on an LAIA form of aripiprazole, but notices there are two

different versions of the medication available. Which of these two forms would be the better choice for J.J. at this time?

Ideally, we would be able to stabilize J.J. on an oral form of aripiprazole before conversion to an LAIA form of the medication, but her nonadherence makes that unlikely. Both forms of aripiprazole LAIA require an overlap of oral medication during initiation: 14 days for the monohydrate salt, and either 21 days for the lauroxil salt or the use of the Initio lauroxil injection with a single 30-mg oral dose. However, the main concern is the dosing of the LAIA. The monohydrate salt has a single dose for all patients, except in cases of renal impairment of P450 inhibitors or inducers. The lauroxil salt is dosed based on a conversion from the dose of oral aripiprazole the patient is currently receiving. Because J.J. was never stabilized on an oral dose of aripiprazole before she stopped taking the medication, it would be very difficult to convert her to an equivalent dose of the lauroxil LAIA. Therefore, it would be easier to initiate the monohydrate salt version at its usual dose of 400 mg every month and then try to provide coverage for the initial 14-day window recommended for the product. Regardless of which form is used, J.J. should be monitored for the development of the parkinsonism she had when being titrated on the oral form of aripiprazole.

Case 85-1, Question 27: Over the next few months, J.J. is maintained on aripiprazole monohydrate LAIA 400 mg/month. Because her symptoms improved but she was still showing some signs of daily auditory hallucinations, haloperidol 5 mg/day was added to her regimen. Her hallucinations subsided within a couple of weeks after an increase to 10 mg/day of haloperidol, but now J.J. comes in with her parents to the ER attached to the clinic. J.J.'s neck is turned clockwise to her right shoulder, and she is unable to move her head back to her centerline and look forward. J.J. says her neck hurts a lot and she wants this feeling to go away. What is the most likely reason for J.J.'s current problem and how should it be managed?

J.J. is most likely experiencing a dystonic reaction, or dystonia, from the recent addition and increase in her haloperidol dose. The specific type of dystonia she has is called *torticollis*, which is

dystonia causing the muscles of the upper spine to contract and cause a twisting motion of the neck. This is another type of EPS, and as seen in J.J. here, can often be painful owing to the strong muscle contraction. FGAs are more likely to cause this problem than are SGAs, so the timing of the reaction to the addition of haloperidol makes sense.

Acutely, J.J.'s dystonia needs to be treated as quickly as possible because it is painful to her. Oral medications could take an hour or longer to work, so an injectable agent is preferred for more rapid action. As with drug-induced parkinsonism, the agent of choice is an anticholinergic medication to offset the EPS. Most ERs will have either benztropine or diphenhydramine (which has appreciable anticholinergic effects) readily available in an IM/intravenous (IV) form for a case such as this. Atropine, although also likely available, is generally not used because of greater systemic and cardiac effects. Benzodiazepines can also be used in IM/IV forms if needed because they too will help relax the contracted muscles and help J.J. calm down.

In addition, J.J.'s medication regimen may need to be adjusted to prevent a future dystonic reaction. A reduction in her haloperidol dose may be needed, or adjunctive oral anticholinergics added to her regimen as prophylaxis.

Case 85-1, Question 28: J.J. has been continued on the combination of aripiprazole monohydrate LAIA and haloperidol over the next 8 years. Over time her symptoms have returned periodically, never requiring hospitalization but necessitating gradual increases in her haloperidol to 15 mg/day. J.J. now presents to the clinic with "shakes in my hands" that are bothering her. During the physical exam, J.J. is noted to have facial grimacing, darting movements of her tongue, lip-smacking, and twisting movements in her hands. The movements in her hands seem to disappear when she grabs an object or performs other activities with her hands. What is the most likely cause of these movements in J.J.?

These movements are most likely an early form of TD. Haloperidol, as a high-potency FGA, has a high risk of causing this movement disorder over time: ~3% to 5% per year of use, or 24% to

40% risk in J.J. The symptoms we are observing in J.J. are consistent with those movements seen in TD that presents with arrhythmic choreoathetoid “snakelike” movements of the orofacial areas, limbs, and trunk. The fact that the irregular hand movements stop or decrease when J.J. performs a conscious task with her hands is also indicative of TD. An AIMS exam should be performed to help confirm and quantify the severity of any TD in J.J.

Case 85-1, Question 29: What can be done to treat the TD seen in J.J. at this time?

There are some strategies that might help alleviate the patient’s dyskinetic movements. Slow decreases in her haloperidol dose over time may help these movements eventually decrease; a rapid reduction in the dose may acutely worsen the current dyskinetic symptoms, so this should be avoided. If the movements persist despite lowering the dosage or discontinuing the haloperidol, a VMAT2 inhibitor, such as valbenazine or deutetrabenazine, could be considered. Considering the high cost of these medications and unclear long-term benefits, adjustments in the baseline antipsychotic regimen would be a more appropriate initial choice. In addition, there are some data supporting the use of clozapine to treat dyskinesia and schizophrenia symptoms. This should be considered cautiously in light of the other concerns related to clozapine treatment.

Inadequate Response

The patient with chronic schizophrenia must be evaluated in a systematic manner to discern whether past medication trials were indeed medication failures. Medication nonadherence, intolerance, and inadequate dosing may often be documented as failed trials. Patients with schizophrenia have been shown to have a deficit in perspective habitual memory, which may cause difficulty in remembering whether they took their medications.[236] This could result in either missed or doubled dosages. An in-depth assessment

of medication adherence should be conducted in a nonpunitive and collaborative manner with the patient. Outreach for collateral information should also be undertaken after acquiring appropriate releases of information. Clinical deterioration often occurs slowly and insidiously with incomplete medication adherence.[237] Poor therapeutic relationship and social supports may also lead to poor adherence in patients with schizophrenia.[238] Other important predictors include lack of insight, concomitant substance abuse, a short illness duration, issues with discharge planning and environment,[239] as well as higher levels of hostility.[240] Patients who have had difficulties with medication adherence in the past should be offered treatment with an LAIA.

A trial of an antipsychotic should be continued for at least 4 to 6 weeks at a therapeutic dosage after initial partial response of symptoms. Switching and augmentation strategies should only be considered after symptoms fail to fully respond to an adequate trial. Patients may wind up in a stalled cross-titration, possibly due to a transition in care, and be continued on multiple antipsychotics. This highlights the need to carefully tease out the patient's medication experience and transition to effective monotherapy to avoid increased adverse effects, pill burden, and cost for the patient.

Between 20% and 30% of patients remain unresponsive despite multiple antipsychotic trials. The most commonly adopted and most stringent criteria for antipsychotic treatment refractoriness were proposed in the landmark trial conducted by Kane and colleagues that resulted in clozapine's approval in the U.S. market. Treatment refractoriness was defined as (a) at least three periods of treatment in the preceding 5 years with antipsychotics from two chemical classes at dosages ≥1000 mg/day of chlorpromazine for a period of 6 weeks, (b) no symptom-free period within 5 years, and (c) a BPRS total score >45.[55,241]

Clozapine is the most efficacious medication in patients with treatment-resistant schizophrenia and should be considered in all patients who fail to respond to at least two adequate antipsychotic trials.[55,111,184,242] It is also the treatment of choice for those at high risk for suicide or violence, or in patients with TD.[106,243] Despite its

superior efficacy, clozapine is often underutilized in the treatment of resistant schizophrenia owing to its adverse effect burden. Close monitoring and follow-up are necessary to ensure safe and effective use of clozapine. Baseline monitoring should include a physical exam (weight, blood pressure, waist circumference), HbA_{1C} or fasting blood glucose, a fasting lipid panel, liver function tests, serum creatinine, blood urea nitrogen levels, and pregnancy test, if indicated. Clozapine has a unique adverse effect profile that ranges from common bothersome adverse effects to life-threatening adverse effects listed in its five black box warnings. The black box warnings caution for risk of agranulocytosis, seizures, myocarditis, other adverse cardiovascular and respiratory effects, and increased mortality in elderly patients with dementia-related psychosis (**Table 85-14**).

Table 85-14
Clozapine Monitoring Requirements

ANC Level	Treatment Recommendation	ANC Monitoring
Normal range for a new patient GENERAL POPULATION ▪ ANC ≥1500/μL BEN POPULATION ▪ ANC ≥1000/μL ▪ Obtain at least two baseline ANC levels before initiating treatment.	Initiate treatment ▪ If treatment interrupted: ▪ <30 days, continue monitoring as before ▪ ≥ 30 days, monitor as if new patient	Weekly from initiation to 6 months ▪ Every 2 weeks from 6 to 12 months ▪ Monthly after 12 months

ANC Level	Treatment Recommendation	ANC Monitoring
Mild neutropenia (1000–1499/μL)[a]	GENERAL POPULATION ▪ Continue treatment.	GENERAL POPULATION ▪ Three times weekly until ANC ≥1500/μL ▪ Once ANC ≥1500/μL, return to patient's last "normal range" ANC monitoring interval.[b]

	BEN POPULATION
	▪ Mild neutropenia is normal range for BEN population, continue treatment.
	▪ Obtain at least two baseline ANC levels before initiating treatment.
	▪ If treatment interrupted
	  ▪ ≤30 days, continue monitoring as before.
	  ▪ ≥30 days, monitor as if new patient
	▪ Discontinuation for reasons other than neutropenia
		BEN POPULATION
		▪ Weekly from initiation to 6 months
		▪ Every 2 weeks from 6 to 12 months
		▪ Monthly after 12 months

ANC Level	Treatment Recommendation	ANC Monitoring
Moderate neutropenia (500–999/μL)[a]	GENERAL POPULATION ▪ Recommend hematology consultation. ▪ Interrupt treatment for suspected clozapine-induced neutropenia. ▪ Resume treatment once ANC normalizes to ≥1000/μL.	GENERAL POPULATION ▪ Daily until ANC ≥1000/μL ▪ Then three times weekly until ANC ≥1500/μL ▪ Once ANC ≥1500/μL check ANC weekly for 4 weeks, then return to patient's last "normal range" ANC monitoring interval.[b]
	BEN POPULATION ▪ Recommend hematology consultation. ▪ Continue treatment.	BEN POPULATION ▪ Three times weekly until ANC ≥1000/μL or patient's known baseline ▪ Once ANC ≥1000/μL or patient's known baseline, check ANC weekly for 4 weeks, then return to patient's last "normal BEN range" ANC monitoring interval.[b]

ANC Level	Treatment Recommendation	ANC Monitoring
Severe neutropenia (<500/μL)[a]	GENERAL POPULATION ▪ Recommend hematology consultation. ▪ Interrupt treatment for suspected clozapine-induced neutropenia. ▪ Do not rechallenge unless prescriber determines benefits outweigh risks.	GENERAL POPULATION ▪ Daily until ANC ≥1000/μL ▪ Three times weekly until ANC ≥1500/μL ▪ If patient rechallenged, resume treatment as a new patient under "normal range" monitoring once ANC ≥1500/μL
	BEN POPULATION ▪ Recommend hematology consultation. ▪ Interrupt treatment for suspected clozapine-induced neutropenia. ▪ Do not rechallenge unless prescriber determines benefits outweigh risks.	BEN POPULATION ▪ Daily until ANC ≥500/μL ▪ Three times weekly until ANC is greater than or equal to patient's established baseline ▪ If patient rechallenged, resume treatment as a new patient under "normal range" monitoring once ANC ≥1000/μL or at patient's baseline

BEN, benign ethnic neutropenia.

[a]Confirm all initial reports of absolute neutrophil count (ANC) <1500/μL (ANC <1000/μL for patients with benign ethnic neutropenia [BEN]) with a repeat ANC measurement within 24 hours.

[b]If clinically appropriate.

Source: Clozaril (clozapine tablets). Package insert. HLS Therapeutics Inc; February 2021.

Agranulocytosis is a rare, yet potentially life-threatening, hematologic reaction affecting ~1% of patients treated with clozapine. It is defined as a drop in neutrophil count <500 cells/mm^3. Agranulocytosis is not dose related and can occur at any point in treatment, although the risk is higher within the first 6 months of therapy. Clozapine may also cause mild-to-severe neutropenia (ANC 500–2000 cell/mm^3). Clozapine-induced neutropenia and agranulocytosis may be in part due to the selective effect on precursors of polymorphonuclear leukocytes; however, the mechanism remains to be fully elucidated. Clozapine is only dispensed through the clozapine risk evaluation and monitoring strategy (REMS) to ensure ANC values are within range before dispensing clozapine. The pharmacy, patient, and provider must all be enrolled in the clozapine REMS program. Monitoring of the absolute neutrophil count (ANC) must occur 7 days before initiation of clozapine and weekly thereafter for the first 6 months. Monitoring frequency can be reduced to biweekly for the next 6 months if all ANC values are within range (>1500/μL). Monthly blood draws are allowed if all values remain within range after 6 months of biweekly monitoring. Certain ethnic groups, including patients of African and Middle Eastern descent, may average a lower ANC value than normal ranges, called benign ethnic neutropenia (BEN). The clozapine REMS program allows for lower ANC values to compensate for patients diagnosed with BEN because they do not suffer from repeated or severe infections as a result of their low baseline ANC values. Severe neutropenia can be deadly because of the body's inability to fight off infection. This is a medical emergency that requires the abrupt discontinuation of clozapine. In other cases, clozapine should be discontinued gradually over a period of ≥2 weeks, to prevent cholinergic rebound (sweating, headache, nausea, vomiting, diarrhea) or recurrence of psychotic symptoms. The patient should not be rechallenged on clozapine after agranulocytosis, but

patients can be successfully rechallenged after neutropenia.[244] More information can be found at https://www.newclozapinerems.com/.

Seizure risk associated with clozapine is a dose-related phenomenon. Risk of seizure is 4.4% at a dose of 600 mg and several case reports implicate serum levels >500 to 1300 ng/mL with higher risk of seizure.[245,246] Prophylactic use of antiepileptic drugs (AEDs) is generally not recommended.[247] However, patients who experience a seizure on clozapine can be safely continued on a lower dose of clozapine and initiated on an AED. Valproate and lamotrigine are preferred over carbamazepine because of its risk of agranulocytosis and extensive interaction profile.[246] Myocarditis is a potentially fatal hypersensitivity reaction that can occur ~3 weeks after initiation of clozapine. Diagnosis is confounded by the variable and nonspecific signs and symptoms of its presentation, but the incidence is estimated to fall between <0.1% and 3%.[248] The monitoring protocol proposed by Ronaldson and colleagues consists of obtaining baseline troponins, C-reactive protein (CRP), and an ECG, and then monitoring troponin and CRP on days 7, 14, 21, and 28 of treatment. In the case of mild elevation in troponins or CRP, persistent tachycardia, or signs or symptoms resembling infection, daily troponins and CRP should be drawn until symptom resolution. Clozapine should be discontinued if troponins reach twice the upper limit of normal or if CRP is >100 mg/L.[59] Successful rechallenge may be possible after symptoms resolve.[249,250]

The black box warning describing “other adverse cardiovascular and respiratory effects” references the risk of orthostatic hypotension associated with clozapine. Approximately 9% of patients will experience orthostatic hypotension, but tolerance develops over 4 to 6 weeks.[177] Risk is higher during initiation, which necessitates the slow titration beginning at 12.5 mg bid and increasing at the rate of 25 to 50 mg/day or slower. Clozapine must also be retitrated after a gap in therapy of >2 days to prevent significant orthostasis and risk of falls. Patients should be counseled to make slow transitions from prone or seated positions and maintain adequate fluid and salt intake. In patients with persistent dizziness and orthostasis after

titration where DR is not an option, a mineralocorticoid, fludrocortisone, may be an option.[177]

Clozapine is also associated with frequent, bothersome adverse effects that, if left unaddressed, can greatly impact the quality of life. Constipation is a common, yet often-overlooked, adverse effect of clozapine that can result in serious complications including paralytic ileus, small-bowel perforation, or death secondary to aspiration of gastric contents. It affects between 14% and 60% of patients taking clozapine. Patients should be screened at every visit for bowel habits and providers should have a low threshold for initiating a bowel regimen. Bowel regimens consist of bulk-forming laxatives and increased fluid intake, stool softeners, or short-term use of stimulant laxatives or enemas. Anticholinergic adverse effects of clozapine can result in gastrointestinal (GI) hypomotility, small-bowel obstruction, and ileus. These are serious concerns that may occur in up to 0.3% of patients treated with clozapine. Adjunctive anticholinergic agents and opioids should be limited and the clozapine dose tentatively decreased or held in cases of ileus. Sedation is usually more pronounced when first initiating clozapine and can be managed by slowing the rate of titration and consolidating the dose to bedtime. As previously described, a benign tachycardia can also result from clozapine use, but patients also presenting with flu-like symptoms, dyspnea, fever, and chest pain should have further workup for myocarditis. Sialorrhea is an embarrassing adverse effect that, in the extreme, can result in sleep disruption or aspiration pneumonia. Treatment options include tentative DR or nonpharmacologic management, such as placing a towel on their pillow, as first line. Topical anticholinergic agents (ipratropium 0.03%–0.06% dosed one to two sprays sublingually or one or two atropine eye drops in 1 ounce of water swished and spit) are preferred over systemic anticholinergics (benztropine 0.5–2 mg at bedtime [HS] or glycopyrrolate 1–2 mg) or the α-2 adrenergic agent, clonidine.[251] Serious cases may be treated with botulinum toxin injected into each parotid gland.[251] Nocturnal enuresis may also be underreported owing to embarrassment. Management includes avoiding fluids in the evening, voiding before bed, and setting alarms to schedule

nocturnal voiding. Desmopressin may also be effectively utilized, but the patient must be monitored for hyponatremia secondary to its use.[177]

Case 85-1, Question 30: J.J.'s psychiatrist decides to start J.J. on clozapine and remove all other antipsychotics in light of her TD and past failures and adverse effects with other antipsychotics. What adverse effects of clozapine should be monitored for in J.J.?

Any patient started on clozapine should be monitored for agranulocytosis and metabolic adverse effects, among others. Because J.J. has a history of metabolic adverse effects (weight gain, increased glucose, and increased triglycerides) with other antipsychotics, these are of particular concern with using clozapine because clozapine has the highest risk of these adverse effects. J.J. should also be counseled about orthostatic hypotension, sedation, anticholinergic effects (especially constipation), and sialorrhea.

Case 85-1, Question 31: Before initiating clozapine therapy, what labs and other tests should be performed on J.J.?

Clozapine therapy requires a baseline ANC before starting the medication to ensure the patient has an adequate number of neutrophils before initiation. In addition, her weight, waist circumference, serum glucose/HbA_{1C}, and lipid panel should be measured to monitor for the development of metabolic adverse effects. Baseline liver and kidney function tests should also be measured. A pregnancy test should also be performed, especially if there is any chance that J.J. could be pregnant.

Case 85-1, Question 32: Once J.J. is started on clozapine, how should she be monitored? What parameters should be checked and how frequently?

Clozapine treatment requires weekly ANC checks for at least the first 6 months of treatment. Assuming there are no problems with her

ANC values (ANC ≥ 1500/μL), she can then go in for ANC checks every other week for 6 months, and then once monthly ANC checks thereafter. In addition, her weight should be monitored at least monthly (and perhaps weekly) for the first few months of treatment, along with at least quarterly serum glucose and lipid panel checks. She should also be asked about any problems with orthostasis (dizziness), constipation, sedation, and drooling during any office visits.

Serum Concentration Monitoring

Data supporting a strong correlation between antipsychotic serum concentrations and efficacy are lacking.[252] Therefore, routine therapeutic drug monitoring (TDM) of antipsychotic serum concentration is not recommended in most situations. The exception is clozapine, which has sufficient data to support a higher rate of response at levels >350 ng/mL.[186,253] The Arbeitsgemeinschaft für Neuropsychopharmakologie und Pharmakopsychiatrie (AGNP) guideline strongly recommends TDM of the FGAs, haloperidol, fluphenazine, and perphenazine, as well as SGAs, clozapine and olanzapine, based on established therapeutic reference ranges. They also recommend monitoring of chlorpromazine, aripiprazole, quetiapine, risperidone, paliperidone, and ziprasidone in cases of suspected altered PK where therapeutic ranges are less well established, but supratherapeutic concentrations may result in adverse effects.[254] Monitoring of serum levels of these agents is appropriate in the following clinical scenarios[255]:

1. Psychiatric decompensation on a previously effective dose
2. Poor response to medication despite adequate dose and trial duration
3. Unexpected adverse effects while on a previously tolerated dose
4. Addition or withdrawal of an interacting medication
5. Patients with potentially altered PK (eg, medically compromised, children, elderly)

6. Suspected medication nonadherence

Nonantipsychotic Agents

Antipsychotics are generally the treatment of choice for most patients with schizophrenia. However, in some situations, other medications may be needed and appropriate for use. Benzodiazepines may be appropriate in patients with acute agitation, as described previously. Other medications, such as mood stabilizers and antidepressants, may be useful for some patients based on their clinical symptoms and presentation.

MOOD STABILIZERS

The mood stabilizers lithium, carbamazepine, valproic acid, and lamotrigine have been studied for use in schizophrenia. These medications are frequently used as an adjunct to antipsychotic treatment in schizophrenia in patients with affective symptomatology as well as core symptoms of schizophrenia. Evidence for these common practices is sometimes found to be equivocal or conflicting.

None of these mood stabilizers have shown efficacy as monotherapy for schizophrenia. Lamotrigine has been found to have modest effects in schizophrenic pathology as an adjunct to antipsychotic treatment but has little efficacy in the patient who is treatment resistant.[256] Lithium was determined by a Cochrane review to have some benefit as an augmenting agent in lower quality studies, but replication in higher quality studies is needed.[257] A recent meta-analysis shows evidence that the practice of augmentation of antipsychotic medications with valproate yields significant improvements in patients treated for schizophrenia or schizoaffective disorder.[258] A recent Cochrane review does not recommend carbamazepine for augmentation of antipsychotics in the treatment of schizophrenia.[259] A need for further study of antipsychotic augmentation with mood stabilizers is warranted. Concomitant use should be carefully considered at this time given

the potential for drug interactions, additional adverse effects, and pill burden.

ANTIDEPRESSANTS

Depression often presents in schizophrenia,[38,260] and ~6% to 10% of patients with schizophrenia commit suicide in their lifetime.[28,261–263] Although controversial, there is evidence that antipsychotics may differ in their ability to treat depressive symptoms in schizophrenia[53,103,264,265] and many consider SGAs to be better for this syndrome than are the FGAs.[265,266] Some of the advantages of SGAs in depression may be due in part to less antipsychotic-induced dysphoria or akinesia or effect on treating negative symptoms.[265,266] There is also substantial literature showing that adding an antidepressant may be a useful option in some patients with depression.[267] The divergent pattern of antidepressant response in numerous studies suggests that those patients whose positive symptoms are well controlled are more likely to respond favorably to antidepressant augmentation.[27] In one trial, the antidepressant bupropion did significantly worse than did placebo in patients treated with thiothixene.[33]

Some also advocate for the possible effectiveness of antidepressant medication to decrease the severity of negative symptoms in schizophrenia.[268] One review found only 5 of 14 studies with selective serotonin reuptake inhibitor (SSRI) antidepressants demonstrated efficacy in ameliorating negative symptoms; however, mirtazapine was promising in 4 of 6 trials.[267] Tricyclic antidepressants do not have robust evidence for the treatment of negative symptoms.[269]

Case 85-1, Question 33: J.J. responds well to clozapine, taking a dose of 450 mg/day, with higher doses causing intolerable adverse effects in J.J. Over time, J.J. begins to become depressed as she realizes that her life has not gone the way she thought it would. Her psychiatrist assesses her as having depression secondary to her schizophrenia, and the decision is made to start her on paroxetine 20 mg daily. Is the addition of paroxetine appropriate for J.J.?

Although paroxetine is an appropriate treatment for depression, it is most likely not a good choice for J.J. There are data that show that paroxetine can cause anticholinergic adverse effects in patients, which could overlap any anticholinergic effects caused by clozapine. J.J. would need to be monitored for increased anticholinergic adverse effects, and possibly be treated for them (eg, bowel regimen for constipation). Selection of an antidepressant with a lower risk of drug interactions, such as escitalopram or sertraline, would be more appropriate.

Treatment Guidelines for Schizophrenia

Clinical guidelines on the treatment of schizophrenia are published by a number of organizations. The most prolific and current guidelines at this time are the APA, Patient Outcomes Research Team on Schizophrenia (PORT), Texas Medication Algorithm Project (TMAP), and the National Institute for Health and Care Excellence (NICE) of the United Kingdom.[44,105–107] These guidelines are an excellent resource and starting point in ensuring evidence-based and safe care of patients with schizophrenia. However, it is important to keep in mind the level of evidence each organization requires to support a given treatment recommendation. For example, the APA utilizes a transparent process of systematically evaluating the literature than rating the strength of evidence for each clinical recommendation (A: high, B: moderate, C: low) in accordance with Agency of Healthcare Research and Quality (AHRQ) guidelines. A higher rating denotes increased confidence that the available evidence reflects a true effect and is unlikely to be changed through further research. In addition, the strength of each statement is rated on the confidence that potential benefits outweigh risk for harm (1: recommendation, benefit outweighs risk, or 2: suggestion, greater uncertainty). The APA also includes a section following each recommendation comparing it to available guidelines from other organizations and listing any differences in opinion in writing group members. Other guidelines may incorporate expert opinion[105,107] or

consensus in areas that lack high-level evidence, such as antipsychotic combination treatment or treatment after nonresponse to clozapine. The bottom line is that these guidelines provide a systematic framework for high-quality treatment, but should by no means be a substitute for clinical judgment and treating the unique clinical picture each individual presents. Any treatment decision should be aligned with the treatment team; caregivers; and, most importantly, the patient. Even the most effective treatment is destined to fail unless the patient is invested and in agreement with their own treatment. **Figure 85-2** is a consolidated view of the current guidelines on the use of antipsychotics in the treatment of schizophrenia.

CONSIDERATIONS IN SPECIFIC POPULATIONS

Pregnancy

The peak onset of schizophrenia in the female population coincides with peak childbearing age, and unplanned pregnancies can be a concern.[270] Patients should be routinely educated on safe sexual practices, offered contraceptives if indicated, and receive pregnancy tests before prescription of antipsychotic medications. The general goals of treatment in pregnant patients are to thoroughly weigh the risks of teratogenicity with the benefit of ongoing treatment and prevention of psychiatric decompensation. Untreated psychosis places both the patient and the fetus at significant risk. Effective treatment with an antipsychotic agent may enable the mother to carry out necessary self-care and prenatal care.[271] Ideally, treatment decisions should be made as part of a multidisciplinary team consisting of the patient, mental health provider, obstetrician, primary care provider, and pediatrician. General guidelines on treatment during pregnancy recommend[271]:

1. Utilizing antipsychotic monotherapy at an adequate dose versus combination therapy

2. Avoiding medication switching to minimize exposure to the fetus and risk of psychiatric relapse
3. Selecting appropriate treatment based on history of efficacy, prior exposure during pregnancy, and available evidence on safety
4. Choosing medications with fewer metabolites, fewer interactions, and higher protein binding are generally preferred.

Data on the safety of antipsychotics during pregnancy are limited owing to ethical barriers to conducting well-designed, prospective controlled trials. There is inconclusive evidence linking fetal exposure to antipsychotics and major congenital malformations, perinatal mortality, high birth weight (SGAs), and low birth weight (FGAs).[270] A large-scale prospective national pregnancy registry for atypical antipsychotics reported three major fetal malformations in a cohort of 214 patients with first-trimester exposure to SGAs. The control group, which included 89 live births, had one major malformation. This translates to an OR of 1.25 (95% CI = 0.13–12.19) between exposed and unexposed infants. Although ongoing data collection is still underway, these results suggest that SGA exposure would be unlikely to increase the risk of major malformations higher than 10-fold of that observed in control groups or in the general population.[272] In 2011, the FDA implemented safety-labeling changes concerning the use of antipsychotic agents during the third trimester of pregnancy. They reported a risk that newborns may experience withdrawal symptoms or EPS; however, many cases were confounded by comorbid substance use and concomitant psychotropic medications. Symptoms usually resolved within hours to days without intervention; however, some may require prolonged hospitalization.[273] There can also be an increased risk of gestational diabetes in females who continue antipsychotic treatment, particularly with either olanzapine or quetiapine, during pregnancy.[274]

Case 85-1, Question 34: Several months later, the clinic receives word from J.J.'s primary care provider that J.J. is pregnant, as confirmed by blood test. J.J. is still receiving clozapine and is fairly stable psychiatrically on the medication, even working part-time in a supermarket. J.J. does not want to lose the baby,

but is worried about the effect of being on medication despite knowing it is what is keeping her stable. Should J.J. be continued on clozapine, and what are the risks to her baby if she does or does not?

Treatment of schizophrenia with antipsychotics during pregnancy must be considered carefully. Because J.J. is currently stable and functional while taking clozapine, there is a significant risk of relapse if she stops the medication. During this relapse, if she were to engage in high-risk behaviors, it could be quite dangerous to both her and her baby. Maintaining stability is of great importance because if J.J. can take care of herself appropriately, it is more likely she will also take care of her fetus simultaneously. However, antipsychotics do carry risks of teratogenicity, and J.J. should be counseled on these risks. Clozapine is rated as pregnancy category B by the FDA, which is better than most antipsychotics but still with some risk involved. The decision to maintain J.J. on clozapine during her pregnancy should be made by her, her psychiatrist, obstetrician, and other care providers to determine whether continuation of clozapine, and presumptive stability of her illness, is appropriate.

First-Episode Psychosis and Early-Onset Schizophrenia

Child and adolescent patients presenting with early psychosis are exquisitely sensitive to EPS and metabolic adverse effects of antipsychotics.[275,276] In general, symptoms of first-episode psychosis (FEP) respond to lower antipsychotic dosages. Therefore, the minimum effective dose should be utilized to minimize adverse effect burden. The question of which interventions are appropriate to initiate and when is complicated. Multiple studies support the effectiveness of antipsychotics in the treatment of early psychosis.[277–280] However, the treatment of prodromal symptoms is an area of debate. Prompt recognition of prodromal symptoms and patients with psychosis risk syndrome is crucial. Features associated with greater rates of conversion to psychosis in patients at ultrahigh

risk of psychosis include genetic risk for schizophrenia, high levels of unusual thought content, high levels of suspicion and paranoia, social impairment, and history of substance use.[281] There is emerging evidence to support early initiation of ω-3 fatty acids or antidepressants to reduce rates of conversion to psychosis in high-risk patients.[276,282,283] Early engagement with appropriate comprehensive, multidisciplinary clinics results in improved quality of life and psychopathology, greater involvement in educational and vocational pursuits, and increased treatment follow-up.[284,285] Reduction in the duration of untreated psychosis leads to improved long-term prognosis and greater likelihood of achieving symptom remission.[43,286,287] Neurocognitive impairment is also a key predictor of functional outcome in early schizophrenia. Unfortunately, available pharmacologic options have a limited impact on neurocognition.[288] Cognitive enhancement therapy, in conjunction with antipsychotic medication, can lead to durable improvements in neurocognitive functioning, social adjustment, and employment for patients with early psychosis.[289,290]

After achieving initial remission, guidelines recommend continued maintenance treatment with an antipsychotic for at least 1 year.[44,106] Studies of medication discontinuation demonstrated 5-year relapse rates from 80%.[291] However, cautious DR strategies as soon as 6 months after remission may improve long-term functional recovery. Wunderink and colleagues conducted a 7-year follow-up study of a 2-year open RCT comparing maintenance therapy (MT) versus DR/dose discontinuation after 6 months' remission of FEP. In the initial RCT, 128 patients were randomized to MT or DR and followed up for 18 months. The MT group showed benefit in short-term relapse rates over the DR group.[292] However, the DR group had approximately twice the recovery rate of patients in the MT group (40.4% vs 17.6%, respectively) at the 7-year follow-up and there were no significant differences in long-term relapse rates.[293] A limitation to the generalizability of the study is that the population who agreed to enrollment in the initial phase had a higher level of functioning, greater adherence, and was easier to engage. These findings demonstrate the potential impact of limiting total

antipsychotic burden on functional recovery rates of patients with remitted FEP. The lower adverse effect burden from minimizing the antipsychotic dose allows for improved social engagement, improved therapeutic alliance, and lower risk of self-discontinuation because of tolerability issues. Functional recovery is the key treatment goal in the early course of schizophrenia. Getting patients engaged in treatment early on in the illness course, utilizing the lowest clinically effective dosages of antipsychotics, and providing psychoeducation can mean the difference in a patient recovering from a psychotic episode and completing college, returning to work, or engaging in meaningful social outlets.

Case 85-1, Question 35: J.J. gives birth to a son, R.J., via a normal delivery. Over the course of time, R.J.'s pediatrician notes he is not socializing like other children, especially into adolescence. He is now age 15 and tends to isolate himself, does not have many peer friends, and recently has started performing poorly in school. His teachers have asked the pediatrician to evaluate R.J. for potential attention deficit hyperactivity disorder (ADHD) because he is often found not paying attention in class. J.J. also tells the pediatrician that she thinks R.J. still has "imaginary friends" because she often sees him alone in his room talking to people who are not there. What is potentially happening with R.J. and how should he be treated at this time?

R.J. is at higher risk for and potentially showing symptoms of early-onset schizophrenia. His lack of socialization and his isolation could be symptoms of the prodromal phase of schizophrenia. His "imaginary friends" could be R.J. responding to auditory and/or visual hallucinations; imaginary friends are not usually seen into adolescence. If these are hallucinations, this could also explain his lack of attention in school, which would not be ADHD. Considering his mother has schizophrenia, there is a definite genetic link to the illness in R.J. Once R.J. is evaluated for schizophrenia, it may be appropriate to initiate an antipsychotic at that time. If so, he should be started on an agent with minimal adverse effect burden at a minimal dose to control his symptoms. He should be evaluated regularly for possible medication discontinuation if warranted, but

may require more long-term treatment depending on his response and prognosis.

Depressive Disorders

Michael C. Angelini

CORE PRINCIPLES		CHAPTER CASES
1	Depression is a common and often chronic disorder that may manifest at any time in an individual's life. Diagnostic criteria for major depression include a minimum of five symptoms persisting for at least 2 weeks. One of these symptoms must be either depressed mood or anhedonia. Suicidal ideation should be assessed in all patients.	**Case 86-1 (Question 1), Table 86-4**

CORE PRINCIPLES		CHAPTER CASES
2	A variety of treatment modalities are available for the management of depression. These include prescription medications, psychotherapy, and somatic treatments. Prescription medications and/or psychotherapy are indicated for depressive symptoms that are moderate to severe in nature, whereas somatic treatments are for severe refractory cases.	**Case 86-1 (Question 2)** **Case 86-2 (Questions 1, 2)** **Case 86-3 (Question 2)**
3	All of the prescription medications that are currently available are equally effective and possess the same delayed onset of therapeutic effects. Selection of an antidepressant is based on many factors, including previous response to medication, age, reproduction status, and both medical and psychiatric comorbidities.	**Case 86-1 (Questions 2, 4)** **Case 86-2 (Question 2)** **Case 86-4 (Question 1), Table 86-6**
4	Selective serotonin reuptake inhibitors are regarded as the initial treatment of choice for most depressed patients. They are inexpensive and effective for comorbid anxiety conditions and possess a lower side effect burden than other antidepressants overall. Side effects are generally mild and transient.	**Case 86-1 (Question 2)** **Case 86-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
5	Educating the patient regarding side effects, how to monitor for efficacy, and the duration of treatment are important actions for successful treatment.	**Case 86-1 (Question 3)** **Case 86-3 (Question 3), Table 86-10**
6	The goal of antidepressant treatment is remission of symptoms. Once remission is achieved, the general recommendation is to continue the effective antidepressant regimen for a minimum of 6 months.	**Case 86-1 (Question 3), Table 86-10**
7	Because only half of depressed patients will achieve remission with the first antidepressant selected, clinicians should have a comprehensive understanding of the role many antidepressants may have in optimizing outcomes. Clinicians should be familiar with switching antidepressants in patients with an incomplete response and the merits of augmentation strategies.	**Case 86-2 (Questions 1–3)**
8	Untreated depression in children under 18 has a significant risk of suicide. Treatment consists of talking therapy and specific antidepressants, which is different than the broad options available to adults.	**Case 86-3 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
9	Depression and chronic pain are commonly comorbid, and pharmacologic treatment that addresses both is recommended. This makes the serotonin/norepinephrine–reuptake inhibitor class of antidepressants preferred.	**Case 86-4 (Question 1)**

INTRODUCTION

Depressive disorders are enormous health concerns that are often misdiagnosed or undertreated. The physical and social dysfunction associated with depression is profound and is believed to outweigh many other chronic medical conditions, including hypertension, diabetes, and arthritis.[1] The Medical Outcomes Study determined that the degree of impairment in depressed individuals is comparable to that seen in patients with chronic heart disease.[2] The financial ramifications of depression are tremendous and place an overwhelming burden on our society. In 2010, the estimated cost of depression in the United States was $210.5 billion annually, with 45% to 47% attributed to direct costs and 48% related to workplace costs such as absenteeism.[3]

Epidemiology

Since World War II, the lifetime incidence of depression has been rising steadily in studied populations. The annual incidence of all mood disorders is ~10% in the adult population, and 1 in 15 adults (6.7%) will suffer from an episode of major depression during any 12-month period.[4] Various studies from Europe and the United

States have estimated the 1 year and lifetime prevalence to be 4.1% and 6.7%, respectively.[5] Although the incidence of depression is remarkably similar across various races and ethnic groups, the illness may be slightly more common in lower socioeconomic classes. Females have double the incidence compared to males.[1,5]

The onset of the first depressive episode may present at any age, although it most commonly occurs in the late 20s. Genetic factors appear to play a major role in the cause of depression. The offspring of depressed individuals are 2.7 times more likely to have depression if one parent is afflicted, and 3.0 times more likely if both parents suffer from depression.[6] Concordance rates for monozygotic (identical) twins range from 54% to 65%, whereas the corresponding rates in dizygotic (fraternal) twins range from 14% to 24%.[7] Genetic factors may also predispose individuals to an earlier onset of depression (younger than age 30 years).[8] Additionally, there is clear evidence that depression may occur as a result of stressful events (ie, environmental factors). These factors include a difficult childhood, physical or verbal abuse, pervasive low self-esteem, death of a loved one, loss of a job, and the end of a serious relationship. Acute depressive episodes are often attributed to a combination of environmental and genetic factors. For instance, individuals carrying a genetic predisposition to mood disorders may undergo a stressful experience that ultimately triggers the manifestation of depressive symptomatology. Depression may also occur spontaneously among people who appear to lack any obvious genetic or environmental predisposition.

Diagnosis and Classification

When assessing a person for depression, it is important to recognize the level of impairment because of the symptoms. Just as with all biologic systems, the body can function well within a particular range (eg, serum potassium or blood pressure). Mood is not different; as long as the depressive symptoms are not prolonged or impairing, there would be no reason to aggressively treat. Once the depression

is severe enough to impact functioning or induce harm, it requires treatment.

Major depressive disorder (MDD) may manifest as a single episode, but it is more commonly a series of recurrent events. Thus, in most patients, depression is a chronic illness.[5] The frequency of recurrent episodes is highly variable, with some people experiencing discrete episodes separated by many years of relatively normal mood (euthymia), and others experiencing residual depressive symptoms between episodes that may never completely remit. The risk of future episodes appears to increase with the chronicity of the illness. For instance, after the first episode, there is a 50% likelihood of a second episode. After the second, there is a 70% chance of a third, and with the third episode comes nearly a 90% incidence of a fourth.

The *Diagnostic and Statistical Manual of Mental Disorders 5th Edition* (*DSM-5*) describes different types of depressed states. These include disruptive mood dysregulation disorder, MDD, persistent depressive disorder, premenstrual dysphoric disorder, substance/medication-induced depressive disorder, depressive disorder because of another medical condition, other specified depressive disorder, and unspecified depressive disorder (**Table 86-1**).[9] The different types of depressive disorders may then be subclassified using cross-sectional symptom features or specifiers. For example, the phrase “with anxious distress” infers that there are anxiety symptoms such as worry and feeling keyed up. The term “with mixed features” infers that there are manic or hypomanic symptoms. The term “with melancholic features” is used when patients possess primary neurovegetative symptoms, early morning awakening, marked psychomotor agitation or retardation, and significant anorexia or weight loss. Melancholia is often a more severe form of depression, and it often lacks apparent environmental triggers.[9,10] It may also be less likely than other forms of depression to remit spontaneously. The phrase “with atypical features” is used when depressive symptoms include weight gain, hypersomnia, leaden paralysis, or rejection sensitivity. When hallucinations or delusions occur in patients who are primarily depressed, the phrase

"with mood congruent or mood incongruent psychotic features" is applicable to the mood disorder. Other diagnostic specifiers used in *DSM-5* include "with catatonia," "with peripartum onset," and "with seasonal pattern."

Table 86-1
Classification of Depressive Disorders

1. Major depressive disorder
2. Persistent depressive disorder
3. Disruptive mood dysregulation disorder
4. Premenstrual dysphoric disorder
5. Substance/medication-induced depressive disorder
6. Depressive disorder because of another medical condition
7. Other specified depressive disorder
8. Unspecified depressive disorder

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. American Psychiatric Association; 2013.

Persistent depressive disorder is a type of depressive illness characterized by fewer symptoms and less intensity than major depression, but the course is much more chronic with symptoms being present most of the time for at least 2 years. In practice, the detection of persistent depressive disorder may be difficult to make because patients often do not seek treatment because they are still functional (eg, go to school, work, care for children) but they have significant morbidity. They will have less satisfaction with work and will get fewer promotions and low financial advancements. The treatment for persistent depressive disorder has traditionally focused on psychotherapy, but evidence suggests that antidepressant medications may actually be more effective.[11]

Differential Diagnosis

Symptoms of depression may be induced or exacerbated by numerous medical illnesses or medications (**Tables 86-2** and **86-3**).[1,5,10] Consequently, *DSM-5* specifies that whenever a medical

event is temporally related to the onset of depressive symptoms, the patient does not fit the criteria for major depression, even if all other criteria are met.[9] The rationale for this stipulation is that if the medical illness is successfully treated or the offending agent is discontinued, the depressive illness would spontaneously resolve, eliminating the need for psychiatric intervention. Although lists of medical illnesses or medications are helpful, the clinician should be aware that the actual evidence demonstrating an association between depression and specific organic causes is limited. If a medication or condition is suspected of causing depression, the chronologic association should be investigated rigorously before other action is taken. Additionally, a patient with a medical illness such as a hormonal abnormality may have depressive symptoms from the condition but can additionally have concomitant MDD. Treating the medical condition will likely lessen the severity, but the MDD will still have to be treated as well.[1,5,10]

Clinical Presentation

For a diagnosis of MDD to be made, symptoms must be present for at least 2 weeks and must not be precipitated or influenced by a medical illness or medication (according to *DSM-5* criteria). Individuals must possess at least five symptoms, one of which is either depressed mood or anhedonia (diminished interest or pleasure in activities). The other seven symptoms are as follows:

1. Change in appetite or significant weight loss or gain
2. Insomnia or hypersomnia
3. Psychomotor agitation or retardation
4. Fatigue or loss of energy
5. Feelings of worthlessness or inappropriate guilt
6. Poor concentration (or difficulty making decisions)
7. Recurrent thoughts of death or suicidal

The diagnostic criteria also state that the mood disturbance must cause marked distress or result in clinically significant impairment of social or occupational functioning. Additionally, the symptoms cannot be because of a medical or organic illness (**Table 86-4**).

Table 86-4

Diagnostic Criteria for Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning: at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (eg, feels sad, empty, hopeless) or observation made by others (eg, appears tearful) (*Note:* In children and adolescents, can be irritable mood.)
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation)
3. Significant weight loss when not dieting or weight gain (eg, a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day (*Note:* In children, consider failure to make expected weight gain.)
4. Insomnia or hypersomnia nearly every day
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiologic effects of a substance or to another medical condition.

Note: Criteria A-C represent a major depressive episode.

Note: Responses to a significant loss (eg, bereavement, financial ruin, losses from a natural disaster, a serious medical illness, or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite,

and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or a hypomanic episode.

Note: This exclusion does not apply if all the manic-like or hypomanic-like episodes are substance induced or are attributable to the physiologic effects of another medical condition.

Pathophysiology

The monoamine hypothesis proposed that decreased synaptic concentrations of norepinephrine (NE) and/or serotonin (5-HT) caused depression. The NE depletion theory was originally based on the observation that reserpine, which depleted catecholamine stores in the central nervous system (CNS), was capable of causing depression.[12,13] This theory evolved into the permissive hypothesis, which emphasized a greater role for serotonin in promoting or "permitting" a decline in NE function. Specifically, this hypothesis suggests that low concentrations of serotonin or NE in the CNS precipitated depressive symptoms. Studies have shown that a 5-HT synthesis deficiency is correlated with depression. This has been shown in both persons genetically unable to produce 5-HT and those who have depleted precursors of 5-HT.[14,15] Selective serotonin reuptake inhibitor (SSRI) and serotonin/norepinephrine–reuptake inhibitor (SNRI) antidepressants, which functionally include the tricyclic antidepressants (TCAs), are believed to relieve depression

by inhibiting the reuptake of serotonin alone or serotonin and NE from the synapse up into the neuron, effectively increasing neurotransmitter concentrations in the synaptic cleft.[16,17] Mirtazapine and monoamine oxidase inhibitors (MAOIs) work via different mechanisms, but also increase 5-HT and NE (and DA for the MAOIs).[16,17]

Depression has been associated with changes in presynaptic and postsynaptic receptor densities (or sensitivities) that have been described as being downregulated or desensitized.[18] Changes include a decrease in postsynaptic α-adrenergic receptor sensitivity, along with alterations in the sensitivities of the α-adrenergic, dopaminergic (D_2), and serotonin-receptor subtypes (5-HT_{1A} and 5HT_{2A}). For example, SSRIs can increase the efficiency of serotonergic neurotransmission acutely (through reuptake blockade), but their therapeutic effects are linked temporally with increased release of serotonin through downregulation of presynaptic autoreceptors (5-HT_{1A}).[19] This downstream impact explains why there is a delay in maximal efficacy seen with all antidepressants.[14,15]

As our understanding of neurobiology increases, it has been found that other neurotransmitter systems can impact mood, and this has resulted in research for non–5-HT direct-effect medications to supplement or replace the monoamine-effecting antidepressants. Such mechanisms include blockade of substance P and antagonism of corticotropin-releasing factor or corticosteroid receptors.[20–23]

Neuroendocrine Findings

Along with dysregulated neurotransmitter systems, neuroendocrine abnormalities may contribute to the development of depression. Depressed patients often have abnormal thyroid function tests (including low triiodothyronine [T_3] and/or thyroxine [T_4] levels).[24] They also may exhibit an abnormal response to challenge with thyroid-releasing hormone, consisting of a blunted or exaggerated thyroid-stimulating hormone response.[25] Clinical hypothyroidism can also induce depressive symptoms, and thyroid supplementation can

reverse this pathology, suggesting an indirect association between mood disorders and thyroid homeostasis.[26] The hypothalamic–pituitary–adrenal (HPA) axis may also influence the manifestation of depression, with a relative hyperactivity of this system commonly reported in depressed individuals.[27–29] Pituitary and adrenal glands are often enlarged in depressed patients, and concentrations of corticotropin-releasing factor are often elevated during depressive episodes and decline with the administration of antidepressant medications or electroconvulsive therapy (ECT).[22,29,30] Exogenous administration of corticotropin-releasing factor has elicited classic symptoms of depression in laboratory animals (including decreased appetite, anxiety, insomnia, and decreased libido).[23] Loss of hippocampal volume in major depression leads to increased levels of circulating glucocorticoids, which leads to neuronal apoptosis.[31] Hypercortisolemia because of chronic stimulation of the HPA axis has been implicated in potentially reducing gray matter loss in humans. It should be noted that the relationship between hippocampal volume and depression is not consistently observed and that various factors may affect these findings.[32] Corticosteroids can also modulate serotonin synthesis, metabolism, and reuptake.[22] However, the data in this area are inconsistent because different medications will have differing effects on cortisol despite being effective as well as depressive subtypes showing different effects on cortisol.[33,34] Increased inflammatory markers are seen in prospective and postmortem studies of depressed patients.[27,29,35] There is also a positive correlation between inflammatory markers and increased glucocorticoid activity. Subsequently, there is a reduction in monoamine levels, particularly serotonin levels.[29]

Genetic Studies

Several genes have been implicated in predictive response or adverse effects to antidepressants. Pharmacodynamic targets have focused on serotonin transporters (5-HTTLPR), tryptophan hydroxylase enzymes 1 and 2 (TPH1 and TPH2), 5-HT_{1A} and 5-HT_{2A}

receptors, brain-derived neurotrophic factor (BDNF), G-protein β-3 subunit (GNB3), and monoamine oxidase enzymes and p-glycoprotein; pharmacokinetic targets have been focused on polymorphic variations in CYP1A2, CYP2C19, CYP2D6, and CYP3A4 enzymes.[36–38] Variations in the serotonin transporter *SLC6A4* gene have been associated with remission and response rate in a meta-analysis of 1435 patients.[37] Researchers found that patients with the *ss* genotype are less likely to reach remission during SSRI treatment and take longer to achieve 50% symptom improvement compared to those with the *ll* genotype. A review stated the genes *SLC6A4*, *HTR2A*, *BDNF*, *GNB3*, *FKBP5*, *ABCB1*, and cytochrome *P450* genes (*CYP2D6* and *CYP2C19*) as being the best correlated with depression.[39] Most likely there are multiple genes that are involved in disease phenotype, drug response, and toxicity. Genetic testing for abnormalities in CYP 450 pathways has shown that initial drug selection by clinicians has equal results as compared to pharmacogenetic-guided decisions but may be helpful in patients who have failed previous trials.[40,41] Gene–environment interactions undoubtedly also play a role in the determination of these phenotypes.

Imaging Studies and Biomarkers

Imaging studies (including computed tomography, magnetic resonance imaging, positron emission tomography, and single-photon emission computed tomography) suggest that patients with depression have regional brain dysfunction, most often affecting the limbic structures and prefrontal cortex. Alterations in cerebral blood flow and/or metabolism in the frontal–temporal cortex and caudate nucleus are associated with common depressive symptoms such as dysphoria, anhedonia, hopelessness, and flat affect.[42] Increased firing of the amygdala in the left hemisphere has been linked in positron emission tomography studies with the future development of depression.[43] Because subtypes of depression have been linked to different regional dysfunctions, a network hypothesis began to

emerge that may lead to improvements in depression diagnosis and targeted treatments.[44] There is also seemingly increased hippocampal loss that is consistent with the severity and duration of illness.[45]

Plasma biomarkers have been inconsistent in predicting and diagnosing MDD. One study found correlations with increased plasma gamma-aminobutyric acid (GABA) and dopamine metabolites along with decreased serotonin.[46,47]

Patient Assessment Tools

Behavioral rating scales have been used for many years in drug efficacy studies and are widely advocated for routine use in the clinical arena today. Rating scales are helpful in assessing the severity of mental illness, quantifying changes in target symptoms, and determining treatment efficacy, but they are not diagnostic. Rating scales can vary in length, content, and format and can be completed by providers, patients, researchers, family members, or conservators. Numerous depression scales have been developed, including the Hamilton Rating Scale for Depression ($HAM\text{-}D_{17}$ or $HAM\text{-}D_{21}$), the Hospital Anxiety and Depression Scale (HADS), the Beck Depression Inventory (BDI), the Montgomery–Åsberg Depression Rating Scale (MADRS), the Center for Epidemiological Studies Depression (CES-D) Scale, the Patient Health Questionnaire (PHQ-9), and the Quick Inventory of Depressive Symptoms ($QIDS_{16}$ or $QIDS_{30}$) (**Table 86-5**).[48–54] Because 30% to 50% of cases are not detected in primary care, enhancing education of the clinicians in this area has shown some benefits. Generally, a two-step process of screening with a simple questionnaire, such as the PHQ-9 or the HADS, and then a more thorough evaluation if the screening results in a positive score are the recommended methods of detecting depression severe enough to require treatment.[5,55]

Table 86-5

Comparison of Selected Depression Rating Scales

Instrument	Minimal	Mild	Moderate	Severe
Hamilton (HAM-D)—17 item (clinician rated)	>8	8–15	16–27	>27
Beck Depression Inventory (BDI)				
BDI (clinician rated)	>10	10–16	17–29	>29
BDI (patient rated)	>10	10–15	16–23	>23
Quick Inventory for Depressive Symptoms (QIDS)				
QIDS-C_{16} (clinician rated)	>6	6–10	11–15	>15
QIDS-SR_{16} (patient rated)	>6	6–10	11–15	>15
Patient Health Questionnaire (PHQ) (patient rated)	>10	11–14	15–19	>19
Montgomery–Åsberg Depression Rating Scale (MADRS) (clinician rated)	>7	7–19	20–34	>34

Nondrug Therapies for Depression

PSYCHOTHERAPY

For the treatment of mild-to-moderate depression, psychotherapy has proved to be comparable to pharmacologic intervention and may be preferred by some patients. There are many types of psychotherapy, and experts suggest that cognitive behavioral therapy (CBT), behavioral activation (BA), and interpersonal psychotherapy (IPT) are effective with CBT being preferred for monotherapy.[5] For the acute treatment of severe depression, antidepressants appear to be more effective than psychotherapy

alone and have a more rapid onset of therapeutic action.[5,26] The beneficial effects of psychotherapy, however, may persist longer than medication-related benefits after the interventions have been formally discontinued. In addition, psychotherapy may be particularly beneficial for preventing relapse among patients who previously demonstrated a therapeutic response to antidepressants.[56] Overall, the combination of psychotherapy and pharmacotherapy is superior to either intervention alone.[5,10]

SOMATIC INTERVENTIONS

ECT is a safe, rapid-acting, and highly effective therapeutic intervention. Fundamentally, ECT features the induction of generalized seizures through an electric current delivered by bilateral or unilateral electrode placement. Medications that raise the seizure threshold, such as benzodiazepines, or promote cognitive impairment (lithium) should be discontinued before the procedure, although this is not always necessary. Adverse effects are generally minimal and consist mainly of transient anterograde amnesia (ie, difficulty remembering events around the time of the procedure), retrograde amnesia, confusion, headaches, and muscle aches. Cardiovascular effects (eg, ventricular arrhythmias, myocardial infarction [MI]) are the most ominous sequelae, but these events are extremely rare.[57]

ECT is recommended for patients with treatment-resistant depression, severe vegetative depression, psychotic depression, and severe depression in pregnancy. Overall, response rates are impressive, ranging from 70% to 90%, and ECT has the distinct advantage of inducing a therapeutic response within the first 2 weeks of treatments.[57–59] The recommended frequency of ECT treatments is variable. Most institutions have used three sessions weekly to induce a therapeutic response acutely, although evidence suggests that twice-weekly sessions are better tolerated and more cost-effective.[60] ECT administered weekly for 1 month and less frequently thereafter may be as effective as aggressive pharmacotherapy in preventing relapse.[61]

Other somatic interventions have also been used successfully to treat depression. Repetitive transcranial magnetic stimulation (rTMS) is a noninvasive procedure involving the application of an electrical magnetic stimulus across the scalp, which ultimately generates an electrical field in the cerebral cortex.[62,63] Unlike ECT, rTMS does not generate an actual seizure, and it is very well tolerated, with common side effects consisting of transient scalp discomfort and headaches. Preliminary investigations successfully used repetitive high-frequency techniques in depressed subjects, and imaging studies have shown functional improvements consistent with antidepressant properties. However, not all studies have shown efficacy, and overall results show only a slight benefit for depression or treatment-refractory depression.[59,64,65] A recently published review found that acute phase depression may respond to rTMS, yet data are lacking regarding long-term maintenance treatment.[66]

Vagus nerve stimulation involves the surgical implantation of an electrical device in the subcutaneous tissue below the clavicle, which sends an impulse along the left vagal nerve into the cerebral cortex. Setting adjustments are through a telemetric wand.[59,67] It is currently U.S. Food and Drug Administration (FDA) approved for the management of treatment-resistant depression, although its effect takes time and cannot be considered an acute therapy. Implantation of the device is an invasive procedure with standard risks associated with this type of surgery. However, long-term safety has been shown in both epilepsy and depression studies. It may be useful when combined with medication treatment.[59]

Light therapy or phototherapy is particularly effective for relieving the irritability and malaise associated with seasonal affective disorder, a milder form of depression that has been attributed to decreases in natural sunlight found with seasonal variation.[10,68] Phototherapy is administered in the form of a light box delivering 1500 to 10,000 lux for a period of 1 to 2 hours daily. It is extremely well tolerated.

LIFESTYLE ADJUSTMENTS

Any therapeutic approach to mood disorders should seek to reverse unhealthy or destructive lifestyle habits and promote other activities that may relieve stress and facilitate well-being. Alcohol and illicit drug use should be minimized (if not prohibited) in patients suffering from depressive disorders. Sleep habits should be evaluated and improved to ensure optimal rest. Dietary factors should be modified to promote diverse, balanced, and nutritional eating habits.

Increased physical activity and sustained cardiovascular exertion can impart a variety of health benefits, including improvement in depressive symptoms.[5] Although investigations examining the effectiveness of exercise for depression have met with mixed results, exercise can regulate appetite, improve sleep patterns, increase energy, enhance self-esteem, and promote a return to euthymic status.[69] Exercise has been shown to increase circulating concentrations of serotonin in the periphery and enhance neurogenesis in the hippocampus.[70] Other activities may also serve to relieve stress and help patients acquire insights into their emotional well-being. These pursuits can range from daily journal writing (journaling), meditation, yoga, and Tai chi. Classes in mindfulness-based meditation, in particular, are offered at many medical centers, and the health benefits of this approach have been demonstrated in a wide range of medical conditions including cancer, chronic pain syndromes, and human immunodeficiency virus (HIV) illness.[71]

MAJOR DEPRESSIVE DISORDER

CASE 86-1

Question 1: A.R. is a 25-year-old female in graduate school who presents to the student health clinic for a routine physical examination. During her visit, A.R. states, “I’ve been feeling pretty down lately and just want to give up.” Her physical examination is unremarkable, and all laboratory tests (complete blood count with differential, chemistry panel, and thyroid function tests) are within normal limits. A human chorionic gonadotropin test is negative. Her medical

history is noncontributory, takes no medication, uses a daily multivitamin, and denies drinking alcohol, smoking cigarettes, or using illicit substances.

When asked, A.R. states that she has had increasing periods of depressed mood during the past few months and often finds herself crying in the morning for no particular reason. She reports that she has no interest in her old hobbies (playing the piano, mountain biking, gardening). During the past 6 months, her appetite has decreased, and she has lost 15 pounds (6.80 kg). She feels overwhelmed about all of her academic work and job and has difficulty sleeping, often waking in the middle of the night and being unable to fall back asleep. She has no energy during the day and finds it difficult to concentrate or make decisions. This is clearly impacting her ability to finish her graduate work as she is falling behind and has been getting extensions for her project due dates.

On examination, A.R. is an appropriately dressed female who appears sad but who is alert, coherent, and logical. Her affect is constricted, apprehensive, and sad. Mood is depressed, and she admits having vague suicidal ideation, but she has no specific plans. She is oriented to person, place, and time, but shows some recent memory deficits. Her intelligence is estimated to be above average. Concentration and abstractions (eg, “don’t cry over spilled milk,” “a rolling stone gathers no moss”) are satisfactory. She denies hearing voices or other hallucinations. She denies any symptoms of mania such as increased periods of energy, rapid speech, and racing thoughts (see Chapter 87, Bipolar Disorders). She has good insight and judgment into her illness. A.R. is asked to complete the PHQ-9 and has a total score of 15 with five different questions scoring 2 or more and as well as question one and two scoring 2 (ie, moderate-to-severe symptoms). After reviewing the PHQ-9 results, a more in-depth interview is conducted and A.R. is diagnosed as having MDD.

What nondrug options have shown efficacy?

From A.R.’s history, she appears to be exhibiting a dysphoric or depressed mood as well as anhedonia (lack of interest in hobbies or pleasurable activities). In addition, she demonstrates frequent episodes of crying, decreased appetite (with an unintentional 15-pound [6.80 kg] weight loss), poor concentration, low energy, suicidal ideation, worthlessness, and inappropriate guilt. Her mental status examination is consistent with these target symptoms, revealing a constricted, sad affect (physical manifestation of inner emotional states), and frequent crying episodes during the interview.

Based on the *DSM-5* criteria (see Table 86-4), A.R. has MDD. During the past 2 weeks, she has consistently exhibited at least five of the associated symptoms, one of which is depression or anhedonia. It does not appear that her symptoms are the result of

any medical condition, medication, thought disorder, or uncomplicated bereavement. These are impacting functioning because she is not able to complete her schoolwork assignments.

Psychotherapy has been shown to have beneficial effects on mild-to-moderate depression. Studies have also shown that combined with medication, the beneficial effects are greater than either alone. ECT is an effective somatic treatment but typically reserved for more refractory cases. rTMS is currently being studied but has not been standardized yet. Lifestyle modifications such as exercise generally have benefit, but typically are not strong enough on their own to treat clinically significant depressed symptoms.

DRUG MANAGEMENT

Drug Selection: General Considerations

Case 86-1, Question 2: A.R. agrees to a therapeutic trial of an antidepressant. What are the drug options available for A.R.'s depressive symptoms? What considerations should be made when selecting antidepressant therapy?

In randomized, controlled trials (RCTs) of antidepressants, a therapeutic response is usually apparent in 60% to 70% of subjects receiving active medication (therapeutic response is defined as a ≥50% decline in depression rating scale score).[5,10]
Antidepressants can be divided into different categories:

1. SSRIs
2. SNRIs
3. TCAs
4. Miscellaneous antidepressants (eg, trazodone, nefazodone, mirtazapine, bupropion)
5. MAOIs

6. Serotonin reuptake inhibitor and receptor modulators (the newest group)

When comparing the impact of antidepressants on changes in depressive symptoms, all antidepressants are considered equal, regardless of class. It is possible that dual-acting antidepressants (SNRIs and TCAs) may be more effective in the severely depressed, but this has not resulted in experts explicitly recommending them over other factors such as comorbid diseases, contraindications, or drug interactions (**Tables 86-6** and **86-7**).[5,10,26,72] Sertraline and escitalopram have the best efficacy to safety/tolerability ratio.[5,10,72,73] Thus, with no other factors influencing the selection of the medication, it may be easier to select either of these.

Table 86-6

Factors to Consider in Selecting an Antidepressant

1. History of prior response (personal or family member)
2. Safety in overdose
3. Adverse effect profiles
4. Patient age
5. Concurrent medical/psychiatric conditions
6. Concurrent medications (eg, potential for drug interactions)
7. Convenience (eg, minimal titration, once-daily dosing)
8. Cost
9. Patient preference

A review of the clinical efficacy, safety and tolerability of the antidepressants vilazodone, levomilnacipran and vortioxetine. *Expert Opin Pharmacother.* 2014;15(17):2525–2542.

One of the first factors to consider is the patient's history of response to previous antidepressant drug therapy. If this history is unavailable (or the patient has never received an antidepressant before), the clinician should inquire about family history. If a first-degree relative had a successful course of antidepressant treatment with minimal adverse effects, that specific medication (or another from the same antidepressant class) would be a prudent choice for initial therapy. The potential impact of an antidepressant on concurrent medical conditions or disease states is often considered next. For example, certain antidepressants (eg, TCA, paroxetine, mirtazapine) can cause significant weight gain and would not be

desirable choices for obese patients, whereas bupropion should be avoided in patients with a history of seizures. Pharmacokinetic drug interactions will also help determine the preferred first-choice option. Among the SSRIs, fluoxetine and paroxetine have significant inhibitory effects on CYP450 2D6, whereas citalopram, escitalopram, sertraline, and fluvoxamine have minimally clinical inhibitory effects on 2D6. Fluvoxamine does have a strong impact on CYP1A1/2, and fluoxetine has a weak-to-moderate impact on 3A4 (see **Table 86-8**).[74] Other important patient-specific factors to consider in the selection of an agent include safety in overdose, ease of administration (once-daily vs divided doses), and necessity for dose titration, cost, and patient preference (Tables 86-6 to **86-9**).[10]

Table 86-8

Drug Interactions of the Cytochrome P-450 System

Relative Rank	CYP1A2	CYP2C9/19	CYP2D6	CYP3A4
Strong	Fluvoxamine	Fluvoxamine		
			Fluoxetine	
				Nefazodone
			Paroxetine	
Moderate			Duloxetine	
			Bupropion	
		Fluoxetine		Fluoxetine
				Fluvoxamine
Weak			Venlafaxine	
	Sertraline	Sertraline	Sertraline	Sertraline
			Escitalopram	
	Paroxetine	Paroxetine		Paroxetine
			Fluvoxamine	
			Citalopram	
	Fluoxetine		Nefazodone	

Table 86-9

Dosage Ranges of Commonly Prescribed Antidepressant Medications

Medication	Starting Dose (mg/day)	Usual Dosage (mg/day)
Selective Serotonin Reuptake Inhibitors		
Fluoxetine	20	20–60
Sertraline	50	50–200
Paroxetine	20	20–60
Paroxetine ER	12.5	25–75
Citalopram	20	20–60
Escitalopram	10	10–20
Serotonin/Norepinephrine–Reuptake Inhibitors		
Venlafaxine, IR	37.5	75–375
Venlafaxine, ER	37.5	75–375
Desvenlafaxine	50	50
Duloxetine	60	60–120
Levomilnacipran	20	40–120
Dopamine Reuptake Inhibitors		
Bupropion, IR	150	300–450
Bupropion, SR	150	300–400
Bupropion, ER	150	300–450
Tricyclic Antidepressants		
Imipramine	25–50	100–300
Desipramine	25–50	100–300
Amitriptyline	25–50	100–300
Nortriptyline	25	50–200
Others		
Mirtazapine	15	45
Nefazodone	50	150–300
Serotonin Reuptake Inhibitors and Receptor Modulators		
Vilazodone	10	20–40

Medication	Starting Dose (mg/day)	Usual Dosage (mg/day)
Vortioxetine	10	20

Treatment Expectations

A similar delayed pattern of therapeutic response has been observed with all antidepressant medications. Patients often begin to show signs of clinical response during the first 1 or 2 weeks of active treatment, and maximum improvement may not be evident until weeks 6 to 8.[5,26,75] The pattern of patient response can also be generalized, with neurovegetative symptoms often the first to subside (eg, altered sleep or appetite, decreased energy, excessive worrying, and irritability). Cognitive symptoms are slower to respond, and 3 to 4 weeks or more may elapse before improvements are evident. These symptoms include excessive guilt or pessimism, poor concentration, hopelessness or sadness, and decreased libido.

Selective Serotonin Reuptake Inhibitors

ADVERSE EFFECTS

There is a delay in onset of full efficacy, but side effects will occur soon after starting the medication. Common side effects of SSRIs are related to the fact that despite their neurotransmitter specificity to increasing the amount of only serotonin in the synapse, there are at least 14 different serotonin receptors having different effects.[15] Distinct side effect profiles have emerged, consisting of gastrointestinal (GI) problems, CNS disturbances, and sexual dysfunction.

All of these medications may induce nausea, but this tends to be a transient effect that diminishes after the first week of treatment. Typically, SSRI-induced nausea occurs 1 to 2 hours after oral

administration. Nausea with SSRIs can be a local effect but is also mediated centrally through the extra serotonin-stimulating serotonin receptors (5-HT_3) that activate the chemoreceptor trigger zone.[76] SSRIs may also cause transient and bothersome increases in GI motility. This diarrhea is generally limited to the first few weeks of treatment and is also related to the extra serotonin-stimulating 5-HT_3 and 5-HT_4 receptors along the GI tract. As with nausea, this diminishes in the first few weeks of treatment unless the dose is increased. In contrast, paroxetine possesses a relatively mild anti-muscarinic effect that can manifest as constipation, dry mouth, or urinary hesitancy. Although this effect is mild, paroxetine use is often discouraged in patients with preexisting constipation or those where any anticholinergic effects are to be avoided such as the elderly.

SSRIs can have myriad effects on the CNS, with disturbances in sleep being a primary concern. SSRIs can have significant but highly variable effects on sleep architecture. In sleep studies, SSRIs have been shown to increase sleep latency and decrease sleep efficiency, often resulting in morning sleepiness or malaise. Many patients also notice that their dreams become more vivid and memorable, which may be an undesirable experience. Rapid eye movement (REM) stage sleep may be prolonged, resulting in less fitful sleep.[77] It should be emphasized, however, that sleep may eventually improve once the antidepressant properties of the medications are apparent and baseline depressive symptoms are relieved (eg, midnocturnal insomnia).

The deleterious effects of SSRI on sexual function can often lead to medication nonadherence.[78] The reported incidence of sexual dysfunction ranges from 1.9% to 75%, reflecting the difficulty in appropriately measuring this adverse event.[79] The actual incidence of SSRI-induced sexual dysfunction is ~30% to 50%, and it appears to be slightly more common in males, but the severity may be worse in females.[79] Delayed orgasm is the most common sexual problem attributed to SSRIs or SNRIs and should be distinguished from decreases in desire or libido, which are considered to be an aspect of the psychopathology of depression itself. This iatrogenic effect on

orgasms has actually been used to clinical advantage in treating males by delaying premature ejaculation, but most patients find it undesirable.[79] All SSRIs are at risk for causing sexual dysfunction because it is due to the increased serotonin-stimulating 5-HT_{2c} receptors. Paroxetine has a higher rate than the others because it also inhibits nitric oxide synthase, reducing nitric oxide levels.[79] It also appears that this is a dose-dependent phenomenon, which may respond favorably to a decrease in daily dosage. Unlike the GI and CNS side effects reported with SSRIs, sexual dysfunction is not usually a transient adverse effect and must be addressed by clinicians if patients are to continue pharmacotherapy.

The detection and proper management of SSRI-induced sexual dysfunction can be one of the most important factors in ensuring medication adherence. Clinicians may be uncomfortable asking patients about their sexual activities and satisfaction, but the high incidence of this side effect (and low likelihood of patients volunteering this information) necessitates a thoughtful and direct approach. Some patients acknowledge sexual dysfunction but decide that improvements in mood and overall health outweigh limitations in sexual performance; however, others simply stop the medication if the side effect is never addressed.

Sexual function may change over time, depending on the type and etiology of sexual dysfunction experienced. Depression itself is associated with a decreased libido in 70% to 90% of untreated patients.[80,81] This symptom will most likely subside with a successful course of antidepressant treatment. Delayed ejaculation or anorgasmia, however, may be caused by SSRIs and SNRIs, often persisting and jeopardizing treatment.

Ordinarily, one of the first options in managing sexual dysfunction is to reduce the dosage, but this may induce a return in symptoms because increasing the dose initially was likely because of a lack of full effect. It is also possible to introduce drug holidays. Small open-label studies with short-acting SSRIs (eg, paroxetine) suggested that if patients skipped their doses on Friday and Saturday, sexual function would return to normal on the weekends.[82,83] Although this

method was reported to be successful, it may also promote nonadherence with medication and lead to an increased risk of relapse and withdrawal symptoms and is therefore not recommended.

If the patient has had a therapeutic response to the antidepressant, the next option in this setting is to consider antidotes to SSRI-induced sexual dysfunction. One option is to add the antidepressant bupropion. Clinical reports and controlled investigations suggest that the addition of bupropion can be helpful for restoring sexual desire and may relieve delayed orgasm or anorgasmia in ~50% of patients.[5,84–87] This therapeutic effect has been demonstrated in depressed and nondepressed patients alike. A common dosing technique is to start with 150 mg of bupropion daily. If unsuccessful, the dose can be increased to 150 mg of bupropion sustained release (SR) twice daily after several days (or 300 mg of the extended-release [XL] preparation). The mechanisms of SSRI-induced sexual dysfunction, and bupropion relief, are not well understood, but likely because of the pro-sexual effects of increasing DA.[88]

Other remedies have been prescribed for SSRI-induced sexual dysfunction. A large randomized, controlled trial examined the impact of sildenafil on male patients suffering from this side effect.[89] Overall, 54% of patients randomly assigned to sildenafil found it to be effective compared with a 4% response rate with placebo. Open-label trials of sildenafil in females experiencing SSRI-induced anorgasmia have also reported improvements. Tadalafil has also shown similar efficacy suggesting a class effect.[90]

Amantadine, buspirone, ropinirole, and yohimbine also have been used successfully to reverse delayed ejaculation or decreased libido, but the evidence for efficacy is limited.[81,91–93] An open-label trial of Ginkgo biloba in male and female patients with sexual dysfunction reported very high success rates, but mixed results have been reported in clinical practice.[94] Mirtazapine is capable of blocking postsynaptic 5-HT_2 receptors and has been shown to have less sexual dysfunction than SSRIs.[95] The 5-HT and histamine receptor

antagonist cyproheptadine has been shown to alleviate this adverse event. However, because of its broad effect on all 5-HT receptors, depression relapse and serotonin withdrawal can occur resulting in it not being recommended. Stimulants such as methylphenidate or dextroamphetamine may increase libido in SSRI-treated patients, but the potential for dependence and abuse discourages their routine administration.[96] Exercise and CBT may also be of benefit.[81]

All antidepressants have a black box warning regarding the possibility of an increase in suicidal thinking, specifically in persons 24 years old and younger. In regard to completed suicide, the rate is less in adult and pediatric patients treated with antidepressants than in those who are not treated.[5,26,97,98] However, studies have shown a rate in suicidal thinking among children and young adults of 4% in the medication arms compared to 2% in placebo arms.[98] Therefore, in order to protect the patient, it is recommended that when an antidepressant is initiated in a child or adolescent, the patient should visit with the clinician every week in the first month, every 2 weeks in the second month, and then monthly for the next month. Adults should also be monitored frequently, and weekly visits initially have shown increased adherence rates. However, other factors may play a role in monitoring, such as access to care and distance the patient needs to travel for the appointment. Therefore, it is recommended to at least speak with the adult patient (eg, via telephone), at least every 1 to 2 weeks in the acute phase (initial 12 weeks) of treatment to assess suicidality but also to check for side effects and adherence.[5,10] SSRIs are dramatically safer in overdose compared to TCAs and are preferred for those with suicidal thinking or comorbidities that put them at risk for impulsive acts of self-harm such as substance misuse.

In addition to GI, CNS, and sexual side effects, a variety of other, less-common adverse sequelae have occurred with SSRIs. Headache can occur with SSRIs at a rate of ~10% to 15% with all agents similar and slightly greater than placebo, with discontinuations because of headache very low at 1% to 3%.[99] This may be due to the stimulatory effects of serotonin on 5-HT_{1b} and 5-

HT_{1d} receptors. It is important to note that SSRIs are actually recommended for migraine prophylaxis as a second-line agent.[100,101] Increased sweating has also been reported with SSRIs and can be particularly uncomfortable or embarrassing.[102] A dosage reduction may help relieve this adverse effect and should be tried first. Adjunctive treatment of α-blockers (eg, terazosin, prazosin), cyproheptadine, and the anticholinergic benztropine has shown some success if a dose reduction is not possible.[103,104] Bruxism, or teeth grinding, can also be a consequence of SSRI treatment, leading to chipped or cracked teeth and generally poor dentition.[105] Often, patients may not be aware of this nocturnal effect and report merely a dull, persistent headache during the morning hours. This, too, may be a dose-dependent side effect of all SSRIs, and several antidotes have been prescribed (eg, buspirone, benzodiazepines, gabapentin).[106,107] In small retrospective studies and several case reports, SSRIs have been linked to dilutional hyponatremia or syndrome of inappropriate antidiuretic hormone (SIADH).[108,109] All SSRIs and SNRIs have been associated with this phenomenon, and elderly patients appear to be uniquely at risk.[110]

SSRIs have been rarely associated with extrapyramidal side (EPS) effects, consisting of akathisia, dystonias, and parkinsonian symptoms that are qualitatively identical to those seen with antipsychotics.[111–113] Although EPS reactions have been documented with all SSRIs, most case reports have correlated with aggressive dosing, often in a patient currently using a DA antagonistic medication, and during the first 1 to 4 weeks of initiation. The theory is that these EPS effects are mediated through the indirect influence of serotonergic neurons on dopaminergic activity.[112] In certain areas of the brain, serotonin and dopamine appear to have an inverse relationship, whereby central stimulation of serotonin receptors results in a net decline in dopaminergic transmission. Management of EPS effects induced by an SSRI is identical to that of those precipitated by antipsychotics. Dystonias and parkinsonian side effects can be treated with anticholinergic agents and subsequent

SSRI dosage reduction. Akathisia usually responds to a reduction in SSRI dosage and/or administration of low-dose β-blockers.[113]

The long-term effects of SSRIs on body weight are variable and difficult to predict. A problem with accurate measurement is because decreased appetite is one of the most common depressive symptoms and that a small weight gain after an antidepressant course may actually be viewed as a therapeutic effect of successful treatment. Conversely, early reports of weight loss with fluoxetine generated much optimism for the use of SSRIs in obesity, but longitudinal studies found this to be a brief, transient phenomenon.[114] All the SSRIs have been reported to cause significant weight gain in long-term use, but it is a rare phenomenon believed to be mediated by genetic markers that have not been conclusively identified. The exception is paroxetine, which has been implicated much more often than other SSRIs as a cause of weight gain. One long-term RCT compared the effects of fluoxetine, sertraline, and paroxetine on total body weight.[115] After 7 months of SSRI use, 25% of the patients receiving paroxetine gained a clinically significant amount of weight (defined as a >7% increase in total body weight) compared with 7% with fluoxetine and 4% with sertraline.[115] Long-term studies with citalopram and escitalopram suggest that 3% to 5% of patients will experience a significant weight gain. The risk of SSRI weight gain is minimal (except with paroxetine) and typically irrelevant, but because appetite changes are part of depression, it is best to monitor weight closely during long-term treatment for both disease- and drug-related reasons.

Epidemiologic studies have also linked SSRIs and SNRIs with an increased risk for upper GI hemorrhage, with a number needed to harm of 3177.[116,117] Recent trials suggest that the risk is modest but can be increased significantly by concurrent ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs) lowering the number needed to harm of 881.[117–119] Alcohol use can also increase the risk of bleeding.[118,119] The mechanism for SSRI-induced GI hemorrhage has been attributed to effects on decreasing platelet activation and aggregation. SSRIs and SNRIs should be avoided in patients with

active GI bleeds, and the concurrent use of high-dose NSAIDs should be discouraged.

DOSAGE TITRATION

Case 86-1, Question 3: A.R. and the clinician agree to start escitalopram 10 mg once a day in the morning (qam). What is considered the standard of care and expected outcomes for dosing and efficacy?

It is very important to establish realistic expectations for treatment with antidepressants from the beginning of therapy. Patients should be informed of the anticipated course of treatment and that the onset of side effects usually precedes that of therapeutic effects. Also, patients should be advised that, although antidepressants may relieve acute depressive symptoms and prevent relapse, they do not abolish environmental stressors such as an abusive relationship or an oppressive work setting.

After receiving the medication for 2 weeks, most improvement in A.R. is likely because of the support she is getting by being involved in treatment as placebo patients show a reduction in symptoms during this period. Medication will start to separate from placebo typically at the 2-week monitoring period and continue to enlarge that separation from placebo up until week 8. A.R. should be reminded that the optimal effects of antidepressants may not be evident for another 2 to 6 weeks. Therefore, a reasonable recommendation would be to continue with the current daily dose of 10 mg and to re-evaluate the medication's effects when she returns to clinic in 2 weeks. If there is no clear improvement at 4 weeks, then switching the medication is necessary. If there is a 25% or more improvement, then the clinician could continue for another 4 weeks (for 8 weeks of treatment) and decide whether the response is acceptable. If the improvement is small, such as just 25% to 30%, then one can increase the dose at this 4-week point and continue to monitor for another 8 weeks.[5,10,26]

DURATION OF TREATMENT

According to the guidelines issued by the Agency for Health Research and Quality, antidepressant treatment can be broken down into three stages (**Table 86-10**).[120] The first stage, acute treatment, lasts ~12 weeks; during this time, the clinician attempts to resolve the presenting symptoms and induce remission, which is defined as having no impairing symptoms of depression and a score of ≤7 on the $HAMD_{17}$ or ≤10 on the MADRS.[5,10] The second stage is commonly called continuation treatment because the patient continues to receive the same antidepressant regimen that induced the initial treatment response, and the clinician attempts to keep the acute symptoms in remission. The duration of continuation treatment is variable (4–9 months after initial treatment or response), but it is recommended that all patients suffering from major depression complete these first two stages. Therefore, the minimum duration of treatment is 7 months. Alternatively, others have advocated that the minimum duration of treatment should be for 6 months after the complete resolution of symptoms.[5]

Table 86-10

Duration of Antidepressant Treatment

Acute treatment phase	3 months
Continuation treatment phase	4–9 months
Maintenance treatment phase	Variable

1. Acute and continuation treatment recommended for all patients with major depressive disorder (MDD) (ie, minimal duration of treatment = 7 months)
2. Decision to prescribe maintenance treatment is based on the following:
   - Number of previous episodes
   - Severity of previous episodes
   - Family history of depression
   - Patient age (worse prognosis if elderly)
   - Response to antidepressant
   - Persistence of environmental stressors
3. Indefinite maintenance treatment is recommended if any one of the following criteria is met:
   - Three or more previous episodes (regardless of age)

- Two or more previous episodes and age older than 50 years
- One or more and age older than 60 years

The third stage of treatment, maintenance treatment or prophylaxis, is not indicated for all patients, and the necessity of continuing medication beyond the first 6 to 7 months depends on many patient-specific factors. One must consider the number of previous episodes, family history of depression, patient's age, severity of presenting symptoms, response to therapy, and persistence or anticipation of environmental stressors. There are specific populations for whom indefinite pharmacologic treatment is advocated: (a) individuals with three or more previous episodes of major depression, (b) individuals older than 50 years with two or more previous episodes, and (c) individuals older than 60 years with one or more previous episodes.[5,10] Continued antidepressant usage in the elderly is recommended to prevent relapse.[121]

Because A.R. is exhibiting a full therapeutic response to escitalopram, the recommendation would be for her to continue with the effective dosage (10 mg/day) for at least 7 consecutive months. At the end of this time frame, the clinician should review with the patient those considerations that enter into the decision to continue treatment. Ultimately, the decision to continue antidepressant medications is left to the patient's judgment, and he/she should be well informed of the potential consequences of stopping treatment.

In the future, if A.R. decides to discontinue her antidepressant, she should fully disclose this to her prescriber so that an appropriate taper schedule and subsequent monitoring can occur. She should be advised of potential withdrawal symptoms (**Table 86-11**).[122] Abrupt discontinuation of chronic SSRI treatment (eg, treatment >2 months) has been associated with dizziness, headache, anxiety, lethargy, dysphoria, and sleep problems.[5,122] The onset of these symptoms is generally within 36 to 72 hours of stopping treatment, and effects may persist for approximately a week. Withdrawal symptoms generally are mild and self-limiting but can be uncomfortable and alarming. Because of their relatively short half-life (and absence of long-acting metabolites), paroxetine, fluvoxamine, and venlafaxine

have been associated with a more profound withdrawal presentation than other SSRIs and SNRIs. Because of its long half-life (and that of its active metabolite), fluoxetine has not been commonly associated with withdrawal symptoms. Nonetheless, it is advisable to taper slowly off all antidepressant medications after an extended treatment course to decrease the risk of withdrawal and subsequent relapse.[123] A defined time for taper has not been established. Switching therapies within classes can be done quickly (eg, from sertraline to fluoxetine) without a cross-taper. When switching to another class or off antidepressant completely, then a 6- to 8-week taper is standard as well as educating the patient to withdrawal symptoms and reassuring them that this is not a life-threatening event. Because withdrawal is not life-threatening, a much faster taper (3–7 days) can be completed with the patient's approval.[10,122]

Table 86-11
Discontinuation of Antidepressants

Withdrawal Syndrome
1. Worse with paroxetine, venlafaxine 2. Symptoms: dizziness, nausea, paresthesias, anxiety/insomnia, flu-like symptoms 3. Onset: 36–72 hours 4. Duration: 3–7 days

Note: Risk of depression relapse is greatest 1 to 6 months after discontinuation.

Suicide Assessment

Patients with major depression should always be assessed for the presence of suicidal thoughts (eg, "Do you ever feel like giving up?" "Are you thinking about hurting yourself?"). Reports have noted that completed suicide rates range from 2% to 15%. Up to 70% of suicides worldwide are persons with MDD.[5,124] Comments made by the patients alluding to suicide (eg, "Life is not worth living anymore," "I am leaving and may never see you again") should be taken seriously. Several factors may place a person at greater risk for a

suicide attempt. These include living alone, having a disabling illness, being unemployed, having a history of alcohol/drug abuse, chronic pain, anxiety, or having a family history of suicide.[10] Gender plays a role as well, with females much more likely to attempt suicide, although males are more likely to complete the act.[10]

For patients who are actively suicidal, hospitalization is often necessary and may be facilitated against the patients will in high-risk settings. Other life-saving interventions include establishing close contact with the patient's family and health care provider, convincing the patient to contract for his/her safety, and ensuring that firearms and other lethal means are removed from the home. Antidepressant classes have different risks of lethality in overdose. Tricyclics are by far much more dangerous than SSRIs. Duloxetine, venlafaxine, and mirtazapine are a much lower risk than TCAs but higher than SSRIs. Among the SSRIs, citalopram has the greatest risk of cardiotoxicity in overdose but still less than venlafaxine.[5] For patients who are at risk for attempting suicide, TCAs and MAOIs are contraindicated.

A.R. is at some risk for suicide, although she does not have a detailed plan at present. She should be monitored closely during the first few weeks of therapy by friends or family members. If her suicidal ideation becomes severe, A.R. should be evaluated in a psychiatric emergency room for her own safety. Unfortunately, it is not always possible to predict whether A.R. (or any depressed patient) will attempt suicide. Even with the most conservative precautions, a small percentage of patients successfully complete their suicide attempts.

Case 86-1, Question 4: After A.R. has been treated for a year, she is asking about coming off her escitalopram partly because she is getting married and considering becoming pregnant. What would be the most appropriate way to proceed with discontinuation and treatment of depression during pregnancy?

A.R.'s escitalopram should be tapered during several weeks (eg, decrease to 5 mg daily for 2–4 weeks, then discontinue). The risk of relapse is relatively low during the first month of medication, but depressive symptoms often return during the second or third months.

The risk of relapse is highest during the first 6 months after therapy is stopped.[125]

Antidepressants in Pregnancy and Lactation

The risk for depression is elevated during pregnancy and during the postpartum period.[126] A prospective investigation reported that females who discontinued their antidepressant upon discovering that they were pregnant were much more likely to relapse prior to delivery (68% relapse rate vs 26% who continued treatment; hazard ratio, 5.0).[127]

Before deciding to treat with an antidepressant during pregnancy, one should make a careful inventory of the benefits and risks. The consequences of maternal depression on the mother and fetus must be compared with the potential risks of in utero medication exposure. From the mother's perspective, untreated depression carries with it a great deal of distress during an emotional time. Sleep and appetite may be compromised at a time when these functions are most important for the baby's development. Mothers may also be tempted to drink alcohol or abuse substances, and studies have also shown that depressed mothers are much less likely to attend prenatal clinic visits.[128] Depression during pregnancy is a very strong risk factor for postpartum depression.

Most of the SSRIs and newer antidepressants pose little risk for the development of serious fetal malformations, and they have been subsequently categorized as class C by the FDA (suggesting that the risk to the fetus is not definitively known). Their relative safety has been corroborated by two large case–control studies in which very small increases in risks were reported.[129,130]

One notable exception is with paroxetine, which was reclassified as class D by the FDA after the demonstration of an increased risk for congenital heart defects in newborns.[131] An additional concern with SSRIs and SNRIs in pregnancy is the risk for a neonatal serotonin withdrawal syndrome immediately after delivery. This has been reported with TCAs in the past as well. A small controlled

investigation (*n* = 40) examined the effects of fluoxetine and citalopram on CNS effects in newborns and found a significant increase in restlessness, tremor, shivering, and hyperreflexia during the first 4 days of life (vs controls); these signs spontaneously remitted shortly thereafter.[132] Although some clinicians have interpreted these findings to suggest that antidepressants should be tapered and discontinued before delivery, others have argued that the delivery and the postpartum periods are major stressors for the new parent, and the risk of relapse during this time would be unacceptably high if the medication is withdrawn. Studies have also reported a small but significant decrease in birthweight among babies exposed in utero to SSRI, although a prospective study found that neither depression nor SSRI use effected infant growth.[133] Clinicians should be reminded, however, that both of these findings have been consistently reported with depression in the absence of antidepressant treatment, and attempts to distinguish the effects of the illness from medication effects in pregnant patients have met with mixed results.[134] The safety of bupropion in pregnancy has not been extensively studied and has an FDA class C rating. Data are even more sparse with mirtazapine, venlafaxine, or duloxetine, but no obvious adverse effects have been identified among infants exposed to these antidepressants in utero. Similarly, fetal malformations have been rarely reported with TCAs and they are generally regarded as safe in pregnancy. MAOIs, however, should be avoided because of increased risks for hypertensive crises. Although screening for depression is not suggested in the general population, it is recommended specifically for those who are pregnant and postnatal.[135] If antidepressants need to be used, then monotherapy is best; avoid first-trimester exposure, do not stop the antidepressant abruptly, and do not discontinue prior to delivery because of the high risk of postpartum depression.[128]

For A.R., it is important to assess her risk for depression if she stops taking her antidepressant. This was her first episode of depression (which occurred under stressful circumstances), she is not currently symptomatic, and she does not have a strong genetic predisposition to mood disorders. If she is committed to starting a

family, she should consider tapering off her escitalopram for several weeks before attempting to conceive. If she becomes pregnant and her depression returns, the risk to the fetus appears to be quite low with most SSRIs. Theoretically, this risk can be reduced further if the antidepressant is started after the first trimester (when most major fetal development occurs). An additional option for pregnant mothers suffering from mild-to-moderate symptoms would be to engage in psychotherapy.[128,136]

Approximately 70% of new mothers report sadness or anxiety during the first few days after delivery (baby blues), but these feelings will usually resolve within 1 to 2 weeks and do not require treatment. Approximately 10% of postpartum patients will experience unremitting symptoms that ultimately satisfy the criteria for MDD. The onset of these symptoms can be quite variable, ranging from the immediate postpartum period to several months later. Not treating depression postpartum results in symptom-related risks to the parent and newborn. Therefore, the priority is on reducing depression, and if an antidepressant is the most effective option for the mother, then efforts should be placed on managing breast-feeding.[137]

Brexanolone is an IV formulation of the naturally occurring neuroactive steroid allopregnanolone.[138] It is the only medication FDA approved for the treatment of postpartum depression. Allopregnanolone levels in the mother drop after birth, although this does not always correlate with depression.[139] It is given as a 60-hour IV infusion with rates during hours 0 to 4 at 30 mg/kg/hour then increased to 60 mg/kg/hour for hours 4 to 24. For hours 24 to 52, the rate is 90 mg/kg/hour, then decreased to 60 mg/kg/hour for hours 52 to 56 and 30 mg/kg/hour for hours 56 to 60. One study showed that for hours 24 to 52, a dose of 60 mg/kg/hour was numerically superior to a higher rate of 90 mg/kg/hour.[140] As the drug is a $GABA_A$-receptor positive modulator, it is required that the infusion be given with a health care provider present for risk of excessive sedation, loss of consciousness, or reduction in O_2 concentrations.[138,139] There is a statistical difference in the reduction of HAM-D scores between 24

and 48, yet this difference was not always maintained at day 30.[140] Thus, maintenance treatment with SSRIs may be required.

Because breast-feeding is widely advocated, the passive transfer of medication from mother to infant must be considered. Studies with TCAs and SSRIs suggest that concentrations of some antidepressants in breast milk are measurable. However, subsequent concentrations in the infant's bloodstream are relatively low, and the sequelae from this exposure have been limited to scattered case reports of increased infant irritability. Among the available agents, fluoxetine and the tricyclic antidepressant doxepin have been associated with the highest concentrations in infants, and although the clinical or developmental consequences of this finding have not been elucidated, it has been recommended that these medications be avoided.[141] Recent studies with SSRIs suggest that the concentrations achieved in breast milk are lowest with sertraline and that paroxetine, citalopram, escitalopram, bupropion, and venlafaxine are somewhere between the extremes of fluoxetine and sertraline.[137,141,142] If an antidepressant is to be continued in a mother who is breast-feeding, the lowest dosage should be prescribed. Concentrations of SSRIs in breast milk will generally peak ~4 to 8 hours after oral administration. If a new mother is particularly concerned about breast milk exposure, she can be advised to pump and save breast milk immediately before taking her antidepressant dose.

Drug Interactions

The SSRIs are inhibitors of the cytochrome P-450 isoenzymes, but important differences exist among the individual agents in their potency for specific metabolic pathways (see Table 86-8). For instance, the cytochrome P-450 1A2 isoenzyme (or CYP1A2) is most sensitive to the inhibitory effects of fluvoxamine. Fluoxetine and paroxetine have the highest impact on CYP450 2D6 with fluoxetine resulting in an approximately fourfold increase in TCAs and paroxetine a fivefold increase.[74,143] Fluoxetine's active metabolite has

weak-to-moderate inhibitory effects on the CYP3A4 isoenzyme. In comparison, sertraline, citalopram, and escitalopram have a much lower potential for CYP450 2D6 drug interactions but still inhibit the metabolism of 2D6-dependent medications. The potency is typically between 30% and 50% increases in area under the curve (AUC) and is often clinically irrelevant. Therefore, CYP450 2D6 drug interactions are less likely to cause harm with sertraline, escitalopram, citalopram, and fluvoxamine, but still require monitoring for a few weeks after the antidepressant is added to the patients' medication list.[74,143–146]

Although in vitro affinities of antidepressants for the respective isoenzymes can be very helpful for predicting potentially dangerous drug combinations, there is wide interpatient variability in the intensity of these interactions. Much of this variability can be attributed to genetic polymorphism. With CYP2D6, for example, ~5% to 10% of Caucasian patients and 1% to 2% of Asian patients are considered poor metabolizers via this isoenzyme.[147] CYP3A4 is the most abundant CYP enzyme found in the human body. Among the SSRIs, only fluoxetine and fluvoxamine have weak and moderate inhibitory effects on this isoenzyme, respectively. This has resulted in ~50% to 150% increase in AUC of the CYP450 3A4-dependent drug alprazolam.[74,145]

SEROTONIN SYNDROME

Serotonin syndrome is a rare but potentially fatal interaction because of excessive and prolonged serotonin within the synapse.[148] The syndrome includes a constellation of symptoms, including anxiety, shivering, diaphoresis, tremor, hyperreflexia, and autonomic instability (increased/decreased blood pressure and pulse rate).[148] Fatalities have been attributed to malignant hyperthermia. It occurs because of excessive serotonin overstimulating 5-HT_{1a} receptors and possibly 5-HT_{2a} (hyperthermia, incoordination, and neuromuscular effects).[148] It can occur within hours of administration of medications that can cause the syndrome. With mild cases of serotonin syndrome, the symptoms ordinarily resolve 24 to 48 hours

after the serotonergic agents have been discontinued. Supportive treatment may be necessary, and for more severe reactions, the serotonergic antagonist cyproheptadine is most commonly prescribed.[148] Dantrolene has been administered successfully to manage hyperthermia.[149]

Excessive serotonin can occur via four mechanisms: preventing its breakdown, preventing its reuptake into the neuron, increasing precursors or agonists, and increasing its release. Most case reports of serotonin syndrome (and most fatalities) have occurred with a combination of an MAOI and an SSRI, which is considered a contraindication. Other case reports involve the combination of an MAOI (or SSRI) with tryptophan, meperidine, SNRI, tricyclics, dextromethorphan, linezolid, and tramadol.[148] One case of serotonin syndrome was reportedly induced by the combination of clomipramine with *S*-adenosylmethionine (SAM-E).[150] Theoretically, the combination of an SSRI with St. John wort may also precipitate this pharmacodynamic interaction, but more recent evidence has suggested that the MAOI properties of the herbal preparation are minimal with therapeutic doses. Nonetheless, a case series of five older patients who exhibited symptoms reminiscent of serotonin syndrome has appeared in the literature, and, given the degree of uncertainty that persists, this combination of antidepressant agents is best avoided.[151] As noted by the previously described reports, the most concerning risk is combining agents that increase serotonin via differing mechanisms such as inhibiting the enzyme monoamine oxygenase and blocking the serotonin reuptake pump. Serotonin syndrome has also been reported with concurrent administration of multiple SSRIs; however, this would generally not be fatal. It is important to note that many medications have monoamine oxidase (MAO) inhibitory effects, although they are not classified as an MAOI. This would include medications such as linezolid, dextromethorphan, and meperidine.

The combination of trazodone with an SSRI could possibly pose some concern because both classes of antidepressants augment serotonin activity in the CNS yet; because both are reuptake inhibitors, it is very unlikely. Trazodone has been associated with

serotonin syndrome in two incidences, one involving the coadministration of buspirone and the other associated with a concomitant MAOI.[152] However, trazodone is recommended and commonly prescribed to patients receiving an SSRI for the treatment of insomnia, with no confirmed cases of serotonin syndrome that have surfaced in the medical literature, thus making it a possible risk only at very high doses.[153,154]

CASE 86-2

Question 1: M.G. is a 35-year-old married female. She is diagnosed with MDD and has been tried on sertraline up to 100 mg qam for 8 weeks, which did not result in a response. She was then tried on fluoxetine 20 mg qam for 8 weeks with only a partial response.

What is the next step for M.G. who has not responded to two antidepressant trials at a therapeutic dose for a therapeutic duration?

Pooled results of clinical trials suggest that the majority of patients with major depression receiving an adequate trial of any antidepressant will have a therapeutic response, defined as at least a 50% reduction in depressive symptoms. However, for a patient who is severely depressed, a 50% reduction in symptoms still leaves him/her with significant psychopathology and associated disability. Consequently, full remission is the preferred therapeutic end point.[5] One longitudinal investigation found that patients with residual symptoms were three times more likely to suffer a relapse during the 12 months after treatment compared to those who had remitted.[155] Not surprisingly, patients with treatment-resistant depression have 40% higher direct medical costs than those without treatment-resistant depression, mainly because of medication and outpatient care costs.[156]

For M.G., the first step would be to confirm her diagnosis and rule out potential medical explanations for her symptoms, specifically bipolar disorder. Bipolar depression is diagnostically indistinguishable from MDD depression episodes. Because antidepressants are minimally effective in bipolar depression, it would explain M.G.'s lack of response if she were to have bipolar

disorder. Iatrogenic causes should also be explored, such as any new medications or substance misuse. Assessing adherence to her previous medication trials is critical. A full therapeutic trial is considered to be a minimum of 4 weeks of treatment at a dosage shown to be clinically effective assuming the patient is compliant with therapy.

Drug Selection

SEROTONIN/NOREPINEPHRINE–REUPTAKE INHIBITORS

Because 30% to 40% of patients will effectively achieve remission and about 20% to 25% of patients will stop an antidepressant because of side effects, many patients started on a given antidepressant may eventually need a significant adjustment or change to their original regimen.[10]

In M.G.'s case, she has previously failed therapeutic trials of sertraline and fluoxetine. Although she had failed a sertraline trial, large controlled investigations suggest that 50% to 70% of patients who are unresponsive or intolerant of one SSRI will experience a therapeutic response to a different SSRI.[157–159] For example, in the STAR*D trial, patients failing an initial course of citalopram were just as likely to respond whether they were randomly assigned to a subsequent trial of a different SSRI (sertraline) or assigned to other antidepressant classes (venlafaxine and bupropion, specifically).[160] Because M.G. has now failed two SSRIs, it is recommended to try an antidepressant from a different class such as an SNRI, α_2-antagonist, or DA reuptake inhibitor.[5,10] For M.G., it was recommended to use an SNRI, and duloxetine was selected.

SEROTONIN/NOREPINEPHRINE–REUPTAKE INHIBITORS

Venlafaxine, duloxetine, desvenlafaxine, and levomilnacipran are categorized as SNRIs (see Table 86-7). At dosages <150 mg/day, venlafaxine's therapeutic effects are mediated exclusively from the blockade of serotonin reuptake. Therefore, associated adverse effects at these dosages are qualitatively and quantitatively very

similar to those found with SSRIs: GI distress, sleep disturbances, and sexual dysfunction. At higher dosages, effects on NE occur, and this can lead to the emergence of different adverse effects (eg, tachycardia, hypertension, and insomnia). NE effects occurring with duloxetine, desvenlafaxine, and levomilnacipran do not appear to be dose-dependent.[161] Levomilnacipran is an SNRI that has more potent effects on NE as compared to its 5-HT reuptake. However, its potency at NE reuptake is similar to duloxetine, and the ratio difference is because of its lower potency at 5-HT reuptake compared to other SNRIs.[162,163] Venlafaxine, which is available as immediate- and extended-release formulations, has a relatively brief plasma half-life (5–8 hours) and is demethylated to an active metabolite (*O*-desmethyl-venlafaxine). This metabolite, desvenlafaxine, was approved by the FDA in 2008 for the treatment of depression. Desvenlafaxine is available as an extended-release tablet that has a similar mechanism of action as venlafaxine. It has no affinity for muscarinic, histaminic, cholinergic, or adrenergic receptors and has a terminal half-life of 11 hours.[164,165] Desvenlafaxine is not affected by CYP2D6 inhibitors; however, CYP3A4 inhibitors may reduce clearance of the drug.[146] Duloxetine also has a relatively short half-life (12 hours) and is metabolized via CYP450 1A2. Levomilnacipran is mainly metabolized by CYP3A4 with a terminal half-life of 12 hours and is available as an extended-release tablet.[166] Venlafaxine, desvenlafaxine, and levomilnacipran are not potent inhibitors of cytochrome P-450 isoenzymes. Duloxetine is a moderate inhibitor of the CYP2D6 isoenzyme.[146,166] As with SSRIs, SNRIs have been associated with serotonin syndrome. Additionally, increased blood pressure (BP) will occur if combined with an MAOI.

As a class, all SNRIs have a risk of increasing BP and heart rate thought to be because of the increase in NE. Venlafaxine averages an increase of 1 mm Hg and 3 bpm.[167] Duloxetine averages 1 mm Hg in BP and 3 bpm.[168] Desvenlafaxine averages an increase of 2 mm Hg and 4 bpm.[169,170] Levomilnacipran has the greatest risk and averages an increase of 4 mm Hg in BP and 8 bpm compared to placebo.[171] There will be some patients who have large changes in

BP with any of the SNRIs; thus, monitoring of vital signs is necessary a few weeks after every dose increase.

Duloxetine has also been shown to increase liver function tests (LFTs) three times the upper limit of normal by ~1.3% compared to 0.2% in placebo-treated patients.[172] Although these numbers are small and similar to other antidepressants, the FDA has given duloxetine a warning that it is not to be prescribed to patients with substantial alcohol use or evidence of chronic liver disease.[172] Levomilnacipran has also been shown to mildly increase LFTs at initiation of therapy.[166]

Case 86-2, Question 2: M.G. is given a prescription of duloxetine 30 mg qam. She has heard from television ads about a new antidepressant called Trintellix (vortioxetine) and she wonders if this new medication is different from what she has been prescribed. What are the differences in mechanisms of action between duloxetine and vortioxetine and do these result in differences in efficacy on symptoms of depression?

Selective Serotonin Reuptake Inhibitors and Serotonin-Receptor Modulators

Vilazodone and vortioxetine are members of a new class of antidepressant. These medications have their primary effect on depression via inhibition of the serotonin reuptake pump, like the SSRIs (see Table 86-10). These two agents also have potency at other serotonin receptors. Vilazodone is a partial agonist at the 5-HT_{1a} receptor.[173] Vortioxetine is a 5-HT_{1a} agonist, 5-HT_{1d}, 5-HT_3, 5-HT_7 antagonist, and 5-HT_{1b} partial agonist. Despite the potential for the added serotonin-receptor effects, head-to-head trials with SSRIs and SNRIs have shown no greater efficacy advantage and similar side effect profiles.[171,173–175] In two separate studies, vortioxetine 20 mg showed less reduction in MADRS compared to duloxetine 60 mg qam, −15.57 versus −16.9, respectively, and −18.8 versus 21.2, respectively, the lower the score the less depression one has.[176,177]

Vilazodone should be taken with food, as this increases absorption by about 50%. It is metabolized primarily by CYP450 3A4 and secondarily through 2C19. Inhibitors and inducers have a small effect on blood levels. Its half-life is ~25 hours.[178] Vilazodone seems to have no effect on CYP450 isoenzymes.[146] Vortioxetine is metabolized via multiple CYP 450 pathways with 2D6 being the primary one. It has a half-life of ~60 hours. It does not appear to effect the metabolism of other drugs using CYP450 (see Tables 86-7 and 86-8).[179]

Nefazodone and trazodone have similar mechanisms of action. Both are serotonin reuptake inhibitors but nefazodone also has a mild NE reuptake inhibitory effect. Both also block 5-HT_2 receptors.[17] This particular characteristic has resulted in very little sexual dysfunction, and switching studies have shown that patients who develop sexual side effects with SSRIs do not have this side effect with nefazodone.[180] Interestingly, trazodone does have the rare but well-documented side effect of priapism.[181] Trazodone, which comes as immediate-release and an extended-release caplet, is rarely used for depression because of its potency of H_1 antagonism centrally resulting in significant sedation and somnolence.[10,154,181] Antidepressive effects with trazodone occur above 150 mg/day with most patients requiring >300 mg/day, yet sedation occurs at low doses such as 25 mg.[181,182] This has caused clinicians to use trazodone as a hypnotic with other antidepressants instead of trying to titrate up and use it as monotherapy. It is also a potent α_1-receptor antagonist and can cause orthostasis.[10,181] A reason that nefazodone has not been used more is because of its potential for hepatotoxicity.[5,10] This event is more common than any other antidepressant. With appropriate monitoring, such as LFTs q3 months for the first 18 to 24 months, this risk is nearly eliminated.[10] However, using other drugs with hepatotoxic risks concomitantly, such as valproic acid, increases this risk making nefazodone more difficult to use than most other antidepressants. Nefazodone is metabolized via CYP450 3A4 and is also a moderate-to-strong inhibitor of CYP450 3A4 (see Table 86-8).[80,183]

When speaking with M.G., it would be accurate to state that the new medication is not likely to be any better than her current prescription. Monitoring vital signs is more important with duloxetine than with vortioxetine although the change in vital signs with duloxetine is minimal and usually clinically irrelevant. Duloxetine has a potential for inhibiting CYP450 2D6 that is greater than vortioxetine. Duloxetine should be titrated to 60 mg qam; thus, a dose increase is necessary to monitor for a therapeutic response (see Table 86-9).

OTHER AGENTS: BUPROPION AND MIRTAZAPINE

Bupropion is an aminoketone with a mechanism of action that is clearly different from that of any other antidepressant because its therapeutic effect is due primarily to DA reuptake inhibition with negligible effects on serotonin (see Table 86-7).[184] This lack of serotonin provides a benefit in regard to both a lack of sexual dysfunction and sedation but has a negative effect in that it is definitively less anxiolytic as compared to the proserotonergic effect of the other antidepressants.[5] At therapeutic dosages, bupropion has a different adverse effect profile compared to SSRIs and SNRIs. Nausea, insomnia, agitation, and jitteriness are the most common, likely because of the stimulatory effect of DA. Seizures are a risk but are unlikely with therapeutic dosing of bupropion, provided patients are not predisposed (eg, history of epilepsy, bulimia, electrolyte abnormalities, or recent history of heavy drinking). Bupropion may decrease appetite. A randomized, placebo-controlled investigation of bupropion in depressed obese patients observing caloric restriction found that bupropion was much more likely to induce significant weight loss than placebo.[185] After 26 weeks of treatment, 40% of the bupropion-treated patients lost more than 5% of their total body weight versus 16% with placebo. This weight loss was positively correlated with an improvement in depressive symptoms. It has little-to-no negative effect on sexual function because of no stimulation of 5-HT receptors. For patients who develop sexual dysfunction from the SSRI or SNRI, bupropion has shown some benefit as an

adjunctive treatment that reduces this side effect. It is also useful for poor responders as an adjunct to SSRI/SNRI because of its unique neurotransmitter effect.[5] Bupropion does not seem to affect cardiac rhythm or induce arrhythmias in susceptible patients.[186] Patients with hypertension should be monitored for increases in BP at the next visit after bupropion is initiated.[187]

Bupropion is converted via the cytochrome CYP450 2B6 isoenzyme to an active metabolite (9-hydroxybupropion). Bupropion (and its metabolite) appears to have a moderate effect at inhibiting the CYP450 2D6 isoenzyme, and significant elevations of venlafaxine and metoprolol have been demonstrated to occur with concurrent administration (see Table 86-8). Because of its short half-life (~8 hours for the parent compound and 12 hours for the active metabolite), therapeutic doses of regular release bupropion must be administered in divided doses. The recommended starting dose is 100 mg twice a day (bid), increasing to 100 mg three times a day (tid) after at least 3 days. Individual doses must not exceed 150 mg and should be given at least 6 hours apart. For the SR formulation, initial daily doses are 150 mg every day, increased to 150 mg bid by the fourth day at the earliest. Individual doses of bupropion SR can be as large as 200 mg, and divided doses should be given at least 8 hours apart. The once-daily formulation is initiated at 150 mg daily and increasing to 300 mg daily as early as the fourth day. Maximum daily doses are 450 mg for regular and XL products, and 400 mg for SR products (see Table 86-9). Staying below the maximum doses should be strictly followed because of the dose-dependent risk of seizures.[10]

Mirtazapine is a novel antidepressant capable of modulating serotonin and NE activity through antagonism at presynaptic α_2-autoreceptors and postsynaptic 5-HT_2 and 5-HT_3 receptors.[188] In addition, it appears to possess some mild inhibitory properties at serotonin reuptake transporters. Therefore, the net effect of mirtazapine is to enhance serotonin and NE in a manner that is clearly distinct from any other antidepressants (see Table 86-8). In a comparative randomized trial with fluoxetine for moderate-to-severe

depression, mirtazapine appeared to be much more effective than fluoxetine after 4 weeks of treatment (58% responders vs 30% with fluoxetine; $P > .05$), but the differences were no longer significant at 6 weeks (63% vs 54%; $P = .67$).[189]

The most common adverse effects experienced with mirtazapine are sedation and weight gain. Because mirtazapine has potent antihistaminergic effects, it can be quite sedating and is often used as a hypnotic similar to trazodone. Unlike trazodone, antidepressant dosing is quite tolerable. Anecdotally, it has been reported that higher daily doses of mirtazapine (>30 mg) are less sedating than lower doses owing to a plateauing of antihistaminic effects at 15 mg but with an increased noradrenergic effect up to 60 mg. In addition to the substantial risk of increasing appetite and total body weight, mirtazapine has been associated with significant increases in total cholesterol and triglycerides. This is likely because of its combination of H_1 and 5-HT_{2c} antagonism, the pharmacology related to atypical antipsychotic metabolic effects. This makes mirtazapine less preferred than SSRIs in patient with diabetes. Mirtazapine does not appear to affect cardiac rhythm or induce arrhythmias.[186] The recommended starting dosage is 15 mg at bedtime, and the therapeutic dosage ranges from 15 to 45 mg/day (see Table 86-9).[190] Data from controlled trials have demonstrated safety and efficacy in doses up to 60 mg daily.[190–192] As with bupropion, mirtazapine is considered a top choice for antidepressant combination therapy in poorly responding patients on an SSRI/SNRI. Despite the fact that mirtazapine is increasing 5-HT and NE as do SNRIs, its unique method of doing this via α_2 antagonism makes the combination with an SNRI or SSRI recommended.[5,10,193]

TRICYCLIC ANTIDEPRESSANTS

SSRIs are recommended over TCAs in the treatment of mood disorders. The popularity of SSRIs can be attributed to numerous advantages over older compounds, including a lower side effect burden, safety in overdose, less dosage titration, and patient preference.[5,10,26] Results of a meta-analysis concluded that although

the overall efficacy of the SSRI and TCA classes was comparable, primary care patients receiving an SSRI were much less likely to discontinue therapy prematurely because of side effects.[194] TCAs cause a variety of adverse effects, ranging from bothersome (dry mouth, sedation, constipation) to serious (cardiovascular effects), which often prevent patients from receiving therapeutic doses of medication.[195] Patient adherence to prescribed medication may also be compromised with TCAs.[196] Even though SSRIs and the newer SNRIs are preferred for the treatment of depression, TCAs continue to be prescribed at low doses for other indications that are comorbid with depression (eg, migraine prophylaxis, chronic neuropathic pain). This requires careful monitoring for drug interactions as TCAs as a class are primarily metabolized via CYP450 2D6 and, as noted, some SSRIs and SNRIs may inhibit this pathway substantially increasing the risk of TCA toxicity.

SIDE EFFECTS

Therapeutic effects of TCAs are primarily through their ability to inhibit the reuptake of serotonin and NE, functionally an SNRI (see Table 86-7).[197] Additionally, TCAs have significant antagonistic effects on acetylcholine, histamine, and α-noradrenergic receptors, all of which are considered potential for side effects. The intensity of these side effects has been shown to adversely affect adherence.[26] Although patients may develop tolerance to these effects, they may never disappear completely.

Because of the potent histamine 1 antagonism centrally, TCAs can be very sedating and are usually administered at bedtime to minimize functional impairments. Confusion or memory deficits may also occur with TCAs and can be particularly onerous in elderly patients. The secondary amines may be more tolerable in this regard, but all TCAs can impair concentration or alertness to some extent and are not recommended in geriatrics.[10] The sedating antihistaminic effect (along with orthostasis) increases the risk of falls. The risk of weight gain and constipation make TCAs undesirable in a patient with comorbid diabetes.

Orthostatic hypotension is the most common and troublesome cardiovascular effect of the TCAs (as well as MAOIs) because it can result in significant morbidity and mortality.[198,199] Major clinical consequences of orthostatic hypotension include falls leading to bone fractures, lacerations, and even MI. Patients with congestive heart failure (CHF) and the elderly are at greatest risk for experiencing orthostatic hypotension. The tertiary amines (eg, amitriptyline, imipramine) may cause more severe orthostatic hypotension than the secondary amines (eg, nortriptyline, desipramine), and research supports the contention that nortriptyline has the lowest risk for causing orthostatic hypotension among TCAs.[200,201]

There are substantial differences among antidepressants (and antidepressant classes) in regard to overall cardiac safety and arrhythmogenic effects in particular. In general, the SSRIs appear to be relatively safe in patients with a history of arrhythmias or recent MI.[186] In a placebo-controlled investigation, hospitalized patients with unstable cardiac disease were randomly assigned to either sertraline or placebo.[202] Overall, both treatment arms were very well tolerated, and there was actually a lower risk of severe cardiac events reported in the sertraline group (vs placebo). Retrospective data suggest that SSRIs may be somewhat cardioprotective in depressed patients with heart disease, a benefit that might be explained by their ability to decrease platelet activation.[203,204]

Alternatively, TCAs increase heart rate, probably via intrinsic anticholinergic properties that increase sinus node activity. Clinically, this effect is generally not significant, especially in the medically healthy depressed patient.[10,205] However, it may be important in those with underlying conduction disease, coronary artery disease, or CHF. TCAs, even when used at therapeutic dosages for the treatment of depression, decrease premature atrial and ventricular contractions in both depressed and nondepressed patients.[206,207] Because TCAs have class 1A antiarrhythmic activity, they have arrhythmogenic activity and thus increase the chances of ventricular arrhythmias and even sudden death. This effect on rhythm and conduction is believed to be related to the inhibitory effects of TCAs

on the fast sodium channels and a decrease in Purkinje fiber action potential amplitude, membrane responsiveness, and slowed conduction.[205,207] TCAs also block the rapid potassium channel similarly.[205] This dual effect of sodium- and potassium-channel blockade results in a greater impact on inducing QTc prolongation compared to the SSRI class.[208] Even nortriptyline, which is believed to be one of the safer TCAs in patients with heart disease, was associated with a greater risk for adverse cardiac events than paroxetine.[209] In patients with preexisting conduction defects and in overdose, there is a greater risk for cardiac arrhythmias.[200] Therefore, patients should receive a baseline electrocardiogram (ECG) before therapy, and use in patients with preexisting cardiac conduction abnormalities should be avoided.[10]

Other risks associated with TCAs are a lowering of the seizure threshold. This seems to be worst with clomipramine and maprotiline compared to the others in the class.[10,210,211] This event is particularly risky in high doses, similar to bupropion. If patients are at risk of seizures or have a seizure disorder, SSRIs are much safer and are preferred over TCAs.[10,210,211] TCAs have also been shown to produce photosensitivity; thus, excessive exposure to sunlight has resulted in severe sunburns. In patients who have had this reaction or whose lifestyle requires frequent contact with sunlight (eg, lifeguard), switching to another class is recommended.[212]

MONOAMINE OXIDASE INHIBITORS

MAOIs are an alternative for patients who have failed multiple antidepressant trials. MAOIs are believed to relieve depressive symptoms by enhancing the activity of monoamines. This is done by blocking the enzyme MAO, which breaks down serotonin, dopamine, and NE. This is in contrast to an SSRI/SNRI, which increases 5-HT and/or NE by preventing its reuptake into the neuron. This may be desirable for refractory cases. Candidates for treatment should be chosen carefully, and MAOIs should be used only by specialist practitioners such as a psychiatrist.

Phenelzine, tranylcypromine, and isocarboxazid were commonly prescribed for the treatment of depression in the 1970s and 1980s, and their usefulness waned primarily because of the risks of serious drug–drug and drug–food interactions.[213] In standard treatment of depression, MAOIs are not recommended, except for the treatment of atypical depression where this class appears to have a small efficacy advantage over other classes.[5,10] Data comparing TCAs with SSRIs for atypical depression suggest that the two classes are comparable in efficacy and both are superior to placebo and so SSRIs should still be tried first because of safety concerns.[10,214]

The "cheese reaction," which can manifest as a hypertensive crisis, is so named because it occurred in patients who were taking nonselective MAOIs and ingested foods high in tyramine, a by-product of tyrosine metabolism that is found in certain foods and beverages, such as aged cheese or Chianti wine (**Table 86-12**). When tyramine is ingested in the absence of an MAOI, it is rapidly metabolized by the MAO enzyme in the GI tract before systemic absorption. In the presence of an MAOI, more tyramine is absorbed, and relatively high concentrations of tyramine may be achieved in circulation, resulting in the displacement of NE (and other catecholamines) from presynaptic storage granules. NE surges into the synapse, and as metabolic degradation is inhibited by the MAOI, a profound pressor response is triggered.[215] A slightly safer version of the MAOI class is the once-daily selegiline transdermal. By avoiding the GI tract, selegiline has less effect on the MAO that reduces tyramine from entering the bloodstream via food. Despite the improved safety of selegiline transdermal to oral MAOIs, there still remains a risk of food–drug interactions resulting in hypertensive reactions, particularly at higher doses, and so the FDA has recommended diet restrictions for doses over 6 mg/24 hours. Additionally, there are application site reactions that occur in ~35% of patients.[5,216,217] This agent is available in 6-, 9-, and 12-mg strengths. Selegiline transdermal as well as oral MAOIs are reserved for refractory cases and should be used only by skilled clinicians.[5,217]

Table 86-12
Foods Containing Tyramine

High Amounts of Tyramine[a]
Smoked, aged, or pickled meat or fish
Sauerkraut
Aged cheeses (eg, Stilton, blue cheese)
Yeast extracts (eg, marmite)
Fava beans
Moderate Amounts of Tyramine[b]
Beer (microbrewed > commercial)
Avocados
Meat extracts
Red wines such as Chianti
Low Amounts of Tyramine[c]
Caffeine-containing beverages
Distilled spirits
Chocolate
Soy sauce
Cottage and cream cheese
Yogurt and sour cream

[a]May not consume.
[b]May consume in moderation.
[c]May consume.

ADVERSE EFFECTS

Orthostatic hypotension, weight gain, edema, and sexual dysfunction are common during MAOI therapy.[198] As is the case with the TCAs, the nonselective MAOIs can cause clinically significant postural decreases in BP. However, with the MAOIs, the mechanism is believed to be a direct sympatholytic effect because both the lying

and the standing systolic BP readings are decreased.[218,219] Phenelzine seems to cause orthostatic hypotension more commonly than does tranylcypromine.[220] Because the orthostatic hypotension appears to be dose-related, a reduction in dosage may be helpful.[221] Sexual dysfunction occurs in up to 20% of patients taking MAOIs but may diminish and disappear spontaneously over time.[222,223] A switch into mania has been reported in up to 10% of patients with a history of bipolar disorder. Therefore, MAOIs should be avoided in this population.[198] Although MAOIs are not known as antimuscarinic medications, some patients report anticholinergic-like side effects, including blurred near vision and urinary retention. Dosage reduction may be helpful, but these effects may also diminish over time. The nonselective MAOIs are not associated with proarrhythmic, antiarrhythmic, or contractility effects when used in therapeutic dosages. Like other MAOIs, selegiline can be quite activating, and insomnia is frequently reported.

Several potentially fatal drug–drug interactions occur with nonselective MAOI antidepressants. Like the reaction with tyramine, indirect sympathomimetics such as phenylpropanolamine and pseudoephedrine (common ingredients in over-the-counter cold preparations and diet pills) can cause a precipitous rise in BP that can result in stroke.

The potential for serotonin syndrome with the combined use of SSRIs and MAOI antidepressants or other medications with MAOI effect is well-documented. A washout period of at least 14 days should separate the use of an SSRI and an MAOI. Because fluoxetine (and its primary active metabolite norfluoxetine) has a much longer half-life, the recommended washout period is at least 5 weeks after discontinuing this particular SSRI. Caution is advised when any other pro-serotonergic mediations are prescribed such as triptans and tramadol.[148]

Case 86-2, Question 3: M.G. still had some residual symptoms despite a therapeutic trial of duloxetine 60 mg qam. An increase to 90 mg resulted in intolerable insomnia. She has had a partial response (~40% reduction in

symptoms) but is still impaired by her depression. What are possible next steps?

Antidepressant Augmentation With Nonantidepressants

Treatment-refractory depression (TRD) is considered to be a failure to reach remission with two or more antidepressant monotherapy trials that were given at a therapeutic dose and given for an appropriately therapeutic period. Generally, a therapeutic dose is for 4 to 8 weeks. This would not include the time it takes to titrate to a therapeutic dose.[224,225] A common strategy for TRD includes combining antidepressants such as an SSRI with bupropion or mirtazapine, as mentioned previously. Other strategies are augmenting an antidepressant with a medication from another class, or somatic treatments, particularly ECT.[5,10,26,224,225]

There are many options to augment an SSRI/SNRI if the patient has not achieved a full response. Some atypical antipsychotics, lithium and triiodothyronine, all have studies showing efficacy. Buspirone has less robust data but is still recommended.[5,224,225] The use of atypical antipsychotics for the management of treatment-resistant depression has become relatively common among mental health providers because of well-designed and replicated studies. Four atypical antipsychotics (olanzapine in combination with fluoxetine, aripiprazole, brexpiprazole, and quetiapine) have received FDA approval as adjunctive agents with SSRIs or SNRIs for depression that has poorly responded to monotherapy, and others have been reported to be effective as well.[5,224,225] Generally, lower doses of second-generation antipsychotics have been successfully used in trials for depression (vs schizophrenia), and relatively rapid improvement was evident. Given the significant risk of metabolic side effects that have been reported, clinicians must carefully weigh the risks and benefits of recommending this augmentation strategy prior to maximizing antidepressant monotherapy trials and antidepressant combinations.[5,10] It is recommended that nonbehavioral health

practitioners use caution when prescribing the atypical antipsychotics for poorly responding patients.[193]

One instance where the use of an atypical antipsychotic adjunct is given during the acute phase is with psychotic depression. Patients with psychosis during the depressed episode, as with multiple previous episodes and depression severity, are at greater risk of chronicity and suicidality.[10] Multiple studies have shown benefit of antipsychotic and antidepressant combination better than either monotherapy. Despite the fact that monotherapy may be appropriate for the maintenance phase, it is recommended to start an antipsychotic with the antidepressant during the acute phase and slowly taper off after the persons depression and psychosis remits.[5,10,226] The least preferred antidepressant is bupropion. Its prodopaminergic effect could worsen the psychosis.[10] ECT is also a recommended treatment.[5,10,226]

Esketamine nasal inhalation is FDA approved as an adjunct to antidepressant therapy. It is an *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonist while also a reuptake inhibitor for monoamines. It also has mild mu-opiate receptor agonism.[227–229] Esketamine has shown to reduce depression as a combination therapy with an SSRI or SNRI compared to placebo by ~4 to 10 points, as measured by the MADRS scale, within the first 24 hours.[230,231] Contrarily, one study did not show a statistical difference of adding esketamine to SSRI/SNRI treatment compared to just switching to a different SSRI/SNRI.[232] The dose of 56 or 84 mg is given at the clinician's office twice weekly for the first 4 weeks, then weekly for the next 4 weeks. Cardiovascular risks include increased heart rate and BP. Dissociative states of mind as well as other CNS and psychomimetic side effects occur in over 50% of the population. Esketamine also carries a risk of abuse.[233] These adverse effects require that the medication be sent directly to the clinician's office and that the patient be monitored by a health care professional at the office for at least 2 hours after every inhalation.[233,234]

Lithium's antidepressant properties as an augmenting agent have primarily been conducted with TCAs.[225] Seven of nine

antidepressant augmentation trials with lithium have reported positive therapeutic effects, usually within 1 week of achieving steady-state dynamics (ie, 3–7 days of daily dosing).[235] Effective lithium blood levels are generally within the range used to treat bipolar disorder (0.5–1.2 mEq/L). Lithium has a very narrow therapeutic index along with multiple significant drug interactions and should only be used by a clinician skilled in its use.[5]

Triiodothyronine (T_3) also has a long history of use in psychiatric circles for patients exhibiting partial or suboptimal responses to antidepressant monotherapy. Five of six RCTs support the use of T_3 supplementation for antidepressant augmentation, with an average effect size of 0.58 reported.[236] Triiodothyronine, at a dosage of 25 mg/day, can accelerate as well as augment antidepressant response, and superior effects have been reported in female patients, in particular. The response to the thyroid supplementation should be noticeable within 1 to 2 weeks, much like that found when lithium is used to augment therapy. Thyroxine (T_4) may also be effective with typical daily doses of 75 to 100 µg daily often used. In the STAR*D trials, T_3 was compared to lithium for antidepressant augmentation with citalopram in patients with two previous treatment failures.[237] Remission rates were modest for both agents in this challenging population (24.7% with T_3 vs 15.9% with lithium), and there was no significant difference between these two therapies.

In the STAR*D trial, augmentation with bupropion was compared to buspirone, and both adjunctive treatments showed 30% remission rates.[237] Buspirone may be of benefit to patients with residual symptoms of anxiety, in particular, and titration up to daily doses of 30 to 60 mg daily is often required.[5,193] Stimulants and modafinil have generally shown no benefit on depressive symptoms overall.[193,238] However, they may provide temporary relief from excessive fatigue and somnolence while waiting for the full antidepressant effect of the primary treatments.[5,225]

Because M.G. had a failure to two monotherapies and some response to duloxetine, the option of adding a medication to the SNRI is the next step. Combinations of duloxetine with another

antidepressant (mirtazapine or bupropion) or with an atypical antipsychotic are both recommended. Mirtazapine, quetiapine, and olanzapine would help if there is any insomnia and would protect against this side effect if duloxetine were to be increased in the future. Bupropion would possibly worsen insomnia. Aripiprazole, brexpiprazole, mirtazapine, quetiapine, and olanzapine (least to most) all could cause weight gain and worsen cholesterol. Discussing the risks of each option is critical and letting M.G. help decide which choice fits her lifestyle will ensure better adherence. M.G. decided to start aripiprazole 2 mg qam and will increase her exercising to mitigate the possible weight gain and cholesterol increase.

Pediatric Depression

CASE 86-3

QUESTION 1: A.A. is a 15-year-old male who has had a mood and behavior change over the last 6 months. A.A. is a sophomore in high school who averages Bs in his classes. He was a member of the varsity lacrosse team, with many friends. Over the last 6 months, he has been less involved with his friends to the point that he now does not want to go out. After lacrosse season, he normally would participate in off-season lacrosse camps. This year he did not want to. His grades have dropped, as he cannot concentrate as well on his schoolwork. He has missed some days of school lately because he does not want to get out of bed. Both illicit drug use and recent trauma have been ruled out. His medical history is unremarkable except for a 10-pound (4.54 kg) weight loss since last year, likely because of a poor appetite. His parents are very supportive.

What are the recommendations for the treatment of pediatric depression?

Rates of pediatric depression are less than in adults. As a person ages, the risk of depression increases with rates of 0.5% in 3- to 5-year-olds increasing to 3.5% in 12- to 17-year-olds.[10,239] Diagnosing pediatric depression uses the same criteria from the *DSM-5* as for adults; however, the interview questions may be slightly different. For example, poor concentration may be mislabeled as procrastination

or anhedonia might be described as "being bored."[9] Treatment guidelines do differ compared to adults. One reason for this is that placebo rates are much higher in pediatric studies resulting in the medication not having as dramatic a difference when compared to the difference between placebo and drug in adult studies. Thus, there are many studies where SSRIs had strong response rates but placebo also did and the medication was not considered to be statistically different.[240–242] Because of this high response rate from placebo and the support given by being a subject in a research study, the expert guidelines recommend supportive care and formal talking therapy be the first option for mild-to-moderate depression.[243,244] Medications can be used if symptoms are moderate to severe. Pharmacotherapy options are limited, though, compared to adults. Fluoxetine is FDA approved down to age 8, escitalopram to age 12. Clomipramine (age 10 and older), fluvoxamine (8 and older), and sertraline (6 and older) are FDA approved for obsessive–compulsive disorder but not depression. The SNRI duloxetine is approved for 7-year-olds and above for generalized anxiety disorder, and imipramine is approved for 6 and older for enuresis. To summarize, only two antidepressants are FDA approved for depression in children, although some other antidepressants do have nondepression indications in children.

Case 86-3, Question 2: The child psychiatrist's initial recommendation is to have A.A. meet with a psychologist. After 4 months of talking therapy, A.A. is improved in general but is still having bouts of sadness that prevent him from going to school a couple of days a month. It is decided to continue talk therapy but to add a medication. Which medication is the preferred agent?

Unlike adults where all antidepressants are similarly effective, pediatric depression guidelines have recommended that SSRIs particularly fluoxetine and escitalopram be the treatments of choice.[243,244] Fluoxetine's starting dose is 10 mg qam with a target dose of 20 to 40 mg a day. Escitalopram's starting dose is 5 to 10 mg qam with a target dose of 10 to 20 mg a day. Interestingly, the separation from placebo increases as the child ages for many of the

SSRIs. For example, escitalopram did not statistically differ from placebo in the under-12-year-old age group but did so in the adolescent age group.[240,245] Paroxetine is not recommended for depression because of the overall lack of efficacy in any age group when studies are combined and a high dropout rate in the younger patient.[240,242] Bupropion, mirtazapine, venlafaxine, and duloxetine have recommendations as treatment options but after failures of the SSRIs.[243] TCAs are not recommended primarily because of a high risk of harm being much greater than the small benefit on symptoms.[243,246]

Case 86-3, Question 3: A.A. is started on fluoxetine 10 mg qam. What safety monitoring is required when starting a young adult or pediatric patient on an antidepressant?

Generally, SSRIs are well tolerated in children. There is a black box warning for suicidal thinking. As with adults, the clinician needs to monitor for suicidality, but in children, there is a doubling of suicidal thoughts, not suicide attempts or completions, from 2% in the placebo arms to 4% in medication arms. It is important to note that actual suicides are much higher in untreated depressed youth compared to those taking antidepressants.[98,247–249] This risk diminishes as age groups increase. For patients over age 24, it is not required to be so vigilant regarding suicidal thinking, although many guidelines recommend continuing to monitor throughout the age ranges because of the possibility of disease-related risk. In pediatrics and young adults, the experts recommend the use of antidepressants with the FDA-sanctioned monitoring for suicidal thinking every week for the first week, every other week for the next 4 weeks, then monthly or as decided by the patient and clinician.[243,250] Talking therapy may have some protection against the side effect of increased suicidal thoughts.[251]

Geriatric Depression

Depression in late life is typically more difficult to recognize than depression in younger adults. Clinicians and patients may inappropriately attribute depressive symptoms to the “aging process” and minimize their significance. In addition, functional expectations are often lowered after retirement, making the degree of impairment difficult to evaluate. Because medical comorbidities are also more common in the elderly, depressive symptoms may be overlooked or misinterpreted in the workup as well.[121,252] In general, the elderly present with the same depressive target symptoms as younger adults, which is reflected in the fact that *DSM-5* diagnosis for major depression in adults is not specific for age. However, qualitatively, the presentation of depression among the elderly may be quite different. For instance, older patients are more likely to present with psychomotor retardation and are less likely to acknowledge “depression” per se, preferring instead to dwell on somatic concerns (eg, poor sleep, low energy, changes in bowel function, bodily aches, and pains).[10] They are also much less likely to share or admit suicidal thoughts, and because elderly males have the highest suicide completion rate, an accurate assessment of depression and attendant risks is critical.[10,121,253] In assessing nonspecific behavioral and cognitive symptoms in the elderly, a careful differential diagnosis between medical and other psychiatric disorders is essential because numerous medical illnesses can mimic depressive symptoms. Anemia, malignancies, CHF, and endocrine abnormalities may all present in a manner similar to that in depressive illness.

Aging does result in monoamine depletion as well as increased MAO activity.[121] One of the more difficult differential diagnoses in this setting involves the distinction of depression from dementias.[254,255] Like depression, patients with dementia may present with apathy, poor memory or concentration, reduced facial expression, and lack of spontaneous interaction. The illnesses are often comorbid, as 30% to 70% of patients with dementia also suffer from major depression.[255] Some experts have suggested, in fact, that new-onset depression in elderly patients may actually be part of a prodrome toward the manifestation of Alzheimer dementia.[255,256] A longitudinal cohort study found that among elderly patients suffering from an

acute episode of major depression, 57% were ultimately diagnosed with Alzheimer dementia within the next 3 years.[254] Diagnostically, there are three notable differences between dementia and depression: (a) the symptoms (slow and subtle changes with dementia, rapid with depression), (b) orientation (markedly impaired with dementia, intact with depression), and (c) principal CNS impairment (short-term memory with dementia, concentration with depression).

Drug Selection in the Elderly

A therapeutic trial of an antidepressant in a depressed individual with cognitive impairment may reverse the symptoms of the affective illness and restore functional capacity. Depression-related cognitive dysfunction will also improve to some degree. Moreover, because primary degenerative dementia is largely a diagnosis of exclusion, a successful trial of an antidepressant may help clarify the underlying pathologic condition and is strongly recommended in patients with a positive personal or family history of mood disorders.[257] The overall efficacy of antidepressants in elderly patients is believed to be comparable to that observed in younger subjects, although the response to treatment is somewhat slower (ie, 6-week therapeutic trial usually warranted).[5] Psychotherapy may be somewhat more effective in the elderly particularly because of the emotional impact of medical comorbidities and neurodegeneration effects as long as there is no dementia hindering talking therapy's effect.[5] Similarly, the comparative therapeutic effects of individual antidepressants do not appear to differ qualitatively between elderly patients and the general population. The selection of antidepressants for geriatric depression is the same as the process for younger patients. The elderly are much more sensitive to side effects compared to younger patients, and the presence of medical comorbidities and concurrent medications will have a greater influence on antidepressant selection. For example, the anticholinergic effects of TCAs preclude their use in elderly patients particularly if they are suffering from

narrow-angle glaucoma, chronic constipation, or urinary hesitancy. Anticholinergic impact on memory and the cardiac-related effects such as arrhythmias, orthostasis, and tachycardia are other critical reasons not to use the TCAs in the elderly. As noted previously, the risk of falls from TCAs because of antihistaminic, anticholinergic, and α-receptor antagonistic properties is another reason not to use them in the elderly population.

SSRIs are recommended as first line, but among this list, paroxetine is considered the worst option because of its anticholinergic effects (albeit mild) compared to no effect from the others. SNRIs also have data showing efficacy.[5,10,26] There does seem to be more dropouts with venlafaxine compared to the SSRIs.[5] Although sedating antidepressants such as mirtazapine may serve to promote sleep in depressed patients suffering from insomnia, other geriatric clients may be candidates for more activating medications that can increase energy or enhance alertness (eg, bupropion).

All antidepressants have a risk of causing SIADH, with SSRIs being the group with the highest reported cases. Elderly patients, compared to younger patients, are at a much greater risk of this event with some reviews reporting hyponatremia up to 32%.[10,258] As with other medications used in the elderly, antidepressants should be started at lower initial doses compared to adults.[5,10,121] Titration to a known therapeutic target dose has the best evidence even if the geriatric seems to be responding to a subtherapeutic dose.[5]

Therapeutic Blood Level Monitoring

Attempts to demonstrate an association between plasma concentrations and therapeutic response for SSRIs and SNRIs have been largely unsuccessful. In contrast, the serum concentration of some TCAs correlates well with clinical response. Nortriptyline exhibits a curvilinear effect, whereas imipramine demonstrates a sigmoidal relationship between serum levels and clinical response.[259,260] Maximum benefit of imipramine is usually associated with serum levels of imipramine plus its demethylated metabolite,

desipramine, in excess of 250 ng/mL. The relationship between plasma concentration of desipramine and clinical response is less clear, but a linear relationship is likely.[261] The most controversy surrounds amitriptyline; studies have shown a linear relationship, a curvilinear relationship, and no relationship between serum concentration and outcome.[262–264] The american psychiatric association (APA) Task Force on the Use of Laboratory Tests in Psychiatry recommends plasma concentration monitoring of TCAs when patients are elderly, not responding to therapy, nonadherent, experiencing adverse effects, or on multiple medications that may result in a possible drug interaction.[265] Plasma concentrations of imipramine, nortriptyline, and desipramine should be obtained after at least 1 week of a constant dosage when steady state has been achieved. Samples should be drawn 12 hours after the last dose has been administered. Routine therapeutic blood monitoring of other antidepressants is not recommended because information concerning their usefulness is limited; however, serum levels may be useful for evaluating adherence in some patients or ruling out serious toxicities.[266]

Antidepressants and Chronic Pain

CASE 86-4

Question 1: D.C. is a 42-year-old female with a history of chronic lower back and left leg pain who has noted increased crying spells and a decreased interest in social activities during the course of the last 4 months. She attributes this downturn to the stress she is experiencing as she cares for her disabled mother who recently moved in with her. When asked, she also notes significant decreases in energy and concentration and difficulties in falling and staying asleep.

In the past, D.C. recalls one previous episode of depression 8 years ago, when she was treated initially with venlafaxine (discontinued because of nausea) and ultimately responded to a course of psychotherapy. Her past medical history is significant for chronic pain from a car accident 7 years ago, which continues to bother her on a daily basis (she rates pain at 5 of 10 currently), hypertension, and hyperlipidemia. Her current medications include lisinopril 10 mg qam and atorvastatin 10 mg qhs. In addition, she started

amitriptyline 50 mg at bedtime 2 months ago for her insomnia but noticed a 12-pound (5.44 kg) weight gain and recently discontinued. In the meantime, she has continued to see her therapist on a weekly basis during this time frame.

What considerations may influence treatment selection in this patient with chronic pain? What treatment should be recommended?

There is a strong and complex association between chronic pain syndromes and mood disorders. Epidemiologic investigations report that 50% of patients with chronic pain will satisfy the criteria for a depressive disorder.[267] Anxiety disorders are also commonly reported in this population as well. On the other hand, 65% of individuals with major depression will experience some symptoms of somatic pain, often presenting with pain as their main problem. Researchers have theorized that this comorbid phenomenon can be explained by deficiencies in the neurotransmitters serotonin and NE, which influence mood disorders in the prefrontal cortex and limbic system, as well as modulate pain sensitivity via descending projections down the spinal column. Other theories implicate elevations in cytokine activity, which commonly occur during the course of mood disorders, as well as mediating inflammatory activity occurring within the context of chronic pain.[267,268]

Treatment plans for depressed patients with chronic pain should target both of these conditions in order to achieve optimal outcomes. In regard to the selection of antidepressants, preference is often given to medications that can address both sets of symptoms associated with these comorbid conditions. For instance, antidepressant agents with pain-relieving properties and agents that promote sleep and relieve anxiety are often preferred. Antidepressants that enhance 5-HT and NE (TCAs and SNRIs) have proven to be quite effective for the management of neuropathic pain conditions, in addition to their benefits on anxiety and depression.[5,267,268] SSRIs are much less effective primarily because of the lack of NE enhancement, which is critical for analgesia.[5]

Drug interactions are often a major consideration in the selection of antidepressants. Certain opioid analgesics are prodrugs and require metabolic transformation to generate the active species.

These analgesics include codeine (metabolized to morphine), hydrocodone (active metabolite: hydromorphone), and oxycodone (oxymorphone), as well as tramadol (*o*-desmethyl tramadol). Patients who require these medications would benefit from antidepressants that do not effect CYP 450 (see Table 86-8).

D.C. meets the criteria for an acute episode of major depression, and medication is clearly indicated. Among the alternatives, SSRIs have not proven to be effective for neuropathic pain. SNRIs and TCAs are effective for neuropathic pain conditions, as well as depression and anxiety. However, there are substantial tolerability and toxicity risks with TCAs not shown with the SNRI class. Additionally, she has experienced significant weight gain with a low-dose TCA (50 mg amitriptyline). An SNRI would be a good choice for the treatment of her depression and chronic pain. Given D.C.'s history of nausea from venlafaxine, an alternate SNRI, such as levomilnacipran or duloxetine, should be initiated. Duloxetine inhibits CYP450 2D6, which is currently not an issue but should be taken into consideration if other medication changes are considered in the future.

Summary

Depressive episodes have a significant morbidity impact and can result in mortality, usually via suicide. Treatment has been shown to reduce acute impact and prevent future episodes. All antidepressants are considered generally equal in regard to efficacy. Comorbid drug–disease and drug–drug interactions help identify best first-choice options. Overall, SSRIs are considered the best first choice because of good tolerability, safety in overdose, and low cost. Of these, sertraline and escitalopram may have a slight advantage. Previous treatment successes or failures and family history of medication response are important determining factors when disease and drug issues are not present. Minimal treatment duration should be 6 months after remission has been achieved, although many patients will require lifelong pharmacotherapy. Patient

education and safety monitoring are critical aspects once the patient enters into treatment. Outcomes for treatment are predictably beneficial with improvements in quality of life and a reduction of suicidal events.

Bipolar Disorders

Megan J. Ehret and Charles F. Caley

CORE PRINCIPLES		CHAPTER CASES
1	Bipolar disorder is a chronic progressive illness that occurs in ~6% of the population. It is characterized by recurrent mood episodes of mania and depression. Life stressors, substance use, treatment nonadherence, and medications are common precipitants of these mood episodes.	**Case 87-1 (Questions 1–3)**
2	Manic episodes are characterized by elevated mood, irritability, increased goal-directed activity, inflated self-esteem, poor judgment, and excessive motor activity.	**Case 87-1 (Question 1)** **Case 87-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
3	Depressive episodes of bipolar share the same diagnostic criteria as major depressive disorder, including depressed mood, decreased interest, feelings of worthlessness, diminished ability to concentrate, and recurrent thoughts of death.	**Case 87-7 (Question 1)**
4	Valproate, lithium, or select atypical antipsychotics are appropriate first-line treatments for acute mania. Depending on the severity of symptoms, these agents may be used alone or in combination.	**Case 87-1 (Questions 4, 5)** **Case 87-2 (Question 1)** **Case 87-5 (Question 2)** **Case 87-6 (Question 1)**
5	Lithium, lamotrigine, quetiapine, lurasidone, or the combination of these agents is appropriate treatment for bipolar depression.	**Case 87-7 (Question 1)**
6	Maintenance treatment of bipolar disorder is imperative to prevent disease progression. The standard of practice is to continue the acute-phase treatment with gradual simplification toward monotherapy, if possible, with lithium, lamotrigine, valproate, or atypical antipsychotics.	**Case 87-5 (Question 1)** **Case 87-8 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
7	Medications used to treat bipolar disorder have a wide range of adverse effects that may impact adherence. The history of response, patient preference, and long-term tolerability profile are important considerations when selecting an agent. Therapeutic blood level monitoring, as well as laboratory monitoring for adverse effects, is commonly required for certain medications.	**Case 87-1 (Questions 6–8)** **Case 87-2 (Questions 1–8)** **Case 87-3 (Question 1)** **Case 87-4 (Questions 1, 2)**
8	Nonpharmacologic treatments including electroconvulsive therapy (ECT) and herbal supplements are important considerations for the treatment of bipolar disorder.	**Case 87-8 (Questions 3, 4)**

INTRODUCTION

Bipolar disorder (BD), once known as manic depression, is a severe life-threatening psychiatric condition that is commonly misdiagnosed and too often insufficiently treated.[1,2] BD is associated with high rates of health care utilization, suicidal behavior, and use of public assistance.[3] The global burden of BD is immense, exceeding many chronic diseases including human immunodeficiency virus, diabetes mellitus, and asthma.[4]

Epidemiology

Using *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition *(DSM-5)* criteria, the lifetime prevalence of bipolar I disorder is estimated to be 2.1%; bipolar II disorder is marginally less common at 0.8%.[5,6] The prevalence rate for other specified bipolar and related disorders (OSBARD) is 3%.[6] There is an equal distribution between males and females in bipolar I disorder, but the prevalence of bipolar II disorder is higher in females.[5] The familial nature of BD has been well established with an 11-fold increased risk in first-degree relatives.[7] Twin studies add further support to the genetic linkage. Goodwin and Jamison reported a 63% concordance rate (rate of illness in co-twin of affected proband) for monozygotic twins compared with 13% for dizygotic twins.[7]

The estimated total U.S. economic burden of BD between 2008 and 2018 was reported to be $195 billion.[8] Direct costs, such as hospitalization, outpatient visits, and medications, accounted for 25% of the total. The remaining 75% was attributable to indirect costs such as lost productivity by patients and caregivers.

The mean age of onset of symptoms for the bipolar spectrum of illnesses is 21 years.[6] Bipolar I is the earliest in onset at age 18, compared with bipolar II at age 20.[6] Approximately 20% to 30% of new cases occur in children between 10 and 15 years old.[9,10] Late-life onset of BD is rare. After age 60, there is a sharp reduction in the new onset of BD; therefore, a presentation of mania at this age should alert the clinician to an underlying medical problem as the possible cause.[11]

Patients may present initially with any affective episode, but it is important to note that 75% of patients report having had multiple episodes of depression before the development of a manic episode.[9] Not surprisingly, misdiagnosis (primarily as major depressive disorder) is common, occurring in roughly 70% of patients.[9] By some accounts, one in four patients visit as many as five physicians before an accurate diagnosis is made. A significant contribution to misdiagnosis is the underreporting of manic symptoms, which may not considered to be particularly problematic by patients.[9]

BD is a recurrent illness; single episodes of mania, unrelated to BD, occur in fewer than 10%.[12] Most patients with BD suffer multiple

episodes of mania, hypomania, or depression separated by periods of euthymia (stable mood) throughout the course of their lives. In the majority, mania occurs just before or immediately after a depressive episode.[12] There may be a 5- to 10-year period from the onset of illness until the first hospitalization or diagnosis of BD.[11]

The course of illness is characterized by the type of episode(s), duration of euthymic intervals, frequency of relapse, severity of episodes, and predominant syndrome (mania, hypomania, or depression). These factors do not remain fixed throughout an individual's illness. For instance, individuals may experience episodes of dysphoria and depression before even experiencing hypomania or mania. Often, the euthymic interval and cycle length decrease with additional episodes. With time, a course of alternating recurrent depression interspersed with manic or hypomanic episodes and no intervening euthymic periods can develop.

A specifier of BD, termed "rapid cycling," occurs in both bipolar I and bipolar II disorder and is defined as a patient experiencing four or more separate mood episodes per year. Rapid cycling is common, occurring with a lifetime prevalence of 25.8% to 43%; females are more often affected than males.[13] Rapid cycling of BD is often refractory to conventional treatment and carries significant morbidity and mortality because of rapid changes in mood states.

The prognosis, even for treated BD, is concerning, with 73% experiencing a recurrent mood episode within 5 years. Furthermore, nearly half of patients continue to have significant mood symptoms between episodes, whereas <20% are euthymic or have minimal symptoms.[14]

Pathophysiology

BD is a complex disease involving developmental, genetic, neurobiologic, and psychological factors.[15] Neuroimaging studies have demonstrated neurochemical, anatomic, and functional abnormalities in those with a diagnosis of BD.[16] Recent studies have demonstrated that altered synaptic and circuit functioning accounts

for mood and cognitive changes rather than the previous theory of dysfunction of individual neurotransmitters.[17] Environmental, or psychosocial, stressors, immunologic factors, and sleep dysfunction have been associated with BD and can negatively influence the course of illness.[18–22]

Clinical Presentation

A manic episode usually begins with a change in sleep patterns along with mood elevation. Presenting symptoms include talkativeness, decreased need for sleep, and bursts of energy during which projects are begun but rarely completed. Mania is often characterized by thought disturbances exhibited by “flight of ideas” (rapid speech that switches among multiple ideas or topics) and grandiose delusions (false beliefs of wealth, special powers, knowledge, abilities, importance, or identity). The behavior of patients with mania is characterized as being impulsive, intrusive, loud, intense, irritable, at times suspicious, and even challenging. Patients often exercise poor judgment, which may include spending large sums of money in business deals that ultimately fail, becoming sexually promiscuous, using substances of abuse, or failing to obey laws.

The symptoms of mania usually develop gradually over the course of several days to more than a week and are defined in three stages.[23] Stage I is characterized by euphoria, irritability, labile affect, grandiosity, overconfidence, racing thoughts, increased psychomotor activity, and an increase in the rate and amount of speech. This stage corresponds to hypomania. Stage II features increased dysphoria (a feeling of extreme discomfort and unrest), hostility, anger, delusions, and disorganized thinking. This stage corresponds to acute mania. Stage III, in which the manic episode progresses to an undifferentiated psychotic state, only occurs in some patients. Individuals in stage III experience terror and panic, their behavior is bizarre, and psychomotor activity is frenzied. They may experience hallucinations, disorganized thoughts become incoherent, and

disorientation to time and place occurs. Just as the manic episode gradually builds, it often declines in a gradual manner. Psychotic symptoms usually resolve first, whereas irritability, paranoia, and excessive behavior persist. Remaining symptoms such as talkativeness, seductiveness, and dysphoria slowly decrease with time.

Depressive episodes of BD share the diagnostic criteria with unipolar depression; however, the presentation of bipolar depression has some distinguishing features. In particular, bipolar depression (type I specifically) is more likely to be associated with mood lability, psychotic features, psychomotor retardation, and comorbid substance use.[24] This contrasts with unipolar depression, which is more likely to be associated with anxiety, agitation, insomnia, somatic symptoms, and weight loss.[24]

Mixed features appear to be common and could represent a more severe phase of bipolar illness. These episodes have been associated with a younger age of onset, more frequent occurrence of psychotic symptoms, major risk for suicide, higher rate of comorbidities, and longer time to achieve remission.[25–27]

Patients with BD have higher rates of mortality from both natural and unnatural causes. Higher rates of natural deaths largely result from cardiovascular disease, in which mortality has been estimated to be twice as frequent as the general population.[28–31] Rates of cerebrovascular disease, coronary heart disease/acute myocardial infarction, and cardiac arrest/ventricular fibrillation are all estimated to be increased in patients with BD.[31] Suicide (more likely during depressive and mixed features) and excessive risk-taking behaviors (more likely to occur during manic or hypomanic episodes) also contribute to the high mortality rate. Suicidal behavior is a complex issue that likely depends on both environmental circumstances and risk factors inherent to BD, and current evidence regarding suicide risk is likely confounded by multiple risk factors.[32] Lifetime risk for an attempted suicide is reported to occur in as many as 25% to 50% of patients with BD, whereas the lifetime risk of a completed suicide may be as high as 17% to 19%.[33] The most rigorously determined estimate for suicide death in BD reports rates of 7.8% in males and

4.8% in females.[34] Previous suicide attempts and the presence of hopelessness are primary risk factors for dying from suicide.[35] Fortunately, overall mortality as well as deaths owing to suicide or cardiovascular disease are significantly reduced when BD is adequately treated.[14]

Approximately 61% of patients with BD type 1 have a lifetime prevalence of comorbid substance use disorders.[36] Comorbid alcohol use in BD is estimated at 50%, whereas comorbid cannabis use is estimated at 30%.[37,38] Those with rapid cycling and dysphoric mania have the highest rates of substance use.[39] The best treatment outcome is achieved with aggressive simultaneous management of both BD and the concurrent substance use disorder.

Individuals with BD are likely to experience stress and upheaval in many areas of their lives, including relationships, employment, and finances. Of patients with BD, 88% have been hospitalized once and 66% at least two times.[40] Divorce rates in those with BD are two- to threefold higher than those found in nonaffected populations. Patients often report having poor relationships with family members, and nearly 75% report that their family members have a limited understanding of BD.[9] Employment problems may result from bizarre, inappropriate, or unreliable behavior. In one study, 60% of patients reported being unemployed, 88% felt the disease affected how well they performed at work, and 63% felt that they were treated differently from their peers.[9] Financial and legal problems are tied to excessive spending, involvement in schemes, substance abuse, and risk-taking behavior.

Diagnosis

Mood disorders are diagnosed using the criteria established in the *DSM-5*.[12] Discrete periods of mood disturbance associated with BD are defined as manic episodes, hypomanic episodes, or major depressive episodes with various specifiers including mixed features and rapid cycling. Although mania and hypomania are the distinguishing features of BD, depression is the mood episode that

predominates and is ordinarily the initial presenting symptom.[41,42] Depressive episodes in BD share the same criteria with major depressive disorder (see Chapter 86, Depressive Disorders).[12]

A person who has experienced one or more manic episodes with or without a depressive episode is diagnosed as having bipolar I disorder. An individual who has experienced one or more episodes of both hypomania and depression (without a history of manic episodes) is diagnosed as having bipolar II disorder.[12]

The *DSM-5* also uses a series of descriptors called specifiers to further characterize the course of illness and the most recent type of episode experienced by the individual. Recent episodes are first classified as hypomanic, manic, or depressed. A mixed specifier is diagnosed when a patient meets criteria for either manic or hypomanic episode with at least three depressive symptoms being present during the current or most recent episode of mania or hypomania, or when a patient meets criteria for depressive episode with at least three manic or hypomanic symptoms being present during the current or most recent episode of depression.[12] The rapid cycling specifier applies to those who experience at least four mood episodes in the previous 12 months that meet criteria for manic, hypomanic, or major depressive episode.[12]

Overview of Treatment

The goals of treatment across the phases of BD illness are numerous, including the control of acute symptoms, achieving symptomatic remission, returning to a normal level of functioning, prevention of relapses, and prevention of suicide.[11] Both the acute treatment of manic and depressive episodes and the maintenance treatment for prevention of future episodes require individualization of therapy. Treatment decisions should consider presenting symptoms, medication history, patient preference, and comorbid medical or substance use conditions.

During the previous 15 to 20 years, several treatment guidelines have been published. The most recent guidelines were published

jointly by the Canadian Network for Mood and Anxiety Treatments (CANMAT) and the International Society for Bipolar Disorders (ISBD).[43,44] The reader is advised that published efficacy research is categorized by bipolar type (I vs II), mood episode (manic vs mixed vs depressed), and treatment phase (acute vs maintenance). As such, treatment guidelines may reflect these specifiers. Additionally, there is often an uneven amount of published evidence supporting treatment recommendations in these different clinical categories.

Initial treatment for acute hypomanic or manic episodes should be with one of the well-established antimanic agents such as lithium, valproate (VPA), or one of several atypical antipsychotics (AAPs). The recent CANMAT/ISBD guidelines recommend quetiapine, asenapine, aripiprazole, paliperidone (>6 mg), risperidone, or cariprazine as first-line atypical antipsychotic treatments for acute mania.[43] During episodes of mania, short-term adjunctive use of a benzodiazepine is often useful to reduce agitation and promote sleep.[11] Agitation related to acute mania may also be treated with intramuscular injections of olanzapine or inhaled loxapine.[43,44] In the case of severe manic symptoms or partial response to an adequate trial of monotherapy (generally 1–2 weeks), a two-drug combination of lithium, valproate, or an AAP is recommended.[45] Carbamazepine (CBZ) and a typical antipsychotic, alone or in combination with a preferred antimanic drug, are potential alternatives. For treatment-resistant cases, electroconvulsive therapy (ECT), clozapine, and a three-drug combination of lithium plus an anticonvulsant (CBZ or VPA) plus an AAP are recommended. When drug combinations are used, the individual agents should be from different medication classes. Lamotrigine, gabapentin, eslicarbazepine/licarbazepine, topiramate, and zonisamide are not recommended for the treatment of acute mania.[43,44]

In the case of acute mixed features, VPA or an AAP is preferred over lithium because of lithium's poor efficacy. If monotherapy with VPA or an AAP is ineffective or undesirable, then a combination of the two is advised. Asenapine, aripiprazole, olanzapine, and ziprasidone have each demonstrated efficacy in treating mixed features.[43,44]

Medications for the treatment of bipolar depression ideally produce an acute antidepressant response and prevent future depressive episodes, all while not inducing mania or mood cycling. Long-term tolerability is critical because of the chronic recurrent nature of depressive episodes in BD. First-line treatment options vary based on the chosen guideline, but it includes choices of lithium, lamotrigine, lurasidone, olanzapine, or quetiapine monotherapy, or lithium or valproic acid, or olanzapine with a selective serotonin reuptake inhibitor (SSRI), lithium plus valproic acid, or lithium or valproic acid plus bupropion.[46–51] Subsequent treatment trials again vary on guideline, but include different combinations of the above choices. Additional options include adjunctive modafinil or other antidepressants. Third-line treatment includes carbamazepine, ECT, or lithium plus pramipexole or a monoamine oxidase inhibitor (MAOI), or a tricyclic antidepressant (TCA). Readers are referred to individual guidelines for complete details.

Maintenance treatment of BD should include continuing the acute mania treatment while periodically simplifying and moving toward monotherapy.[43,44] Many AAPs are effective in maintenance treatment of BD; however, they must be used cautiously because of the long-term risk of metabolic and neurologic complications.[47] Regardless of the regimen selected, medication adherence is critical to long-term recovery. Patients and caregivers must be actively engaged in discussing causes of nonadherence, including ambivalence, adverse effects, lack of insight, and a strong desire to re-achieve the experience of euphoria and energy of a manic episode.[11] Patients should also be advised to maintain regular patterns of daily activities, a consistent sleep–wake cycle, meals, exercise routines, and other schedules to promote stability.

CLINICAL ASSESSMENT

Clinical Presentation and Diagnosis

CASE 87-1

QUESTION 1: T.R. is a 25-year-old male, accompanied to the clinic by his wife, A.R., who reported much of the following information. T.R. states that he was doing well until about 3 weeks ago, when he returned home from a crab fishing trip. Given the stress of the job, he borrowed some "nerve pills" from his fellow co-worker. Since then, T.R. has been acting increasingly "wild." He has been staying up later at night and often bursts into the bedroom at 2 or 3 AM and loudly awakens A.R. Sometimes, he presents her with expensive gifts, which they cannot afford. He often jumps on the bed and starts singing her love songs in a loud voice. A.R. notes that T.R. then almost always demands sex, after which he sleeps for 2 to 3 hours and then loudly gets up and leaves the house.

During the last several weeks, he drove his car recklessly and well beyond the speed limit. The police have pulled him over several times and given him multiple tickets for speeding, running red lights, and passing on double yellow lines. Last week, when his boss called to express concern about his behavior, T.R. said he was quitting his job. He wrote a rambling, disorganized resignation note, which was 10 pages long, called an overnight air delivery service to send the note to his employer (who is located only 3 miles from his home), and then left the house before the driver arrived to pick it up. T.R. returned several hours later with a brand-new car and wearing an expensive new suit, red cowboy boots, and a bright green hat with a large feather. He told A.R. that he had a new job, which was going to make him a millionaire. Last night, she found a large sum of money in his pants pocket when emptying the clothes hamper. He did not come home at all, but he called her at 4 AM to tell her to pack for Dallas, where he was going to become the new head coach of the professional football team.

On arriving at the clinic, T.R. insists, "I don't need no doc. I am supercalifragilistic!" He then bursts into song. He is dressed flamboyantly but needs a shave and shower. He gives the examiner (a stranger) a bear hug and has trouble sitting still, listening, or allowing others to talk. His speech is pressured and loud; he often fails to complete sentences or communicate entire ideas, and he is rhyming and punning. His mood is elevated, but he becomes increasingly irritable throughout the examination. He is oriented to person and place, but thinks it is tomorrow. Intelligence seems average. When asked to interpret a proverb, T.R. becomes angry and throws a chair across the room.

How is T.R.'s presentation consistent with the diagnosis of a manic episode?

The hallmark of a manic episode is changes in mood, behavior, cognition, and perception (**Table 87-1**).[23] T.R. demonstrates an elevated mood. He is exuberant and notes how great he feels. Nevertheless, patients with mania often demonstrate lability in their mood, and they may become irritable and easily frustrated,

especially when challenged. In this case, T.R. becomes irritable and resentful when questioned by the examiner. His quick displays of anger further demonstrate the volatility of his mood.

Table 87-1
***DSM-5* Criteria for a Manic Episode**

Manic Episode
A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).[a]
B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior: 1. Inflated self-esteem or grandiosity 2. Decreased need for sleep (eg, feels rested after only 3 hours of sleep) 3. More talkative than usual or pressure to keep talking 4. Flight of ideas or subjective experience that thoughts are racing 5. Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (ie, purposeless non-goal-directed activity) 7. Excessive involvement in activities that have a high potential for painful consequences (eg, engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
D. The episode is not attributable to the physiologic effects of a substance (eg, a drug of abuse, a medication, other treatment) or to another medical condition.
Note: A full manic episode that emerges during antidepressant treatment (eg, medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiologic effect of that treatment is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.
Note: Criteria A-D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

[a]Criteria for a hypomanic episode are identical to a manic episode; however, the symptoms need only to be present for 4 days and are not severe enough to cause marked impairment in social or occupational functioning, necessitate hospitalization, or for psychotic features to be present.

Manic-like or hypomanic-like episodes that are clearly caused by somatic antidepressant treatment (eg, medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar disorder.

T.R. displays behavior and speech typical of acute mania. He has a reduced need for sleep, behaves recklessly, and is overactive. His speech is pressured, loud, and full of rhymes and puns, and he sings to express his emotions and skips from topic to topic reflecting a flight of ideas. T.R. dresses flamboyantly, hugs his examiner, writes an unnecessarily lengthy letter of resignation, seeks an overnight courier service for local delivery, and presents his wife with lavish gifts.

Delusions are often present in acute mania and are grandiose or religious in nature and deal with inflated abilities, self-importance, wealth, or special missions in life. T.R. makes unrealistic comments about his money-making schemes, his singing ability, and his position as the coach of a professional football team.

Patients with acute mania are often disorganized and do not complete tasks. They tend to skip from idea to idea and scheme to scheme. In this case, T.R. neglects his hygiene and neglects sending out his resignation letter.

Precipitating Factors

Case 87-1, Question 2: What factors make T.R. vulnerable to the occurrence of a manic episode at this time?

T.R. is at an age where his disorder would likely first manifest itself. In addition, manic episodes are often precipitated by

psychosocial and recurring life stressors in those who are vulnerable to developing BD.[7] Working long hours with reduced sleep may have served as a contributing factor for the manic episode.

A variety of medications and clinical states can induce or precipitate manic episodes (**Table 87-2**).[52–73] The drugs that most commonly precipitate mania affect monoamine neurotransmitters, such as antidepressants and stimulants.[52] Corticosteroids, anabolic steroids, isoniazid, levodopa, caffeine, and over-the-counter stimulants can induce or aggravate mania.

Table 87-2
Selected Drugs Reported to Induce Mania

Anticonvulsants	Gabapentin, lamotrigine, topiramate
Antidepressants	MAOIs, TCAs, SSRIs, SNRIs, bupropion, nefazodone, trazodone, mirtazapine, vortioxetine
Antimicrobials	Clarithromycin, ofloxacin, cotrimoxazole, erythromycin, isoniazid, metronidazole, zidovudine, efavirenz
Antiparkinsonian drugs	Levodopa, amantadine, bromocriptine
Anxiolytics/hypnotics	Buspirone, alprazolam, triazolam
Atypical antipsychotics	Aripiprazole, olanzapine, quetiapine, risperidone, ziprasidone
CNS stimulants	Caffeine, cocaine, methylphenidate, amphetamine
Drugs of abuse	Marijuana, PCP, LSD
Endocrine	Corticosteroids, thyroid supplements, androgens
Herbals	Saint-John's-wort, SAMe, ma-huang, omega-3 fatty acids, tryptophan
Sympathomimetics	Ephedrine, phenylpropanolamine, pseudoephedrine, phenylephrine
Miscellaneous	Cimetidine, tramadol, sibutramine

CNS, central nervous system; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; PCP, phencyclidine; SAMe, *S*-adenosyl-L-methionine; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Source: See references 53-74.

Case 87-1, Question 3: If the "nerve pills" borrowed by T.R. were antidepressants, could they have contributed to the development of his manic episode?

Antidepressants are commonly prescribed for patients with bipolar depression (35%–40%).[46] Their use is controversial though with criticisms that they lack efficacy or that they destabilize mood and can cause a switch to mania. All of the major classes of antidepressants including monoamine oxidase inhibitors, tricyclic antidepressants (TCAs), SSRIs, and serotonin and norepinephrine reuptake inhibitors (SNRIs) have been associated with precipitating mania in patients with BD.[5] Despite this risk, up to 50% of patients with BD are treated with antidepressants of which only half are receiving a concurrent mood stabilizer.[74] There are numerous case reports of mania or hypomania with antidepressant treatment, but few controlled studies, making it difficult to make comparisons across antidepressant classes.[75] See Case 87-7 for complete details of the use of antidepressants in bipolar depression.

A meta-analysis found a higher "switch" to mania rate for TCAs (11%) than for SSRIs (4%).[76] A controlled trial with bupropion, sertraline, and venlafaxine (all in combination with a mood stabilizer) found an overall switch rate of 19% during acute treatment and 37% during the continuation phase of the study with no difference among agents.[77] Antidepressants may also cause cycle acceleration, which effectively decreases the time between mood episodes. The risk for cycle acceleration may be heightened for patients who experience manic or hypomanic symptoms on antidepressants despite receiving antimanic treatment concurrently.[78] Other recent literature has suggested that adjunctive antidepressants to mood stabilizers versus placebo are not associated with an increased efficacy or with increased risks of treatment-emergent affective switches.[79] In the case of T.R., an antidepressant may have precipitated the manic episode or shortened his cycle, moving him into an episode of mania from a preexisting state of depression or euthymia.[80] Any patient presenting with an acute manic episode should have a review of

medications completed to determine the risk of continuing antidepressant medications.[33]

Current guidelines state that the dual-action monoamine reuptake inhibitors carry a greater risk of precipitating a switch to mania than single-action drugs.[43,44] Additionally, they state that antidepressant medications appear unlikely to induce mania when used in combination with a drug effective for manic symptoms.[46]

TREATMENT OF ACUTE MANIA

Case 87-1, Question 4: Why does T.R. require treatment?

Manic episodes have a number of severe complications. Left untreated, severe mania can result in confusion, fever, exhaustion, and even death. The impairment in judgment, the excesses, and the risk-taking that occur during manic episodes may be devastating. Detriments to relationships, careers, and finances and physical harm or loss of life may occur. Individuals with mania may also engage in illegal activities. T.R. drives recklessly; may have lost his job; spends excessive amounts of money on gifts, clothing, and automobiles; and plans to participate in a variety of money-making schemes. He has acquired a great deal of cash suddenly, perhaps from withdrawing all of his family's savings or from some type of illegal enterprise. Patients with mania may engage in risky sexual encounters, leading to infection with sexually transmitted diseases including human immunodeficiency virus. Alcohol and substance abuse are common and may exacerbate or even precipitate mood episodes. Irritability, such as that demonstrated by T.R., can lead to episodes of violence, resulting in potential harm to the patient or to others. The goals of treatment are to reduce the severity and duration of the current mood episode and to prevent recurrence of future episodes.

Valproate (Divalproex Sodium, Valproic Acid)

Case 87-1, Question 5: What is the appropriate treatment for T.R.'s acute manic episode?

Depending on the type and severity of mania, first-line treatment involves selecting from lithium, VPA, select AAPs, or a combination of these agents.[43–49] If psychosis is present, an AAP would be an appropriate choice either as monotherapy or in combination with a mood stabilizer. VPA is an ideal choice for T.R. considering the rapid onset, tolerability, and the established efficacy of this agent for preventing future mood episodes.[81–83]

DOSING AND MONITORING

Case 87-1, Question 6: VPA was chosen for the management of T.R.'s mania. How should VPA be initiated, and what baseline tests are necessary? How will T.R.'s response to therapy be monitored?

The initial dose of VPA for T.R. should be 250 mg three times per day.[11] The dose should then be increased by 250 to 500 mg every 2 to 3 days to achieve steady-state serum VPA levels between 50 and 125 µg/mL, or a maximum dosage of 60 mg/kg/day.[84] An alternative strategy is to use an oral loading dose regimen of 20 to 30 mg/kg/day given on a three times a day schedule during the acute manic episode. This approach has been used during inpatient management and may result in a more rapid onset of effect.[85] Although VPA levels of 50 µg/mL are the minimum threshold, higher concentrations offer greater benefit. Serum concentrations >84 µg/mL by the third day of treatment may have greater early symptom improvement.[86] A pooled analysis demonstrated a linear relationship between serum concentration and efficacy with the greatest improvement found in patients with VPA levels in excess of 94 µg/mL.[87] VPA levels >125 µg/mL are more often associated with side effects and should be avoided.[81]

Before VPA is initiated, baseline laboratory tests, including a complete blood count (CBC) with differential and platelets, and liver

function tests should be measured. T.R.'s baseline weight and neurologic status should be recorded. In premenopausal females who have not undergone surgical sterilization, a baseline pregnancy test is warranted because VPA is a known teratogen. Attention should be given to any medications that might be administered concurrently. Interactions with aspirin, lorazepam, phenytoin, phenobarbital, lamotrigine, rifampin, warfarin, felbamate, and CBZ are cited frequently (also see Chapter 60, Seizure Disorders).

VPA should decrease the severity and duration of T.R.'s current manic episode, decrease the frequency of subsequent episodes, and increase his time spent in a euthymic state. Once treatment has started, T.R. should be monitored for response of his initial target symptoms, including grandiosity, decreased need for sleep, pressured speech, distractibility, and impulsivity. Initial symptom improvement with VPA can be expected in ~5 days.[87]

Side effects

Case 87-1, Question 7: What are the potential side effects of VPA therapy? How should T.R. be monitored for these possible effects?

T.R. should be monitored for dose-related adverse reactions of VPA, including various gastrointestinal symptoms (nausea, diarrhea, dyspepsia, anorexia), sedation, ataxia, tremor, transaminase elevations, and thrombocytopenia. Dose reduction, changing to an extended-release preparation,[88] or administering an antacid or histamine H_2-antagonist may mitigate gastrointestinal symptoms. Central nervous system effects such as ataxia and sedation may respond to dose reduction, although sedation may resolve with continued treatment. If a tremor is bothersome or interferes with the patient's functioning, a dose reduction or change to the extended-release preparation may provide relief.[84] Small elevations in transaminases are considered benign; however, VPA should be discontinued if elevations are more than two to three times the upper limit of normal.[89]

Weight gain occurs in up to 20% of patients receiving VPA.[81] The increase in body weight is particularly distressing to some patients and may contribute to medication nonadherence. Weight gain has been associated with VPA at different concentrations, so a dosage reduction may not be helpful.[81,90] In females, VPA has been associated with the development of polycystic ovary syndrome.[91] Core features of polycystic ovary syndrome include oligomenorrhea and hyperandrogenism, which develop in about 10% of females with BD taking VPA. Alopecia occurs in 0.5% to 12% of patients and may improve with dose reduction.[92]

There are several reports of VPA-induced hyperammonemic encephalopathy.[93,94] Patients presenting with mental status changes or coma should have serum ammonia and liver functions tests ordered. If VPA-induced hyperammonemic encephalopathy is suspected, then VPA should be discontinued. Other serious adverse events with VPA include fulminant hepatic failure, agranulocytosis, and pancreatitis. All of these adverse events require immediate discontinuation of therapy.

In January 2008, the U.S. Food and Drug Administration (FDA) issued a warning to health care professionals about the potential for an increased risk of suicidality associated with antiepileptic drugs (AEDs), including VPA. For its analysis, FDA used data from 199 randomized clinical trials of 11 AEDs involving 43,892 study participants with either psychiatric or neurologic disorders. In the “Warnings and Precautions” section of AED product labels, it is stated that the risk of suicidality for those treated with AEDs during clinical trials was approximately twice that of placebo treatment (0.43% vs 0.24%; adjusted relative risk = 1.8, 95% CI = 1.2, 2.7; number needed to harm = 530). In these clinical trials, there were a total of four suicides in AED-treated patients and zero suicides in placebo-treated patients. As a result, practitioners are advised to inform patients and caregivers to be vigilant about the emergence or worsening of signs and symptoms of depression or mood/behavior changes, especially if they involve thoughts or behaviors centered on self-harm when patients receive AED treatment.[95]

Once VPA therapy is initiated, liver function tests, VPA serum levels, and CBCs with differential and platelets should be monitored at least monthly for the first 3 months and every 3 to 6 months thereafter.[11] Body weight should also be determined at baseline and monitored monthly during therapy.

Case 87-1, Question 8: T.R. was titrated to a total daily VPA dosage of 2500 mg/day and determined to have a steady-state plasma concentration of 95 µg/mL after 1 month of treatment. A routine CBC with differential and platelet count was ordered at this time, and the following data were reported:

Red blood cells, 5.2 × 106/µL
Hemoglobin, 14.5 g/dL
Hematocrit, 43%
White blood cell count, 8.5 × 103/µL
Neutrophils, 59%
Lymphocytes, 27%
Monocytes, 6%
Eosinophils, 2%
Basophils, 0.5%
Platelets, 75 × 10^3/µL

How should T.R.'s VPA-induced thrombocytopenia be managed?

VPA-induced thrombocytopenia occurs in 18% of patients and is associated with female gender and higher VPA levels (>100 µg/mL in females and >130 µg/mL in males).[96] Clinicians should educate patients to look for signs such as easy bruising or bleeding. In most patients, thrombocytopenia is asymptomatic and responds to a lowering of the VPA dosage; complete discontinuation of the drug is usually unnecessary.[97] T.R.'s dosage should be reduced, and his platelet count should be monitored closely. In addition, he should be observed for reemerging symptoms of mania.

LITHIUM

Prelithium workup

CASE 87-2

QUESTION 1: C.N., a 21-year-old female, was diagnosed with her first episode of mania 3 weeks ago. At that time, she was hospitalized and treated with olanzapine 15 mg daily. C.N. was stabilized, and after 10 days, she was discharged from the hospital. She was scheduled to see an outpatient psychiatrist for follow-up 1 week later, but she failed to keep the appointment. Today, C.N. arrives at the emergency department at the request of her mother. C.N. is grabbing her mother's hair and kicking wildly as she is pulled from the car. She can be heard screaming "The FBI is after me, Mom! You want them to find me, don't you? I would have made it out of the country if you hadn't gotten in the way! I was going to marry Prince Charles and become the new queen of England." On evaluation, C.N.'s mood is irritable, and she is pacing around the interviewer. She is dressed in a short skirt and high heels and is wearing an excessive amount of makeup and costume jewelry. During the interview, she interrupts the examiner, smiles, and says in a loud, provocative voice, "Let's you and me get out of here!" Her mother states that after C.N. was discharged from the hospital, she stopped taking her olanzapine because of gaining some weight and, within several days, stopped attending her classes at the local community college. She began staying out late, playing her radio loudly, and driving recklessly, finally hitting the side of the garage while parking early this morning. The clinician would like to admit C.N. to the inpatient unit and initiate lithium treatment.

What laboratory tests are required before initiating lithium therapy for C.N.?

Because lithium can affect many organ systems, baseline laboratory values must be evaluated before therapy is initiated. Baseline laboratory tests are useful in determining contraindications to the use of lithium or conditions that may require an adjustment in dosage. As a young, healthy female, C.N.'s prescreening laboratory battery should include electrolytes, blood urea nitrogen, creatinine, urine specific gravity, thyroid-stimulating hormone (TSH), thyroxine (T_4), and a CBC (**Table 87-3**). A serum human chorionic gonadotropin pregnancy test should also be obtained before starting therapy because lithium is a known teratogen.

Table 87-3
Routine Monitoring During Lithium Therapy

	Baseline	Every 1–3 Months	Yearly
CBC	X		
Electrolytes	X		X

[a]Monitor more often in patients with history of kidney disease.

[b]Patients 45 years or older, or those with history of cardiac disease.

[c]Weekly monitoring during the first month of treatment is often recommended.

[d]Females of childbearing potential.

Dosing

Case 87-2, Question 2: C.N.'s baseline laboratory parameters were normal, and her pregnancy test was negative. How should lithium treatment for C.N. be initiated?

Although there are many strategies for calculating lithium dosage requirements, it is simplest to begin C.N. at a dosage of 300 mg twice daily. This is a common starting dose for a healthy adult patient.

Patients experiencing an acute manic episode require higher lithium levels compared with maintenance therapy. The goal for the acute management of C.N. is a serum level between 0.8 and 1.2 mEq/L.[11] Because lithium is not immediately effective, C.N.'s lithium dosage can be adjusted based on the results of lithium serum levels

checked weekly until the manic episode resolves. As she recovers and enters the maintenance phase of treatment, both C.N.'s lithium dosage and her lithium levels will require re-evaluation (see Case 87-8, Question 1).

Case 87-2, Question 3: How long will it take for C.N. to get the full effect of lithium?

The half-life of lithium in a young patient with normal renal function is approximately 24 hours; therefore, steady-state concentrations are typically achieved in approximately 5 days. The onset of action is slow, taking as long as 1 to 2 weeks to fully exert therapeutic effects.[11] Because of the delay in onset, it is appropriate to use an adjunctive medication to help reduce C.N.'s acute symptoms. Both benzodiazepines and antipsychotics are used.[11] AAPs are preferred over typical antipsychotics (see also Chapter 85, Schizophrenia) and have been demonstrated to enhance efficacy and accelerate time to response when used in combination with lithium in acute mania.[47] Benzodiazepines work rapidly to reduce agitation, anxiety, and decreased need for sleep.[98]

Adverse effects

Case 87-2, Question 4: After 3 weeks of lithium therapy, C.N. is demonstrating significant improvement in her sleep, impulsivity, delusions, and activity level. She has achieved a lithium carbonate dose of 1200 mg/day, and her lithium level is 0.8 mEq/L. Today she describes to the clinical staff a fine hand tremor she has developed. Soon after her clinician arrives to evaluate her, C.N. asks to be excused so that she can go to the bathroom. How might C.N.'s presentation be related to her medication?

When considering adverse effect management early in lithium therapy, it becomes important to monitor lithium levels closely. When patients start to recover from acute mania, the rate of lithium clearance may decrease and patients may demonstrate an increase in lithium levels and worsening side effects (**Table 87-4**). This does

not seem to be the case with C.N. because her lithium level is within the accepted range for the management of acute mania.

Table 87-4
Lithium Adverse Effects

Adverse Effect	Considerations
ECG changes	T-wave suppression, delayed or irregular rhythm, increase in PVCs; SSNS; myocarditis
Edema	Primarily ankles and feet; transient or intermittent; secondary to effects on sodium and carbohydrate metabolism; caution about diuretics and sodium restriction to avoid lithium toxicity
Dermatologic	Acne worsens; psoriasis worsens; maculopapular/follicular rashes possible
Hypothyroidism	About 5% goiter; about 30% clinically significant hypothyroidism; may diminish sex drive
Teratogenicity	Ebstein anomaly (tricuspid valve malformation, atrial septal defect); educate female patients, encourage advanced planning regarding pregnancy
Anorexia, nausea (10%–30%)	Usually early in treatment and usually transient; may be early sign of toxicity
Diarrhea (5%–20%)	Slow-release preparations may help
Tremor (10%–65%)	Dose-related; males more than females; worse with antidepressants and antipsychotics; reduce dose or use β-blocker
Cognitive disruption (10%)	Worsens compliance; perceived as “mental dulling”
Fatigue or weakness	May be early toxicity; may mimic depression
Polyuria–polydipsia (nephrogenic diabetes insipidus)	May be an indication of morphologic changes; requires adequate hydration

CBZ, carbamazepine; ECG, electrocardiogram; PVC, premature ventricular contraction; SSNS, sick sinus node syndrome.

CN describes a hand tremor. She should be interviewed and examined to determine its origin. Lithium-induced tremor occurs in 10% to 65% of treated patients and is characteristically rapid, regular, and fine in amplitude.[98,99] It is qualitatively different from the parkinsonian-like tremor associated with antipsychotic treatment. Often, the lithium-induced tremor occurs early in therapy and improves with time. Caffeine, personal or family history of tremor, alcoholism, anxiety, antidepressants, antipsychotics, and possibly older age enhance the risk of lithium-induced tremor.[100] The tremor is more common in patients with higher serum concentrations and may be worse at times of peak lithium levels.[11] If C.N. is not bothered by the tremor and suffers no impairment, treatment is not necessary. If the tremor becomes problematic, her lithium dosage may be reduced or a β-adrenergic blocking agent can be added. Propranolol is used most commonly. Additionally, switching to a sustained-release lithium preparation may reduce peak serum levels and ameliorate tremors if associated with peak concentrations.[11] Because it is early in treatment and C.N. has only a moderate lithium level, it is reasonable to add propranolol 10 mg three times a day rather than to reduce the lithium dosage (if an intervention is required). Propranolol usually is effective at dosages <160 mg/day.[99] C.N. should be educated about her tremor, the adverse effects of propranolol (see Chapter 9, Essential Hypertension) and minimizing her caffeine consumption.

In addition, C.N. should be asked about her trip to the bathroom during this clinic visit because lithium may cause both diarrhea and polyuria. Polyuria and polydipsia are common, occurring in up to 60% of patients.[100] Nephrogenic diabetes insipidus is less common, affecting about 10% of patients on long-term treatment.[101] Nephrogenic diabetes insipidus (see Chapter 53, Diabetes Mellitus) is dose-dependent, so C.N. can be told that a lower lithium dose may minimize the symptoms. Although the advantages of once-daily administration of lithium are not universally accepted, switching a

stabilized patient to this schedule with its lower trough levels may help to reduce urine volume.[11] If C.N. were to fail to respond to either of these interventions, amiloride could be administered, which minimizes lithium's effect on free water clearance.[11,102]

If C.N.'s trip to the bathroom was because of diarrhea, lithium should be evaluated as a possible cause; up to 20% of patients started on lithium experience diarrhea, epigastric bloating, and sometimes stomach pain early in therapy.[103] Diarrhea from lithium is associated with high serum levels, once-daily dosing, and rapidly absorbed preparations; therefore, divided doses may help to alleviate the problem. Use of lower doses and switching to sustained-release preparations are alternative strategies that could be used if C.N. is experiencing diarrhea or polyuria. Her fluid status and lithium level also should be monitored closely. Dehydration and sodium loss lead to increased lithium reabsorption in the proximal tubule and could result in accumulation and lithium toxicity.

Case 87-2, Question 5: What should C.N. be told regarding potential renal damage from lithium?

C.N. should be informed that over time lithium could adversely affect her kidneys. Long-term treatment has been associated with reduced kidney function and, rarely, end-stage renal disease.[104] Routine monitoring of renal function (Table 87-3) allows for the identification of patients with precipitous declines in glomerular filtration. In such patients, lithium should be discontinued to prevent progression to end-stage renal disease. Risk factors for renal insufficiency include episodes of lithium intoxication, medical conditions that impair glomerular filtration (eg, hypertension, diabetes mellitus), and concurrent medications that are damaging to the kidney.[105] Communication with her prescriber about situations that increase the risk of lithium toxicity (see Case 87-2, Question 7) and cooperation with regular lithium and renal function monitoring can vastly reduce the risk of renal disease. Finally, C.N. must be

informed that polyuria is not related to any of the more serious renal side effects.

Patient education

Case 87-2, Question 6: What lithium education should C.N. receive prior to discharge from the hospital?

As with all medications, C.N. should be instructed to disclose all medications she is taking to each of her health care providers. She should be informed that dehydration, fever, vomiting, or sodium-restricted diets could lead to increases in her lithium level. Therefore, she needs to drink plenty of fluids and should avoid restricting sodium.

C.N. should be instructed to contact her prescriber if she starts to experience any symptoms of lithium toxicity, including worsening tremor, slurred speech, muscle weakness or twitches, or difficulty walking. C.N. should be told to use caution in selecting over-the-counter medications. Specifically, she should be warned to avoid the use of preparations containing nonsteroidal anti-inflammatory drugs, which can increase lithium levels.[106] C.N. should know that caffeine can sometimes be troublesome in patients taking lithium, worsening tremor on a short-term basis, and lowering lithium levels during the long term.[106] With regard to serum lithium level monitoring, C.N. needs to know that lithium levels usually are drawn ~12 hours after a dose of lithium. If she is taking lithium in the evening and the morning, she should take her evening dose and then report for a blood sample to be drawn in the morning before taking her morning dose.

Toxicity

Case 87-2, Question 7: About 6 months after discharge, C.N.'s mother calls, concerned that C.N. has been experiencing symptoms of nausea, vomiting, and diarrhea for several days. During the past few hours, C.N. has become

confused and has developed a coarse tremor and slurred speech. It has been 4 months since C.N.'s lithium level has been checked. The only change is that C.N. recently started taking naproxen for headaches. What action should be taken?

There is a strong possibility that C.N. is suffering from lithium toxicity, which can occur acutely from an overdose or insidiously from reduced lithium clearance. Mild toxicity at levels <1.5 mEq/L causes feelings of apathy, lethargy, and muscle weakness accompanied by nausea and irritability. Moderate toxicity occurs between 1.5 and 2.5 mEq/L with symptoms progressing to coarse tremor, slurred speech, unsteady gait, drowsiness, confusion, muscle twitches, and blurred vision. Severe toxicity at levels >2.5 mEq/L can result in seizures, stupor, coma, renal failure, and cardiovascular collapse. C.N. seems to be experiencing moderate lithium toxicity. She should stop any medications that can decrease lithium clearance and the lithium itself until instructed to resume it. She should be taken to the emergency department immediately, where stat laboratory tests, including a lithium level, electrolytes, and renal function tests, should be ordered. There is no antidote for lithium intoxication. Intravenous solutions should be started to ensure that C.N. is hydrated adequately, and electrolyte abnormalities should be corrected promptly. Depending on the results of physical examination and laboratory tests, cardiac monitoring should be instituted and hemodialysis should be considered. Hemodialysis is used to shorten the exposure of different tissues of the body to the elevated lithium concentration and to lower the lithium level to 1.0 mEq/L. Candidates for hemodialysis include those with compromised renal function, severe (irreversible) neurologic symptoms, acute lithium ingestions where symptoms are clear and serum levels are >4.0 mEq/L, or a chronic toxicity where lithium levels exceed the therapeutic values with a clearly manifested clinical picture.[107]

Hypothyroidism

Case 87-2, Question 8: After receiving lithium 1200 mg/day for 1 year, C.N. returns stating that the lithium is slowing her down. She is tired and has gained weight in recent weeks and thinks that she is becoming depressed. In the examining room, C.N. state that the temperature is too cold. What is the most likely cause of C.N.'s symptoms? What treatment should be instituted?

C.N.'s symptoms are consistent with those of hypothyroidism.

Lithium affects the incorporation of iodine into thyroid hormone, interferes with secretion of thyroid hormones, and may interfere with the peripheral conversion of T_4 to T_3 (triiodothyronine).[108] According to laboratory indices, the incidence of hypothyroidism in lithium-treated patients with BD ranges from 28% to 32% compared with 6% to 11% in patients not taking lithium.[109] Risk factors for lithium-induced hypothyroidism include female gender, family history of hypothyroidism or thyroid illness in first-degree relatives, weight gain, elevated baseline TSH, preexisting autoantibodies, an iodine-deficient diet, rapid cycling, and elevated lithium levels.[110] For females, the first 2 years of treatment is a period of heightened risk as well as for any middle-aged patient starting lithium.[110]

Thyroid function tests should be ordered to evaluate C.N.'s current symptoms. If she is found to be hypothyroid, discontinuation of lithium is not necessary. She should receive levothyroxine in doses that normalize her thyroid function tests. Even if she has an elevated TSH with normal levels of T_3 and T_4, low-dose thyroid supplementation may help to resolve her symptoms and prevent breakthrough depression.[108]

Drug and dietary interactions

CASE 87-3

Question 1: T.J., a 35-year-old male, is hospitalized and treated with lithium for a severe manic episode. He had a stable lithium level of 0.84 mEq/L for several weeks, but his last two levels were 0.65 and 0.61 mEq/L without any change in his drug therapy. T.J. insists that he is taking the medication as prescribed. The

nursing staff believes that he is adherent with his medication but notes that he is spending more time off the unit and in the cafeteria.

What factors could contribute to a decrease in T.J.'s lithium levels?

Drug interactions are a common cause of changes in lithium levels, but there have been no changes in T.J.'s regimen (**Table 87-5** provides a list of clinically significant drug interactions). Changes in formulation or brand may sometimes have an impact on lithium levels. Nevertheless, lithium is relatively well absorbed and has a long elimination half-life, so this usually does not result in large changes in the 12-hour postdose lithium level. Occasionally, patients switched from lithium citrate to solid dosage forms experience small changes in lithium levels.

Table 87-5

Lithium Drug Interactions of Clinical Significance

Drugs That Increase Lithium Levels
NSAIDs
Many NSAIDs have been reported to increase lithium levels as much as 50%–60%. Enhanced reabsorption of sodium/lithium secondary to inhibition of prostaglandin synthesis is probable mechanism.
Diuretics
All diuretics contribute to sodium depletion that can cause an increased proximal tubular reabsorption of sodium and lithium. Thiazide-like diuretics cause the greatest increase in lithium levels, whereas loop diuretics and potassium-sparing diuretics seem to be somewhat safer.
Angiotensin-converting enzyme (ACE) Inhibitors
Both ACE inhibitors and lithium result in volume depletion and in a reduction in glomerular filtration rate. This results in reduced lithium excretion.
Angiotensin II receptor blockers (ARBs)
ARBs decrease in sodium and reabsorption via AT_1 blockade results in reduced lithium excretion.
Drugs That Decrease Lithium Levels
Theophylline and caffeine
Theophylline and caffeine may increase renal clearance of lithium and result in a decrease in levels in the range of 20%.
Acetazolamide
Acetazolamide may impair proximal tubular reabsorption of lithium ions.
Sodium

High dietary sodium intake promotes the renal clearance of lithium.
Drugs That Increase Lithium Toxicity
Methyldopa Cases of sedation, dysphoria, and confusion owing to the combined use of lithium and methyldopa have been reported. *Carbamazepine* Cases of neurotoxicity involving the combined use of lithium and carbamazepine have been reported in patients with normal lithium levels. *Calcium-channel antagonists* Cases of neurotoxicity involving the combined use of lithium and the calcium-channel blockers verapamil and diltiazem have been reported. Lithium interferes with calcium transport across cells. *Antipsychotics* Cases of neurotoxicity (encephalopathic syndrome, extrapyramidal effects, cerebellar effect, EEG abnormalities) have been reported owing to the combined use of lithium and various antipsychotics. The interaction may be related to increase in phenothiazine levels, changes in tissue uptake of lithium, or dopamine-blocking effects of lithium. Studies attempting to demonstrate this effect have yielded differing results. *Serotonin-selective reuptake inhibitors* Fluvoxamine and fluoxetine have been reported to result in toxicity when added to lithium. Sertraline has been reported to cause nausea and tremor in lithium recipients.

ACE, angiotensin-converting enzyme; EEG, electroencephalogram; NSAIDs, nonsteroidal anti-inflammatory drugs.

T.J. should be questioned about his visits to the cafeteria because diet can have a major influence on lithium excretion. If T.J. is consuming large amounts of caffeinated beverages or salty snacks, a reduction in lithium levels could occur. Increases in dietary sodium intake and the ingestion of methylxanthines (eg, caffeine, theophylline) can increase lithium clearance.[106]

Finally, acute mania can increase lithium clearance.[7] If T.J. was showing signs of a relapse, his decrease in lithium levels might be attributable to his return to a manic state.

Lithium in pregnancy

CASE 87-4

Question 1: A.J., a 36-year-old female, has been maintained successfully on lithium therapy for 5 years for BD. She asks whether she should stay on lithium because she plans to become pregnant in the near future.

Can lithium be used during pregnancy?

Although there is considerable disagreement about the importance of lithium as a teratogen, it has been associated with a variety of congenital malformations, including the rare cardiac malformation, Ebstein anomaly.[111] Lithium was originally thought to increase the risk of Ebstein anomaly 400 times; however, the risk is more likely 20 to 40 times higher than in the general population.[112] One estimated overall risk for congenital malformations related to lithium treatment is ~4% to 12% (compared with 2%–4% in controls).[113] A large cohort study of 1.325 million pregnancies identified 663 infants exposed to lithium in which cardiac malformations were present in 16 (2.41%). The investigators determined that the adjusted risk for any cardiac malformation (including Ebstein anomaly) was related to lithium dose (RR = 3.22 [95% CI, 1.47–7.02] for lithium doses > 900 mg/day).[114] A recent meta-analysis determined that the risk for cardiac anomalies related to lithium exposure was low, but that higher dose and first trimester exposures had relatively higher risks.[115] Because malformations are most likely to occur in the first trimester of pregnancy, it is advisable for patients to avoid lithium, when possible, during this high-risk period.

In addition to cardiac malformations, infants exposed to lithium have been reported to have hypotonia, nephrogenic diabetes insipidus, and thyroid abnormalities.[111] Lithium administration during pregnancy increases the risk of premature delivery by a factor of two to three.[116] Unfortunately, the relative safety of other psychotropic agents commonly used in BD is either not ideal or unknown. VPA has risks of neural tube defects, skeletal abnormalities, hypospadias, limb malformations, cardiovascular defects, and cerebral hemorrhage. CBZ has risks of spina bifida, developmental delay, and lower IQ scores. The general consensus is that these medications are genuine teratogens and should be avoided.[117] Among 1558 exposures, lamotrigine had 35 major congenital malformations

among first trimester monotherapy exposures (2.2%, 95% CI = 1.6%–3.1%).[118]

The use of antipsychotics for which more safety evidence is available is recommended whenever possible in females who require them while pregnant. In a comparison of AAPs of placental passage, olanzapine was associated with the highest exposure (72% ratio of umbilical cord-to-maternal plasma concentrations), followed by haloperidol (65%), risperidone (49%), and quetiapine (24%).[119] Olanzapine was also associated with the highest rates of low birth weight and neonatal intensive care unit admissions.

A.J. and her prescriber should discuss her individual risks related to lithium treatment. In addition to the risks of teratogenicity, they must consider the harm that could result from the possible recurrence of episodes of mania or depression and the risks inherent in discontinuing lithium or switching to another antimanic agent. A.J. should be actively involved in the decision-making process.

If A.J. and her prescriber decide that she is to remain on lithium, her serum levels must be monitored closely during pregnancy and her dosage adjusted accordingly. Lithium clearance increases during the third trimester by 30% to 50%, resulting in a reduction in lithium levels and a need for dosage adjustment.[112] Approximately 16 to 18 weeks after conception, screening tests, high-resolution ultrasound, and fetal echocardiography can be used to determine whether cardiac defects have developed.[112] If possible, A.J.'s prescriber should consider decreasing the lithium dose before delivery to minimize lithium levels in the newborn and to offset the reduction in lithium excretion that occurs after delivery.[112]

If A.J. and her prescriber decide that she is to discontinue lithium, they must be prepared for the risks of lithium discontinuation. Several cases of presumed rebound mania have occurred after abrupt cessation of lithium therapy. If lithium is to be discontinued in A.J., it should be gradually reduced over at least 4 weeks.

Case 87-4, Question 2: A.J. did not use lithium throughout her pregnancy. After delivery, A.J. and her prescriber decide to restart lithium. How soon can lithium be reinitiated in A.J.?

Lithium can be restarted as soon as A.J.'s urine output is established and she is fully hydrated. However, this decision also may be affected by whether A.J. chooses to breastfeed her child because lithium distributes into breast milk and is present in concentrations up to 72% of that found in the maternal blood.[112] Risks to the newborn include hypothyroidism, cyanosis, hypotonia, lethargy, and cardiac dysrhythmias. Hydration status must be closely monitored because lithium toxicity may develop during infantile illnesses. Thus, A.J. and her prescriber must discuss the advantages of breastfeeding versus the risks of exposing the newborn to lithium or withholding lithium during the postpartum period. A.J. should be informed that ~40% to 70% of females with BD experience affective episodes after delivery.[112–119]

If A.J. chooses to breastfeed while taking lithium, she should consider using infant formula when the child becomes ill because febrile illness, vomiting, and diarrhea can increase the risk of lithium toxicity. She also should be instructed to contact her pediatrician if the infant experiences diarrhea, vomiting, hypotonia, poor sucking, muscle twitches, restlessness, or other unexplained changes in behavior.

Atypical antipsychotics

CASE 87-5

Question 1: D.W., a 34-year-old female singer and musician, recently experienced her fourth hospital admission for a manic episode. Her past medical history includes psoriasis and asthma. A trial of lithium led to worsening of her psoriasis and an unacceptable tremor, which interfered with her guitar playing. Use of propranolol was not considered because of her asthma. She was subsequently switched to VPA monotherapy; however, tremor has again become problematic. Furthermore, she is concerned about her appearance because she has begun to experience weight gain and hair loss from the VPA.

What other medications are available for the treatment of acute mania?

AAPs can be selected as first-line choices for the treatment of acute mania.

Three systematic reviews and meta-analyses support the efficacy of AAPs as a class.[120–122] Perlis et al[120] reviewed data from 12 randomized, placebo-controlled, monotherapy studies and 6 adjunctive studies and found a collective response rate of 53% for AAPs compared with 30% for placebo. There was no difference in response between the individual AAPs. In adjunctive studies, the mean odds ratio was 2.4 for a 50% improvement with the addition of an AAP to a mood stabilizer (primarily lithium or VPA). Scherk et al[121] conducted a meta-analysis of 24 randomized controlled trials and found superiority of AAPs for acute mania in comparison with placebo and equal efficacy to lithium, VPA, and haloperidol. In this analysis, the addition of an AAP to lithium, VPA, or CBZ was found to be more effective in reducing manic symptoms and yield less treatment discontinuation than lithium or an anticonvulsant alone. The results of a different meta-analysis specifically designed to evaluate combination treatment of AAPs with lithium or an anticonvulsant also found greater efficacy for the combined regimen.[122] In most combination therapy studies, AAPs were limited to patients having no response or only a partial response to lithium or an anticonvulsant. Thus, the utility of drug combinations as initial therapy cannot be directly assessed.

In a more recent systematic review of 68 randomized controlled trials comparing the efficacy and acceptability of antimanic drugs either against placebo or against one another in the treatment of acute mania was completed via a multiple-treatment meta-analysis. Fourteen treatment options were analyzed including aripiprazole, asenapine, carbamazepine, valproic acid, gabapentin, haloperidol, lamotrigine, lithium, olanzapine, paliperidone, quetiapine, risperidone, topiramate, ziprasidone, and placebo. All of the antipsychotic drugs were found to be significantly more effective than mood stabilizers in the treatment of acute mania, with risperidone and olanzapine being ranked as superior for efficacy and tolerability. Lamotrigine, topiramate, and gabapentin were not significantly better

than placebo in terms of efficacy and should not have a place in the treatment of acute mania.[123]

Additionally, a comparative analysis of 32 placebo-controlled trials demonstrated that young mania rating scale (YMRS) scores improved significantly more with second-generation antipsychotics than mood stabilizers, but the efficacy needs to be balanced against anticipated common adverse effects.[124] A significant concern about the use of AAPs is the risk of metabolic complications, including weight gain, glucose dysregulation, and dyslipidemia (see also Chapter 85, Schizophrenia). Clozapine and olanzapine have the highest risk for metabolic complications, quetiapine, iloperidone, paliperidone, and risperidone are associated with an intermediate risk, and ziprasidone, brexpiprazole, cariprazine, asenapine, lurasidone, and aripiprazole appear to have the lowest risk.[47,125] Clozapine is also associated with significant safety concerns, including agranulocytosis, seizures, sialorrhea, anticholinergic side effects, and orthostasis. Efficacy data with clozapine are limited compared with the other AAPs, but clozapine appears to be effective in treatment-resistant mania and long-term mood stabilization.[126–128]

Sedation is common with clozapine, olanzapine, asenapine, and quetiapine, and this effect may be beneficial in the treatment of acute mania; however, sedation can also lead to nonadherence with long-term use.[129] Aripiprazole and ziprasidone are less sedating; thus, the adjunctive use of a benzodiazepine is often necessary in the acute management of mania with these AAPs. Adjunctive benzodiazepines may also benefit treatment of emergent akathisia, which occurs in 11% to 18% of patients treated with aripiprazole.[130,131] Cariprazine has also been associated with treatment-emergent akathisia and extrapyramidal disorders (>10%).[132] Asenapine can cause dysgeusia or oral hypoesthesia, although a black-cherry formulation can help with the unpleasant taste.[133] Ziprasidone may cause activation; however, this effect is attenuated at doses of 120 mg/day or more.[134] Risperidone may overall be the best tolerated of the AAPs, but this drug carries a higher risk for serum prolactin elevation and extrapyramidal symptoms.[135]

D.W.'s concern about her weight gain makes aripiprazole, cariprazine, asenapine, or ziprasidone rational choices for her manic episode. In addition to symptom response, D.W. should be monitored for characteristic antipsychotic side effects, such as movement disorders, and metabolic complications. If D.W. fails to respond to the initially selected AAP, a switch to a different AAP may prove beneficial given the variability in individual response.[46] **Table 87-6** provides dosing information for AAPs approved for the treatment of acute mania.

Table 87-6
Atypical Antipsychotic Dosing in Acute Mania

Atypical Antipsychotic	Initial Dose	Titration	Effective Dose Range
Aripiprazole	15 mg/day	Not required	15–30 mg/day
Asenapine	10 mg twice daily	5 mg twice daily	5–10 mg twice daily
Cariprazine	1.5 mg/day	Increase to 3 mg on day 2, then increase as needed in 1.5 or 3 mg increments	3–6 mg/day
Olanzapine	10–15 mg/day	5 mg/day	5–20 mg/day
Quetiapine	50 mg twice daily	50 mg twice daily	200–400 mg twice daily
Quetiapine XR	300 mg/day	300 mg/day	400–800 mg/day
Risperidone	2–3 mg/day	1 mg/day	1–6 mg/day
Ziprasidone	40 mg twice daily	20–40 mg twice daily	40–80 mg twice daily

Case 87-5, Question 2: What alternative agents are available for acute mania if lithium, VPA, or an AAP fail?

Anticonvulsants

CBZ represents an alternative treatment for the management of acute mania when lithium, VPA, and AAPs fail.[11,45,46] In 2005, the FDA-approved extended-release CBZ for the treatment of acute

manic and mixed episodes based on the results of two double-blind, randomized, placebo-controlled trials.[136] A meta-analysis of four randomized, controlled trials (*n* = 464 patients) found that maintenance treatment with carbamazepine has similar efficacy as, and fewer discontinuations because of adverse effects than, lithium.[137] Despite demonstrated efficacy, CBZ remains a less than popular choice in BD because of significant tolerability and drug–drug interaction risks. If elected for treatment, CBZ should be started at 100 to 200 mg twice daily. The dose should be increased by 200 mg every 3 to 4 days until adequate serum levels have been reached.[11] Although no correlation between CBZ serum levels and response in BD has been established, serum levels >12 μg/mL are associated with sedation and ataxia. The recommended target serum level for seizure prophylaxis is 4 to 12 μg/mL.[11] Average daily doses for maintenance therapy range from 200 to 1600 mg/day (see Chapter 60, Seizure Disorders).

Oxcarbazepine, a structural analog of CBZ, offers some advantages over CBZ, including improved tolerability and fewer drug interactions; however, there is a paucity of well-designed clinical trials in BD.[138] Cochrane reviews suggest that there are insufficient trials of adequate methodologic quality to recommend use for either acute or maintenance treatment for bipolar disorder.[139,140]

Other anticonvulsants studied in mania include lamotrigine, gabapentin, topiramate, tiagabine, zonisamide, and levetiracetam. Initial open-label studies of lamotrigine in mania were promising, but two unpublished trials were negative.[141] Currently, experts doubt that lamotrigine has any significant effect in acute mania. Open trials and case reports suggested adjunctive treatment with gabapentin was effective in manic, hypomanic, and depressive states of BD.[142–144] A more recent controlled trial found no benefit of gabapentin.[145] In this double-blind, placebo-controlled trial, gabapentin was administered as an adjunctive treatment in patients with bipolar I disorder whose current episode was manic, hypomanic, or mixed. At 12 weeks, gabapentin failed to show any significant benefit compared with placebo. In fact, the placebo group did significantly better than the gabapentin-treated patients.

In four double-blind, placebo-controlled trials, topiramate did not separate from placebo and was less effective than lithium in the treatment of acute mania.[146,147] Tiagabine, levetiracetam, and zonisamide have been studied in BD but lack adequate safety or efficacy data to receive any formal evaluation.

COMBINATION TREATMENT

Despite the array of treatments available for the management of acute mania, large numbers of patients fail to respond to monotherapy, and combination therapy is becoming a first-line treatment option.[148] Potentially useful combinations include lithium plus AAPs, VPA plus AAPs, and lithium plus VPA.[33,45] A combination to be avoided is CBZ and clozapine owing to the increased risk of hematologic adverse effects. Also, combinations of CBZ with either olanzapine or with risperidone result in more side effects and decreased efficacy; therefore, these combinations are not recommended.[46]

BENZODIAZEPINES AND ANTIPSYCHOTICS FOR ACUTE AGITATION

CASE 87-6

Question 1: M.B. is a 39-year-old male hospitalized for an acute manic episode, but is refusing all medications, reporting "I will be robbed of my superpowers." He is found pacing around the inpatient unit shouting orders for his release. When asked to return to his room by the clinical staff, he becomes agitated, picks up a chair, and begins swinging it wildly at anyone who approaches him. In the past, M.B. experienced a documented acute dystonic reaction to haloperidol. M.B. has a medical history of diabetes mellitus and hypertension.

What is an appropriate pharmacologic intervention for M.B.?

Benzodiazepines and antipsychotics are useful in treating agitation, irritability, and hyperactivity associated with acute manic episodes. Oral formulations are preferred and are favored by patients in psychiatric emergencies.[149] Oral dose delivery can be

facilitated with liquid concentrates and orally disintegrating tablets. Patients refusing oral medications may require intramuscular (IM) injections.[150] Traditionally, the combination of IM haloperidol and IM lorazepam has been used. Currently, ziprasidone and olanzapine are available in rapid-acting IM dosage forms. IM ziprasidone at doses of 10 and 20 mg are effective in psychotic agitation.[151,152] Additionally, IM olanzapine 10 mg is effective for manic or mixed-state agitation.[153] Repeat doses of IM ziprasidone and olanzapine can be administered 2 to 4 hours after the first dose, if needed. The concurrent use of a benzodiazepine with an antipsychotic is generally safe and potentially more effective than either agent alone. In the case of IM olanzapine, concurrent benzodiazepines should not be used because the combination may cause excessive sedation and cardiorespiratory depression.[154,155]

Lorazepam is the preferred benzodiazepine for acute manic agitation. Advantages of lorazepam include availability as both an IM and oral formulation (tablet and concentrate), lack of active metabolites, and safety in hepatic and renal impairment. The Expert Consensus Guideline recommends dosing lorazepam at 1 to 3 mg orally or 0.5 to 3 mg IM, with repeat doses at least 60 minutes apart. The maximal dose should not exceed 10 to 12 mg in the first 24 hours.[156] The primary concern regarding the use of benzodiazepines for agitated mania is sedation. The risk of abuse and addiction is minimal with short-term inpatient use.

M.B. is uncooperative and an immediate danger to others, thus warranting IM therapy. Because of M.B.'s history of acute dystonia to haloperidol, an IM AAP (such as olanzapine or ziprasidone) should be used. As M.B. becomes calmer and more receptive to treatment, he can be transitioned to oral therapy.

TREATMENT OF ACUTE BIPOLAR DEPRESSION

CASE 87-7

QUESTION 1: H.C., a 31-year-old female, was hospitalized for treatment of an acute manic episode 3 months ago. She was discharged on VPA 1750 mg/day with a favorable response. Starting about 2 weeks ago, her parents become concerned because H.C. started spending most of the day in bed. When out of bed, H.C. sits on the couch without moving for hours and only nibbles at the food her parents offer her. She has no other signs or symptoms of physical illness and has not taken any additional medications, alcohol, or drugs of abuse to her parents' knowledge. They report that H.C. was diagnosed with diabetes mellitus type 2 last year, and her serum glucose has been controlled by diet. On further questioning, H.C.'s parents report that she has been intermittently tearful and expressed remorse for her behavior when she was manic. They also recall her as saying "I am as low as I can go, and I just want to die." Hence, they suspect she is suicidal. H.C.'s parents report that she is taking VPA as prescribed and that the last time she experienced this level of depression, the addition of lithium to VPA did not seem to help. Her VPA level on discharge was 84 μg/mL.

What change in H.C.'s treatment should be instituted at this time?

Bipolar depression is both recurrent and chronic, accounting for three-quarters of the time spent ill in BD.[157] Depression is often difficult to treat and puts patients at significant risk for suicide, which occurs at a rate 20 times greater than that of the general population.[158]

In bipolar depression, complete remission of symptoms is the primary goal of treatment. The ideal regimen should target acute depressive symptoms, decrease suicide risk, and prevent future mood episodes (both manic and depressive). These goals should be achieved without precipitating mania (switching) or mood cycling. Because simply addressing the acute depressive symptoms is often shortsighted in an illness with recurrent depressive episodes, the ability to prevent future depressive episodes and the long-term tolerability are important considerations.[159]

A logical first step in the management of bipolar depression is to verify adherence and optimize the dose of the current mood stabilizer.[33] For H.C., she is already on a therapeutic level of VPA; thus, no change in dose is needed.

Lithium

Lithium remains a first-line treatment for bipolar depression.[43,44] The CANMAT guidelines recommend a level of 0.8 mEq/L or more for optimal response.[48] The benefit of lithium was demonstrated in seven of eight placebo-controlled crossover studies with a mean response rate of 76%.[160] Lithium may also be effective for preventing depressive episodes. A 6-year follow-up study of patients maintained on lithium found a reduction in the annual rate of depressive episodes by 46% and the time spent ill by 53%.[161] A meta-analysis of 1- or 2-year-long studies found a 22% relative risk reduction for a depressive relapse compared with placebo (risk ratio, 0.78; 95% CI = 0.60–1.01).[162] The difference from placebo was not statistically significant.[156] Beyond antidepressant effects in BD, lithium also has the vital benefit of reducing the risk of suicide, deliberate self-harm, and all-cause mortality.[163,164]

Lamotrigine

Lamotrigine is also recommended as a first-line treatment for bipolar depression by both the World Federation of Societies of Biological Psychiatry (WFSBP) and CANMAT guidelines; although the efficacy of lamotrigine for long-term treatment is well established, the efficacy of it in the acute management of bipolar depression is less compelling. Data from five double-blind, placebo-controlled trials [46,48] did not detect any benefit from lamotrigine on the primary end points (change in Hamilton Depression Rating Scale [HAM-D], or Montgomery–Åsberg Depression Rating Scale [MADRS]) relative to placebo. An independent meta-analysis of the same five studies found significant (but only modest) benefits for lamotrigine with a relative risk of response of 1.27 for the HAM-D and 1.22 for the MADRS.[165] The ability of lamotrigine to reduce the risk of relapse to depression is less controversial. A pooled analysis of two long-term studies (up to 18 months) with lamotrigine found a 36% reduction in the risk of relapse to depression.[166] Lamotrigine was well tolerated with no difference from placebo in any side effect. Because

lamotrigine has limited antimanic properties, patients with a history of severe, recent, or recurrent mania should only take lamotrigine in combination with an antimanic drug, such as lithium.[45]

The combination of lamotrigine and lithium may confer additional benefits on reducing depressive symptoms and should be considered for bipolar depression. Patients stabilized on lithium (predefined range of 0.6–1.2 mEq/L, mostly >3 months' duration) were randomly assigned to receive lamotrigine (200 mg/day) or placebo. The lithium–lamotrigine group had a response rate of 52% (based on MADRS scores) compared with 32% for the lithium–placebo group.[167] From the results of this study, clinical experience, and the need for long-term tolerability, the combination of lamotrigine and lithium is an appropriate treatment when monotherapy with these medications has failed.

Because of valproate's inhibition of UGT2B7, it can increase lamotrigine's area under the concentration–time curve (AUC) by 2.6-fold. Clinicians should pay particular attention to the dosing with initiating or discontinuing either medication in the presence of the other medication.[89]

Atypical Antipsychotics

AAPs offer another option for the treatment of bipolar depression. Quetiapine has demonstrated efficacy in a total of four 8-week double-blind, placebo-controlled studies (300 or 600 mg/day).[168–171] Response rates ranged from 58% to 69% for the 300-mg dose, and 58% to 70% for the 600-mg dose. Both doses were commonly associated with sedation, somnolence, dry mouth, and dizziness. Clinically significant weight gain (≥7% of baseline weight) was detected in roughly 5% to 10% of subjects receiving quetiapine.

The combination of olanzapine with fluoxetine is effective for patients with bipolar depression.[172] In a 7-week acute-phase treatment, OFC was superior to lamotrigine in symptom improvement but not significantly different in response rate (69% with OFC vs 60% with lamotrigine).[173] The rate of relapse to

depression during the 6-month study was low and similar between OFC and lamotrigine (14% vs 18%). In an extension of this study (for a total of 6 months), OFC caused significant elevations in all metabolic parameters (weight, glucose, prolactin, cholesterol).[174] Most alarming was a 34% incidence of clinically significant weight gain in the OFC group (vs 2% with lamotrigine). Therefore, the risk of metabolic complications should be taken into consideration when selecting this treatment.

Lurasidone has demonstrated efficacy in two 6-week, randomized, double-blind controlled clinical trials as monotherapy at either 20 to 60 mg/day or 80 to 120 mg/day. Response rates were 53% for the low dose, 51% for the high dose, and 30% for placebo. An additional study with a similar design failed to separate from placebo. An adjunct to lithium or VPA trial demonstrated response rates of 57% of lurasidone with either lithium or VPA compared to 42% of placebo with either lithium or VPA.[175–177] **Table 87-7** provides dosing information for AAPs approved for the treatment of bipolar depression.

Table 87-7

Atypical Antipsychotic Dosing in Bipolar Depression

Atypical Antipsychotic	Initial Dose	Titration	Effective Dose Range
Cariprazine	1.5 mg/day	Increase to 3 mg/day on day 15	3 mg/day
Lurasidone	20 mg/day	20 mg every 2 days	20–120 mg/day
Olanzapine/fluoxetine	6/25 mg/day	As indicated	12/50 mg/day
Quetiapine (IR and XR)	50 mg/day	100 mg on day 2 200 mg on day 3 300 mg on day 4	300 mg/day

IR, immediate release; XR, extended release.

Sources: Vraylar (cariprazine). Package insert. Forest Laboratories; May 2019; Latuda (lurasidone). Package insert. Sunovion Pharmaceuticals; January 2017; Symbyax (olanzapine/fluoxetine). Package insert. Lilly USA, LLC; January 2015; Seroquel XR (quetiapine XR). Package insert. AstraZeneca; June 2016.

Recent approval of cariprazine for the treatment of bipolar depression was based on short-term (6 or 8 weeks with endpoints at week 6) double-blind, placebo-controlled, randomized phase II/III clinical trials. Both the 1.5 and 3.0 mg/day doses are approved

doses for bipolar depression. Maintenance trials are in progress.[178,179]

Despite its efficacy in treatment-resistant unipolar depression, aripiprazole does not appear to be effective for bipolar depression on the basis of two randomized, controlled trials.[171,180] Considering these findings, the CANMAT guidelines have listed aripiprazole as not recommended for acute bipolar depression.[43] Other AAPs have not been systematically studied in bipolar depression.

Antidepressants

The use of antidepressants in BD has been hotly debated. Some guidelines recommend restrictive use of antidepressants because of concerns about mood switching and cycle acceleration.[47] Other guidelines recommend early treatment with antidepressants, particularly SSRIs, to address the recurrent depressive episodes.[46] In either case, there is agreement that antidepressants should only be used in combination with antimanic agents such as VPA, lithium, or an AAP.[46,47] The largest controlled trial of antidepressant augmentation in bipolar depression was conducted as part of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study. This study was a naturalistic 26-week, double-blind, placebo-controlled trial comparing antidepressants (bupropion or paroxetine) with placebo as adjunctive treatment to an antimanic agent.[79] The primary end point of durable recovery (euthymia for 8 weeks) was achieved in 24% of antidepressant-treated subjects compared with 27% receiving placebo. There was no significant difference between groups in treatment-emergent mood switch. A meta-analysis of 15 studies, primarily with bupropion or SSRIs, found that antidepressants were no more effective than placebo for acute (>16 weeks) bipolar depression.[79] This study also did not find an increased risk of mood switch. Therefore, although it appeared to be safe to add the antidepressant in regard to switching into mania, there is question about whether there is a large benefit on depressive symptoms.

Because H.C. did not respond to lithium in combination with VPA during her past depressive episode, an alternative first-line agent such as lamotrigine is a reasonable choice. OFC or quetiapine may compromise her type 2 diabetes control and thus are not appropriate options. Lurasidone or cariprazine could also be an alternate choice, although no current data exist in comparing them to lamotrigine, quetiapine, or OFC for the treatment in bipolar depression. Dosing of lamotrigine needs to account for H.C.'s concurrent use of VPA, which is known to inhibit the metabolism of lamotrigine. Therefore, the initial dose for H.C. is 25 mg every other day for weeks 1 and 2 followed by an increase to 25 mg/day for weeks 3 and 4. The dose can be increased to 50 mg/day for week 5 and then to a maximum of 100 mg/day beginning at week 6. In the absence of VPA, the recommended target dose of lamotrigine is 200 mg/day. In patients taking enzyme inducers (eg, CBZ), the target dose is 200 mg twice daily.[181] The appropriate titration schedule must be followed for lamotrigine (see also Chapter 60, Seizure Disorders) because of the risk of skin rash, which may progress to life-threatening Stevens–Johnson syndrome. The combination of lamotrigine and VPA is a risk factor for the development of this dangerous cutaneous reaction; therefore, H.C. should be instructed to contact her prescriber immediately if a skin rash develops.

MAINTENANCE THERAPY OF BIPOLAR DISORDER

CASE 87-8

Question 1: R.L., a 33-year-old male, has been treated for an episode of acute mania with lithium 600 mg twice a day for 3 weeks. He is no longer overtly manic. Because of R.L.'s past episodes of depression and mania, his prescriber decides to institute prophylactic (maintenance) lithium therapy.

What are the goals of maintenance lithium therapy for R.L.? How should he be monitored during this maintenance phase? How long should R.L. be maintained on lithium?

Recurrent episodes are associated with decreased quality of life, poorer response to treatment, longer hospitalizations, and cognitive impairment.[33] Thus, early maintenance (prophylactic) treatment is indicated to prevent disease progression. Appropriate goals for maintenance therapy include an increase in the interval between episodes, a decrease in the frequency of episodes, and a reduction in the duration and severity of mood episodes. In most cases, patients will have been started on an acute treatment for a manic or depressive episode. These agents should generally be continued because abrupt switches in medications may predict poorer treatment outcomes.[33]

Lithium

The aforementioned meta-analysis (Case 87-7, Question 1) of long-term lithium therapy for relapse prevention in BD included five randomized, placebo-controlled studies.[162] Although lithium did not effectively reduce the risk of relapse to depression, it did reduce the risk of relapse to any mood episode (risk ratio, 0.66) and to manic episodes specifically (risk ratio, 0.62). The average risk of relapse to any mood episode on lithium was 40% versus 60% for placebo. The average risk of relapse to a manic episode was 14% for lithium versus 24% for placebo.

In the case of R.L., he should be continued on lithium. The target levels for maintenance therapy with lithium should be in the range of 0.5 to 0.8 mEq/L.[11] Higher levels ranging from 0.8 to 1.0 mEq/L are associated with a reduced number of relapses (compared with levels between 0.4 and 0.6 mEq/L) but also have an elevated risk of side effects.[182]

In addition to determining an appropriate maintenance lithium level for R.L., it is important to consider whether once-daily administration of lithium can improve adherence or adverse effects. During periods of dosage readjustment, R.L. will require monitoring of his lithium serum level more frequently. Once stabilized, the monitoring

frequency can be reduced to quarterly. See Table 87-3 for recommended lithium monitoring guidelines.

Case 87-8, Question 2: What other maintenance treatments for BD are available should R.L. fail to respond to lithium?

Anticonvulsants

VPA and lamotrigine are reasonable alternatives to lithium that have shown efficacy in BD maintenance therapy. In the first controlled trial of VPA for the maintenance treatment of BD, patients were randomly assigned to receive VPA, lithium, or placebo and followed for 52 weeks.[183] The three groups did not differ with regard to the primary outcome of time to any mood episode. However, a lower percentage of patients discontinued treatment for any reason in the VPA group (62%) than lithium (76%) or placebo (75%); patients on VPA remained in the study longer (198 days) than patients on lithium (152 days) and placebo (165 days). The mean VPA serum concentration was 85 μg/mL. Lamotrigine has been studied rigorously in the maintenance treatment of BD. A pooled analysis of two placebo-controlled studies found that lamotrigine and lithium more than doubled the time to intervention (eg, addition of pharmacotherapy or ECT) for any mood episode compared with placebo (see Case 87-7, Question 1).[166] The time to intervention was 197 days for lamotrigine, 187 days for lithium, and 86 days for placebo. Lithium preferentially prevented manic relapses, whereas lamotrigine preferentially prevented depressive episodes.

Atypical Antipsychotics

AAPs have become increasingly popular alternatives and adjunctive treatments for maintenance therapy of BD. To date, aripiprazole, olanzapine, quetiapine (adjunctive), risperidone long-acting injection, and ziprasidone (adjunctive) have received FDA approval for the maintenance treatment of BD (**Table 87-8**). A meta-analysis

evaluated 20 trials (*n* = 5364) in the efficacy of maintenance treatments for BD. No monotherapy options were associated with significantly reduced risk for both manic/mixed and depressive poles compared to each other, whereas the only combination, quetiapine plus lithium or VPA demonstrated significant reduction in risk versus the comparator of placebo in reduced risk for both poles.[83] The long-term risk of side effects, including metabolic complications and extrapyramidal symptoms (EPD), should be the primary consideration for selecting one AAP over another (see Case 87-5, Question 1).

CASE 87-8, QUESTION 3: What is the role of psychotherapy in BD?

Psychotherapy can have a profound effect on the prevention of acute illness, as well as a sustained effect on maintenance treatments. Excessive stress, for example, is often implicated in the onset of affective episodes, particularly early in the lifetime course of

BD.[7] If individuals and their families can learn to avoid these triggers or to develop coping skills, the acute impact can be minimized and future episodes averted.

Therapy may also help the family to cope with the emotions and disruption that are the hallmark of acute manic and depressive episodes. Violent outbursts, infidelity, financial debts, substance abuse, suicidal thinking, and loss of self-esteem may all be a byproduct of mood recurrence, and family members must learn to treat such calamities, as well as fears surrounding future episodes. Regular sleep–wake cycles seem vital to the maintenance of euthymic states; thus, improvements in sleep hygiene may be encouraged in these sessions. Last, sustained medication adherence must also be emphasized; individuals with BD will often stop their medications in an effort to resume the “highs” of mania or because of the cumulative side effect burden of complex psychotropic regimens.

The specific psychotherapeutic approach to BD is generally quite similar to interventions offered to individuals with schizophrenia. Family-focused therapy seems to be quite effective, as are cognitive-behavioral and interpersonal and social rhythm therapy. Collaborative care models have been extensively studied for unipolar depression in primary-care settings, but the effectiveness of collaborative care models for bipolar illness is less clear. In fact, in the STEP-BD trials, collaborative care was the least effective intervention.[184] Reported response rates were 77% with family-focused therapy, 64% with interpersonal and social rhythm therapy, 60% with cognitive-behavioral therapy, and 54% with collaborative care. Experts contend that the collaborative care intervention was comparatively less intensive than the other three treatment modalities in this report.

Although most experts advocate for regular physical activity to prevent bipolar mood swings, the body of literature supporting such an approach is very limited. Lifestyle surveys have demonstrated that people afflicted with BD are less likely to exercise and more likely to exhibit poor dietary habits than those without a serious mental illness.[185] Theoretically, exercise may improve dietary habits,

regulate sleep, increase energy, and promote euthymic moods. As a result, increased physical activity would be expected to improve the prognosis of bipolar illness and should be encouraged at the very least for the physical health benefits.

Case 87-8, Question 4: Are there other treatment options for BD?

Alternative Medicines

A wide variety of herbal preparations and dietary supplements have been studied for the treatment of BD. A meta-analysis of double-blind, placebo-controlled trials of combined bipolar and unipolar depression found benefit of omega-3 fatty acid supplementation compared with placebo in patients with depressive episodes.[186] In most cases, omega-3 fatty acid supplementation, including eicosapentaenoic acid alone or in combination with docosahexaenoic acid, was used as adjunctive treatment. The doses studied ranged from 1 g/day of eicosapentaenoic acid to 9.6 g/day of combined eicosapentaenoic acid and docosahexaenoic acid.

Inositol was compared with lamotrigine and risperidone in an augmentation trial for bipolar depression.[187] The three treatments were equivalent with regard to recovery from depression; however, the study was open label and the sample size was small (n = 66). Saint-John's-wort and *S*-adenosyl-L-methionine may be effective for depressive episodes; however, these agents, like traditional antidepressants, should generally be avoided in BD owing to the risk of mood destabilization.[54,55]

Electroconvulsive Therapy and Transcranial Magnetic Stimulation

ECT is effective in all phases of BD and continues to play a vital role in the contemporary treatment of mood disorders. The efficacy of ECT in bipolar depression is equivalent to unipolar depression with

~80% of patients achieving a response and 60% meeting criteria for remission.[188] The benefits of ECT in acute mania are similarly impressive. In a review spanning 50 years of research, “remission or marked clinical improvement” was achieved in 80% of patients.[189,190]

BD medication regimens need to be carefully evaluated before ECT treatment. Anticonvulsants and benzodiazepines raise the seizure threshold and interfere with the effectiveness of ECT. A retrospective analysis found that patients taking anticonvulsants achieved the same overall clinical response but required more ECT treatments and a longer hospital stay.[191] An exception is the concurrent use of lamotrigine, which appears to have no significant effect on electrical stimulus dose or seizure duration.[192] Lithium use with ECT has been discouraged on the basis of early reports of organic brain syndrome; however, a more recent prospective study found the combination to be safe in a younger population without risk factors for ECT complications.[193,194] Small case series and clinical experience suggest that AAPs are safe to use during ECT.[195–197]

ECT remains an effective and important tool for the treatment of BD, particularly bipolar depression, which is highly recurrent and has limited safe and effective treatment options. All patients failing to respond to standard BD pharmacotherapy, presenting with severe mood symptoms, or not otherwise appropriate for medication treatment should be considered for ECT.

TMS was recently granted breakthrough designation of adult patients with bipolar I or II disorders who failed to show satisfactory improvement with prior pharmacologic therapy.[198]

Developmental Disorders

Kimberly Lenz and Neha Kashalikar

CORE PRINCIPLES

CHAPTER CASES

CORE PRINCIPLES		CHAPTER CASES
1	Developmental disorders are a group of conditions in which early brain development is impaired. This very large group of disorders includes diagnoses such as intellectual disability (ID) and autism spectrum disorder (ASD). The core diagnostic features of ASD include impairment in reciprocal social communication and social interaction, and restricted, repetitive patterns of behavior, interests, or activities. These symptoms must be present from early childhood and impair everyday functioning. ASD is diagnosed clinically, although standardized behavioral diagnostic instruments can assist this process. ASD is more common in males than in females, and the core diagnostic features can be addressed through multiple different types of nonpharmacologic interventions, including specialized education, physical therapy, occupational therapy, speech and language therapy, and behavioral therapy, such as applied behavior analysis (ABA).	**Case 88-1 (Question 1), Table 88-1**

CORE PRINCIPLES		CHAPTER CASES
2	Individuals with ID/ASD have high rates of comorbid attention-deficit/hyperactivity disorder (ADHD). Treatment of ADHD, especially hyperactivity, in individuals with ID/ASD is similar to the treatment of ADHD in neurotypical individuals and includes stimulants, α_2-agonists, and atomoxetine. Compared to their neurotypical peers though, individuals with ID/ASD and comorbid ADHD experience lower effect sizes with ADHD treatment, lower tolerated doses of ADHD medication, and more risk of adverse effects, including increased rates of decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal.	**Case 88-1 (Question 2)**

CORE PRINCIPLES		CHAPTER CASES
3	Some individuals with developmental disorders demonstrate symptoms of irritability and aggression, which can sometimes be helped with a pharmacologic intervention if nonpharmacologic interventions are ineffective. The strongest evidence for the pharmacologic treatment of irritability/aggression in individuals with developmental disorders exists for the use of risperidone and aripiprazole to treat irritability in children with ASD. Doses for this purpose are likely lower than those used to treat schizophrenia or bipolar disorder, and adverse events are relatively common and may include sedation, weight gain, and extrapyramidal symptoms.	**Case 88-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
4	Individuals with developmental disorders are at high risk of having comorbid anxiety and depression. Although no large prospective, randomized, controlled trials (RCTs) exist to support the use of selective serotonin reuptake inhibitors (SSRIs) for this purpose, case studies and open-label studies have shown possible benefits. RCTs of SSRIs for the treatment of repetitive behavior in children with developmental disorders have shown mixed results, although they have demonstrated that individuals with developmental disorders may be at increased risk of emotional and behavioral adverse events from SSRIs, and therefore, target dosing should be lower than in individuals with typical development.	**Case 88-3 (Questions 1, 2)**
5	Individuals with developmental disorders have high rates of comorbid medical and psychiatric disorders, and therefore may often be prescribed multiple different concurrent medications. Precaution should be taken to avoid any pharmacodynamic or pharmacokinetic drug–drug interactions, and such interactions should always be considered to describe any adverse events.	**Case 88-3 (Questions 1, 2)**

CORE PRINCIPLES		CHAPTER CASES
6	Sleep disturbances are common in individuals with developmental disorders. Melatonin has the strongest body of evidence for being a safe and effective treatment of sleep disturbances in this population.	**Case 88-4 (Question 1)**

INTRODUCTION

Developmental disorders are a group of conditions characterized by impaired early brain development, resulting in deficits of cognitive, communicative, behavioral, sensory, or motor functioning. This broad group of disorders includes diagnoses such as intellectual disability (ID); autism spectrum disorder (ASD), which will be the focus of this chapter; attention-deficit/hyperactivity disorder (ADHD) and tic disorder, which are covered in other chapters; and communication disorders, learning disorders, cerebral palsy, congenital hearing loss, and congenital blindness. ID, previously labeled mental retardation, is a disorder with deficits in intellectual and adaptive functioning. Although ID is typically reserved for older children, for whom intellectual testing is more valid and reliable, global developmental delay (GDD) is the diagnosis given to younger children in which delays exist in two or more developmental domains. ASD, which includes prior diagnoses of autistic disorder, Asperger disorder, and pervasive developmental disorder (PDD), not otherwise specified, are conditions involving deficits in social communication, as well as the presence of restricted and repetitive patterns of behavior, interests, or activities.[1]

EPIDEMIOLOGY, NATURAL COURSE OF THE DISEASE, AND PROGNOSIS

Developmental disorders are common in the community, affecting as many as 15% of children in the United States, based on parent report.[2] Collectively, developmental disorders are nearly twice as likely in males and children insured by Medicaid, relative to females and those insured by private insurance, respectively.[2] Additionally, a higher prevalence of developmental disorders is reported by families with incomes below the federal poverty level and with lower maternal education (any educational attainment less than a college degree).[2]

For ID and GDD, the overall prevalence is estimated to be between 1% and 3% of the population, although with considerable variability depending on how the diagnosis is defined and reported in the literature.[3,4] ID is more prevalent in males versus females, and in low- and middle-income countries relative to high-income countries.[3]

ASD is increasing in prevalence, with the Centers for Disease Control and Prevention reporting about 1 in 68 children (1.47%) being identified with the disorder.[5] Although around one-third of children with ASD may also qualify for ID, the proportion of children with average or above-average intelligence being diagnosed with ASD has been steadily increasing over the years and may explain some of the increase in overall ASD prevalence.[5] The proportion of children with ASD who are male has consistently been four to five times that of females.[5] In the United States, around 30% of children with ASD have some level of ID.[5]

The course and prognosis of both ID and ASD vary considerably depending on the severity of the deficits, the impact of comorbid medical and psychiatric conditions, and the access to services and treatments. Many individuals will go on to live rich and fulfilling lives, with minimal required assistance in daily life functioning, although some will require constant supervision in supportive group housing, and assistance for basic tasks of daily living.

PATHOPHYSIOLOGY: DISEASE ETIOLOGY, ANATOMY, AND PHYSIOLOGY

Many different known and unknown genetic and environmental factors can lead to the impairment in early brain development associated with developmental disorders.

For both ID and ASD, risk factors include preterm birth, low birth weight, small for gestational age, and low Apgar scores, although all of these are associated more strongly with ID.[6] For ID specifically, risk factors may differ depending on the severity of ID. Studies have shown risk factors for mild ID to include mothers under age 20 years or older than 30 years, paternal age older than 40 years, increasing birth order, increasing social disadvantage, maternal education less than high school, being part of a multiple birth, and being second or later in the birth order.[7,8] The risk of severe ID was consistently increased with increasing maternal age and decreasing level of maternal education.[7] For ASD without ID, additional risk factors include mothers ages 35 years or older, first-born infants, male infants, and increasing socioeconomic advantage.[8]

In only about half of all cases of ID can a specific etiology be identified and may include genetic anomalies, intrapartum asphyxia, cerebral dysgenesis, and environmental causes.[9] In only about 30% of children with ASD can an identifiable genetic etiology be determined.[10] Although inherited genetic forms of ID likely represent a minority of identified cases, ASD, on the other hand, is widely considered to be one of the most heritable neuropsychiatric conditions with heritability estimates of 60% to 90%.[11] For parents with one child with ASD, the recurrence rate in future siblings is thought to be 5% to 20%, with higher rates if the original child with ASD is female.[12] This recurrence rate increases to about 33% if a family already has two children with ASD.[12]

For inherited genetic anomalies, X-linked gene defects account for 10% to 12% of all ID cases in males, with fragile X syndrome being the most common.[13] Fragile X syndrome, marked by a CGG triplet

repeat expansion in the *FMR1* gene on the X chromosome, is also the most common single-gene cause of ID, accounting for about 0.5% to 3% of individuals with ID,[14] and ASD, accounting for around 1% to 3% of cases.[10,15] Single-gene disorders, some heritable like fragile X syndrome, account for about 5% to 7% of ASD cases and include *PTEN* macrocephaly syndrome (~1%), tuberous sclerosis complex (~1%), and Rett syndrome (~1%).[10,15] Other inherited causes of ID and ASD include inherited metabolic disorders, such as phenylketonuria, adenylosuccinate lyase deficiency, and Smith–Lemli–Opitz syndrome.[15] Although inherited metabolic disorders are relatively rare, accounting for only 1% to 5% of cases of ID, the potential for positive prognosis with treatment is high.[4]

Other genetic anomalies that can lead to ID and ASD include noninherited, or de novo, single-gene mutations, chromosomal aberrations, and imprinting/epigenetic disorders.[14] Chromosomal aberrations may account for up to 25% of individuals with ID, about 8% or 9% of which is because of trisomy 21, or Down syndrome, the most common known cause of ID.[14,16] Prader–Willi and Angelman syndromes, both associated with developmental delays, are two examples of disorders involving imprinted genes.

Environmental causes of ID range in the literature from 2% to 13% and include antenatal toxin exposure (eg, fetal alcohol spectrum disorders), antenatal infection (eg, TORCH infections), and early severe psychosocial deprivation.[17,18] Environmental causes of ASD include first-trimester intrauterine exposure to valproic acid, thalidomide, misoprostol, the organophosphate insecticide chlorpyrifos, and phthalates, in addition to first-trimester rubella infection.[19] While receiving much scrutiny, multiple studies have shown no data supporting the conclusion that vaccines cause autism.[20]

CLINICAL PRESENTATION

Developmental disorders are typically recognized clinically once it becomes clear that a child is delayed in meeting one or more developmental milestones. Primary care providers have been tasked by the American Academy of Pediatrics (AAP) to assess development at every routine preventative visit throughout childhood.[21] Additionally, the AAP encourages pediatricians to use standardized developmental screening tools (eg, Ages and Stages Questionnaires—ASQ and Parents' Evaluation of Developmental Status—PEDS) at the 9-, 18-, and 24- or 30-month visit, and an autism-specific screening tool at the 18- and 24-month visits (eg, Modified Checklist for Autism in Toddlers—MCHAT).[21,22] Once concerns are raised by routine surveillance or screening measures, children should be referred to early intervention and early childhood programs, as well as to developmental specialists, when indicated.[21]

Early recognition of developmental disorders depends on children having access to preventative medical care, and almost 25% of children with special health care needs might not have that access.[23] The nature and severity of the developmental deficits also contribute to the age at recognition. The sensitivity of developmental and autism screening measures rarely reaches 0.9,[21] and so relatively mild developmental deficits may go undetected. For children with ASD, the mean age of diagnosis has been around 53 months,[5] although children with ID and those diagnosed with autistic disorder are typically diagnosed earlier; children with higher IQ scores and those eventually diagnosed with Asperger disorder, whose limitations do not include communication delays, are typically diagnosed later.[5] Some individuals with particularly subtle deficits may not be diagnosed until adulthood. Individual symptoms that may lead to an earlier diagnosis of ASD may include severe language deficits, hand flapping, toe walking, and sustained odd play.[24]

DIAGNOSIS

ID is defined by both the American Psychiatric Association and the American Association on Intellectual and Developmental Disability (AAIDD) as a disorder with deficits in intellectual and adaptive functioning in conceptual, social, and practical domains.[1,25] The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) requires that the disability has onset "during the developmental period," whereas the AAIDD requires the disability to start before age 18 years. Intellectual functioning is assessed clinically and by standardized tests of intelligence, like IQ testing (eg, Wechsler Intelligence Scale for Children and the Stanford–Binet Intelligence Scale), with a cutoff being two standard deviations below the mean for the general population, or a score of around 65 to 75, for disability.[1] Older references focused diagnosis primarily around IQ scores, and subcategories of ID (then called mental retardation) were set to specific IQ scores.[1] Current methods of diagnosis focus more on measures of adaptive functioning because this is more relevant to planning treatment and supports. Adaptive functioning is also assessed clinically or with standardized tests of adaptive functioning (eg, Vineland Adaptive Behavior Scales). Subcategories for ID in the *DSM-5* are now based on levels of adaptive functioning, mild, moderate, severe, and profound. As standardized testing for intellectual and adaptive functioning is typically valid for children above the age of 5 years, for children younger than 5 years, the diagnosis of GDD is used and describes significant delays in two or more developmental domains, including gross/fine motor, speech/language, cognition, social/personal, and activities of daily living.[26]

ASD is defined by the *DSM-5* as the presence of persistent impairment in reciprocal social communication and social interaction, and restricted, repetitive patterns of behavior, interests, or activities, present from early childhood, and impairing everyday functioning (**Table 88-1**).[1] The diagnosis is made clinically, although standardized behavioral diagnostic instruments, including caregiver interviews, questionnaires, and clinician observation measures (eg, Autism Diagnostic Interview and Autism Diagnostic Observation Schedule), are available to potentially assist in diagnosis.

Table 88-1

DSM-5 Criteria for Autism Spectrum Disorder

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples below):

1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication
3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples below):

1. Stereotyped or repetitive motor movements, use of objects, or speech (eg, simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases)
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (eg, extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day)
3. Highly restricted, fixated interests that are abnormal in intensity or focus (eg, strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests)
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (eg, apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement)

Severity is based on social communication impairments and restricted, repetitive patterns of behavior (Level 1 [requiring support], Level 2 [requiring substantial support], Level 3 [requiring very substantial support])

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.
Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

After a child is identified to have a developmental disorder, further diagnostic workup is warranted to identify an etiologic cause, because some causes may be treatable (eg, metabolic disorder), some may inform of other potential comorbid medical problems (eg, cardiac conditions in Down syndrome and fragile X syndrome), and some may help inform parents of risks for future children. This further etiologic workup should include a thorough medical history (including prenatal and birth history), a family history going back three or more generations, and a physical and neurologic examination focused on findings consistent with recognizable syndromes.[4]

If children with ID or GDD still do not have a known etiologic cause after this workup, they should be referred for chromosomal microarray and possibly screening for inborn errors of metabolism given the treatable nature of some metabolic disorders.[4] The American College of Medical Genetics and Genomics proposes that in the event of a diagnosis of ASD without a known cause despite the above workup, all children should undergo chromosomal microarray, those children with clinical indicators should undergo metabolic or mitochondrial testing, fragile X testing should be

performed for all males, MECP2 (Rett syndrome) testing should be performed in all females, PTEN testing in children with macrocephaly, and neuroimaging only if specific clinical indicators (eg, seizures, regression, history of stupor/coma, microcephaly are present).[27]

CASE 88-1

QUESTION 1: L.B. is a 3-year-old male who is brought to his pediatrician for a well-child visit. During the behavioral health screening, his mother notes that L.B. speaks very few words, does not express many different emotions on his face, does not seem to share enjoyment in activities, and remains fairly unmotivated to interact with other children in daycare. He has more recently been making repetitive loud "woop"-ing sounds that are nonprompted and occur multiple times per day. He also becomes quite aggressive during any transitions. During the visit, the pediatrician completes the Childhood Autism Rating Scale, Second Edition (CARS-2). The result is a score of 32, suggesting a diagnosis of ASD. The pediatrician refers L.B. and his mother to a developmental pediatrician, who specializes in ASD, for further evaluation. After a thorough evaluation, and review of the differential diagnosis, L.B. is given a diagnosis of ASD and is referred for applied behavior analysis (ABA) services.

What signs and symptoms of ASD does L.B. demonstrate?

Based on the *DSM-5* criteria for ASD, L.B. is showing persistent deficits in social communication and social interaction in multiple settings, as demonstrated by his deficits in nonverbal communication (poor facial expressions), lack of relationship building with children, and poor social–emotional reciprocity (lack of shared enjoyment). L.B. also demonstrates restricted, repetitive patterns of behavior with his stereotyped "woop"-ing noises and his inflexible insistence on sameness, with aggression associated with transitions.

OVERVIEW OF TREATMENT

Therapy and Psychosocial Interventions

Individuals with ID or ASD can benefit from many different services to help with issues of communication, social skills, sensory integration, behavior modification, gross and fine motor skills, executive functioning, and adaptive functioning. Most of these services are provided to children through the public education system, at no cost to the families, as ensured by the Individuals with Disabilities Education Act (IDEA). The IDEA provides all states with grants to provide early intervention services for children with developmental delays under the age of 3. Services vary between states, although each child and family are evaluated and given an Individualized Family Service Plan (IFSP), which spells out the services to be provided, which may include, but are not limited to, physical therapy, occupational therapy, speech and language therapy, and behavioral therapy. For children reaching the age of 3 years, and still eligible for specialized education, an Individualized Education Plan (IEP) is drafted, which outlines the services to be provided in the school setting, starting in preschool. IEP services could include all of the same types of services as above, as well as academic support, social skills groups, social pragmatics counseling, vocational training, and emotional counseling. IEPs are required to be reevaluated every 3 years, with updated testing and evaluation. Families must consent to both IFSPs and IEPs, and if they disagree with the supports proposed, there is a process by which they can appeal to have changes made.

Despite the services assured by the IDEA, children and families with developmental disabilities also often receive psychosocial services in their communities. In fact, in the 2011 Survey of Pathways to Diagnosis and Services, almost two-thirds of children with ASD and/or ID were receiving a community-based service.[28] The odds of using any school- or community-based service were almost eight times more likely for children with ASD and over nine times more likely for children with ID, compared to children without those respective diagnoses.[28]

To address the core symptoms of ASD, which include social communication deficits and repetitive, restricted behaviors and interest, the most prevalent treatment modality has been ABA. ABA

is a behavioral therapy rooted in the concepts of operant conditioning, in which an antecedent leads to a behavior, which results in a consequence. In ABA, preferred behavior, such as an appropriate social response, is reinforced with an incentive. Classic ABA employs the use of discrete trial training (DTT), in which specific skills are broken down into discrete components and systematically taught in highly structured settings, often using incentives like food and stickers. Critics of this form of ABA worry that children with ASD are unlikely to apply the learned skills outside of the trial setting. As a result, multiple different therapy approaches have been created, such as Pivotal Response Therapy and the Early Start Denver Model, both derivations of ABA, and the Developmental, Individual-Differences, Relationship-based (DIR) Floortime approach, which all operate in more naturalistic settings, focus more on building child initiation and motivation, and employ natural incentives like positive affect and affection. The research evidence to support such interventions for children and young adults with ASD varies widely, as is explored in Wong et al's[29] comprehensive recent review. Operant conditioning though, and the principles of manipulating antecedents, behavior, and reinforcements, remains the mainstay for the treatment of aggressive behaviors in individuals with developmental disabilities.[30]

Individuals with ID often require the same types of interventions as individuals with ASD, although perhaps with a stronger emphasis on adaptive functioning training, and building skills of independent living. Likewise, for individuals with ID, the evidence base for psychological interventions is varied. One recent review and meta-analysis of psychological therapies for individuals with ID showed that in the literature, individual therapy seems to be superior to group interventions, and moderate-to-large effect sizes exist for therapy for depression and anger, although there is no evidence that therapy has an effect on interpersonal functioning.[31]

Pharmacologic Interventions

The evidence supporting psychopharmacologic interventions in individuals with ID/ASD is relatively limited. There are only a few large double-blind, randomized, placebo-controlled trials (RCTs), many of which were funded by, or affiliated with, the manufacturers of the particular study medications. Most of the existing RCTs are for individuals with ASD and are of children and adolescents, likely, in part, because of the complications involved in consenting adults with ID/ASD to participate in research. Additionally, the targets for medication intervention with the strongest research evidence are behaviors, which relay little about any possible underlying emotional etiology for the individual. Pharmacologic treatment typically targets behaviors such as anxiety, depression, aggression, self-injurious behavior, hyperactivity, inattention, compulsive-like behaviors, repetitive or stereotypic behaviors, and sleep disturbances.[32]

Despite the limitations of the evidence, medications may be an important component of a comprehensive treatment plan for individuals with ID/ASD. Although much of the literature is of studies of children with ASD, it should be noted that a large percentage of these studies contained many individuals with comorbid ID (76%,[33] 71%,[34] 53%,[35] mean IQ, 63[36,37]). However, the literature confirms that individuals with ID/ASD are more sensitive to adverse events from medications compared to their neurotypical peers, and therefore, pharmacologic interventions should be performed with caution.

At the time of this writing, there are no medications approved by the U.S. Food and Drug Administration (FDA) to treat any of the core diagnostic elements of ID/ASD. The target symptom behaviors with the most research evidence include hyperactivity, irritability, repetitive behaviors, and self-injurious behavior. As anxiety disorders are the most common comorbid psychiatric conditions in individuals with ID/ASD, anxiety/depression is another frequent target for psychopharmacologic intervention, although with considerably less research support. Sleep disturbances are also remarkably common in individuals with developmental disabilities and often are a target for medication intervention (**Table 88-2**).

Table 88-2
Summary of Target Symptoms and Pharmacologic Treatment

Target Symptom	Treatment Medications/Classes to Consider
Hyperactivity	Stimulants, atomoxetine, α_2-agonists
Irritability/aggression	Risperidone, aripiprazole
Repetitive behaviors	Risperidone, aripiprazole, fluoxetine, clomipramine, fluvoxamine
Self-injurious behavior	Risperidone, clomipramine, naltrexone
Anxiety/depression	SSRIs
Sleep	Melatonin, ramelteon, clonidine, trazodone, mirtazapine, zolpidem, donepezil, benzodiazepines

SSRI, selective serotonin reuptake inhibitor.

Hyperactivity

Individuals with ID/ASD have high rates of comorbid ADHD, with literature in children with ASD showing prevalence rates of about 30% for children derived from community, nonclinical, populations (28%[38] and 31%,[39]), and 41% to 78% for children evaluated in the clinical setting.[40] The mainstay of treatment for symptoms of ADHD in individuals with ID/ASD, like their neurotypical peers, includes stimulants, α_2-agonists, and atomoxetine. Children with ASD may experience more side effects and show less response than non-ASD patients with ADHD.[41]

Stimulants

Stimulants are a group of medications derived either from methylphenidate or amphetamine that act by increasing the amount of dopamine and norepinephrine in the neuronal synaptic cleft. This increase in dopamine and norepinephrine is the result of blocking the reuptake of dopamine and norepinephrine (methylphenidate and

amphetamine) and increasing the release of dopamine and norepinephrine (amphetamine).

Reichow et al,[42] in their recent meta-analysis of pharmacologic treatments of symptoms of ADHD in children with PDD, found four RCTs of stimulant medications. All four RCTs studied methylphenidate and found it to be superior to placebo for the treatment of global ADHD symptomatology and specifically hyperactivity. In the largest of the four RCTs (n = 66),[43] effect sizes for hyperactivity and impulsivity symptoms were greater than for inattention symptoms (0.77 vs 0.60 for parent rating; 0.48 vs 0.35 for teacher rating).[36]

The effect size for the treatment of ADHD symptoms in children with PDD (0.67 for methylphenidate),[42] however, was lower than estimates in a meta-analysis of stimulant treatment of typically developing children with ADHD (0.77 for methylphenidate and 1.03 for amphetamine).[44] In the study conducted by the Research Units on Pediatric Psychopharmacology (RUPP) group,[43] 49% of children experienced a therapeutic response, compared to 69% in the Multimodal Treatment Study of Children with ADHD (MTA), which studied mostly neurotypical children (ID was an exclusion criteria, and ASD was not mentioned as a comorbid diagnosis in any participants).[45]

Adverse events were more common in children with PDD treated with methylphenidate versus placebo, with increased rates of decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal.[42] Rates of adverse events with methylphenidate were also larger in children with PDD compared to typically developing children, as evidenced by 18% of RUPP study participants[43] discontinuing the medication because of adverse events (primarily irritability), compared to 1.4% in the MTA study.[45]

Mean dosage in the seven RCTs ranged from 0.29 to 0.45 mg/kg/dose.[36,42,44,46,47] Secondary analysis of the RUPP study data showed that methylphenidate doses of 0.25 and 0.5 mg/kg/dose were more consistently effective for treating ADHD symptoms than the lower 0.125 mg/kg/dose.[36] The highest dose used in the RUPP study was 0.625 mg/kg/dose, compared to the MTA study, in which

the highest dose used was 0.8 mg/kg/dose.[43] Daily methylphenidate doses may be titrated weekly until an optimal dose is obtained. Improvement in symptoms should be noted within the first week.[48]

Overall, the research literature shows that methylphenidate can be used to improve ADHD symptoms, especially hyperactivity, in children with PDD, though with lower effect sizes, lower tolerated doses, and more risk of adverse effects than children without developmental disabilities.

Although no RCTs have been conducted studying the effects of amphetamine-derived stimulants for the treatment of ADHD in children with ASD, consensus guidelines suggest that amphetamine salts can be an option for children demonstrating insufficient benefit or dose-limiting adverse events from methylphenidate.[49]

α_2-Agonists

Although the exact mechanism in ADHD is unknown, α_2-agonists are thought to work by stimulating the α_2-adrenoceptors on norepinephrine-containing neuron cell bodies in the locus coeruleus, which modulates the tonic and phasic firing to the prefrontal cortex. This allows the person to have increased attention on the desired task.[50]

α_2-Agonists include clonidine, a nonselective α_2-adrenergic receptor agonist, and guanfacine, a selective α_2-adrenergic receptor agonist. α_2-Agonists were initially marketed for the treatment of hypertension, although have been shown to also improve symptoms of ADHD.

For clonidine, one small study (n = 8)[51] was identified by Reichow et al[42] looking at clonidine versus placebo for the treatment of ADHD in children with PDD. Although the original study found no statistically significant results, the effect size calculated by Reichow et al[42] for improvement in ADHD symptoms and irritability was in the medium range (g = 0.51 and 0.64, respectively) and smaller for improvements in hyperactivity (g = 0.30) and stereotypic behavior

(0.24). The authors of the original study[51] report increased rates of hypotension and drowsiness in some children who took clonidine. Mean dosage ranged from 0.15 to 0.20 mg/day.

A retrospective chart review evaluated (*n* = 80) children and adolescents ages 3 to 18 years with PDD with target symptoms of hyperactivity, inattention, and impulsivity. Treatment with a guanfacine immediate-release (IR) mean daily dose of 2.6 ± 1.7 mg showed significant improvement in target symptoms based on Clinical Global Impression Scale-Improvement (CGI-I) and Clinical Global Impression Scale-Severity (CGI-S) scores. In these studies, adverse events included drowsiness, irritability, and enuresis, as well as diarrhea, constipation, and social withdrawal; additional adverse events from an open-label study of guanfacine in children with PDD include sleep disturbance (insomnia or mid-sleep awakening).[52–54]

In an RCT (*n* = 62) evaluating guanfacine extended release (ER) in children ages 5 to 14 years with autistic disorder, Asperger syndrome, or PDD accompanied by hyperactivity, impulsiveness, and distractibility, treatment with guanfacine ER exhibited a significant decrease in scores on the Aberrant Behavior Checklist (ABC) Hyperactivity subscale compared to a placebo group. Additionally, treatment with guanfacine ER demonstrated a greater improvement on the ADHD rating scale compared to placebo.[55]

Overall, a small collection of literature suggests that clonidine and guanfacine may be beneficial for the treatment of ADHD symptoms in children with ASD/ID, with similar adverse events as reported in neurotypical children, although more evidence is needed to draw any more extensive conclusions about the use of these medications in the ID/ASD population.

Atomoxetine

Atomoxetine is a medication for ADHD that acts by inhibiting the reuptake of norepinephrine, therefore increasing the amount of norepinephrine in the synaptic cleft. Dosing is generally once daily,

with adjustments after a minimum of 3 days to a target daily dose. Clinical benefit has been noted within the first 1 to 2 weeks.[56]

Reichow et al's[42] meta-analysis found two RCTs comparing atomoxetine to placebo in children with PDD, although only the larger of the two (n = 97)[56] showed statistically significant benefits for the treatment of global ADHD symptoms and hyperactivity (effect sizes calculated by Reichow et al[42] of g = 0.83 and g 0.80, respectively). In this study by Harfterkamp et al,[56] changes in the subscales of inattention and oppositional behavior did not reach statistical significance for children on atomoxetine compared to placebo.

Children with PDD in the Harfterkamp et al[56] study demonstrated increased rates of nausea, decreased appetite, and early morning awakening compared to study participants taking placebo. Mean dosage in the two studies was 1.2 mg/kg/day[56] and 44.2 mg/day.[57] This dosing is perhaps only slightly lower than other large studies of atomoxetine in children with ADHD without developmental disorders (mean final atomoxetine dose was 1.45 mg/kg/day, 53.0 mg/day[58]), although documentation from the drug manufacturer's studies, of presumably mostly neurotypical children with ADHD, indicates no additional benefits for doses above 1.2 mg/kg/day.[56]

Similar to the α_2-agonists, it seems that atomoxetine shows benefits for addressing ADHD symptoms in children with PDD, particularly for hyperactive symptoms, with similar dosing and adverse events to children with ADHD without developmental disorders.

Other Medications

Tricyclic antidepressants (TCAs), which primarily act as serotonin/norepinephrine–reuptake inhibitors (SNRIs), had been a part of older treatment algorithms for the treatment of ADHD in typically developing children[59] and, as a result, have also been studied in children with ASD. In Gordon et al's crossover RCT of clomipramine and desipramine versus placebo[60] (5 weeks each

intervention), both drugs were significantly superior to placebo for reducing the hyperactivity domain of the Children's Psychiatric Rating Scale (CPRS) Autism Relevant Subscale, although no different from each other. TCAs are known for adverse effects, primarily antimuscarinic in nature, which includes dry mouth, blurred vision, decreased gastrointestinal motility, and urinary retention. TCAs can also cause irregular heart rhythms, tachycardia, and hypotension and should be used with caution in patients with preexisting cardiac conditions and can be fatal with just small excesses in dose. TCAs are also highly metabolized by the cytochrome P450 hepatic enzymes, including 3A4 and 2D6. Therefore, inhibitors of these enzymes can lead to increased concentrations and a higher risk of side effects including cardiac abnormalities.

Although antipsychotic medications are not typically part of the treatment algorithm for ADHD in children with typical development,[59,61] studies of risperidone and aripiprazole for the treatment of children with ASD and irritability/aggression symptoms did show statistically significant improvement in hyperactivity subscales (risperidone,[33–36] aripiprazole[62–64]). As a result, atypical antipsychotics are part of a treatment algorithm developed by the Autism Speaks Autism Treatment Network Psychopharmacology Committee Medication Choice Subcommittee for symptoms of ADHD in individuals with ASD, if they have not shown adequate improvement from stimulants, atomoxetine, and α_2-agonists.[49]

Other medications, which have not yet been included in standard practice, although have shown some promising evidence for improvement in hyperactivity symptoms in RCTs of children with ASD, include ω-3 fatty acids,[65] tianeptine.[66] Pentoxifylline[67] and topiramate,[68] as adjuncts to risperidone, also have positive outcomes.

Case 88-1, Question 2: L.B., now 5 years old, has been receiving ABA services for nearly 2 years and has been progressing well. At home though, L.B. has become increasingly disobedient and hyperactive. In school, his teachers note that he is inattentive, wandering around the classroom and

staring out the windows. In addition, during story time and craft time, he is disruptive and hyperactive, running around the room. In response, L.B.'s pediatrician facilitates an increase in the number of hours of in-home ABA services, whose providers also work with L.B.'s parents' teaching behavioral management techniques. The pediatrician also recommends certain classroom modifications to help with attention. This, however, does not reduce the outbursts or inattentive and hyperactive behavior, both at home and school. The pediatrician believes that a trial of pharmacotherapy may be helpful. The pediatrician consults you, the clinical pharmacist, to discuss an appropriate treatment plan. What pharmacotherapy and formulation would be most appropriate for L.B.'s target symptoms?

Clinical trials have shown that stimulants can be a very effective treatment option for children with ADHD. The American Academy of Child and Adolescent Psychiatry (AACAP) and the AAP recommend the use of methylphenidate, over that of amphetamines or nonstimulant medication, in preschool children where behavioral modification therapy has not been adequate. The metabolism of methylphenidate in preschool children is slower than that of older children, and therefore the starting dose is lower, and the optimal dose is likely lower than in older children.

Based on this information, you recommend starting L.B. on methylphenidate IR solution 1.25 mg twice daily, with an increase to 2.5 mg twice daily on day 3, with subsequent dose increases every 3 days to reduce target symptoms, up to a maximum of 7.5 mg three times daily. You recommend that the parents keep a journal of the responses and possible experienced adverse effects during this period with a report back to the pediatrician at the end of the week.

Irritability/Aggression

Irritability/aggression is the pharmacologic target behavior with the most robust RCT evidence in children with ASD. Two national and one international consensus guidelines recommend risperidone and aripiprazole for the treatment of irritability associated with autism.[32,42,69] Most of this evidence comes from four large RCTs of either risperidone or aripiprazole.[33,34,62,63] In this context, risperidone

and aripiprazole are the only two medications with FDA approval for use in individuals with developmental disabilities. Specifically, each has an FDA-approved indication for the treatment of autistic disorder-associated irritability in children and adolescents (risperidone—age 5–17 years; aripiprazole—age 6–17 years).

Risperidone

Both McCracken et al's[33] and Shea et al's[34] studies of risperidone were 8 weeks in duration, in a population of children and adolescents with solely autistic disorder[33] or mostly autistic disorder[34] (70% of the study population had autistic disorder; the rest were diagnosed with PDD NOS, Asperger disorder, or childhood disintegrative disorder), and with mostly comorbid ID (64% of study population[34]; 81% of study population[33]). Both showed risperidone to have statistically significant improvements, compared to placebo, in the Irritability subscale of the Aberrant Behavior Checklist (ABC-I) (ABC-I is a 15-item subscale that includes items such as "injures self," "physical violence to self," "aggressive to other children and adults," "irritable," "temper outbursts," "depressed mood," "mood changes," and "yells" or "screams" inappropriately; individual items are rated on a scale ranging from 0—not at all a problem, to 3—severe),[63] as well as the ABC subscales for hyperactivity and stereotypy. The subscales for social withdrawal and inappropriate speech only showed statistically significant improvements for risperidone compared to placebo in Shea et al's study.[34] The definition of "response" was different in each study. In McCracken et al's study,[33] positive response was defined as at least a 25% decrease in the ABC-I score and a rating of much improved or very much improved on the Clinical Global Impression rating scale (CGI) and CGI-I. With this definition, 69% were responders in the risperidone group and 12% in the placebo group. In Shea et al's study,[34] a responder was defined as having a 50% or greater decrease from baseline in at least two of the five ABC subscales with none of the other subscales presenting a 10% or larger increase.

With this definition, 69% of subjects in the risperidone group were responders, compared to 40% in the placebo group.

In McCracken et al's study,[33] participants in the risperidone group, compared to placebo, experienced significantly higher rates of increased appetite, fatigue, drowsiness, dizziness, and drooling, with trends of increased rates of tremor, tachycardia, and constipation ($P = .06$). In a 16-week open-label extension of McCracken et al's study,[33] the most common adverse events were excessive appetite, enuresis, tired during the day, dry mouth, excess saliva, rhinitis, coughing, and anxiety.[69] Risperidone-treated participants in Shea et al's study[34] experienced significantly greater increases in weight, pulse rate, and systolic blood pressure and had a significantly higher rate of reported somnolence (73% risperidone vs 8% placebo). Extrapyramidal symptoms (EPSs) were endorsed by 28% of the risperidone-treated participants in Shea et al's study,[34] compared to 13% in the placebo group. Mean weight gain in both 8-week studies for those taking risperidone was 2.7 kg. Mean final daily risperidone dose was 1.8 mg[33] and 1.48 mg,[34] which is in contrast to the mean final daily risperidone dose of 2.8 mg in a large RCT of the antipsychotic treatment of early-onset schizophrenia and schizoaffective disorder in children and adolescents (ID was an exclusion criterion).[70–73]

Several studies have confirmed that risperidone treatment may be associated with an increase in serum prolactin levels.[33,74,75]

McDougle et al's[76] study of risperidone in adults with ASD showed similarly beneficial findings for the reduction in aggressive behavior, compared to placebo, and common adverse events also included sedation and weight gain. The mean final daily dose of risperidone was 2.9 mg, which is in contrast to the mean daily dose of risperidone of 3.9 mg in a large RCT of adults with schizophrenia.[77]

Aripiprazole

Both Marcus et al's[63] and Owen et al's[62] studies of aripiprazole versus placebo in children and adolescents with autistic disorder

were 8 weeks in duration. Prevalence of comorbid ID was not mentioned in either study. Both studies showed statistically significant improvement in children treated with aripiprazole, compared to placebo, for ABC-I, CGI-I, as well as ABC subscales of hyperactivity and stereotypy. Although Owen et al's[62] flexible dosing schedule showed statistically significant improvements in the ABC subscale for inappropriate speech with aripiprazole versus placebo, in Marcus et al's[63] fixed-dose study, only the 15 mg/day dose of aripiprazole showed statistically significant improvement in inappropriate speech. Neither study showed statistically significant improvement for aripiprazole, versus placebo for the ABC lethargy/social withdrawal subscale. Both studies defined response as at least a 25% reduction from baseline to end point in the ABC-I subscale and a CGI-I score of 1 (very much improved) or 2 (much improved) at end point. With this definition, the response rate was 52.2% for aripiprazole in Owen et al's study[62] (14.3% for placebo), and although response rates for each dose of aripiprazole (5 mg—55.8%, 10 mg—49.2%, 15 mg—52.8%) were higher than placebo (34.7%) in Marcus et al's study,[63] only the response rate at 5 mg/day separated from placebo with statistical significance.

In Marcus et al's study,[63] the three most common adverse events leading to discontinuation of aripiprazole were sedation, drooling, and tremor, none of which were reported in the placebo group. The most common adverse events reported in the aripiprazole group of Owen et al's study[62] were fatigue, somnolence, vomiting, increased appetite, and sedation. In Owen et al,[62] 14.9% of aripiprazole-treated subjects (vs 8% for placebo) endorsed EPS symptoms, with the most common being tremor (8.5%). In Marcus et al's study,[62] EPS symptoms were reported at roughly twice the rate in all aripiprazole doses (5 mg/day—23.1%, 10 mg/day—22.0%, and 15 mg/day—22.2%) compared to placebo (11.8%), the most common of which were tremor and extrapyramidal disorder. Aripiprazole was associated with statistically significant gains in weight compared to placebo after 8 weeks, with the mean weight gain on aripiprazole in Owen et al[62] being 2.0 kg, and for Marcus et al,[62] 1.3 kg (5 mg/day), 1.3 kg (10 mg/day), and 1.5 kg (15 mg/day). Interestingly, both

studies showed aripiprazole to have statistically significant reductions in prolactin levels compared to placebo. Mean final daily dosing for aripiprazole in Owen et al[62] was 8.9 mg/day. In a 52-week open-label follow-up study of participants from both Owen et al[62] and Marcus et al,[63] as well as newly enrolled subjects, the mean final daily dosing of aripiprazole was 10.6 mg/day.[78] In a 2-month RCT of aripiprazole versus risperidone in children with ASD, the mean final daily dose of aripiprazole was 5.5 mg.[79] Manufacturer recommended daily dosing of aripiprazole in pediatric patients with schizophrenia or bipolar disorder is 10 mg/day.[80]

Overall, the literature shows that risperidone and aripiprazole, in doses likely lower than that used in children with schizophrenia or bipolar disorder, can be used effectively to reduce symptoms of irritability and aggressive behavior in children and adolescents with ASD,[81–85] although treatment should be monitored closely for relatively common adverse events of sedation, weight gain, and EPS. Of note, although risperidone has been shown to consistently increase prolactin levels, aripiprazole was shown to consistently lower prolactin levels.

Although risperidone and aripiprazole are the two antipsychotic medications with FDA approval for the treatment of irritability in children with ASD, other typical and atypical antipsychotics have also demonstrated benefits for treating symptoms of irritability in children with ASD. Haloperidol, dosed in the range of 0.5 to 4.0 mg/day, has shown benefits in four RCTs and two long-term follow-up studies, although with significant rates of dyskinesia (34%).[86] One RCT supports the benefits of pimozide, one RCT supports the use of olanzapine, and either open-label studies or case reports exist to support the benefits of olanzapine, clozapine, quetiapine, ziprasidone, and paliperidone.[87] A head-to-head comparison RCT of risperidone and haloperidol in children with autistic disorder showed risperidone to be significantly more effective than haloperidol at reducing aberrant behavior and symptoms of PDD.[88] A RCT evaluated risperidone, haloperidol, and placebo for treatment of aggression in adults with ID. All three treatment arms demonstrated

decreased aggression, with no significant difference between the three treatments arms.[89]

Other Medications

VALPROATE

Two RCTs of similar size (*n* = 30[90] and *n* = 27[37]) looked at valproate versus placebo in children and adolescents with ASD and irritability/aggression with somewhat conflicting results. Hellings et al[90] found no significant difference in improvement of irritability or aggression (including ABC-I and CGI-I) between valproate and placebo after 8 weeks, whereas Hollander et al,[37] after 12 weeks, showed valproate to be significantly superior to placebo at improving CGI-I and the rate of improvement of ABC-I. Whereas in Hollander et al's study,[37] there were no significant differences in adverse events between valproate and placebo, in Hellings et al's study,[90] there was a significantly increased rate of endorsed appetite increase in the valproate group, and two individuals in the valproate group developed elevated ammonia levels, one with clinically associated symptoms. Both studies had target blood valproate levels (at least 50 μg/mL,[37] 70–100 μg/mL[90]).

Additional medications with limited RCT data, open-label studies, or case reports to support its use for irritability in individuals with ASD include buspirone, clomipramine, clonidine, escitalopram,[91] lamotrigine, levetiracetam, memantine, mirtazapine, oxcarbazepine,[92] pioglitazone, topiramate (monotherapy or when added to risperidone),[93] riluzole, sertraline, and trazodone,[87] as well as fluvoxamine[94] and lithium.[95] Reichow et al recently published a meta-analysis of medications for the treatment of ADHD symptoms in children with PDD. Methylphenidate had moderate, although not statistically significant, benefits in treating irritability.[42]

CASE 88-2

Question 1: C.Y., a 9-year-old female with ASD has been well maintained on risperidone for the last 3 years. At the most recent checkup, the prescriber

notes that she has gained ~25 pounds (11.34 kg) over the last 2 years (note that the average weight gain for a 9-year-old child is ~5 pounds [2.27 kg] per year). The majority of weight gained seems to be in the abdominal area. Blood tests note an elevated hemoglobin A1C of 8.4%. The provider discusses diet and exercise, but C.Y.'s mother notes no change over the last few years. She believes her weight gain started with the addition of risperidone, which is now at 4 mg/day.

What would you for a recommendation based on your knowledge of the metabolic profiles of atypical antipsychotics?

Although risperidone and aripiprazole are not necessarily interchangeable, both are indicated for the treatment of irritability in children with ASD, and aripiprazole may convey less of a risk for weight gain than risperidone. Although the two medications are of equal benefit, there is a possibility that a patient may respond to one agent and not the other. In this context, you may recommend for the prescriber to decrease risperidone by 1 mg every other week, while starting aripiprazole 2 mg/day for 7 days followed by an increase to 5 mg daily. Additional 5-mg dose increases can be made weekly up to a maximum of 15 mg/day. C.Y. should be monitored for tolerability during both the cross-taper/titration period and beyond.

REPETITIVE BEHAVIORS

Numerous different types of medications have been studied for the treatment of repetitive behaviors in individuals with ASD. Selective serotonin reuptake inhibitors (SSRIs) and TCAs have been studied likely because of perceived similarities between the repetitive behaviors and compulsions exhibited in children with obsessive–compulsive disorder as well as the clinical observation that repetitive behaviors may increase in children with PDD because of underlying anxiety. However, the literature is mixed to support the use of SSRIs or TCAs for this indication.

Selective Serotonin Reuptake Inhibitors

Two RCTs looking at SSRIs for children with ASD and repetitive behavior demonstrate conflicting results. Hollander et al's[96] crossover trial (*n* = 39, mean age 8.2 years) showed that low-dose liquid fluoxetine was superior to placebo for treating repetitive behaviors, as measured by the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) compulsion subscale, with a medium to large effect size (0.76), though did not separate from placebo for improvements in other aspects of global autism severity. In King et al's[97] large study of citalopram (*n* = 73) versus placebo (*n* = 76) to target repetitive behaviors in children with ASD, there were no statistically significant differences between citalopram and placebo in improvements in overall symptomatology (CGI-I) or repetitive behaviors on the modified CY-BOCS-PDD rating scale. An RCT of fluvoxamine versus placebo in adults with ASD (*n* = 15 in each group), however, did show fluvoxamine to be significantly superior to placebo for improving repetitive thoughts and behavior.[94] (See Anxiety/Depression section for more details on SSRI prescribing in children with ASD.)

Tricyclic Antidepressants

Clomipramine was studied in Gordon et al's[60] RCT, in which it was shown to be significantly superior to both placebo and desipramine for the treatment of repetitive behavior in children with ASD as shown by the modified CPRS OCD subscale, the modified National Institute of Mental Health (NIMH) OCD Scale, and the modified NIMH Global OCD and Anxiety scales. The mean final week daily dose of clomipramine was 152 mg; the mean final week clomipramine blood level was 235 ng/mL, and desmethyl clomipramine level was 422 ng/mL. Overall, adverse events were relatively minor, although in those taking clomipramine, one person had a seizure, and two had cardiac adverse events, one with a prolonged corrected QT interval (0.45 seconds) and the other with severe tachycardia (160–170 beats/minute), both of which resolved with reduction in dose. In Remington et al's[98] crossover RCT (7

weeks each intervention) comparing clomipramine to haloperidol in children with autistic disorder, the most striking finding was that only 37.5% of participants taking clomipramine finished the study (compared to 69.7% haloperidol and 65.6% for placebo), with adverse events contributing to discontinuation, including behavioral problems, fatigue or lethargy, tremors, tachycardia, insomnia, diaphoresis, nausea or vomiting, and decreased appetite. The mean daily dose of clomipramine was 128.4 mg, range 100 to 150 mg.

Overall, for the reduction of repetitive behaviors, SSRIs, specifically fluoxetine, and TCAs, specifically clomipramine, may be helpful in children with ASD, although adverse events may be particularly limiting for clomipramine. For adults with ASD, SSRIs, specifically fluvoxamine, may be helpful in reducing repetitive behaviors.

Antipsychotics

Antipsychotics have shown the most robust evidence in reducing repetitive behaviors in children with ASD. Nearly all of the data to support antipsychotics for this purpose come from the same studies that targeted irritability. Both aripiprazole[62,63] and risperidone[33,34] were superior to placebo for reducing the score on the ABC Stereotypy subscale. In McDougle et al's[99] secondary analysis of the 8-week RUPP Risperidone trial,[33] risperidone resulted in significantly greater reductions, compared to placebo, in the scores on the modified compulsion subscale of the CY-BOCS (effect size 0.55) and the sensory motor behaviors subscale of the Ritvo–Freeman Real Life Rating Scale (effect size 0.45). Similar findings for risperidone's benefit for reducing repetitive behaviors have been found in adults with ASD, including McDougle et al's RCT,[76] which found statistically significant reductions in the modified version of the Y-BOCS (focusing only on repetitive behavior, not thoughts). In a study evaluating olanzapine versus placebo (n = 11), no statistical differences in outcomes tied to obsessive–compulsive symptoms,

aggression, or irritability; however, greater adverse effects (including weight gain) were seen in the olanzapine group.[100]

Stimulants

In Reichow et al's recent meta-analysis of medications for the treatment of ADHD symptoms in children with PDD, methylphenidate had moderate, although not statistically significant, benefits in treating stereotypies.[42]

Other Medications

Despite valproate demonstrating efficacy for the treatment of irritability in Hollander et al's study of children with ASD, it showed no significant improvement in repetitive behavior, compared to placebo.[37] One small RCT of 1.5 g/day of ω-3 fatty acids (fish oil n = 7, placebo n = 5) showed no significant difference compared to placebo in reduction of ABC Stereotypy, although the effect size was 0.72.[65] Chugani et al evaluated buspirone versus placebo (n = 166) found no significant difference in composite treatment scores but concluded buspirone may be a useful adjunct therapy to target restrictive and repetitive behaviors.[101]

SELF-INJURIOUS BEHAVIOR

Depending on the rating scale or etiologic theory, self-injurious behavior is commonly thought of as either an act of aggression toward the self or as a repetitive, stereotyped behavior. Consequently, pharmacologic approaches to the treatment of self-injury have been rooted in the approaches for the treatment of aggression or repetitive behavior. Self-injurious behavior has its own literature base though, with similar and dissimilar findings.

Typical and Atypical Antipsychotics

RCTs of typical antipsychotics for the reduction of self-injurious behavior in individuals with developmental disabilities have had mixed findings. There has been relatively unconvincing data for the benefit of haloperidol, fluphenazine, chlorpromazine, or thioridazine in reducing self-injurious behavior.[102] Risperidone is the atypical antipsychotic with the most robust RCT data for improving self-injurious behavior, with two relatively large RCTs in children with ID showing improvement in the self-injury/stereotypic subscale of the Nisonger Child Behavior Rating Form,[103,104] one of which was statistically significant,[104] and statistically significant reductions in self-injurious behavior in adults with ASD, as measured by the Self-injurious Behavior Questionnaire.[76] Similar to studies in children with ASD, weight gain and somnolence were markedly higher in children taking risperidone than placebo.

Antidepressants

Clomipramine has been shown to be effective in reducing self-injurious behavior, but again with significant adverse effects.[102] Fluoxetine has been shown to be effective at reducing compulsive skin picking in two RCTs,[105,106] and fluvoxamine has been effective for reducing repetitive behavior and aggression in adults with ASD.[94] Case reports and open-label studies have shown possible benefit for buspirone and paroxetine as well.[102]

Naltrexone

A recent systemic review of naltrexone used in adults with ID showed 8 out of 10 RCTs demonstrating a reduction in the frequency of self-injurious behavior.[107] More specifically, 50% of participants had improvement in self-injury, with improvement being more pronounced in individuals with severe and profound ID. Nine percent experienced minor adverse events, which included weight loss, loss

of appetite, thirst, yawning, mild liver function test abnormalities, nausea, and tiredness. Dosing ranged from 0.5 to 2 mg/kg and doses from 25 to 100 mg.

Overall, despite very limited evidence, it seems the literature supports the use of risperidone, naltrexone, and clomipramine for the reduction of self-injurious behavior in individuals with developmental disabilities. Additionally, fluoxetine and fluvoxamine may have benefits as well, though less well evidenced.

ANXIETY/DEPRESSION

Selective Serotonin Reuptake Inhibitors

Studies have found that individuals with PDDs are at high risk of comorbid anxiety and mood disorders.[38,39] Because of the demonstrated benefits and relative safety of SSRIs in typically developing children, SSRIs are very commonly prescribed for anxiety and depression in children with developmental disorders. No large double-blind, placebo-controlled trials have been conducted looking at the use of SSRIs for depression or anxiety in children with developmental disorders, although the literature has numerous case reports and open-label studies demonstrating SSRI-induced improvements in anxiety in individuals with ASD.[108,109]

Overall, the literature indicates that children with developmental disorders may respond differently to SSRIs compared to children with typical development. Three areas in which response to SSRIs may differ include risk of adverse events, dosing requirements, and target symptoms. If poor response to SSRIs, a trial with risperidone may be appropriate with continued monitoring for worsened anxiety.[41]

Adverse Events

Compared to children with typical development, children with developmental disorders are more likely to experience adverse events to SSRIs and specifically are more likely to endorse emotional/behavioral adverse events. The only two RCTs looking at SSRIs in children with developmental disorders evaluated fluoxetine[96] and citalopram[97] for the treatment of repetitive behaviors. In the crossover study (8 weeks each phase) of low-dose fluoxetine by Hollander et al[96] (*n* = 39, mean age 8.2 years), although there was no statistically significant difference in treatment-emergent adverse events between fluoxetine and placebo, the most common adverse events emerging during fluoxetine treatment were agitation (46%), insomnia (36%), and anxiety/nervousness (16%). Additionally, 16% of subjects required a dose reduction because of agitation while on fluoxetine, compared to 5% on placebo.

In contrast, both Geller et al[110] and Liebowitz et al[111] conducted RCTs of fluoxetine for the treatment of OCD in typically developing children (Geller: 13 weeks; *n* = 71 fluoxetine, 32 placebo; mean age 11.4 years/Liebowitz: 8-week acute phase; *n*=21 fluoxetine, 22 placebo; mean age 12–13). In Geller et al,[110] there was no statistically significant difference in reported adverse events, and the most common adverse events reported in the fluoxetine group were headache (28%), rhinitis (27%), and abdominal pain (16%), with no reports of agitation. In Liebowitz et al,[112] six adverse events occurred significantly more frequently in the fluoxetine group: palpitations, weight loss, drowsiness, tremors, nightmares, and muscle aches, and the most common adverse events reported by those taking fluoxetine were headache (52%), abdominal pain (43%), decreased appetite (38%), difficulty staying asleep (38%), and drowsiness (38%).

For citalopram, in the 12-week study by King et al[97] (*n* = 73 citalopram, 76 placebo; mean age ~9 years), 97.3% of subjects with ASD treated with citalopram experienced at least one treatment-emergent adverse event. They were significantly more likely to experience adverse events compared to those treated with placebo, specifically: increased energy level (38%), impulsiveness (19%), decreased concentration (12%), hyperactivity (12%), stereotypy

(11%), diarrhea (26%), insomnia (23.3%), and dry skin or pruritus (12%).

In contrast, in RCTs of citalopram for the treatment of depression in children and adolescents with typical development, the most commonly reported adverse events were headache, gastrointestinal issues, and insomnia.[112] Specifically in the 8-week RCT by Wagner et al[113] of citalopram for typically developing children with depression (*n* = 89 citalopram, 85 placebo; mean age, 12 years), rhinitis (14%), nausea (14%), and abdominal pain (11%) were the only adverse events reported in >10% of subjects taking citalopram, and in the 12-week RCT by von Knorring et al[114] of citalopram for typically developing adolescents with depression (*n* = 124 citalopram, 120 placebo; mean age 16 years), headache (26% and 25%), nausea (19% and 15%), and insomnia (13% and 11%) were the most common in both groups (citalopram and placebo, respectively), with only fatigue being the adverse event reported significantly more often in the citalopram group (6%) than the placebo group (1%).

Dosing

Children with PDD typically require smaller doses of SSRIs compared to children with typical development and may experience adverse emotional/behavioral events at higher doses. For fluoxetine, the mean final daily dose in Hollander et al's study[96] of children with PDD was 9.9 mg, or 0.36 mg/kg. This is compared to Geller et al[110] and Liebowitz et al's[111] studies of typically developing children with OCD, in which the mean final daily fluoxetine dose was 24.6 and 64.8 mg (after the acute phase), respectively. Additionally, in RCTs of typically developing children with depression and other forms of anxiety, fluoxetine was well tolerated at mean daily doses of 20 mg,[115–117] 28.4 mg and 33.3 mg,[118] and 40 mg.[119]

For citalopram, the mean daily dose in the King et al study[97] of children with ASD and repetitive behavior was 16.5 mg. In studies of citalopram use in typically developing children and adolescents with

depression, citalopram was tolerated at mean daily doses of 24 mg[113] and 26 mg.[114]

The issue of individuals with PDD requiring lower dosages of SSRI might diminish in adulthood because RCTs of SSRIs in adults with ASD demonstrate mean daily doses close to that expected for typically developing adults: fluoxetine—36.7 mg[120] and 64.8 mg[120]; fluvoxamine 276.7 mg.[94]

CASE 88-3

Question 1: N.W. is a 6-year-old female with a history of supraventricular tachycardia (SVT) at birth, well controlled on propranolol since infancy. N.W. also has a diagnosis of ASD. Over the past year, she has been trialed on varying stimulant formulations and doses for the treatment of ADHD symptoms. However, N.W.'s mom reports only small improvement, but significant worsening of repetitive behavior and aggression. N.W. has been pushing, hitting, and throwing things at school and home. Additionally, N.W. has had a decrease in appetite and lost ~4 pounds (1.81 kg). At home, N.W. has recently developed a lot of anxiety, refusing to go to school and participate in outdoor activities. Her mother notes that N.W. appears to be isolating herself more and not enjoying activities that used to make her happy. The prescriber discontinues methylphenidate and starts N.W. on risperidone 1 mg/day for aggression and repetitive behaviors. She also starts on fluoxetine 10 mg/day for depression and anxiety.

You get a call from N.W.'s mother 3 days after N.W. starts the new medication regimen. N.W.'s mother reports that N.W. is extremely lethargic and seems confused. She fell the last few times she tried to get out of bed. You have the mother use a blood pressure cuff she has at home to measure N.W.'s vital signs. Based on the results, N.W. is bradycardic and hypotensive.

What is your recommendation?

The dose of risperidone that N.W. was started on is high. Additionally, fluoxetine is a strong 2D6 inhibitor, and risperidone and propranolol are 2D6 substrates. Therefore, fluoxetine may be decreasing the clearance of both risperidone and propranolol. You decide to call the provider and discuss the interaction and adverse effects that N.W. is experiencing.

Case 88-3, Question 2: The prescriber is thankful for the call and asks for your advice on altering the current regimen. What changes would you recommend?

You recommend discontinuation of the fluoxetine and initiation of sertraline 12.5 mg/day because sertraline is a weaker inhibitor of 2D6. You would recommend the continuation of risperidone at a reduced dose of 0.5 mg/day.

Target Symptoms

Most studies looking at symptoms of anxiety and depression in children with ASD have used rating scales validated in typically developing children. For anxiety, predictors that children with ASD will manifest a high level of parent-reported anxiety include the following: IQ >70,[121–123] higher levels of parent-rated social impairment,[121,122] and increased age[122]; additionally, it seems that children with IQ >70 might experience higher levels of parent-reported anxiety if they demonstrate more adaptive social behaviors.[121,122] For depression, higher IQ and age seem correlated with higher depression ratings,[124] and both seem to predict lower self-perceived social competence in children with ASD.[125] Lower self-perceived social competence, in turn, seems to predict high levels of depression symptomatology.[125] Additionally, it seems that adults with ASD with less social impairment (higher social functioning) were more likely to be categorized as depressed.[126] All of this seems to indicate that the more individuals with ASD are aware of social impairments, or exposed to social interactions, the more likely they are to demonstrate classically recognizable symptoms of anxiety or depression.

However, this body of literature, because of the scales that are used, only addresses anxiety and depressive mood symptoms that are also seen in typically developing individuals. Clinicians who work with individuals with PDD are well aware that anxiety and depression might manifest in alternative ways in this population. Individuals with

ASD often have impaired abilities to communicate their emotional experiences to others and can have significant trouble managing their emotions. This routinely leads to alternative manifestations of emotions like anxiety and depression, in the forms of rigidity, tantrums, oppositionality, social avoidance, hyperactivity, repetitive behaviors, irritability, aggression, and self-injury. As mentioned above, studies of SSRIs to target some of these behaviors have been mixed.

Overall though, it seems that case studies and open-label trials have shown possible benefits for the use of SSRIs in children with PDD for the treatment of classically recognized symptoms of anxiety and depression. To avoid significant emotional and behavioral adverse events though, target dosing should be lower than in children with typical development.

SLEEP

Melatonin

The medication with the strongest research backing for the treatment of sleep disturbance in individuals with developmental disabilities is melatonin. Consensus guidelines from the British Association for Psychopharmacology around the treatment of ASD recommend that for comorbid sleep disorders, consider melatonin, if possible, in combination with a behavioral intervention. Of note, guidelines do not recommend prolonged use of benzodiazepines and related γ-aminobutyric acid (GABA) agonists.[41]

Hollway and Aman's review[127] found 13 RCTs of individuals with sleep disturbance, many of which also with developmental disabilities. All 13 RCTs had positive findings, particularly for sleep initiation and sleep maintenance, with the longest trial being 10 weeks in duration. The effect sizes for sleep onset latency ranged from 0.25 to 1.63, and for total sleep time from 0.25 to 1.0. Adverse

effects were generally mild and similar to placebo. Doses ranged from 2.5 to 10 mg.

Ramelteon

The MT_1/MT_2 melatonin receptor agonist has limited evidence in children with developmental disabilities, although considerable positive findings in adults with typical development, specifically in primary insomnia and sleep maintenance.[127] Adverse effects were mild and similar to placebo, and doses ranged from 4 to 64 mg.

Clonidine

Although no RCTs have been conducted in children with developmental disabilities and sleep disturbance, retrospective reviews have shown benefits in helping with sleep disturbance, with doses ranging from 0.05 to 0.1 mg.[127]

Trazodone

Although no RCTs have been conducted in children with sleep disorders, four open-label studies in children and two in adults showed benefits for improving sleep, including sleep architecture.[127] Doses ranged from 25 to 150 mg.

Mirtazapine

One open-label study in children and one RCT in adults showed benefits for the treatment of sleep problems, with mild adverse effects, which included increased appetite, irritability, and sedation.[127] Doses ranged from 7.5 to 45 mg.

Diphenhydramine

Despite its abundant use in pediatric patients for sleep disturbance, only three RCTs were identified by Hollway and Aman for its use in pediatric subjects.[129] Two of the studies were negative, one showed benefit, and none of them were specifically in children with developmental disabilities.

Zolpidem

Studies are limited, and none seem to have studied individuals with developmental disabilities, though benefits seem greater in adolescents and adults, and less effective in children.[127]

Donepezil and Memantine

Limited data demonstrated mixed results with the use of donepezil and memantine to target symptoms of ASD, including autistic disorder, Asperger disorder, and PDD. Donepezil has demonstrated improvement in rapid eye movement (REM) sleep. At the time of this writing, recommend additional studies continue to evaluate their place in therapy.[128–134]

Benzodiazepines

In partially or uncontrolled studies in children, and controlled studies in adults, it seems that benzodiazepines may be most effective at helping sleep disturbances associated with parasomnias (eg, periodic limb movement disorder, tongue biting, REM sleep behavior disorder), though with considerable risks of adverse effects, including tolerance, dependence, rebound insomnia, daytime sedation, and cognitive impairment.[127]

Overall, it seems that melatonin is the most well-studied, effective, and safe medication option for treating sleep disturbance in individuals with developmental disabilities. Although promising evidence for ramelteon, trazodone, mirtazapine, and clonidine exists, further research is needed in individuals with developmental

disabilities. Research evidence does not seem to support the wide use of diphenhydramine for sleep disorders in children, and although zolpidem and benzodiazepines may be of benefit for sleep in some, they should be used with caution, and primarily in adults for zolpidem, and those with parasomnias for benzodiazepines.

CASE 88-4

QUESTION 1: T.T. is a 10-year-old male with ASD and significant sleep disturbances. His father has tried diphenhydramine for the last few weeks but has not seen any meaningful improvement in T.T.'s total sleep time. Last year, T.T. had a trial of melatonin 2.5 mg daily with only a small recognized improvement. T.T.'s clinician is thinking about starting a low-dose benzodiazepine, however, is weighing the concerns for adverse effects.

T.T.'s clinician asks for your opinion. What do you recommend?

You note that the dose of melatonin last year may have been on the lower range and you would recommend another trial of melatonin before considering a controlled substance. The dose you would recommend is 5 mg taken ~1 hour to T.T.'s bedtime. You note that this dose can be increased to 10 mg if an adequate response is not seen.

Attention-Deficit Hyperactivity Disorder in Children, Adolescents, and Adults

Michael C. Angelini and Joel Goldstein

CORE PRINCIPLES		CHAPTER CASES
1	Attention-deficit hyperactivity disorder (ADHD) is a heterogeneous psychiatric disorder that consists of multiple subtypes, including inattention, hyperactivity/impulsivity, and a combination of these two types. For diagnostic criteria to be met, there must be evidence that these symptoms are present in multiple settings and that the individual exhibited this psychopathology before age 12 years. These symptoms cannot be because of other illnesses.	**Case 89-1 (Question 1), Table 89-1**

CORE PRINCIPLES		CHAPTER CASES
2	Behavioral therapy and parent guidance are important components of any effective treatment plan and typically include educational interventions, creation of a structured environment for the child, and introducing contingency training.	**Case 89-1 (Questions 1–3)**
3	Stimulant medications are highly effective for the rapid relief of ADHD symptoms and substantially improve a child's prognosis. Individuals who fail to respond adequately to one type of stimulant will often do well with another, suggesting that subtle differences exist in the pharmacologic mode of action. Although the duration of pharmacologic action is relatively brief for stimulants, a variety of preparations have been approved that can prolong the relief of ADHD symptoms and permit once-daily dosing.	**Case 89-1 (Questions 3–5), Table 89-2**

CORE PRINCIPLES		CHAPTER CASES
4	There are a number of nonstimulant medications that have proven to be effective for ADHD over the years, including norepinephrine (NE) reuptake inhibitors and α_2-agonists. These medications may be viable options for the management of treatment-resistant illness as well as in patients with a history of substance abuse. They also possess a different side effect profile than stimulants and have a delay until therapeutic effects are evident.	**Case 89-1 (Question 6), Table 89-2**
5	Many people are reluctant to consider stimulant medications for ADHD treatment because of unfounded fears about drug tolerability and abuse. As a result, there have been a wide variety of alternative treatments considered for use, including behavioral treatment strategies, changes in dietary habits, ingestion of herbs and supplements, and other somatic interventions. At the present time, the evidence supporting these options is sparse, although the rigor of investigations has steadily improved in recent years, and there is hope that some of these options may prove to be beneficial.	**Case 89-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
6	ADHD is commonly associated with several psychiatric and medical comorbidities, and these concurrent conditions often influence treatment plans. Tic disorders such as Tourette syndrome are frequently found in children with ADHD. Research evidence suggests that stimulants are not only safe but also effective in this particular population.	**Case 89-1 (Question 1)**
7	Some children with ADHD will continue to have symptoms of their illness well into their adult years, usually of the inattention subtype. There is a growing awareness that adults with ADHD have significant social and occupational impairments. Fortunately, medications used to treat ADHD in children appear to be equally effective in adults. Stimulants are the most effective agents but have the unique side effect risk of abuse and diversion. Monitoring for this is essential. If abuse or diversion occurs, then a reevaluation of the diagnosis is necessary as well as a change to a medication with less risk of misuse.	**Case 89-2 (Question 2)**

INTRODUCTION

Attention-deficit and hyperactivity disorder (ADHD) is a serious psychiatric condition that has been well described in the medical literature for more than two centuries.[1] There are highly effective pharmacologic treatments that ameliorate the core symptoms of the illness. These agents are generally safe and have been shown to improve long-term prognosis.[2]

By definition, ADHD symptoms manifest in childhood and will often persist into adulthood in many cases. If left untreated, ADHD can produce significant impairments in academic performance and social functioning; adults with ADHD are often hindered in occupational settings as well.[3] Psychiatric comorbidities are commonly encountered among individuals suffering from ADHD, including developmental disorders, mood disorders, and substance abuse.

Although hyperactivity had been recognized as a troublesome childhood behavior for many years, ADHD was not formally described in the *Diagnostic and Statistical Manual of Mental Disorders* until the third edition was released in 1980. The recently released *DSM-5* describes three different subtypes of ADHD including "predominantly inattentive presentation," "predominantly hyperactive/impulsive presentation," and "combined presentation."[4] The *DSM-5* also requires the diagnosis by age 12. Qualitatively, the core symptoms of ADHD will differ according to gender, with males more likely to exhibit the hyperactive/impulsive subtype (vs females).[5] These symptoms often change with time as hyperactive and impulsive behaviors recede during adolescence, and inattention predominates among adolescents and adults with ADHD.[6]

Although the effectiveness of pharmacologic treatments for ADHD has been widely replicated, many children and adolescents with ADHD will receive suboptimal treatment for a variety of reasons, including parental reluctance to consider psychotropic medications, the perceived stigma of mental illness, poor access to psychiatric care in many areas and disparities in access to care for minority youth.[7] It is important to note that ADHD poses a huge economic burden to Western society. A meta-analysis by Doshi et al reports overall national incremental costs of $143 to $266 billion in the United States.[8] The economic impact related to adults with the

disorder from productivity and income loss is greatest, although there are also significant costs associated with youth with the disorder from educational and health expenses. Further, the study documents significant “spillover costs” for family members of individuals with ADHD.[8]

Stimulants such as methylphenidate (MPH) and amphetamine have been the mainstay of ADHD treatment in children for more than 30 years, and recent studies have demonstrated acute and long-term benefits in adolescents as well as adults.[1,9–11] Unfortunately, stimulants have not been consistently shown to decrease delinquency rates. They have also been implicated with rare but serious side effects, and they carry an elevated risk of diversion and abuse.[11–13] Pharmacologic alternatives to stimulants have been identified in recent years and have proven to be useful, albeit often as second-line agents among individuals who have significant side effects and those with medical or psychiatric comorbidities.[11] The benefits of cognitive-behavioral psychotherapy have also been emphasized in recent years, and most experts now contend that the combination of pharmacotherapy with family-based cognitive-behavioral interventions will generate the best long-term prognosis for individuals with this disorder.[2]

Recent landmark studies have helped clarify important aspects of diagnosis and treatment with regard to ADHD. The Multimodal Treatment of Attention-Deficit Hyperactivity Disorder Study (MTA) is considered a groundbreaking study of ADHD treatments and outcomes. The main findings were released in 1999, but additional findings have been subsequently released. MTA was a multisite study that differed from earlier studies of ADHD in that the duration of the study was significantly longer (up to 14 months) and that the study compared the use of both medication and cognitive-behavior therapy (CBT), both alone and in combination with routine community-based treatment. The central findings of MTA included the following: (a) medication alone and in combination with CBT was more effective than intensive behavioral treatment alone or routine community-based care, (b) youth receiving combined treatment required lower doses of medication, and (c) youth with associated

mental health issues, in addition to ADHD, had better outcomes with combined treatment than with medication alone.[14,15]

The question of medication treatment for preschool children presenting with ADHD symptoms is a controversial issue. The "Preschool ADHD Treatment Study" (PATS) is considered a landmark study in this arena. The majority of the findings were released in 2006. The central findings include the following: (a) preschool children tend to respond better and with fewer adverse effects with lower doses of medication and (b) preschool children are more sensitive to the adverse effects of psychostimulants and require closer monitoring. In particular, younger children tend to have more emotional adverse effects such as irritability and a tendency toward crying.[16,17]

EPIDEMIOLOGY

ADHD is a chronic neurobehavioral disorder, with an overall estimated prevalence of 6% to 12% in school-aged children worldwide.[18] The Centers for Disease Control and Prevention analyzed data from the 2006 National Survey of Children's Health and reported that the incidence of ADHD diagnoses has risen annually by an average of 3% between 1997 and 2006.[19] In 2006, 7.4% of U.S. children ages 4 to 17 years were diagnosed with ADHD. The *DSM-5* reports that "ADHD occurs in most cultures in about 5% of children and about 2.5% of adults." The diagnosis is more common in males with a ratio of 2:1 in children and 1.6:1 in adults.[4] It is hypothesized, however, that this gender predominance may be exaggerated because the more overt hyperactive subtype is more common in males and the less overt inattentive subtype is more common in females. As ADHD transitions into adulthood, the prevalence falls to 4.4% (standard error 0.6), with a higher risk found in previously married males who are unemployed and non-Hispanic White.[19]

PATHOPHYSIOLOGY

Various abnormal genetic and neurochemical abnormalities are associated with ADHD. Estimates of heritability of ADHD range in the area of 0.7, indicating that ADHD is one of the most heritable conditions in psychiatry.[20] Family studies have demonstrated that the relative risk of ADHD is six to eight times higher among first-degree relatives of persons with ADHD compared with the general ADHD population.[21] Several candidate genes associated with ADHD have been identified, such as the dopamine receptor, dopamine transporter receptor, and serotonin transporter gene.[22,23] Despite a small causal effect, no single gene is responsible for the symptoms seen with ADHD, but rather these symptoms are likely the result of interactions among several genes, which influence multiple neurotransmitters, including serotonin, dopamine, and norepinephrine (NE).[22]

Multiple neuroimaging studies have documented consistent abnormalities in brain structure and development with youth and adults with ADHD. Subjects with ADHD have been shown to have reductions in global brain volume.[24] Specifically, the reduction in volume is most prominent in the prefrontal cortex, basal ganglia, cerebellum, and parietotemporal regions.[24] Functional magnetic resonance imaging studies have also shown hypoperfusion with memory tests in the anterior cingulate areas in ADHD patients.[25] This area of the brain is responsible for behavioral and functional abilities that may manifest in patients with ADHD as difficulties in organization, mood, motivation, self-regulation, and ability to retain specific information while performing a particular task, which are abilities referred to as executive functioning. These findings are research population–based findings. These studies are not yet useful in clinical practice for accurate diagnosis.

Etiology

ADHD is a heterogeneous behavioral disorder with a variety of theorized etiologies. Clearly, the research suggests a strong genetic component. However, to this point, no specific genetic risk factor has been identified.[20] As a result, other environmental and congenital etiologies have been considered and studied. Examples of studied etiologies for ADHD include maternal smoking, dietary factors, prematurity/low birth weight, and family environment/parenting behavior. Of these proposed factors, low birth rate is the factor with the most confirming research evidence.[20,26] The potential impact of parenting behavior, in particular, is a complex question as youth with ADHD often present more significant challenges to parents. Further, as ADHD is highly heritable, many parents of youth with ADHD may have ADHD themselves. Therefore, it is generally accepted that ADHD is a complex set of disorders with genetic and environmental risk factors and contributors.

DIAGNOSIS, SIGNS, AND SYMPTOMS

The diagnosis of ADHD is a clinical diagnosis that may be supported by various types of screening tools and neuropsychologic assessment. The diagnosis of ADHD in a child is based on the *DSM-5* criteria (**Table 89-1**). The evaluation should include clinical interviews with the patient and/or parent, physical examination (including neurologic status), obtaining history regarding functional pattern in school or daycare setting, evaluation for comorbid psychiatric disorders, and review of the patient's medical, social, and family histories.[2] Other sources of valuable information include performance reports (eg, report cards or job reviews) and ADHD rating scales scored in two different settings.[4] There are a number of validated rating scales available both proprietarily and in the public domain. Some of the rating scales have different versions for parents and teachers. Rating scales are helpful both for diagnosis and for monitoring treatment outcome.

Table 89-1

Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

A. A persistent pattern of inattention and/or hyperactivity–impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, work is inaccurate)
   b. Often has difficulty sustaining attention in tasks or play activities (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading)
   c. Often does not seem to listen when spoken to directly (eg, mind seems elsewhere, even in the absence of any obvious distraction)
   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (eg, starts tasks but quickly loses focus and is easily sidetracked)
   e. Often has difficulty organizing tasks and activities (eg, difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines)
   f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers)
   g. Often loses things necessary for tasks or activities (eg, school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones)
   h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts)
   i. Is often forgetful in daily activities (eg, doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments)

2. **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with the developmental level and that negatively impacts directly on social and academic/occupational activities:

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fidgets with or taps hands or feet or squirms in seat
   b. Often leaves seat in situations when remaining seated is expected (eg, leaves their place in the classroom, in the office or other workplace, or in other situations that require remaining in place)

c. Often runs about or climbs in situations where it is inappropriate (Note: In adolescents or adults, may be limited to feeling restless)
d. Often unable to play or engage in leisure activities quietly
e. Is often "on the go," acting as if "driven by a motor" (eg, is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with)
f. Often talks excessively
g. Often blurts out an answer before a question has been completed (eg, completes people's sentences; cannot wait for turn in conversation)
h. Often has difficulty waiting his or her turn (eg, while waiting in line)
i. Often interrupts or intrudes on others (eg, butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing)

B. Several inattentive or hyperactive-impulsive symptoms were present before age 12 years.

C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (eg, at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (eg, mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication, or withdrawal).

Per the *DSM-5*, to meet the criteria for ADHD, the child must have six or more symptoms present in two different settings (eg, home, school) for a minimum of 6 months. Furthermore, there must be evidence that these symptoms were present before age 12 years. Based on these criteria, three types of ADHD are identified: predominantly inattentive, predominately hyperactive/impulsive, and combined. The diagnostic criteria require that the symptoms interfere with or impact functioning in daily life so that care providers will look for symptoms that have a negative impact on the child's education, relationships, or social life (see Table 89-1). On occasion, however, parents or teachers may "pressure" clinicians into writing

psychostimulant prescriptions for a “let’s see if it helps” trial. If the medication is helpful, they may assume incorrectly that the diagnosis of ADHD is validated. Additionally, *DSM-5* eliminated the exclusion criteria for autism spectrum disorder. However, the *DSM-5* mandates that the symptoms of ADHD “do not occur exclusively during the course” of another psychiatric disorder.[4]

Establishing a diagnosis of ADHD in an adult who has never been treated for the disorder during childhood is difficult. In adults, ADHD is a clinical diagnosis that relies on their recollection of ADHD symptoms as a child to which *DSM-5* criteria validated for children are applied. Unlike teachers who are ordinarily familiar with the symptoms associated with ADHD in children, spouses, coworkers, and employers are often unfamiliar with ADHD as a disorder that can also affect adults. They may attribute the individual’s difficulties to laziness, disinterest, or underachievement.

COMORBIDITY AND PROGNOSIS

Between ages 10 and 25 years, the signs and symptoms of ADHD decrease in frequency and severity by about 50% every 5 years but will often persist into adulthood.[6] In the differential diagnosis of ADHD, it is critically important to distinguish ADHD from various behavioral, developmental, or medical conditions. Psychiatric comorbidity is more common with ADHD as up to 87% of children will be diagnosed with at least one additional psychiatric disorder and 67% have at least two or more disorders.[27] Other psychiatric conditions that are frequently comorbid with ADHD or present with similar symptoms as ADHD include conduct disorder; oppositional defiant disorder; Tourette syndrome; mood disorders including depression, bipolar disorder, and disruptive mood dysregulation disorder; anxiety disorders; and obsessive–compulsive disorder. Of these conditions, anxiety disorders and mood disorders are most commonly misdiagnosed as ADHD. The comorbidity of ADHD and learning disabilities is both complex and often leads to significant

academic challenges. Studies suggest that 25% to 35% of youth with ADHD will also have language-based or other learning disabilities.[27] Clinical wisdom suggests that ADHD often presents early in the child's academic career (eg, kindergarten or first grade), whereas learning disabilities may present later in the elementary years, when children are "reading to learn" rather than "learning to read." Medication is a central treatment component for ADHD, whereas learning support and specialized teaching strategies are the interventions of choice for youth with learning disabilities. Medications are not helpful for the treatment of learning disabilities.

Family histories from first-degree relatives of probands with ADHD reveal increased rates of ADHD (25% concordance rate), polysubstance dependence, antisocial personality disorder, depression, and anxiety disorders.[28] Genetic studies have shown a strong correlation in genetic abnormalities, particularly with the *FOXP2* gene, although multiple genes are likely related.[29] Children with ADHD are at an increased risk of having antisocial behavior, depression, and substance abuse problems as adults. ADHD symptoms persist into adulthood in the majority of these comorbid patients.[11] Adults with ADHD are usually self-sufficient, but they have poorer academic performance, poorer job performance, and lower socioeconomic status than do their siblings. They also have more frequent divorces, job changes, and car accidents. Most adults with ADHD report a high level of subjective distress (79%) and interpersonal problems (75%).[30]

Medical conditions often complicate the diagnosis of ADHD and should be excluded before initiating treatment. These medical conditions include head injuries, seizure disorders, metabolic disorders, cerebral infection, toxic exposures (eg, chronic lead exposure), sleep problems, substance abuse, and hyperthyroidism.

CASE 89-1

QUESTION 1: M.T. is a 12-year-old female who recently started middle school. M.T.'s mother calls the pediatrician looking for advice. M.T. was adopted at age 2 months from Guatemala and little is known about prenatal care or her life

before the adoption. M.T. is having a good deal of difficulty with the transition to middle school. She seems overwhelmed with the amount of work and has become withdrawn and angry. The guidance counselor has called the parents because M.T. has missed most of her homework assignments. M.T.'s mother feels at a loss because M.T. now has many more teachers and they don't seem to know her or to support her in the same way as the teachers in the elementary school. M.T. has begun counseling with a social worker in the community but does not want to go. Her mother is interested to know if medication may be of help.

How do you think about the differential diagnosis?

Depression is the most prominent diagnosis that comes to mind. However, it is important to remember that comorbidity is quite common in youth with psychiatric disorders. It is important to consider if there are underlying, less obvious disorders or circumstances that may be contributing.

Case 89-1, Question 2: What are the next steps in the evaluation?

The pediatrician refers M.T. to a child/adolescent psychiatrist for evaluation. The professionals help the parents request an educational assessment through the school. The latter includes both academic and psychologic assessments. The assessments suggest underlying poor self-esteem. However, there is also evidence of slow processing speed and other evidence of ADHD and executive functioning deficits. The Vanderbilt rating scales confirm the diagnosis of ADHD.

There are a number of validated instruments to assist with the diagnosis and clinical management of ADHD. Often, these instruments have a parent and teacher version. Commonly used instruments include the Conners Global Index, the SNAP IV, DuPaul Rating Scale for ADHD, and the Vanderbilt Rating Scale. Some rating scales are proprietary, and others such as the Vanderbilt are in the public domain.[31]

Case 89-1, Question 3: What are the first-line interventions?

The psychiatrist provides psychoeducation to M.T. and her parents about ADHD. They discuss that ADHD may be missed more commonly in females and that youth with ADHD often develop concurrent depression, anxiety, conduct disorders, and substance-use disorders because their experience in school and activities often leads to feelings of inadequacy. Additionally, an Individualized Educational Plan (IEP) is developed for M.T. to provide more support in the school setting. Special accommodations such as added time for exams, a seat in the front of the class, and the availability of fidget toys are specified in the IEP.

M.T. continues in counseling with the social worker, in which they focus on cognitive and behavioral strategies to manage both her ADHD symptoms and her depression and poor self-esteem. All agree that it is prudent to hold off on any medication for depression to see if the other interventions are effective in alleviating the symptoms of depression.

The ADHD symptoms are tracked with Vanderbilt rating scales completed by parents and teachers. Medication treatments for ADHD are discussed. With informed consent, a trial of a psychostimulant is begun.

TREATMENT

Optimal strategies to manage ADHD symptoms that are moderate to severe in nature should focus on the combined use of behavioral and pharmacotherapy interventions. It is important to recognize that ADHD is a chronic disorder with symptoms that frequently continue into adolescence and adulthood. Before developing a treatment plan, defined and realistic treatment goals should be established collaboratively with the child, parent, and school.

Several ADHD consensus statements, practice parameters, and guidelines have been developed, based on both evidence-based literature evaluation and expert opinions, to assist clinicians in

evaluating, diagnosing, and managing patients with ADHD in a consistent manner.[2,32–35]

Behavioral Therapy

During the years, numerous psychosocial or educational programs have been studied for their potential benefit in controlling ADHD symptoms and maximizing function.[2] Behavioral interventions have been among the most popular nonpharmacologic approaches, with programs emphasizing the creation of a structured environment containing minimal distractions both at home and in school. Contingency training is another common component of behavioral therapy for ADHD, with children receiving tokens for specific tasks or achievements, as well as punishments (eg, revoking privileges) for maladaptive behaviors. Although most treatment guidelines continue to advocate trying some type of structured behavioral modification, the empiric evidence that such programs improve functioning or prognosis is certainly not as strong as it is for pharmacotherapy.[34]

The previously mentioned Multimodal Treatment Study of Children with ADHD reviewed the relative impact of medication and nonpharmacologic treatment.[14] The MTA Cooperative Group study, as it is commonly known, was designed to compare long-term medication and behavioral treatments with respect to efficacy and acceptability. A group of 579 children between ages 7 and 10 years with the combined type of ADHD were recruited and randomly assigned to four different treatment groups: medication management, behavioral treatment, medication plus behavioral treatment, or typical community treatment. Behavioral interventions were delivered in a group-based recreational setting and included an 8-week, 5-days/week, 9-hours/day, intensive program administered by a counselor or aide. Once school started, the subjects in this arm of the study received 60 school days of a part-time, behaviorally trained, paraprofessional aide who worked directly with the child. In addition, the child's teacher received 10 to 16 sessions of biweekly consultation that focused on classroom behavior management

strategies. Daily behavior report cards were sent home to parents. At the same time, families were involved in 27 group therapy meetings plus 8 individual family meetings. Of the children receiving medication, 75% received MPH, 10% received dextroamphetamine, and 15% received pemoline (no longer available in the United States), imipramine, clonidine, guanfacine, or bupropion. After the 14-month study, it was concluded that drug treatment was more effective than behavioral treatment according to parents' and teachers' ratings of inattention, and teachers' ratings of hyperactivity/impulsivity. Combined treatment (drug treatment plus behavioral modification) was preferred by parents, but the therapeutic advantage versus medication did not achieve statistical significance. Combined treatment was significantly more effective than behavioral treatment and community care for reducing ADHD symptoms, according to both parent and teacher reports, but a subgroup analysis of children with comorbid conditions (eg, conduct, oppositional defiant, anxiety, or affective disorders) found behavior management to be as effective as medication monotherapy. A 3-year follow-up study revealed that all four interventions were equally effective in improving academic performance and social functioning with time, but given the costly and labor-intensive nature of the behavioral modification in contrast to other interventions, most notably, pharmacotherapy, medication continues to be regarded as the first-line treatment for children with at least moderate ADHD symptoms.[15] There have been a variety of school-based, clinic-based, and home-based interventions to address ADHD symptoms, mainly with positive results. Additionally, specialized summer treatment programs have been established to provide more intensive intervention when school is not in session.[36]

Pharmacotherapy

STIMULANTS

Stimulants are considered the most effective option to treat ADHD, with more than 60 years of clinical experience accrued. Currently,

there are two basic types of stimulants marketed in the United States, MPH-based and amphetamine based, and they have all been reported to improve academic performance and behavior in children with ADHD (**Table 89-2**).[33]

Table 89-2

Overview of Common Drugs to Treat Attention-Deficit Hyperactivity Disorder

Drug		Duration of Action	Pediatric Dose	Adult Dose	
Stimulants					
Methylphenidate C-II	Aptensio XR™	Long	20–60 mg/day	20–60 mg/day	Adult doses may need to be higher and can be titrated up based on tolerability.
	Concerta®	Long	18–72 mg/day	18–72 mg/day	
	(generic)	Long	20–60 mg/day	20–60 mg/day	
	Metadate CD®	Intermediate	20–60 mg/day	20–60 mg/day	
	Metadate ER®	Intermediate	20–60 mg/day	20–60 mg/day	
	Methylin ER®	Long	20–60 mg/day	20–60 mg/day	
	Quillichew ER™	Long	20–60 mg/day	20–60 mg/day	
	Quillivant XR®	Short	20–60 mg/day	20–60 mg/day	
	Ritalin® IR	Intermediate	20–60 mg/day	20–60 mg/day	
	Ritalin® SR	Long	20–60 mg/day	20–60 mg/day	
	Ritalin® LA	Long	10–30 mg/9-hour patch	10–30 mg/9-hour patch	
	Daytrana® transdermal patch	Long		20–100 mg a day	
	Jornay PM™		20–100 mg a day		
Dexmethylphenidate C-II	Focalin®	Short	5–20 mg a day	20 mg a day	
Serdexmethylphenidate/dexmethylphenidate	Focalin® XR	Long	5–20 mg a day	20 mg a day	
	Azstarys™	Long	39.8/7.8 to 52.3/10.4 mg a day		

Ampheiamine C-II	Adzenys* XR ODT Adzenys ER™ Dyanavel* XR Evekeo*	Long Long Long	6 3–18 8 mg/day 20 mg/day 2.5–40 mg/day	No approved max dose No approved max dose No approved max dose	Adult doses likely to be similar to pediatrtc doses and titrated as tolerated
Amphetamlne/ dextroamphetamine C-II	Adderall* Adderall* XR Mydayis*	Short Long Long	10–40 mg/day 10–30 mg/day 12.5–50 mg/day	10–40 mg/day 10–20 mg/day 12.5–50 mg/day	Doses may be inoeased as tolerated.
Dextroamphetamine C-II	Dexedrine® Dexedrine® XR ProCentra® Zenzedi*	Short Long Short Short	5–40 mg/day 5–40 mg/day 5–40 mg/day 5–40 mg/day	5–40 mg/day 5–40 mg/day 5–40 mg/day 5–40 mg/day	
Lisdexamfetamine C-II	Vyvanse®	Long	30–70 mg/day	30–70 mg/day	
Methamphetamine	Desoxyn*	Long	5–25 mg/day	No approved dose	Strongly recommended not to use this product
Nonstimulants					
Noradrenergic-Reuptake Inhibitor					
Atomoxetine Viloxazine	Strattera® Qelbree™	Long Long	40–100 mg/day 100–400 mg/day	40–100 mg/day	
ayReceptor Agonist					
Clonldine Guanfacine	Clonldine Kapvay™ Guanfacine Intuniv®	Short Long Short Long	0 1–0.3 mg/day 0.1–0.4 mg/day 1–4 mg/day 1–4 mg/day	0.1–0.3 mg/day 0.1–0.4 mg/day 1–4 mg/day 1–4 mg/day	Use in adults not well studied Higher doses have been used to control BP. Monitoring for hypotension is recommender

BP, blood pressure; CD, controlled delivery; IR, immediate release; ODT, orally disintegrating tablet; SR, sustained release; ER and XR, extended release.

A review of short-term clinical trials that evaluated the safety and efficacy of stimulants in nearly 6000 children and adults with ADHD showed a 75% to 80% improvement in patients treated with stimulants compared with 5% to 30% treated with placebo.[37] Although stimulant drugs are grouped as a class based on their pharmacologic effect of increasing dopamine and NE levels in the synapse, the mechanisms by which stimulant drugs exert this effect vary slightly. These subtle differences in the mechanism of action support the possibility that patients who respond partially to one stimulant may respond completely to another. In fact, ~20% to 25% of those who respond poorly to one medication will respond positively to another and up to 90% of children will respond if both are tried.[38] Stimulants are rapid acting and have predictable effects, with response typically within 2 hours.[39]

MPH blocks the reuptake of dopamine from the synaptic cleft into the presynaptic neuron via the dopamine transporter protein. MPH

consists of a racemic mixture of *d* and *l* isomers. Preparations are available as *d-/l*-methylphenidate and solely as dexmethylphenidate. *d*-MPH has greater potency at DA reuptake inhibition than NE. *l*-MPH is also more potent at DA reuptake than NE but to a lesser degree than *d*-MPH.[40,41] *d*-MPH also achieves higher serum concentration than the *l*-isomer because of a lesser impact of carboxylesterase CES1A1, the enzyme primarily responsible for MPH metabolism, on the *d*-isomer compared to the *l*-isomer.[40,41]

The most common side effects of MPH include appetite suppression, insomnia, headache, nausea and vomiting, and abdominal pain.[41]

A long-acting MPH transdermal formulation is available. As with any transdermal system, drug delivery can vary greatly because of heat and site-related skin porosity differences. Area under the curve (AUC) and C_{max} can increase 300% if the patch is applied to an inflamed area and 250% if the patch area is exposed to heat such as going outside and exercising in the sun.[2,42–44] The patch is applied to the hip area for 9 hours, and MPH is steadily released and absorbed into the circulation for about 11.5 hours. When compared to the oral long-acting Oros release system, MPH's side effects were similar between the two products but numerically higher in the transdermal arm compared to the oral arm. One side effect exclusive to the patch is skin irritation, which can occur from 3% to 40%.[42] A very slow-release product uses a multilayered system that does not allow the release of MPH for up to 10 hours after ingestion. Peak dose is achieved ~16 hours after ingestion. This allows for dosing in prior to be on the previous night if that is necessary.[45]

Amphetamines, including mixed amphetamine salts, dextroamphetamine, and lisdexamfetamine, enhance the release of both dopamine and NE from storage vesicles in the presynaptic neuron and block their storage in addition to blocking their reuptake from the synaptic cleft. They also have a weak monoamine oxidase inhibitor (MAOI) effect.[46,47] AMP consists of *d,l* racemic mixture. *d*-AMP has a greater effect at increasing DA within synapse compared to the *levo* enantiomer. Both the *d* and *l* enantiomers increase

synaptic NE but to a lesser extent than DA.[48] AMP also has a small effect at increasing serotonin with *d* enantiomer greater than the *l* enantiomer, but this effect is likely clinically irrelevant with both.[49]

Dextroamphetamine is metabolized via CYP2D6. A strong inhibitor of 2D6 could increase levels twofold. The long-acting prodrug lisdexamfetamine requires enzymatic hydrolysis in the blood to cleave off the L-lysine portion of the molecule. This leaves just dexamphetamine available for activity.[50–52] Lisdexamfetamine is rapidly absorbed, but the step of hydrolysis results in a delayed release of dextroamphetamine in the circulation allowing for once-a-day dosing. In addition, this formulation is helpful for youth who are at risk for misuse of psychostimulants through inhalation.

Because approximately two-thirds of children and adolescents with ADHD respond equally to MPH or amphetamine products, the preferred agent should be based on the duration of action, formulation preferences, and cost.[34] As shown in Table 89-2, stimulant preparations are classified based on duration (ie, immediate [2–5 hours], intermediate [6–8 hours], and long-acting [10–12 hours]) and available delivery systems. Long-acting formulations are usually preferable to intermediate and short acting because it provides uninterrupted benefit allowing the child to avoid going to the school nurse for doses or lack of effect between doses.[53] There are some clinical situations that indicate immediate-release preparations, often to minimize adverse effects. Many long-acting options are biphasic, which provide an immediate-release (IR) dose and then a second long-acting dose a few hours later. For example, Ritalin LA®, Metadate CD®, Focalin XR®, and Adderall XR® all contain both immediate and enteric-coated, delayed-release beads that mimic the blood concentrations seen with IR stimulant preparations given twice daily. Although a prescription methamphetamine product does have Food and Drug Administration (FDA) approval for the treatment of ADHD, no expert guidelines recommend it because of high-abuse liability and neurotoxicity.

Adverse effects

Both types of stimulants are similar in their side effect profiles. Adverse drug reactions such as insomnia and appetite loss are mild, and tolerance often develops within a few days. These reactions can be easily managed by adjustment in dose and timing if necessary (**Table 89-3**). One head-to-head trial of mixed amphetamine salts compared to MPH found no statistical differences in side effects but numerically amphetamine had higher rates of stomachache, irritability, mood changes, and tics.[54]

Table 89-3

Managing Adverse Effects of Stimulants Used in Children With Attention-Deficit Hyperactivity Disorder

Adverse Effect	Management
Decreased appetite, nausea, or growth impairment	Schedule evening meals after the medication has worn off. Take drug after meals. Encourage foods with high caloric density or nutritional supplements. Encourage evening/bedtime snack. Switch from long- to short-acting preparation. Provide drug holidays when appropriate.
Sleep disturbance	Administer doses earlier in the day. If using a sustained-release product, consider changing to a short-acting preparation. Discontinue afternoon/evening dose.
Behavioral rebound	If using short-acting preparation, consider changing to a long-acting preparation.
Irritability	Assess time of symptoms: Related to peak: reduce dose or try long-acting preparation Related to withdrawal: change to long-acting preparation Evaluate for comorbid diagnosis.
Dysphoria, moodiness, agitation, dazed, or withdrawn behavior	Decrease dose or change to long-acting preparation. Consider comorbid diagnosis.

Adverse Effect	Management
Dizziness	Monitor blood pressure. Encourage fluid intake. Lower dose or change to long-acting preparation to reduce peak effects.
Development or increase in tic disorder	Stop stimulant. Consider trial of clonidine, guanfacine, or atomoxetine.

There is an association between stimulant use and slight growth retardation. The relative impact of this seems minimal and can be reduced or eliminated with drug holidays.[55–57] There seems to be no loss of efficacy if the child does have a drug holiday and stops the medication over weekends holidays or summer months.[58] The risk of drug holidays is a worsening of symptoms during these drug-free days. For some children, this may have an impact on social maturation.

Regarding cardiotoxicity risk, population studies suggest that the overall risk of sudden death associated with stimulant use has been shown to be the same, if not lower, than that of the general population.[59] Slight increases in BP and heart rate (HR) are seen with MPH and amphetamines, although ECG changes are very rare.[60–62] Clinicians should follow current recommendations suggested by the American Academy of Pediatrics and the American Heart Association, which advocate screening for a personal or family history of cardiovascular disease in all children with ADHD. Continual monitoring for these risks along with routine blood pressure and heart rate assessments should be performed.[63] Pretreatment ECGs are not required but recommended by the American Heart Association (AHA) as a general practice for all children. Stimulants should not be used in those with known structural cardiac abnormalities.[64]

NONSTIMULANTS

For patients with ADHD only, it is recommended to initiate treatment with either MPH or amphetamine.[2,33–35] For patients who fail both

types of stimulants or when stimulants are not preferred, a trial of a nonstimulant is warranted (see Table 89-2). Nonstimulants are typically less effective than stimulants and usually require at least 4 weeks until a full response is evident. A meta-analysis of 29 double-blind, placebo-controlled trials evaluated the efficacy of stimulant and nonstimulant agents using 17 outcome measures in 4465 children and adolescents with ADHD.[65] It found that the effect size of amphetamine and MPH was significantly greater than that for atomoxetine, bupropion, and modafinil (P = .02).[65] If atomoxetine fails or is not indicated, the α_2-adrenergic agonists clonidine and guanfacine should be considered.[32–34]

Norepinephrine reuptake inhibitors

Atomoxetine inhibits the presynaptic NE transporter and is classified as norepinephrine reuptake inhibitor (NRI). Clinical trials have shown that atomoxetine is superior to placebo in reducing the symptoms of ADHD in children, adolescents, and adults.[66,67] However, trials comparing atomoxetine with stimulants have found atomoxetine to be less effective.[2,68–71]

Atomoxetine is likely to have some immediate benefit after initiation, but unlike the stimulants, a longer trial of 6 to 8 weeks is recommended as efficacy continues to grow. Atomoxetine requires a 10- to 14-day titration to achieve a therapeutic dose of 1 to 1.5 mg/kg/day to avoid nausea (12%), vomiting (15%), and asthenia (11%).[72] As with stimulants, atomoxetine can also raise blood pressure and heart rate, with reports of high systolic and diastolic blood pressures occurring in 8.6% and 5.2% of pediatric subjects, respectively. Increases in heart rate of more than 110 beats/minute and more than 25 beats/minute above baseline were observed in 3.6% of patients.[72] Atomoxetine is metabolized via CYP 450 2D6, with the major metabolite being 4-hydroxyatomoxetine, which is also a potent inhibitor of NE reuptake but only achieves low blood concentration levels. It has a half-life of 4 to 5 hours but can be extended by about 3 hours with a high-fat meal.[73]

There have been postmarketing cases of reversible hepatic injury in association with atomoxetine, but this is quite rare.[74] Baseline liver enzyme testing should be performed, and evidence of jaundice or liver injury should warrant immediate discontinuation. Atomoxetine also contains the warning regarding increased risk of suicidal thoughts that are part of all antidepressant class labeling. However, a meta-analysis of 14 trials found that no subject committed suicide. Suicidal ideation in the atomoxetine group was 5/1357 (0.37%) and placebo group was 0/851 (0%).[75] So, despite the low risk, monitoring frequently for the first 3 months of treatment is required by the FDA.

Viloxazine is another NE reuptake inhibitor that has much less effect on the NE reuptake pump compared to atomoxetine. It also has effects as an agonist at 5-ht_{2c} receptors and as an antagonist at 5-ht_{2b} receptors.[76,77] Its efficacy seems to be a little less than atomoxetine however, no direct head-to-head trials have been conducted. Common side effects include gastrointestinal (GI) distress at 14%, somnolence at 16% decreased appetite at 7% and headache at 11%. HR and diastolic increases can occur and must be assessed prior to, and monitored while, taking viloxazine.[78,79] Medications that inhibit CYP450 2D6 may result in a small increase in vilazodone levels (around 25%). Viloxazine is a potent inhibitor of CYP450 1A2 and has been shown to double theophylline levels.[78,80]

α_2-Agonists

Clonidine and guanfacine are α_2-agonists that have been used for years off-label to control hyperactive/impulsive or aggressive symptoms and insomnia.[81] They are believed to directly stimulate the postsynaptic NE receptors in the prefrontal cortex and locus coeruleus. Guanfacine is most specific for the α_{2a}-receptor, whereas clonidine is less specific and agonizes α_{2a}, α_{2b}, and α_{2c}. Extended-release formulations for clonidine and guanfacine are FDA approved both as monotherapy and as adjuncts to stimulants. Although they are a monotherapy option, they are not considered as first line as

they are less effective than stimulants. They are particularly useful for behavioral comorbidities, such as aggression and tics.[32–35,82–84]

Guanfacine is primarily metabolized via CYP 3A4, and potent inhibitors can increase blood levels by 200%. Guanfacine extended release provides ~60% of the serum levels of the IR version. Clonidine is partially metabolized via CYP 2D6, although inhibitors of this pathway have only minor changes in serum levels.[85] The extended-release version has an AUC ~89% of the immediate release.

The side effect profile of α_2-agonists is quite different than the stimulants and atomoxetine. Sedation and related side effects can occur in nearly 40% for both. Reductions in BP and HR can occur and thus need to be monitored. Bradycardia (HR <60 bpm) can occur in up to 20% of children with clonidine and is a side effect of guanfacine also but to a lesser degree. This is likely because of guanfacine's specificity to α_{2a}. Rebound hypertension can occur if either of these medications is stopped abruptly.[82]

Despite positive studies with IR formulations, the short duration of action makes them less desirable than the QD dosing of guanfacine extended release (ER) and the bid dosing clonidine extended-release formulation.[33]

Case 89-1, Question 4: It is agreed upon by the parents and the pediatrician that M.T. will begin using a medication for her ADHD symptoms. What would be the first-line option for M.T.?

Either stimulant group is considered first line, and, in this case, MPH 10 mg qam is tried. After steadily increasing the dose to 30 mg qam, the parents feel that there is minimal change in attention, but that there are significant side effects of nausea and loss of appetite.

Case 89-1, Question 5: What would be the next trial of medication for M.T.?

Expert guidelines state that if medication is decided upon, then the greatest efficacy is from the stimulants. None of the stimulant is

considered superior to the other, and initial choice should be based on the comfort level of the clinician and patient/parent acceptance. If the initial choice of stimulant is ineffective, it is recommended to trial an agent from the other stimulant class. By doing this, 90% of children will display efficacy. Therefore, the next trial for M.T. should be the initiation of dextroamphetamine 5 mg qam and titrate as tolerated to a maximum of 40 mg/day.

Case 89-1, Question 6: M.T. is showing some improvement on 10 mg qam of IR dextroamphetamine, but it is clearly wearing off about 4 hours after dosing. Dosing of 10 mg bid was tried during a school vacation and found to be somewhat effective; thus, the pediatrician decided to switch to long-acting dextroamphetamine spansules 20 mg qam. This clearly has shown to last throughout M.T.'s school day, but efficacy is not maximized, and some residual symptoms of poor attention and hyperactivity exist. What is the next step of pharmacotherapy for M.T.?

Increasing the dose to 30 mg qam is possible. Although a switch from a stimulant to atomoxetine could be tried, data have shown that atomoxetine is less effective than stimulants. Experts recommend that combination therapy of a stimulant and an α_2-agonist is appropriate, and studies have shown an increase in efficacy when switching from monotherapy to combination therapy.

Comorbidities

TOURETTE SYNDROME AND TIC DISORDER

Tourette syndrome is neuropsychiatric condition, which has tics as a hallmark symptom. Children with ADHD have a higher risk of comorbid tic disorder than the general population; however, stimulants are relatively safe in this population. As an example, the Tourette Syndrome Study Group contrasted the effect of MPH, clonidine, and the combination of the two to placebo in the treatment of 136 children (7–14 years old) diagnosed with ADHD and Tourette syndrome.[86] The group concluded that prior recommendations to avoid MPH in these children because of concerns of worsening tics

were unsupported. As such, expert recommendations are that a child with ADHD should start on MPH, and if tics emerge or worsen, then a switch to atomoxetine or clonidine is warranted. A meta-analysis of studies with subjects who have ADHD and Tourette syndrome concluded that MPH shows the greatest improvement in ADHD symptoms without worsening tics for most youth. α_2-Agonists offer less efficacy in ADHD symptoms but greater control over tics compared to MPH. Atomoxetine offers benefit for both groups of symptoms and is an option.[33,83,84] Amphetamines should be avoided because although they do treat ADHD symptoms, they have a higher chance of worsening tics compared to MPH.[83,84]

A review regarding the treatment of tic disorders without comorbid ADHD states that the α_2-agonists guanfacine and clonidine are recommended as first-line options. Guanfacine may be preferred because of less sedation than clonidine.[87]

ANXIETY DISORDER

Anxiety disorders are more frequently comorbid in the ADHD-affected children (approximately ninefold) and adults (approximately fourfold) compared to the frequency seen in the general population. Despite the fact that the anxiety disorder may be a separate disorder, anxiety symptoms in the child are sometimes directly related to poor school and social performance because of ADHD symptoms. Treatment with a stimulant that subsequently improves performance will reduce anxiety. However, after a trial with a stimulant, some children will experience no change or worsening of anxiety-related symptoms. At this point, a trial with atomoxetine is recommended rather than treating the anxiety with a selective serotonin reuptake inhibitor (SSRI) and continuing the stimulant.[2,88]

SUBSTANCE ABUSE

Despite the fact that stimulants are medications with the risk of misuse or abuse, multiple studies have shown a protective effect against developing a substance-use disorder with children who derive a benefit to their ADHD symptoms from psychostimulant

medication. A meta-analysis of epidemiologic literature led to the conclusion that stimulant-treated patients with a diagnosis of ADHD were less likely to be diagnosed with substance-use disorder than those not treated with stimulants.[89] Using a stimulant to treat ADHD in a patient with comorbid substance abuse has contradictory results. Stimulants do treat the ADHD symptoms but not as robustly as those without a concurrent substance-use disorder. In these comorbid adult patients, the psychostimulant medications do not seem to reduce the substance use but do not worsen it either.[90] Expert opinion suggests that those with current substance-use disorders should be tried on nonstimulant options first, but stimulants are not fully contraindicated and can be used with close monitoring. There is growing data to support that there is a high rate of diversion of stimulants in the college population. One report positively correlated an increased incidence of stimulant diversion with the increased difficulty in the academic program.[33,91,92]

If misuse and diversion are of concern and a stimulant is necessary, the preferred dosage form of MPH is the transdermal patch formulation, and dextroamphetamine is the prodrug lisdexamfetamine.[33,35,44,46,50]

Despite the potential for being less effective than a stimulant, atomoxetine has preferred benefits in specific patient subtypes. Because it is not a stimulant, its risk of abuse and diversion are low and is preferred in patients with an addictions disorder history or living in a household where someone other than the patient (eg, parent or sibling) has an addiction disorder and may take the patients medications.

PSYCHOSIS

Stimulants may cause psychosis. This is because of the enhancement of DA centrally. If the child is acknowledging hallucinations or exhibiting bizarre behavior, then cessation of the stimulant is required. A rechallenge can occur but at a lower dose. If a child stabilized on the medication starts to exhibit psychotic symptoms, assess for drug interactions. As amphetamines are

metabolized by CYP450 2D6, any drug that inhibits this pathway could result in toxicity such as psychosis. The MPH transdermal patch formulation can have greater unexpected fluctuations in blood levels because of a greater range of absorption compared to the oral formulations.[43,44] The absorption of the transdermal patch is influenced by placement site and temperature of the skin. Switching to an oral formulation or lowering the dose is the preferred treatment, whereas adding an antipsychotic is not recommended.[33]

Other Non-FDA Pharmacotherapy

BUPROPION

Bupropion has been shown to be effective compared to placebo, but it is less effective than stimulants in the treatment of ADHD.[71] Randomized controlled trials (RCTs) have established the effectiveness of bupropion as an alternative to the psychostimulants in the treatment of ADHD in children, adolescents, and adults.[93–95] The two most common adverse effects encountered with bupropion in ADHD studies were dermatologic reactions and seizures. Dermatologic reactions occurred twice as often with bupropion compared with placebo. Severe bupropion-induced urticaria required discontinuation in 5.5% (4 of 72) of the patients in one study.[96] In adults, the risk of seizures increases by about fourfold if extended-release doses of >450 mg/day or >400 mg/day sustained-release doses of bupropion doses are exceeded.[97] Although there are no case reports of seizures in children receiving therapeutic doses of bupropion, it is recommended to limit doses to <6 mg/kg/day in the treatment of ADHD and to avoid using bupropion in patients with a history of seizure disorders.

MODAFINIL

Modafinil has been found to be effective in the treatment of prepubescent, adolescent, and adult patients with ADHD.[98,99] The 2006 Pediatric FDA advisory committee reviewed the efficacy and safety of modafinil for ADHD and determined the drug was effective

but rejected its approval for ADHD based on concerns about safety. Twelve of 933 patients developed a skin rash, with one case thought to be Stevens–Johnson syndrome.[100]

TRICYCLIC ANTIDEPRESSANTS AND SEROTONIN–NOREPINEPHRINE REUPTAKE INHIBITORS

As recently as 2007 guidelines reported, tricyclic antidepressants (TCAs) could be an option for ADHD. However, their poor tolerability and dangerous effect on cardiac conduction have resulted in more recently published guidelines in 2014 and 2019 to not recommend them.[2,33–35]

The serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine has shown efficacy in both adolescents and adults with ADHD. This is a legitimate choice for comorbid anxious or depressed older patients, but because of antidepressants having a small (2% for placebo, 4% for antidepressant) risk of increasing suicidal thinking in children, other options should be tried first. Adults often have these comorbidities, and venlafaxine in that population is more likely to be used.[33]

Alternative Therapy

There have been a number of studies that have tried to discern if certain diets may result in ADHD. One of the most famous regimens is the Feingold Diet. Recent reviews on the topic have found the evidence to be of low quality and of small benefit. Most studies have not been blinded, and when efficacy is noted, it is of lower rates than the FDA-approved pharmacotherapies. Additionally, there is a practical limitation to the implementation of these diets as it eliminates many of the foods that are regular parts of American meals. At this time, it does seem reasonable to assume that some children's ADHD-like behavior may be related to intolerance to certain dyes, artificial sweeteners, and flavors. Do not discourage a parent to promote healthier food selection for their child, but the effectiveness of lowering their symptoms is marginal. Additionally, if

a child has a delay in the administration of pharmacotherapy because of trials of different types of diets, then this could result in persistency of symptoms longer than is necessary.[101]

Many companies have created dietary supplements that have been touted as effective remedies for treating and preventing ADHD, but convincing results derived from rigorous trials are currently lacking and are likely to benefit only a very few children with food allergies or intolerances.[101–103] For instance, the use of very high doses of vitamins or minerals has been promoted as a possible intervention, but all RCTs conducted to evaluate the effectiveness of megavitamin therapy have been negative to date.[104] Omega-3 fatty acids have been considered as possible treatments for ADHD, based largely on population studies demonstrating an association between high dietary intake and a reduced risk of various neuropsychiatric disorders. Omega-3 supplementation, specifically eicosapentaenoic acid (EPA) content, may have a small benefit as monotherapy. Studies of ω-3 as an adjunct to stimulants have shown little added benefit.[105,106] Similarly, there have been reports of children with low serum zinc, vitamin D, or iron that benefit from replenishment, but children with normal levels have no benefit on symptoms from extra doses.[107,108] There have been other reports of magnesium, *Hypericum* (St. John's wort), and ginkgo all relieving ADHD symptoms, but the evidence to support these interventions is very limited at the present time.[108,109]

There have been other somatic treatments aimed at relieving ADHD symptoms.[109] Several small randomized studies have reported benefits with neurofeedback, in which children are trained to modify certain brain activities demonstrated on electroencephalographic tracings (eg, increased slow wave or α-activity). Preliminary evidence also supports the exploration of meditation as an effective intervention for ADHD, particularly mindfulness-based methods that have proven to be particularly helpful for depression and chronic pain conditions.[110] Clinic-based interventions have included cognitive-behavioral therapy, social skills training programs, and computer-based cognitive training programs. Early studies of some of these intervention strategies have been

promising, and there is a need for further research to establish efficacy.[36] Regarding acupuncture, a recent systematic review failed to find any studies of sufficient rigor to include in their analysis.[111]

ADULTS WITH ATTENTION-DEFICIT HYPERACTIVITY DISORDER

CASE 89-2

QUESTION 1: K.C., a 27-year-old female adjunct professor in a pharmacy program, comes to a retail pharmacy wanting to fill a prescription for dextroamphetamine IR 10 mg tid #90.

What are the treatment recommendations for an adult with ADHD?

It is estimated that two-thirds of children with ADHD will continue to have significant symptomatology as adults albeit with less severity than in childhood.[11] Often the hyperactivity/impulsivity aspect of the illness becomes less pronounced once the child reaches adolescence, but the symptoms of inattention may persist into adulthood.[6] Even though many of the children with ADHD may no longer satisfy strict diagnostic criteria for ADHD as adults, the severity and persistence of inattentive symptoms can continue to cause considerable social and functional difficulties. One investigation followed 128 children with ADHD for several years and reported that hyperactivity and impulsivity symptoms were seen to decline at a higher rate than inattention symptoms.[6] Other researchers have followed children with ADHD to adulthood by comparing the academic records of control subjects and ADHD adults. The latter had significantly higher rates of repeated grades, tutoring, placement in special classes, and reading disability.[112,113] Children with ADHD will have greater morbidity in psychosocial and educational areas in adulthood compared to adults who did not have ADHD as children.[114] Adults with ADHD have been found to achieve lower socioeconomic status and experience more work difficulties

and more frequent job changes.[115] Adults with ADHD reported more psychologic maladjustment, more speeding violations, and more frequent changes in employment.[116] More adults with ADHD had their driver's licenses suspended, had performed more poorly at work, and had quit or been fired from their job. Adults with ADHD were also more likely to have had multiple marriages.[11]

The diagnostic criteria for ADHD in adults are the same as for children and adolescents (*DSM-5*).[4] However, only five, instead of six as required in children, of either hyperactivity/impulsivity or inattention symptoms must be present for a minimum of 6 months, impairing function in two or more settings. A diagnosis of ADHD in adults also requires evidence that symptoms were present before age 12. One study compared the functional outcomes of adults with ADHD before age 7 with adults, who had the requisite symptoms but lacked conclusive evidence of childhood onset. The investigators found no difference between the two groups in primary outcomes, such as learning disabilities, arrests, motor vehicle accidents, and divorce.[117] Thus, a lack of diagnosis in childhood could simply be that the adult was never assessed for ADHD, not that they didn't fulfill the criteria.

Current treatment recommendations for ADHD in adults continue to support pharmacotherapy as the first-line option for moderate-to-severe symptoms.[33] Although benefits have been noted for psychotherapeutic approaches such as cognitive-behavioral therapy and dialectic behavioral therapy, these interventions are recommended only for adults with mild symptoms or exhibiting suboptimal response to approved medications.[118,119]

A variety of medications have been reported to be beneficial for ADHD in adults, including MPH, dexmethylphenidate, mixed amphetamine salts, lisdexamfetamine, desipramine, bupropion, atomoxetine α_2-agonists, venlafaxine, and modafinil.[94,99,120–127] The stimulants and atomoxetine are FDA approved in adults.[33] In general, the effect sizes for these ADHD medications in adults have been very similar to what has traditionally been reported in children. A meta-analysis of medications for ADHD in adults found that long-

acting stimulants were significantly more effective than nonstimulant drugs, but that the effectiveness of shorter-acting stimulants was comparable to the latter.[9] The authors also noted that lower doses appeared to be more effective for inattention than hyperactivity. For example, doses for IR MPH were more conservative (0.3 mg/kg per dose in adults) when inattention was the predominant feature. In contrast, doses of up to 0.6 mg/kg IR MPH were often necessary to optimally control the behavioral feature of the disorder in children.[128] These MPH doses are consistent with 0.5 to 1.0 mg/kg/day doses found to be effective in children.[121] Mixed amphetamine salts were effective in doses of 20 to 60 mg/day.[122] The effective dose of desipramine was ~150 mg/day.[125] Bupropion was generally dosed at 3 mg/kg/day.[94] The two large studies of atomoxetine used doses that ranged from 60 to 120 mg/day.[125,126] The mean effective dose for modafinil was 207 mg/day.[99]

Treatment with stimulants or atomoxetine has shown improvements in reduced criminality and driving accidents.[129–132]

Case 89-2, Question 2: Before filling the prescription for K.C., the pharmacist reviews it and finds that it is written within 30 days. He also checks the prescription drug–monitoring program in his state and finds that she has filled a prescription for the same drug and directions 25, 28, 54, and 56 days ago at other retail pharmacies. These double-fills are also written by two different physicians. What would be an appropriate response by the pharmacist to K.C.'s request?

As noted above, ADHD symptoms can persist into adulthood for many children. A positive history of either an ADHD diagnosis or untreated symptoms in childhood is required for an adult to be diagnosed with ADHD. However, a number of other conditions can lead to a similar presentation. Complete blood counts, urine toxicology, and head injury must all be evaluated along with psychiatric conditions such as bipolar disorder, anxiety disorders, and major depressive disorder.[133] Also, the possibility of substance-use disorder cannot be ruled out. As with other drugs that have an abuse liability, stimulants can either be abused by the patient or

diverted and sold to those who want to use them for their euphoria-inducing effect instead of helping treat ADHD. There is an increasing amount of data reporting the intermittent use of stimulants by college students for study enhancement and abuse, particularly when mixed with a sedating drug of abuse. Therefore, the pharmacist should consult with the clinician who wrote the prescription alerting him to the recent fill at another pharmacy. It is quite possible that this new prescription is legitimate, but it is also possible that K.C. is misusing the dextroamphetamine herself or diverting them to others. A reevaluation of her diagnosis is necessary. If it is confirmed that the patient does have ADHD, then options would be to switch to a less abusable stimulant such as lisdexamfetamine or MPH transdermal patch. Switching to the nonabusable atomoxetine is recommended because even though these stimulant formulations are less abusable, they are not devoid of abuse risk. Atomoxetine or the non-FDA adult-approved agents such as α_2-agonists or bupropion, venlafaxine, and modafinil will likely be less effective than the stimulant for ADHD but provide a safer abuse-risk possibility.

Substance Use Disorders

Swati Betharia and Michael C. Angelini

CORE PRINCIPLES		CHAPTER CASES
1	Substance use disorder is a chronic disease with progressive deterioration of psychological and physiologic activity secondary to the habitual use of a drug. This complex disease disrupts many, if not all, aspects of an individual's life; therefore, multimodal treatment is necessary.	**Case 90-1 (Question 1) Case 90-11 (Question 1), Table 90-1**

CORE PRINCIPLES		CHAPTER CASES
2	Opioid misuse includes illicit drugs, such as heroin, and the nonmedical use of prescription pain relievers. Opioid withdrawal is characterized as a flulike syndrome, involving nausea, vomiting, sweats, diarrhea, pain, and elevations in pulse and blood pressure. The full agonist methadone, partial agonist buprenorphine, and antagonist naltrexone all can be used as maintenance therapy to reduce relapses. Treatment considerations during pregnancy consist of fetal risks if the mother goes into opiate withdrawal or if the mother relapses into addictive behavior. Neonatal abstinence syndrome occurs in the newborn if the mother has been maintained on methadone or buprenorphine.	**Case 90-2 (Question 1) Case 90-3 (Question 1) Case 90-4 (Question 1) Case 90-5 (Questions 1, 2), Table 90-2**

CORE PRINCIPLES		CHAPTER CASES
3	Sedative-hypnotic drugs of abuse include benzodiazepines, barbiturates, some skeletal muscle relaxants, such as carisoprodol, and γ-hydroxybutyrate acid (GHB). Withdrawal symptoms, similar to those of alcohol withdrawal, may include tremors, insomnia, anxiety, elevations in pulse and blood pressure, seizures, and hallucinations, and may be potentially life-threatening. In clinical practice, three general medication strategies are used for withdrawing patients from sedative-hypnotics: gradual tapering of the drug of abuse, substituting and gradually tapering phenobarbital, and substituting and gradually tapering a long-acting benzodiazepine.	**Case 90-6 (Question 1), Table 90-3**

CORE PRINCIPLES		CHAPTER CASES
4	Major central nervous system (CNS) stimulants of abuse include cocaine and amphetamines. These drugs are associated with serious acute and chronic adverse effects, such as hyperthermia, paranoia, psychosis, hypertension, arrhythmias, myocardial infarction, seizures, and strokes. Withdrawal from stimulants is not associated with severe symptoms. Primarily, withdrawal consists of fatigue and hypersomnolence. There is currently no U.S. Food and Drug Administration (FDA)-approved treatment for withdrawal or maintenance treatment of stimulant use disorder.	**Case 90-7 (Questions 1, 2)**
5	The use of hallucinogens, including lysergic acid diethylamide (LSD), psilocybin, mescaline, and 3,4-methylenedioxymethamphetamine (MDMA), may result in psychological, but not physical, dependency. Adverse reactions during intoxication, such as anxiety, paranoia, and fear, may necessitate benzodiazepine or antipsychotic therapy, but are best managed using a “talk-down” method.	**Case 90-8 (Questions 1–3)**

CORE PRINCIPLES		CHAPTER CASES
6	Marijuana is a widely used substance. The withdrawal syndrome is generally mild, characterized by anxiety, depression, irritability, and insomnia, and does not require treatment. Chronic use has been shown to result in increased risks of car accidents, pulmonary complications, psychosis, and anxiety.	**Case 90-9 (Questions 1–3)**
7	Alcohol use disorder is defined by acute and chronic alcohol use. It can result in toxicity, withdrawal, and addiction. Alcohol toxicity is an acute, life-threatening condition that requires aggressive medical attention. Symptoms include a strong smell of alcohol, depressed and shallow respiration, and cardiac arrest. Management generally consists of respiratory support and a thorough diagnostic evaluation to rule out coingestion of other drugs or other underlying medical conditions that may also need attention.	**Case 90-10 (Question 1), Tables 90-4, 90-5**

CORE PRINCIPLES		CHAPTER CASES
8	Alcohol withdrawal is the neurobiologic syndrome associated with increased tolerance or physical dependence resulting from chronic alcohol consumption. This syndrome results in a continuum of signs or symptoms including paresthesias, headache, nausea, anxiety, shaking, increased heart rate and blood pressure, and seizures. Symptom-triggered assessment and treatment of alcohol withdrawal is extremely important because untreated withdrawal can result in death. Treatment may be complicated not only by the physical or cognitive deterioration that can occur but also by the lack of attention to other serious medical or psychological conditions that could be contributing to, or resulting from, chronic alcohol use. Adjunctive treatments including fluid (eg, normal saline solution), nutritional (eg, thiamine, folic acid, and multivitamins), and electrolyte (eg, magnesium, potassium) replacement should also be initiated to address the physiologic consequences of chronic alcohol use.	**Case 90-10 (Questions 2–4), Table 90-6**

CORE PRINCIPLES		CHAPTER CASES
9	Chronic alcohol use disorder (alcohol dependence) is a lifelong relapsing disorder that consists of signs of alcohol abuse (continued drinking despite alcohol-related physical, social, psychological, or occupational problems, or drinking in dangerous situations, such as while driving) to the extent that the person also experiences at least three of the following seven symptoms: neglect of other activities, excessive use of alcohol, impaired control of alcohol consumption, persistence of alcohol use, large amounts of time spent in alcohol-related activities, withdrawal symptoms, and tolerance of alcohol. Approved pharmacotherapies include disulfiram, naltrexone (tablets and injection), and acamprosate. The best option is determined by many factors such as home support, medical comorbidities, and concomitant medications.	**Case 90-11 (Question 1), Tables 90-4, 90-6**

INTRODUCTION

Substance Use Disorder

Physical dependence occurs when repeated administration of a drug causes an altered physiologic state (neuroadaptation). After

neuroadaptation, a characteristic set of withdrawal symptoms occurs when the drug is abruptly discontinued. Psychological addiction or psychological dependence refers to a "maladaptive pattern of substance use leading to clinically significant impairment or distress."[1] Habituation is a state of either chronic or periodic drug use characterized by a desire (but not a compulsion) to continue using the drug, no tendency to increase the dose, and an absence of physical symptoms despite some degree of psychological dependence. A different clinical syndrome is associated with each drug, but all involve a chronic process with progressive deterioration of psychological and physiologic activity secondary to the habitual use of a drug. Addiction is not a diagnosis, but is defined by the American Society of Addiction Medicine as a chronic disease of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits has biologic, psychological, social, and spiritual effects. There is a pathologic pursuit of the substance with an inability to abstain, loss of control, craving, and diminished recognition of the intensity of the problem. It is cyclic, with periods of relapse and remission. Without treatment, it is significantly disabling and will result in premature death. Addiction is frequently used as a descriptor of the most disabling and intense form of a substance use disorder.[2] Although the neurochemistry of the addictive process is possibly the same for all drugs, the psychosocial and pharmacokinetic aspects vary from drug to drug. Evidence, consistent with models established for alcoholism, indicates that genetically inherited traits may result in expression of addictive disease when the person is exposed to certain drugs and other habituating psychic stimuli.[3]

CASE 90-1

QUESTION 1: R.L., age 26, was recently arrested for possession and driving under the influence (DUI) of oxycodone. This is his second DUI offense in the past year. R.L. does not use oxycodone daily, but admits to weekly use.

Does R.L. meet the criteria for a diagnosis of a substance use disorder?

The *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (*DSM-5*) cites criteria for substance-related disorders and divides them into two groups: the substance use disorders (**Table 90-1**) and the substance-induced disorders (intoxication, withdrawal, and others).[1] In 2018, an estimated 53.2 million persons age 12 or older were classified as current illicit drug users.[4]

Table 90-1

American Psychiatric Association, *Diagnostic and Statistical Manual of Mental Disorders*, Criteria for Substance Use Disorders

A. A problematic pattern of use of an intoxicating substance not able to be classified within the alcohol; caffeine; cannabis; hallucinogen (phencyclidine and others); inhalant; opioid; sedative, hypnotic, or anxiolytic; stimulant; or tobacco categories and leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

1. The substance is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control the use of the substance.
3. A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects.
4. Craving or a strong desire or urge to use the substance
5. Recurrent use of the substance resulting in a failure to fulfill major role obligations at work, school, or home
6. Continued use of the substance despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of its use
7. Important social, occupational, or recreational activities are given up or reduced because of use of the substance.
8. Recurrent use of the substance in situations in which it is physically hazardous
9. Use of the substance is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
10. Tolerance, as defined by either of the following:
    a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect

b. A markedly diminished effect with continued use of the same amount of the substance

11. Withdrawal, as manifested by either of the following:
    a. The characteristic withdrawal syndrome for other (or unknown) substance
    b. The substance (or a closely related substance) is taken to relieve or avoid withdrawal symptoms.

Pharmacologic treatment is only one aspect of the management of substance use disorders. Treatment of withdrawal (when needed depending on the chemical of abuse) is the first step in management and should be followed by individualized, psychosocial treatment that is effective in the least restrictive and most cost-effective manner. A strong therapeutic alliance between care provider and patient based on a supportive, empathic, nonjudgmental, and clinically appropriate relationship is predictive of successful therapy outcomes. Substance use disorder is a complex disease that disrupts many, if not all, aspects of an individual's life. Therefore, multimodal treatment is necessary. Psychosocial therapies that may or may not include pharmacologic agents consist of individual as well as group counseling, cognitive-behavioral therapies (CBTs; learning triggers for use, new coping mechanisms, and relapse prevention), motivational enhancement therapies, family counseling, and voucher-based reinforcement therapy, among others. These therapies are often augmented with involvement in support groups, such as the 12-step programs.[3]

R.L. has a pattern of oxycodone use in situations in which it is physically hazardous, as well as two arrests in the past year for DUI. R.L. meets the *DSM-5* criteria for substance use disorder.

OPIOIDS

Abuse of opioids includes illicit drugs, such as heroin, and the nonmedical use of prescription pain relievers. According to the Drug Enforcement Administration (DEA), prescription pain relievers appear to be increasingly diverted from legitimate and illegitimate sources of supply via the Internet.[5] The 2018 National Survey on Drug Use and Health reports, among persons age 12 years or older, that there are 9.9 million nonmedical use of pain relievers.[4] The non–FDA-approved opiate heroin is produced in four major source areas, South America, Mexico, Southeast Asia, and Southwest Asia. Mexico has been the predominant supplier to the west coast of the United States and is expanding distribution in eastern U.S. markets because South American production has decreased.[6] Mexican heroin black tar is potent, 40% to 80% pure, but contains more plant impurities than does the white powder refined heroin from Asia or South America.[7] The purity of available heroin enables a new, younger user population, who can smoke or snort this high-purity heroin and avoid the stigma and hazards associated with needle use. As the substance use disorder intensifies and the user's "habit" (amount used daily) increases, the user will often begin injecting the drug. The Centers for Disease and Prevention (CDC) estimates there are roughly 900,000 persons who have used heroin in the United States in 2020. The 2018 National Survey on Drug Use and Health found that usage of heroin was higher than that reported between 2000 and 2008, but similar to that in more recent years.[4] Some prescription opioid abusers will eventually switch to using heroin, because it is less expensive.

Opioid Use Disorder

Physical dependence occurs in any patient after a few days of continuous administration of an opioid. In the management of acute pain, opioid dependence is generally not clinically significant because the patient is tapered off opioid analgesics naturally because the pain condition resolves. If the opioid is abruptly stopped, the patient may experience withdrawal symptoms; however,

the intensity of those symptoms varies depending on the individual's physiology, as well as the dose and duration of use of the opioid. Although the exact dose and duration of opioid administration required to produce clinically significant physical dependence is not known, higher doses and longer times of administration correlate with more severe symptoms of withdrawal on cessation of opioid use.

Physical dependence is defined as a neurobiologic adaptation that occurs with chronic exposure, and occurs with many drug classes regardless of whether they have an abuse potential (eg, β-blockers, steroids, and selective serotonin reuptake inhibitors [SSRIs]). Physical dependence and tolerance (the need for increasing doses to achieve the initial effects of the drug) can occur in the setting of substance use disorder, but are also expected, nonpathologic sequelae of chronic opioid therapy.

Most studies evaluating the occurrence of opioid use disorder resulting from the therapeutic treatment of pain have concluded that the risk is low.[8] Historically, a much greater problem has been the undertreatment of pain. Yet, people at risk environmentally or predisposed genetically for substance use disorder may have their first exposure through a legitimate, therapeutically dosed prescription of an opiate for an acute pain syndrome. This then progresses to an inappropriate use of the opiate and resultant substance use disorder. Thus, pain management with opiates requires a baseline risk management assessment and careful monitoring (see Chapter 55, Pain and Its Management).

Certain pharmacologic properties, such as high potency, rapid onset and shorter duration of action, and water solubility, may increase the likelihood of abuse of that medication. Although all opioids have some abuse liability, some are intrinsically more abusable than are others. For example, the controlled-release formulations have been promoted as less likely to cause substance use disorder than are their immediate-release counterparts, because some of the reinforcing properties such as multiple peaks and troughs are reduced. When tablets, such as OxyContin®, are crushed, however, the drug's controlled-release properties are

compromised, and the result is much higher dosages than what is available in the immediate-release formulation tablets. Despite the manufacturer's attempts at altering the formulation of OxyContin® to make it harder to tamper with, this product can still be abused. Mixed agonist–antagonist opioids (pentazocine, nalbuphine, butorphanol, and buprenorphine) have less potential for misuse than do the pure μ agonists (eg, morphine, hydromorphone, and oxycodone); however, misuse of all has been observed.[8] Other options to reduce diversion and misuse are formulary management strategies that help the clinician limit opiate prescriptions.[9,10] In total, the best method of reducing this problem is a combination of psychosocial therapy, pharmacotherapy, and policy.

The term *pseudoaddiction* has been coined to describe the inaccurate interpretation of certain "drug-seeking behaviors" in patients who are inadequately treated for pain.[8] Their preoccupation actually reflects a need for pain relief, but is erroneously interpreted as a severe substance use disorder (addiction).

Medical Complications

The common practice of sharing needles and syringes between friends has resulted in transmission of various infectious diseases. Chief among those is viral hepatitis, specifically the hepatitis C virus (HCV). According to the CDC, in the United States, human immunodeficiency virus (HIV) infection caused by injection drug use had an overall prevalence of 4% in 2018.[11] Other infectious diseases such as syphilis, tetanus, botulism, and malaria can be transmitted in a similar manner, and should be considered when evaluating these patients. When heroin is prepared for self-administration, cotton is used as a filter to trap adulterants; thus, some of the drug remains trapped in the cotton. These crude filters are saved, and when money or drug availability is poor, water or other solvents are added to the "old cottons" to extract any remaining drug for intravenous (IV) use. "Cotton fever" is an acute febrile reaction. The onset is within 30 minutes of injection, with shaking chills, diaphoresis, postural

hypotension, tachycardia, and low-grade fever. These symptoms are initially suggestive of sepsis, but most of the symptoms resolve without treatment in 2 to 4 hours, with complete recovery in 1 day. The causal agent is probably *Pantoea* (formerly *Enterobacter*) *agglomerans*, via a heat-stable endotoxin.[12] Cotton and cotton plants are heavily colonized with *P. agglomerans*.[13] IV drug users will often use the term *cotton fever* to describe any short-term illness characterized by fever, chills, aches, and pains.[14]

Opioid Toxicity/Overdose

CASE 90-2

Question 1: T.F., a 21-year-old male, was found unconscious after an alleged "OD" (overdose) on heroin. He had a decreased respiratory rate of 4 breaths/minute, cyanosis, symmetrically "pinned" (maximally miotic or pinpoint) pupils, and a slightly decreased blood pressure, 117/72 mm Hg. He has one needle puncture wound and several old needle marks and healed scars in the antecubital fossa area.

What is the immediate treatment of choice for this patient?

Immediate treatment includes airway management, cardiorespiratory support, and opioid reversal with naloxone. Naloxone is a full opioid competitive antagonist that rapidly reverses the respiratory depression and hypotension associated with OD. The preferred route of administration is IV; if access cannot be gained, it may be given via the intramuscular (IM), subcutaneous (SC), or intranasal route, or by endotracheal tube. Intranasal use of naloxone by first responders and friends or family members of those who have overdosed has shown to have saved lives.[15–17]

Initial IV administration of 0.2 to 0.4 mg naloxone should be slow, and should be discontinued if T.F. responds. It is not necessary to precipitate opioid withdrawal symptoms; the end point of naloxone therapy is a relative stabilization of the patient's vital signs. A naloxone-precipitated, sudden-onset withdrawal syndrome is more severe than are the symptoms produced by abstinence alone.

Repetitive doses should be given if the patient remains unresponsive, up to a maximal dose of 10 mg of naloxone.[15] If the patient still has not responded, the diagnosis of opioid OD should be reconsidered.[15]

The duration of action of naloxone ranges from 20 to 60 minutes, depending on the dose and route of administration. Treatment of the methadone-overdosed patient will require serial dosing of naloxone every 20 to 60 minutes because the toxic effects of this long-acting opiate recur.[15] The patient must be carefully observed after the termination of naloxone therapy to detect any reappearance of opioid intoxication. An IV infusion of naloxone may be appropriate if high doses are needed or if the patient has recurrent respiratory depression.

Treatment of Opioid Withdrawal Syndrome

Opioid Withdrawal

CASE 90-3

QUESTION 1: D.J. arrives at the detoxification clinic 10 hours after his last dose of heroin. He is sweating and shaking and keeps yawning. His pulse is 92 and his blood pressure is 130/86 mm Hg. He is a 28-year-old who has been injecting two "quarter bags" ($25 worth) of heroin daily for about a month. He explains he began smoking the heroin, but has now progressed to injecting it. D.J. developed a "big habit" (tolerance developed, and his daily requirement of drug to maintain euphoria had increased). He could not afford his daily use. When he tried stopping, his use abruptly became "dope sick" (typical heroin withdrawal symptoms).

What withdrawal symptoms would D.J. experience and what treatment options would be available for treatment of his opiate withdrawal?

Abstinence precipitated a withdrawal syndrome in D.J.; therefore, he is physically dependent on heroin. The powerful ability of the drug to rapidly alleviate withdrawal symptoms results in reinforcement to continue using the drug. D.J.'s ongoing desire to continue using heroin despite his inability to afford it and his all-day hustling

constitutes a psychological dependence on heroin. Noticeable opioid physical dependence is highly variable, but it is assumed that the potential for an abstinence syndrome exists after repeated administration for only a few days.[2,18]

Six to 12 hours after the last dose of morphine or heroin (diacetylmorphine), patients who are physically dependent will experience symptoms of anxiety, hyperactivity, restlessness, and insomnia with yawning, sialorrhea, rhinorrhea, and lacrimation. There may also be profuse diaphoresis with concurrent shaking chills and pilomotor activity, resulting in waves of gooseflesh of the skin (thus, the term *cold turkey*). Anorexia, nausea, vomiting, abdominal cramps, and diarrhea may occur. Severe back pain may accompany muscle spasms that cause kicking movements ("kicking the habit"). These symptoms are most severe 48 to 72 hours after the last opioid dose. D.J. is exhibiting typical heroin withdrawal symptoms, and supportive therapy would be appropriate.

During withdrawal, the heart rate and blood pressure may be elevated. Inadequate nutrition and hydration, combined with vomiting, sweating, and diarrhea, can result in marked weight loss, dehydration, ketosis, and acid–base imbalance. Rarely, cardiovascular collapse has occurred during the peak phase of opiate withdrawal. The more dramatic symptoms of heroin withdrawal subside after 7 to 14 days of abstinence even without treatment; however, a return to complete physiologic equilibrium may require months or longer.[2,3]

The character, severity, and time course of withdrawal symptoms that appear when an opioid drug is discontinued depend on many factors, including the particular opioid, total daily dose, interval between doses, duration of use, and the health and personality of the user. Unlike the withdrawal symptoms from sedative-hypnotic drugs, opioid withdrawal symptoms are seldom life-threatening.

Physiologic withdrawal symptoms from all opioid drugs are qualitatively similar but quantitatively different in onset, duration, and severity. Opioids with shorter durations of action tend to produce brief, intense abstinence syndromes, whereas those eliminated from

the body at much slower rates produce prolonged but milder withdrawal syndromes.

Treatment options for detoxification usually involve either an abrupt cessation of the opioid with supportive nonopioid pharmacotherapeutic options or opioid substitution. Currently, methadone and buprenorphine are FDA approved for the opiate substitution indications. The nonopiate approach involves symptomatic treatment of withdrawal. The mainstay of this approach is the α_2-agonist clonidine. A third approach uses rapid detoxification precipitated by an opioid antagonist under general anesthesia.[2,18]

METHADONE DETOXIFICATION

Methadone is a synthetic oral opiate agonist with a prolonged duration of action of 12 to 24 hours. Pharmacologically, it is qualitatively identical to morphine and other opioid analgesics. Methadone detoxification involves stabilizing the patient on a daily methadone dose that is determined by the patient's response based on objective symptoms of withdrawal. This may involve the use of standard rating scales for withdrawal, such as the Clinical Opiate Withdrawal Scale.[19] Initially, methadone may be given in 5-mg increments up to a total of 10 to 20 mg during the first 24 hours.[19] Larger methadone doses (ie, a 20-mg starting dose) may be required for patients with larger habits. If initial withdrawal symptoms persist 2 to 4 hours after initial dose administration, the dose can be supplemented with an additional 5 to 10 mg. Federal regulations allow a maximum of 40 mg as an initial dose unless a program physician documents that 40 mg was insufficient to suppress opioid withdrawal symptoms.[20] Once a stabilizing dose has been reached (usually 40–60 mg/day, but may be as high as 120 mg/day), methadone is tapered by 20% a day for inpatients or 5% a day for outpatients.[15,19,20] Studies have suggested that slow tapers are associated with better outcomes. The duration of the taper varies, but a period of 3 to 4 weeks is generally used. The gradual taper may last as long as 6 months. The most common side effects of methadone are constipation, sweating, and sexual dysfunction.[15,19] A

Cochrane review of studies comparing methadone tapers with other detoxification methods (adrenergic agonists and other opioid agonists) found that programs vary widely in design, duration, and treatment objectives, but overall the effectiveness of the treatments was similar.[21] A reasonable starting dose of methadone would be 20 mg orally. An additional 5 to 10 mg could be administered after 2 to 4 hours for persistent withdrawal symptoms. The daily dose should be titrated upward every third day by 10 mg until stabilized on a methadone dose of 60 mg/day.

BUPRENORPHINE DETOXIFICATION

Buprenorphine, a synthetic partial opioid agonist, was approved by the FDA in October 2002 for the treatment of opioid dependence. It is a partial agonist at mu receptors, and in opioid-dependent patients, it prevents withdrawal symptoms. Because of its partial effects, it produces maximal “ceiling” analgesia with sublingual doses of 24 to 32 mg, a dosage equivalent to ~60 to 70 mg of oral methadone. Buprenorphine is associated with a milder withdrawal syndrome compared with full opioid agonists.[22]

Because buprenorphine is a Schedule III medication, it can be prescribed in an office-based setting under the Drug Addiction Treatment Act of 2000. The film and tablets contain buprenorphine hydrochloride alone or in combination with naloxone. The naloxone is poorly absorbed orally, and its presence in the combination tablets is to discourage the IV abuse of buprenorphine. Both forms can be used in an inpatient setting, but the combination product is preferred in the outpatient setting to decrease the risk of diversion. When initiating buprenorphine, the first dose should not be given until >4 hours after the last dose of a short-acting opioid, such as heroin, or 24 hours after a long-acting opioid, such as methadone. As previously discussed, evaluation of objective opioid withdrawal signs may involve use of standard rating scales. Induction dosing should begin with 2 or 4 mg on the first day, which can be repeated every 2 to 4 hours if withdrawal symptoms subside and then reappear, up to a maximum of 8 mg. The dose can then be titrated the second day in

2- to 4-mg increments to a dose of 12 to 16 mg.[22] Higher doses during induction may precipitate withdrawal symptoms. In the inpatient setting, the patient may be stabilized on a relatively low daily dose (eg, 8 mg/day) and then tapered in increments of 2 mg/day over the course of several days.[15] In the outpatient setting, the patient should be initially stabilized on a daily dose (probably 8–32 mg/day) of buprenorphine that suppresses withdrawal. The dose should then be gradually tapered during a period of 10 to 14 days. Buprenorphine is not associated with any significant adverse effects when used to manage opioid withdrawal. Buprenorphine (and methadone) detoxification should be accompanied by psychosocial treatments and support groups as mentioned.[3]

A Cochrane review found that relative to clonidine, buprenorphine is more effective in alleviating opioid withdrawal symptoms; patients treated with buprenorphine stay in treatment longer, and are more likely to complete treatment.[23] The severity of withdrawal appears to be similar for withdrawal managed with buprenorphine or methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. The authors of the meta-analysis concluded that although there is limited evidence comparing buprenorphine with methadone, both agents have similar effectiveness in the management of opioid withdrawal.

Nonopiate Symptomatic Therapy of Opioid Withdrawal

Although opiate replacement has been shown to provide a safe withdrawal, treatment with opiates is not always necessary. The ability of the α_2-adrenergic agonist, clonidine, to ameliorate some of the opioid withdrawal symptoms has led to its widespread use as a nonopioid alternative. Other α_2-adrenergic agonists (lofexidine, guanfacine, and guanabenz acetate) have also been investigated.[2,3,24] Noradrenergic outflow from the locus coeruleus is increased during opioid withdrawal, and is blocked by the administration of mu agonist opioids. Symptoms of opioid

withdrawal, therefore, are partly caused by excessive sympathetic activity in the locus coeruleus. Central α_2-adrenergic agonists inhibit locus coeruleus noradrenergic outflow during opioid withdrawal, thereby significantly reducing some of the symptoms.

Clonidine is therefore commonly used in a multidrug regimen. Contraindications to clonidine use include diastolic blood pressure <70 mm Hg, concurrent dependence on sedative-hypnotics, and clonidine hypersensitivity or previous intolerance. The most common adverse effects are sedation and hypotension. A Cochrane review examined studies comparing clonidine with methadone taper and found no significant difference in efficacy between the two for the treatment of heroin or methadone withdrawal.[24] A separate Cochrane review did find buprenorphine to be more effective than is clonidine in alleviating opioid withdrawal symptoms.[23]

A sublingual or oral test dose of 0.1 mg (0.2 mg for patients > 200.62 pounds [91 kg]) of clonidine is given: If diastolic blood pressure remains >70 mm Hg, additional doses may be instituted. Oral clonidine can be used at a dose of 0.1 to 0.2 mg/dose two to four times daily to a maximum of ~1 mg/day for 2 to 4 days after cessation of opioids, then tapered and discontinued by 7 to 10 days.[24] Because opiate withdrawal consists of other effects such as musculoskeletal aches and pains, anxiety, insomnia, and gastrointestinal (GI) disorders, it is common to use medications such as dicyclomine, loperamide, and ibuprofen as adjuncts. This is particularly true when the detox protocol does not contain opiates[2,18] (**Table 90-2**).

Table 90-2

Symptomatic Therapy of Opiate Withdrawal

Symptom	Medication
Bone, muscle, joint, or other pain	Ibuprofen, naproxen, other NSAID
Insomnia, anxiety	Benzodiazepine
Gastrointestinal hyperactivity	Loperamide, dicyclomine
Nausea	Prochlorperazine, ondansetron

NSAID, nonsteroidal anti-inflammatory drug.

Sources: Schuckit MA. Treatment of opioid-use disorders. *N Engl J Med*. 2016;375:357–368; ASAM Public Policy Statement on Treatment for Alcohol and Other Drug Addiction. Adopted May 1, 1980. Revised January 1, 2010. https://www.asam.org/quality-care/definition-of-addiction.

D.J.'s blood pressure and drug history should be evaluated for clonidine therapy. Provided his diastolic blood pressure is >70 mm Hg after the clonidine test dose, he can receive oral clonidine 0.1 mg with additional medications to treat his withdrawal symptoms, along with psychosocial counseling.

Ultrarapid Opiate Detoxification

Ultrarapid opiate detoxification (UROD) is a method to shorten the opioid detoxification period by precipitating withdrawal with an opioid antagonist. The opioid antagonist causes rapid stripping of the agonist from opioid receptors. UROD is performed under heavy sedation or general anesthesia so that the patient does not consciously experience the acute withdrawal symptoms. The protocols for UROD vary in terms of the setting of the procedure (inpatient or outpatient), opioid antagonist (naloxone, nalmefene, or naltrexone), anesthetic agent, adjunctive medications, and duration of anesthesia.[25]

The UROD procedure includes risks, such as vomiting with aspiration; cardiovascular complications, including cardiac arrest; pulmonary edema; and death.[25] Some patients have reported residual withdrawal symptoms for several days. Little information exists regarding referral to ongoing treatment or relapse rates after UROD.[26] A review of five randomized, controlled trials found no benefit of UROD compared with safer, less expensive treatments.[26] UROD has been criticized for being simply a "quick fix" that fails to address the underlying behavior changes necessary for recovery. In addition, it subjects patients to possible morbidity and mortality when safer, established procedures are available. The high cost of UROD limits its accessibility. The American Society of Addiction Medicine

recommends against this method of treating opiate withdrawal because of cardiac complications and anesthesia-related events.[2]

Pharmacotherapies for Maintenance Treatment of Opioid Use Disorder

Maintenance Therapy

The ultimate goal of outpatient substance use disorder programs is to assist the addicted patient into a drug-free healthy lifestyle. This results in reductions in medical conditions for the patient and reduced crime and health care cost for societal members. Methadone for maintenance treatment of opioid substance use disorder is federally regulated and is only available through specially licensed opioid treatment programs. The Drug Addiction Treatment Act of 2000 allows qualified physicians to prescribe Schedule III, IV, and V medications approved for the treatment of opioid dependence in an office-based setting.[27] Currently, only buprenorphine, a Schedule III medication, is approved for this indication.

CASE 90-4

QUESTION 1: A.X., a 27-year-old male, has a severe opiate use disorder (addiction) to heroin for the past 3 years, but is tired of the street scene and wants to "get clean" (complete abstinence). He can no longer afford his growing daily habit, but is not sure he can stop using opioids. He seems willing and determined to receive treatment for his heroin dependence.

What therapeutic options are available to him?

The gold standard of treatment is completely eliminating illicit opiate use; however, a more realistic expectation is reduced use and subsequent harm reduction. Even temporary reductions in heroin use are a benefit because of the reduced risk of developing major health (HIV, hepatitis C) and social (crime) issues.[2] Medical management (MM) of opioid dependence should be accompanied by psychosocial treatments, such as CBTs, behavioral therapies, and self-help groups, such as Narcotics Anonymous (NA).

Methadone maintenance is the most common form of pharmacologic treatment for opioid dependence. During methadone maintenance, heroin-dependent patients are stabilized on a dose of methadone that will be sufficient to suppress cravings for 12 to 24 hours without producing euphoria. Studies have shown that patients maintained on methadone doses of ≥60 mg had better outcomes than did those maintained on lower doses.[28] Most patients do well on a dose range of 60 to 120 mg/day, although some patients require more and some require less.[20] Because methadone is metabolized via cytochrome P450 (CYP) 3A4, drugs that induce this enzyme can precipitate withdrawal in patients maintained on methadone. Similarly, drugs that inhibit this enzyme extend the duration of methadone's effects. The half-life of methadone is typically 25 hours (15–60 hours), but can extend up to 120 hours with frequent dosing.[29] The drug is administered daily at the clinic as a single liquid oral dose. With the aid of daily counseling and rehabilitation, the goal is to eventually taper the patient from methadone as well. Patients who relapse repeatedly despite supportive treatment will require long-term maintenance therapy. This may take years, and it is shown that longer duration in treatment correlates with better outcomes. Methadone's efficacy comes from the fact that it reduces cravings without producing euphoria itself, primarily due to its slow time to peak. This produces a high degree of cross-tolerance to other opioids so that it is extremely difficult to obtain euphoria with IV injection of other opioids. However, patients have been able to reach euphoric states through the concomitant IV administration of other opioids. The higher purity heroin and the fact that fentanyl is often added to it has required even higher doses of methadone to achieve cross-tolerance.[28]

Buprenorphine has the advantage of office-based availability, thus removing the stigma associated with attending a methadone clinic and providing more places for patients to receive treatment because methadone clinics are limited as to how many patients can enroll and may be hundreds of miles away from the patient's home. Buprenorphine and high-dose methadone (60–100 mg) therapies were compared with low-dose methadone (20 mg); all three

therapies were effective in treating opioid dependence compared to baseline, and the buprenorphine and high-dose methadone arms were superior to low-dose methadone.[30] Trials comparing 12 to 16 mg/day of buprenorphine with moderate doses of methadone (50–60 mg/day) have generally shown comparable outcomes, although higher doses of methadone (>80 mg) appear to be superior to buprenorphine.[30] Low-dose buprenorphine seems to have worse outcomes compared to low-dose methadone.[31] Patients on buprenorphine are more likely to be employed, have less medical comorbidity, and a shorter duration of drug use compared to patients attending a methadone clinic.[32,33] There are multiple formulations of buccal and sublingual buprenorphine, and absorption rates are different between some of them. All are compared to the original buprenorphine sublingual tablet (Subutex® and Suboxone®) regarding pharmacokinetics, blood levels, and efficacy. There is also a buprenorphine implant available, which was found equally effective in lowering doses of buprenorphine sublingual.[34] An SC long-acting buprenorphine injection is also available. For maintenance treatment with the sublingual and buccal formulations, buprenorphine combined with naloxone is the standard of care, and pregnancy or allergy to naloxone are the only two reasons not to use the combination product.[2]

Buprenorphine has a long half-life of around 35 hours (24–60 hours) and it produces a relatively mild withdrawal when discontinued.[35] It is believed to be a safer alternative to methadone because life-threatening respiratory depression is much less likely to occur than with a pure μ agonist, unless another CNS depressant is taken concurrently. Most deaths involving buprenorphine have been caused by a combination of the drug with benzodiazepines and through injection of the monotherapy formulation.[22,36] Naloxone bolus doses often are ineffective in reversing respiratory depression caused by buprenorphine because of its prolonged occupancy on mu receptors. Continuous infusion of naloxone is necessary to overcome buprenorphine-induced respiratory depression.[37] Another safety advantage compared to methadone is the lower risk of prolonging QTc.[29] Similar to methadone, buprenorphine is also

metabolized by the CYP3A4 enzyme. The buprenorphine SC dosage form produces average blood concentrations similar to the 24-mg dose of buprenorphine sublingual (Suboxone®/Subutex®). The dose is given monthly in the abdomen, and can be initiated after at least 7 days of transmucosal buprenorphine.[38]
